The need for CoA and its derivatives is primarily controlled by the cell's ability to make and utilize ATP. A relative increase in cellular ATP has the potential to down-regulate energy-generating processes (glycolysis, citric acid cycle) and modulate energy-consuming pathways,

such as those involved in amino acid synthesis or gluconeogenesis. Conversely, a cellular decrease in CoA reduces mitochondrial energy generation due to reduced citric acid cycle activity.

As noted, pantothenic acid kinase serves as the primary control point in CoA synthesis. Accordingly, feedback inhibition of pantothenic acid kinase occurs by end products of the synthetic pathway (e.g., CoA or CoA derivatives). Other inhibitors and activators for CoA synthesis include L-carnitine, essential for transporting fatty acids into mitochondria. Carnitine does not affect pantothenic kinase activity independently but reverses the inhibition of pantothenic acid kinase by CoA. However, reversal of kinase inhibition by CoA does not occur when carnitine is acylated.

### Metabolism

Pantothenic acid in food is present as CoASH or as protein- or peptide-bound 4'-phosphopantetheine. Near quantitative release of pantothenic acid or 4'-phosphopantetheine is achieved by the sequential actions of two intestinal hydrolases with pyrophosphatase and phosphatase activity. Another intestinal hydrolase, pantetheinase, further hydrolyzes 4'-phosphopantetheine to pantothenic acid. The uptake of luminal pantothenic acid occurs by a sodium-dependent multivitamin transporter (SMVT) found at the surface of intestinal and colonic enterocytes. As a multivitamin transporter, SMVT is also a transporter for biotin, lipoic acid, various sugars, myo-inositol, iodide, short-chain fatty acids, and choline.

Pantothenic acid status is reflected by both whole blood concentration and urinary excretion. Whole blood concentrations typically range from 1.6 to 2.7  $\mu\text{mol/L}$ . A value of  $<1 \mu\text{mol/L}$  is considered low. In blood, circulating pantothenic acid is not bound tightly to a specific protein. Whole-body retention of pantothenic acid is mainly by renal tubular reabsorption. The daily excretion of pantothenic acid is closely linked to intake.

The cellular concentrations of pantothenic acid in the liver and heart are 10–15  $\mu\text{mol/L}$  and  $\sim 100 \mu\text{mol/L}$ , respectively, i.e., 10–100 times that in blood. Also, the concentration of CoA derivatives is 100–400  $\mu\text{M}$ , and the concentration of ACP is 10  $\mu\text{M}$  or more in the cytosol of typical cells. Mitochondria account for 70–90% of the total cellular CoA content.

Adequate intakes (AIs) for adult men and women throughout the life cycle have been established based on observed mean intakes and estimates of basal excretion in urine. Five milligrams per day appears adequate, with an additional one milligram per day recommended during pregnancy and lactation (six milligrams per day). However, an Estimated Average Requirement (EAR) or Recommended Daily Allowance (RDA) has not been established. CoA and ACP are involved in so many aspects of metabolism that biochemical markers or clinical deficiency criteria specific for pantothenic acid deficiency have been challenging to define.

## Methyl transfer reactions: biotin, folic acid, vitamin B12

### Biotin

Biotin is a cofactor for enzymes collectively known as biotin-dependent carboxylases that catalyze the transfer of carboxyl groups between donor and acceptor molecules (cf., Table 2). To activate biotin-dependent apocarboxylases, biotin must be attached to a given apocarboxylase by biotin ligase (holocarboxylase synthetase, HCS). An amide linkage binds biotin to a lysyl  $\epsilon$ -amine group at the apocarboxylase active site to form biocytin.

Scheme 12

The attachment reaction requires ATP and precedes via a biotinyl-AMP intermediate. The resulting structure combines the aliphatic chains of biotin and lysine to permit the ring structure of biotin to extend approximately 14 Å from the enzyme's surface. Such extensions facilitate transfers from the donor sites on one enzyme or enzyme subunit to another containing receptor sites. For perspective, a C-C bond is about 1.5 Å in length.

The catalytic site on biotin is the N in its 5-member ring. The reaction occurs in two steps. The first requires the formation of a carboxy biotinyl intermediate. The mechanism involves tautomerization of the ureido nitrogen, which enhances the intermediate's nucleophilicity. The second step is phosphorylation of bicarbonate by ATP to produce carbonyl phosphate, an electrophilic

**Table 2** The biotin-dependent carboxylases.

Substrate	Enzyme	Product	Importance
Acetyl CoA	Acetyl CoA carboxylase	Malonyl CoA	Acetyl CoA carboxylase catalyzes the formation of malonyl-CoA for the biosynthesis of fatty acids.
Pyruvate	Pyruvate carboxylase	Oxaloacetate	Pyruvate carboxylase is essential to gluconeogenesis. Oxaloacetate is a TCA cycle intermediate,
Propionyl CoA	Propionyl CoA carboxylase	Methylmalonyl CoA	The conversion of Propionyl CoA to malonyl CoA is an essential reaction in the catabolism of odd-chain fatty acids, methylated-branched-chain fatty acids, and amino acids, such as valine, isoleucine, and methionine. In a subsequent step (see vitamin B-12), methylmalonyl CoA isomerizes to the TCA cycle intermediate succinyl-CoA.
3-Methylcrotonyl CoA	3-Methylcrotonyl CoA carboxylase	3-Methylglutaconyl CoA	3-Methylcrotonyl CoA is utilized in leucine catabolism.

**Scheme 13**

mixed-acid anhydride, which reacts to generate as a product, a carboxylated biotinyl-enzyme. The carbon in the CO<sub>2</sub> takes on carb-anion character facilitating subsequent reactions, such as converting acetate to malonate or pyruvate to oxaloacetate.

Another recently identified function of biotin is the biotinylation of histones. Nuclear holocarboxylase synthetases catalyze the covalent binding of biotin to histones. Eleven biotinylation sites have been identified in histones H2A, H3, and H4. Recruitment of histone-modifying complexes enables the regulation of targeted target genes (e.g., the biotinyl carboxylases). Thus, there are two biotin-dependent roles; the metabolic one related to biotin's carboxylase cofactor functions and a distinct regulatory function mediated by nuclear holocarboxylases.

### Metabolism

Biotin is present in relatively high concentrations in cereal grains; however, the bioavailability of biotin varies widely. Absorption involves the proteolysis of biotin-containing enzymes to release biocytin. Biocytinase is an enzyme that catalyzes the cleavage of the peptide linkage between biotin and lysine to release free biotin. Like the other water-soluble vitamins, biotin is taken up by specialized Na-dependent multivitamin carrier-mediated mechanisms. In adult humans, biotin uptake is significantly higher in the duodenum and jejunum compared to the ileum. When biotin-containing carboxylases are degraded in cells, biotin is also released as biocytin. Cellular biocytinases catalyze cleavage to release free biotin for reutilization.

An intake of 30 µg of biotin per day is recommended for adult humans. The dietary biotin intake in Western populations has been estimated to be 35–70 µg/d. The biochemical manifestation of biotin deficiency includes ketolactic acidosis, organic aciduria, and hyperammonemia. Symptoms of overt biotin deficiency include hair loss and dermatitis. Neurological symptoms include lethargy, numbness, and tingling of the extremities. In addition, hepatic steatosis may occur.

Nutritional biotin deficiency is rare, although problems may arise because biotin and biocytin have an affinity for certain proteins, particularly avidin in egg white. Avidin is not easily digested, and as a consequence, biotin is not released in regions of the small intestine where efficient absorption occurs. The inclusion of raw eggs in diets can cause biotin deficiency. For example, the response in commercial fur-bearing animals (alopecia, hair loss) to ingestion of significant quantities of raw egg white has been described as "egg white injury." The search for the "egg white injury" factor eventually led to the discovery of biotin. Genetic disorders involving cellular biocytinase can also precipitate a biotin deficiency. Although rare (<1 in 50,000), biotinidase deficiency is an autosomal recessive disorder in which the body cannot recycle biotin. Its signs and symptoms typically appear within the first few months of life and, if severe, can cause seizures, muscle hypotonia, ataxia, skin rashes, and alopecia. Affected children have delayed development.

Lifelong treatment can prevent some of these complications from occurring or improve them if they have already developed. For example, symptomatic children with biotinidase deficiency improve after treatment with 5–10 mg of oral biotin per day; however, some of the features, such as developmental delay, optic atrophy, and hearing loss, are often irreversible.

## Folic acid

### Functions

Folic acid (folate) is essential for DNA, RNA, and amino acid metabolism. Folate-catalyzed reactions include one-carbon transfers required for purine synthesis, methylation of DNA, thymidine, choline, and *S*-adenosylmethionine [cf. 11]. Folate catalyzed one-carbon transfers are also crucial in the catabolism of histidine and tyrosine.

The structure of folic acid (N-pteroyl-L-glutamic acid) is composed of a pteridine ring attached to *p*-aminobenzoic acid (PABA) linked via the carboxyl group to the  $\alpha$ -nitrogen of glutamic acid. The active coenzyme, tetrahydrofolate (FH<sub>4</sub>), is formed by dihydrofolate reductase, adding four electrons and four hydrogens to the pteridine ring. Mechanistically, hydride ions are transferred from NADPH to the C6 and C8 positions of the pteridine ring. In addition, FH<sub>4</sub> may have up to seven glutamyl residues and exist in different chemical forms, although many are inconvertible.

Scheme 14

One-carbon group transfers are initiated by adding a one-carbon group from serine to form tetrahydrofolate (THF). The reaction is catalyzed by serine hydroxymethyltransferase with glycine and 5,10-methylenetetrahydrofolate (5,10-CH<sub>2</sub>-THF) as products (Fig. 15A). Next, methylenetetrahydrofolate dehydrogenase oxidizes 5,10-methylenetetrahydrofolate, which is hydrolyzed to produce 5-formyl-THF or 10-formyl-THF. Alternative carbon sources include formate. Formate–tetrahydrofolate ligase catalyzes the addition of formate to yield 10-formyl-THF. Glycine, histidine, and sarcosine can also directly contribute to the pool of single

**Fig. 15** Folic Acid and single carbon metabolism. (A)-carbon group transfers are initiated by adding a one-carbon group from serine to tetrahydrofolate (THF). The reaction is catalyzed by serine hydroxymethyltransferase with glycine and 5,10-methylenetetrahydrofolate (5,10-CH<sub>2</sub>-THF) as products. Next, methylenetetrahydrofolate dehydrogenase oxidizes 5,10-methylenetetrahydrofolate, which is hydrolyzed to produce 5-formyl-THF or 10-formyl-THF. Depending on the process, folic acid cofactors can facilitate the transfer of one-carbon units as methyl, formyl, formimino, or methylene groups. (B) Folic acid plays a key role in the methionine cycle. The methionine cycle generates the methyl donor *S*-adenosyl methionine for the transmethylation of proteins, nucleic acids, and other molecules. The cycle also yields homocysteine which can lead to cysteine and glutathione production.

carbon units. Depending on the process, folic acid cofactors can facilitate the transfer of one-carbon units as methyl (Fig. 15B), formyl, formimino, or methylene groups (Lyon et al., 2020).

### Metabolism

By the late 1940s, folic acid was recognized as one of the factors associated with macrocytic anemias. Two proteins, glutamate  $\gamma$ -carboxypeptidase (folate conjugase) and reduced folate carrier protein are essential to the folate absorption process. Following deconjugation or hydrolysis of glutamyl residues, folic acid is taken up by enterocytes and reduced and methylated to 5-methyl-THF. It is the 5-methyl-THF form that is transported across the intestinal basolateral membrane and carried to target organs, such as the liver.

The uptake of 5-methyl-THF by the liver and other tissues involves carrier-mediated transport. 5-methyl-THF is converted to folylpolyglutamate, which keeps the coenzyme inside cells and directs its binding to specific enzymes. Regarding folate turnover, 5%–20% of liver folate undergoes biliary secretion (as 5-methyl-THF) and is subject to enterohepatic recirculation with the remaining passes into the systemic circulation. Maintenance of body pools is also dependent on renal filtration and reuptake. About 1% of the total body folate pool is excreted daily in the urine and 0.1% in the feces. Absorption of folic acid is about 85%, compared to 50% or less for the more complex dietary forms of folylpolyglutamates.

The requirements for folic acid range from 2 to 5 mg per kg of diet or 0.5–3 mg per 1000 kcal. Because folate is required for maintaining nucleotide balance during DNA synthesis, its deficiency is expressed by increased cell death and, in some cases, by a compensatory increase in cell proliferation. For example, in bone marrow, megaloblastosis and macrocytosis of enterocytes reflect defective DNA synthesis. There is a production of larger dysfunctional cells that eventually translates into macrocytic anemia, a condition in which the larger red cells are insufficient in number and hemoglobin. Folic acid deficiency can also result in developmental and neural tube defects and contribute to the development of cardiovascular disease. Hyperhomocysteinemia due to folic acid deficiency is associated with carotid artery narrowing.

As a final point, the discovery that THF is required for DNA synthesis led to the identification of antimetabolites, which function as inhibitors of folic acid reductase and DNA synthesis. The best example is methotrexate, which inhibits the proliferation and regeneration of rapidly replicating cells. Methotrexate irreversibly inhibits dihydrofolate reductase, an enzyme that participates in THF synthesis. With insufficient THF, cell division is blocked in the S phase due to impaired DNA synthesis. Drugs such as methotrexate are widely used to treat autoimmune diseases and cancer chemotherapies.

### Vitamin B12

Among its unique features, B<sub>12</sub> is the only vitamin with a transition metal ion, cobalt, coordinated to its structure. The presence of a cobalt(III) allows the formation of an alkyl bond, which in effect promotes catalysis comparable to a chemical Grignard reagent. The core of the vitamin consists of a corrin ring with a central cobalt atom. The corrin ring contains four pyrrole rings linked together, similar to a heme structure. The cobalt atom within the ring can have a +1, +2, or +3 oxidation state. A fifth valence (below the ring plane) allows dimethylbenzimidazole attachment. Depending on the reaction or enzyme, the remaining sixth valence can either associate with a methyl group, an –OH group, or a 5'-deoxyadenosyl group. Vitamin B12, as 5'-deoxyadenosylcobalamin, is the most common form of the coenzyme found in cells. The 5'-deoxyadenosylcobalamin arises by an attack on the -5'-carbon of ATP by the Co<sup>+</sup>, which displaces the entire triphosphate group. Enzymes that require B<sub>12</sub> fit one of two functional categories: those that transfer methyl groups from the coenzyme to the substrate and those that take part in the positional rearrangement of neighboring groups on the substrate or group transfer reactions.

Scheme 15

**Fig. 16** Methylmalonyl-CoA mutase. Methylmalonyl-CoA mutase catalyzes positional rearrangement reactions, such as converting methylmalonic acid to succinyl-CoA. Methylmalonyl-CoA mutase uses deoxyadenosyl-cobalamin as a cofactor. The reaction mechanism begins with the homolytic cleavage deoxyadenosyl-cobalamin C—Co(III) bond with the C and Co atoms, each acquiring one of the electrons. The Co ion fluctuates between its Co(III) and Co(II) oxidation states and serves as a reversible generator of a free radical.

Methionine synthase catalyzes the methyl-B12-dependent methylation of homocysteine to methionine (Fig. 15B). The reaction is required to produce methionine and generate S-adenosylmethionine, an essential methyl group donor in cells.

In contrast, methylmalonyl-CoA mutase is an example of a positional rearrangement reaction. It is required for the catabolism of branched-chain amino acids into anaplerotic substrates, i.e., substrates essential in maintaining a high level of efficiency in metabolic cycles, such as the TCA cycle. An example is the conversion of methylmalonic acid to succinyl-CoA for ultimate use as a metabolic fuel. Moreover, methylmalonyl-CoA mutase uses the deoxyadenosyl-cobalamin derivative as a cofactor. Thus, the inability to generate deoxyadenosyl-cobalamin may also result in impaired protein catabolism and concomitant mitochondrial energy disruption (Fig. 16).

### Metabolism

Vitamin B12 absorption is complex owing to vitamin B12 instability in acid and nonspecific interactions with proteins and complex carbohydrates. For example, vitamin B12 released from food sources immediately associates with so-called “R-proteins” (haptocorrins and cobalophilins). This action serves to protect vitamin B12 during the process of digestion in acidic environments. At acidic pH, these binding proteins have a very high affinity for vitamin B12.

In addition, another vitamin B12 binding protein, intrinsic factor (IF), is synthesized by the gastric parietal cells in humans. However, this binding protein functions more effectively at neutral pH. In the small intestine, pancreatic proteases digest the R-binding proteins, releasing vitamin B12 which then binds to intrinsic factor. For eventual absorption, it is the B12-IF complex that is recognized by the receptors specific for vitamin B12 located in the terminal ileum. Thus, interference with R-protein or IF production can influence the availability of vitamin B12. Although gastric acid production is highly regulated, hypochlorhydria and achlorhydria can occur. When there is low or no gastric acid in the stomach, there is a greater risk of digestive tract infections. In addition to the potential for impaired vitamin B12 absorption, bacterial overproduction increases the possibility of competition between the host and bacteria for vitamin B12. Such problems are often associated with aging.

The recommended daily amount of vitamin B12 for adults is 2.4 µg per day. Although cobalamin can be synthesized by intestinal flora in the colon because the primary absorption site is the ileum, benefits from endogenous synthesis are precluded. Fortunately, the daily requirement of cobalamin is very small compared to the body pool size (1–2 mg); therefore, it takes many weeks or months to become deficient from dietary inadequacy alone. Nevertheless, nutritional vitamin B12 deficiencies do occur. Diseases of the stomach (e.g., hypochlorhydria and achlorhydria), proximal duodenum, ileum, or pancreatic insufficiency can decrease vitamin B12 absorption. Such conditions left untreated can lead to anemia, fatigue, muscle weakness, intestinal problems, nerve damage, and mood disturbances.

In this regard, it is also important to review the relationships between folate and vitamin B12, along with sparing effects that may be ascribed to methionine. The interrelationship is explained by the so-called “methyl trap hypothesis,” the physiological response to a methyl group deficiency resulting from a low supply of methionine or a decrease in the cellular S-adenosyl-methionine (SAM) concentration (Lyon et al., 2020). In such situations, 5'-methyltetrahydrofolate accumulates in a vitamin B12 deficiency due to the inability to transfer methyl groups to homocysteine, which alters the rate of folate reduction. Moreover, 5-methyl-THF is a poor substrate for folylpolyglutamate synthetase. Thus, there is a decrease in folylpolyglutamates synthesis and retention in tissues.

Restoring the methyl group on methionine primes the system to further methylation because methionine can act independently as a primary donor of methyl groups for SAM production (Lyon et al., 2020). The sparing effect of methionine can also be explained by adenosylmethionine inhibition of methylenetetrahydrofolate reductase, which prevents the buildup of 5-methyl-THF, i.e.,

a vitamin B12 deficiency does not, in itself, cause a folate deficiency if there is sufficient methionine. Nevertheless, deficiencies of any one of these conditions can provoke abnormalities that range from anemia to neurologic deficits to oxidative stress. For example, Vitamin B12 deficiency is associated with increased cellular  $\text{H}_2\text{O}_2$  and reduced glutathione levels, because SAM is involved in the up-regulation of cystathionine- $\beta$ -synthase.

### Conditional nutrients

Compounds with a conditional dietary requirement are often grouped with vitamins, particularly if they act as cofactors and catalytic facilitators in metabolic processes or are involved in metabolite transport (Laurie, 2014). Table 3 lists compounds that are often considered “conditional nutrients,” i.e., there may be a dietary need under certain conditions. Those derived from amino acids or glucose include carnitine, choline, taurine, and inositol. Although not described in Table 3, amino acids such as glycine, arginine, cystine, and methionine are often included. For example, in late pregnancy and early development, the capacity for glycine biosynthesis does not satisfy its use related to collagen production and neonatal growth. In addition, glycine is a precursor in metabolic pathways for creatine, glutathione, heme, purines, and  $\delta$ -aminolevulinic acid, a porphyrin precursor; thus, a lack of glycine may affect their relative production.

Some lipid-derived products also have conditional requirements (e.g., lipoic acid, lutein, zeaxanthin, and ubiquinone). Moreover, a case for a conditional need may be made for nucleic acid-derived products, such as queuine, a component of tRNA that is symbiotically derived from the microbiome, and bipterin, a cofactor for the aromatic amino acid hydroxylases.

Finally, natural products, such as the plant-derived natural polyphenols, are worthy of mention. Natural polyphenols have been consistently a part of the human diet throughout our entire biological evolution. More than 8000 types of polyphenols have been identified and fall into four general classes of compounds:

- Flavonoids (e.g., flavonoids, proanthocyanidins, anthocyanins) accounts for ~60% of food-derived polyphenols.
- Phenolic acids (e.g., stilbenes and lignins) accounts for ~30% of food-derived polyphenols.
- Polyphenolic amides (e.g., capsinoids and avenanthramides).
- Other polyphenols (e.g., ellagic acid, lignans, tyrosol, and pyrroloquinoline quinone).

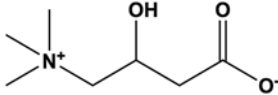

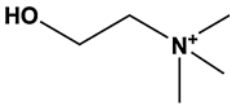

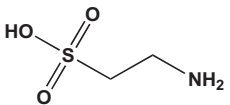

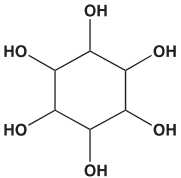

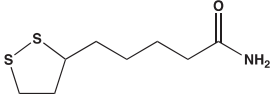

Although consistent physiological effects have been challenging to demonstrate for individual polyphenolic compounds (e.g., quercetin, rutin, curcumin, resveratrol), as a group of compounds, a case can be made for a conditional dietary need. For example, for individual polyphenolic compounds, a given therapeutic response often requires dietary intakes in the hundreds of mgs/day range; but most are present in typical diets at levels less than 10 mg/day. However, in the aggregate, Western diets provide from 0.3 g to 2 g of total polyphenolics per day. Further, many polyphenolic compounds promote physiological responses through the same signaling pathways (e.g., MAP kinase-related signaling pathways) or contribute synergistically to overall ROS defense. Collectively, polyphenolic compounds also cause modification in the expression of cytochrome p450-related xenobiotic pathways. In this regard, arguments have been made using the evolutionary principles of xenohormesis that molecules like polyphenols, which respond to stress-related signals in the plants, have the same health-conferring effects in organisms that evolved as consumers of plants.

Moreover, although consistent physiological effects have been challenging to demonstrate for many individual polyphenolic compounds, there are exceptions. For example, effective doses of [–]-epicatechin (EC) and pyrroloquinoline quinone (PQQ) may be obtained from foods without additional supplementation (Jonscher et al., 2021). EC is associated with increased nitric oxide production, improved blood flow, and physical endurance. Moreover, EC modulates cell signaling, including the MAP kinase-related pathways involved in cell proliferation. In humans, supplementation with EC-rich foods improves insulin sensitivity and glucose. Regarding pyrroloquinoline quinone, PQQ is a biofactor for which a nutritional deficiency can be defined in multiple species of animals (Jonscher et al., 2021). A clear and specific mechanism of action has also been reported for PQQ, and dietary requirements are definable and dose dependent.

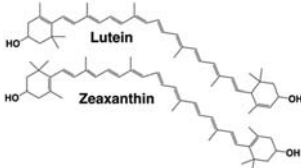

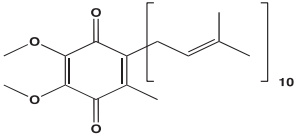

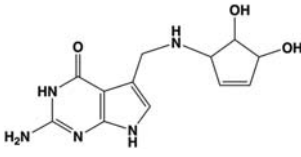

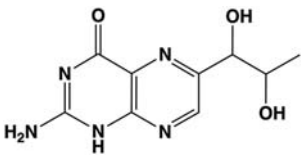

Scheme 16

**Table 3** Vitamin-like conditionally nutrients.

Nutrient	Source	Function	Structure
<b>Amino acid and glucose derived</b>			
Carnitine	The L-isomer of carnitine is a derivative of the amino acid lysine. Typical diets result in 40–250 mg L-carnitine/1000 Kcal daily intakes.	Carnitine is essential for the trans-membrane transport of medium- to long-chain fatty acids into the mitochondria. Acyl-CoA is attached to the hydroxyl group of carnitine to form acylcarnitine. This transesterification is catalyzed by carnitine acyltransferase. The acylcarnitine ester is then transported through the intermembrane space facilitated by carnitine-acylcarnitine translocase.	
Choline	Choline can also be synthesized de novo from ethanolamine when the supply of methionine, dimethylcysteine, and betaine is adequate. Lecithin is the most abundant source of choline in the diet. Humans make choline de novo; however, production is generally insufficient.	Choline is a component of phosphatidylcholines and sphingomyelins found in all cell membranes. Phosphatidylcholines are also needed for the synthesis of VLDL and pulmonary surfactants. Moreover, choline is required to produce the neurotransmitter acetylcholine. In addition, choline can serve as a source of methyl groups for SAM production and oxidized in liver mitochondria to glycine betaine aldehyde, which can be converted to trimethylglycine. Trimethylglycine is utilized as an osmoregulator. Therefore, an adequate dietary intake level for choline is 400–600 mg/day for adults. However, the dietary choline requirement is reduced by increased folate, methionine, and vitamin B12.	
Taurine	Taurine is a product of the cysteine sulfinic acid pathway and the transsulfuration pathway for the conversion of homocysteine into cystathionine. About 400 mg of taurine are consumed per day.	Taurine has multiple functions and is essential to physiological processes, such as osmoregulation, immunomodulation, and bile salt formation. Furthermore, it has biological roles in the conjugation of bile acids, ROS defense, osmoregulation, membrane stabilization, and calcium signaling. In addition, it is essential for cardiovascular function and the development of skeletal muscle, the retina, and the central nervous system.	
Inositol (myo-inositol)	Myo-inositol is synthesized from glucose 6-phosphate	Inositol derivatives (inositol, phosphatidylinositol, and various mono- and polyphosphates) act as intracellular second messengers in regulating thyroid-stimulating hormone, follicle-stimulating hormone, and insulin. Inositol derivatives also facilitate the binding of given neurotransmitters and steroid hormones to their receptors. Such actions are essential to insulin signal transduction, neuro signaling, and cell membrane potential regulation.	
<b>Lipid derived</b>			
Lipoic acid	Lipoic acid is synthesized in mitochondria from octanoic acid (C8:0). There is no established dose. However, subjects with diabetic neuropathy benefit from daily doses of ~600 mg.	Lipoic acid participates in the oxidative decarboxylation of α-ketoacids in the TCA cycle. The biosynthesis of lipoic acid links mitochondrial fatty-acid synthesis and SAM metabolism with TCA cycle oxidative capacity.	

(Continued)

**Table 3**     Vitamin-like conditionally nutrients.—cont'd

Nutrient	Source	Function	Structure
Lutein and zeaxanthin	Lutein and zeaxanthin, however, can be interconverted in the body. Adults in the United States consume on average 1.5–2.5 mg/day of lutein and zeaxanthin combined.	There is some epidemiological evidence that increasing lutein and zeaxanthin intake may lower the risk of cataract development.	
Coenzyme Q10 Ubiquinone	Coenzyme Q10 or ubiquinone is derived from tyrosine following conversion to <i>p</i> -hydroxybenzoate. The benzoquinone ring is conjugated with isoprenoid units (derived from the cholesterol synthesis pathway). There is no ideal dose for ubiquinone. The average dietary intake is 3–6 mg/day.	Ubiquinone is a mobile component of the mitochondrial electron transport chain. The ability of the benzoquinone moiety of coenzyme Q10 to accept and donate electrons is a critical feature of its electron transport function. Ubiquinone exists in three oxidation states. In its reduced form, ubiquinol is an effective fat-soluble antioxidant. In addition, it may facilitate the recycling of $\alpha$ -tocopherol.	
<b>Nucleic acid derived</b>			
Queuine Queuosine	Queuine or its nucleotide form is found in the tRNA of nearly all eukaryotic organisms; however, it is produced exclusively by bacteria. Humans obtain queuine from the diet or salvage it from symbiotic microbes. The human queuine requirements are not well understood, and the prevalence of queuine deficiency in humans is unknown.	tRNAs possess numerous modified nucleosides, which are essential in maintaining specific tRNA structures, translational efficiency, and codon recognition. One of the modified nucleosides is queuosine. Queuosine is irreversibly inserted during the maturation of Q-tRNAs (queuosine-modified tRNAs) associated with cell proliferation. Humans acquire queuine from the diet and intestinal microflora. In the absence of queuosine modification, translation at Q-decoded codons slows down, and proper protein folding is affected. In addition, queuine depletion impairs the recycling of the reduced forms of biopterin, resulting in a deficit of tetrahydrobiopterin (see below), which impairs the activity of the aromatic amino acid hydroxylase enzymes.	
Biopterin	Guanosine-5'-triphosphate serves as the substrate for de novo biopterin synthesis. Under rare circumstances, a deficiency of the active form of biopterin may occur due to genetic defects in synthesis pathways. Treatment of BH4 deficiencies consists of BH4 2–20 mg/kg per day supplements or diet to control blood phenylalanine, which is toxic when abnormally elevated.	Reduced biopterin (tetrahydrobiopterin, THB) is a cofactor for aromatic amino acid hydroxylases involved in neurotransmitter synthesis, including dopamine, norepinephrine, epinephrine, and serotonin. Nitric oxide synthesis also uses biopterin derivatives as cofactors. In addition, biopterin is needed to produce skin pigments (catecholamines, melanin, serotonin, and melatonin) and cell signaling (nitric oxide).	

PQQ acts as an accessory factor for lactate acid and other dehydrogenases, promoting NADH oxidation to NAD<sup>+</sup>. Consequently, the effects of PQQ exposure, both in vivo and in vitro, mimic cellular NAD<sup>+</sup> augmentation (cf., [Fig. 2](#)). As noted (see Niacin), NAD<sup>+</sup> is a substrate in deacetylase, desuccinylase, demalonylase, demyristoylase, and depalmitoylase reactions catalyzed by sirtuins. Maintaining cellular NAD<sup>+</sup> levels optimizes mitochondriogenesis and neural-muscular communication. PQQ also appears essential for reproduction in mice and rodent models. In humans, PQQ is associated with attenuating of clinically relevant dysfunctions such as ischemia, neurogenic losses, inflammation, and lipotoxicity. Notably, the levels of PQQ needed for given responses in tissues are in the pM to nM range and easily achieved. For example, PQQ and its derivatives, such as imidazopyrroloquinoline (IPQ) compounds, are found in human milk at levels compatible with reproduction and normal growth in animal models ([Jonscher et al., 2021](#)).

## Conclusion

A mechanistic understanding of function facilitates the effective and meaningful translational of findings at all levels. Although the criterion for mechanistic insight varies among disciplines, such insight is nevertheless interdependent. Knowledge of mechanisms at a chemical and physical level aids in identifying the question to be asked related to given cellular and organ regulatory functions. At the population level, mechanistic information is essential in defining limits regarding a recommended level of intake. As it relates to fat- and water-soluble vitamins, the current focus on individualized diets requires an abundance of basic information ranging from a person's genetics to the potential of microbiome synergisms with different dietary exposures. A goal for many of the descriptions and examples was to emphasize that a better understanding of mechanisms helps to link genetics, metabolomics, and clinical observations to recommendations for nutrient provision. In this regard, much may be learned from animal models when appropriate attention is given to the allometric approaches needed for correct comparisons.

There is still much to be done. For example, the role of vitamins and related nutrients on the potential and beneficial promotion of the microbiota remains unclear. In addition, more information is needed regarding the potential synergisms between dietary biofactors and groups of biofactors, such the natural polyphenolics. Further, there are compounds, such as pyrroloquinoline quinone, for which a case may be made for essentiality.

### Key points

- When administered orally, ethanol travels down the gastrointestinal tract until absorbed.
- Absorbed ethanol is oxidized to acetaldehyde.
- Alcohol dehydrogenase (ADH), Microsomal ethanol oxidizing system (MEOS) or Catalase are the three main enzyme systems that catalyze the conversion of ethanol to acetaldehyde.
- Acetaldehyde is highly toxic and forms harmful adducts by binding cellular constituents.
- Acetaldehyde is oxidized to acetate.
- The further metabolism of acetate and its role in alcohol-induced disease are incompletely understood.
- Up to 90% of all ethanol metabolism is hepatic.

## Glossary

**Alcohol dehydrogenase** Alcohol dehydrogenase (ADH) is an enzyme that couples oxidation of ethanol to reduction of nicotinamide adenine dinucleotide (NAD<sup>+</sup>) to NADH. ADH has a wide range of substrates and functions, including dehydrogenation of steroids and oxidation of fatty acids

**Aldehyde dehydrogenase** Aldehyde dehydrogenase (ALDH) is an enzyme that couples oxidation of acetaldehyde to reduction of NAD<sup>+</sup>. The presence of ALDH in tissues may reduce the toxic effects of acetaldehyde

**Blood ethanol concentration** Blood ethanol concentration is commonly used as a measure of intoxication. It is commonly expressed as mg L<sup>-1</sup>, g dL<sup>-1</sup>, or mmol L<sup>-1</sup>

**Catalase** is a common enzyme found in nearly all living organisms. The main action is the decomposition of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) to water. It can also oxidize ethanol in a reaction that requires H<sub>2</sub>O<sub>2</sub>

**First-pass metabolism** First-pass metabolism of ethanol. Reduces the concentration of ethanol before it reaches the systemic circulation

**Microsomal ethanol oxidizing system** The microsomal ethanol oxidizing system (MEOS) is another pathway of ethanol metabolism. The key enzyme of the MEOS is cytochrome P4502E1 (CYP2E1). This catalyzes the oxidation of NADPH to NADP<sup>+</sup>

## Introduction

After caffeine, ethanol is the most commonly used recreational drug worldwide. Alcohol is synonymous with ethanol, and drinking often describes the consumption of beverages containing ethanol. In the United Kingdom (UK), a unit of alcohol (standard alcoholic drink; [Table 1](#)) contains 8 g (equivalent to 10 mL) of ethanol (ethyl alcohol).

In 2016, the Department of Health in the UK published updated guidelines for low risk alcohol intake based on these units of alcohol. This guidance suggests that regularly consuming any amount of alcohol is associated with long-term risks ([Department of Health, 2016](#)). However, rather than advocating universal abstinence, the [Department of Health \(2016\)](#) advised regular drinkers (both male and female) to drink less than 14 units per week spread over at least three days. Women were also advised not to drink any alcohol at all while pregnant ([Department of Health, 2016](#)).

However, as the amount of ethanol in one unit or a standard alcoholic drink varies throughout the world ([Table 2](#)), the unit system does not allow international comparisons. It is therefore important to note that the guidance from the UK [Department of Health \(2016\)](#) recommends consumption of less than 112 g ethanol per week (i.e., 14 UK Units of alcohol). Recommendations for sensible limits for alcohol intake also vary worldwide.

Despite these guidelines, the quantity of alcohol consumed varies widely. Many enjoy the pleasant psychopharmacological effects of alcohol. However, some experience adverse reactions due to genetic variation of enzymes that metabolize alcohol. Misuse of alcohol undoubtedly induces pathological changes in most organs of the body ([Preedy and Watson, 2004](#)). Many of the effects of alcohol correlate with the peak concentration of ethanol in the blood during a drinking session ([Morgan and Ritson, 2003](#); [Abraham et al., 2017](#)). It is therefore important to understand the factors that influence the blood ethanol concentration (BEC) achieved from a dose of ethanol.

**Table 1** Unit system of ethanol content of alcoholic beverages.<sup>a</sup>

<i>Beverage containing ethanol</i>	<i>Units of ethanol</i>
Half pint of low-strength beer (284 mL)	1
Pint of beer (568 mL)	2
500 mL of high-strength beer	6
Pint of cider	2
One glass of wine (125 mL)	1
Bottle of wine (750 mL)	6
One measure of spirits (e.g., whisky, gin, vodka)	1
Bottle of spirits (e.g., vodka; 750 mL)	36

<sup>a</sup>The unit system is a convenient way of quantifying consumption of ethanol and offers a suitable means to give practical guidance. However, there are several problems with the unit system. The ethanol content of various brands of alcoholic beverages varies considerably (for example, the ethanol content of beers/ales is in the range 0.5–9.0% so a pint may contain 2–5 units) and the amounts of alcohol consumed in homes bear little in common with standard measures.

**Table 2** Geographical variation in the amount of ethanol in one unit.<sup>a</sup>

Country	Amount of ethanol (g)
Sweden	20
Japan	19.75
United States	14
Australia and New Zealand	10
United Kingdom	8

<sup>a</sup>The unit system does not permit international comparisons.

To avoid confusion, all subsequent references to “units” of alcohol or “standard drinks” will allude to the UK definition (i.e., 8 g) unless otherwise specified. In addition, all concentrations specified as a percentage will refer to the weight volume (i.e., w v<sup>-1</sup>) percentage.

### Physical properties of ethanol

Ethanol is produced from the fermentation of glucose by yeast. Ethanol ([Fig. 1](#)) is highly soluble in water due to its polar hydroxyl (OH) group. The nonpolar (C<sub>2</sub>H<sub>5</sub>) group enables ethanol to dissolve lipids and thereby disrupt biological membranes. As a relatively uncharged molecule, ethanol crosses cell membranes by passive diffusion.

### Absorption and distribution of alcohol

The basic principles of alcohol absorption from the gastrointestinal (GI) tract and subsequent distribution are well understood. Beverages containing ethanol pass down the esophagus into the stomach. The endogenous flora of the GI tract can also transform food into a “cocktail” containing several alcohols including ethanol ([Cordell et al., 2019](#)). This is particularly important if there are anatomical variations in the upper GI tract (e.g., Crohn disease or diverticulae; [Cordell et al., 2019](#)).

Alcohol continues down the GI tract until absorbed ([Halsted et al., 1973](#)). The ethanol concentration therefore decreases down the GI tract. There is also a concentration gradient of ethanol from the lumen to the blood. The concentration of ethanol is much higher in the lumen of the upper small intestine than in plasma ([Table 3](#); [Halsted et al., 1973](#)). Alcohol diffuses passively, traversing the mucosal cell membranes to enter the submucosal area and then the submucosal capillaries ([Kalant, 2004](#)).

Absorption occurs across all of the GI mucosa but is fastest in the duodenum and jejunum ([Kalant, 2004](#)). The rate of gastric emptying is the main determinant of alcohol absorption. This is because most ethanol absorption occurs after it has passed from the stomach via the pylorus ([Kalant, 2004](#)).

Alcohol diffuses from the blood into tissues across capillary walls. Ethanol concentration equilibrates between blood and the extracellular fluid within a single pass ([Kalant, 2004](#)). However, equilibration between blood water and total tissue water may take several hours, depending on the cross-sectional area of the capillary bed and tissue perfusion ([Kalant, 2004](#)).

**Fig. 1** Chemical structure of ethanol (ethyl alcohol). Ethanol is soluble in water due to its polar hydroxyl (OH) group. The non-polar (C<sub>2</sub>H<sub>5</sub>) group enables ethanol to dissolve lipids and thereby disrupt biological membranes.

**Table 3** Approximate ethanol concentrations in the gastrointestinal tract and in the blood of a 70 kg male after consumption of 7 units of alcohol.<sup>a</sup>

Site	Ethanol concentration	
	g/dL	mmol/L
Stomach	8	1740
Jejunum	4	870
Ileum	0.1–0.2	22–43
Blood (15–120 min after dosage)	0.1–0.2	22–43

<sup>a</sup>Ethanol appears in the blood as quickly as 5 min after ingestion and is rapidly distributed around the body. A dose of 0.8 g ethanol per kg body weight (56 g ethanol (7 units) consumed by a 70 kg male) should result in a blood ethanol concentration of 100–200 mg dL<sup>-1</sup> (22–43 mmol L<sup>-1</sup>) between 15 and 120 min after dosage. Highest concentrations occur after 30–90 min.

Ethanol enters most tissues but its solubility in bone and fat is negligible. Therefore, in the post-absorption phase, ethanol's volume of distribution will reflect total body water composition. Thus, after a specific dose of ethanol, the BEC will correlate with lean body weight.

## Metabolism of alcohol

The rate at which alcohol is eliminated from the blood by oxidization varies from 6 to 10 g h<sup>-1</sup> (Kalant, 2004). This is reflected by the BEC, which falls by 9–20 mg dL<sup>-1</sup> h<sup>-1</sup> after consumption of ethanol (Kalant, 2004). After a dose of 0.6–0.9 g per kg body weight without food, elimination of ethanol is approximately 15 mg dL blood<sup>-1</sup> h<sup>-1</sup> (Fisher et al., 1987). However, several factors may modulate this rate and there is considerable individual variation.

Absorbed ethanol is initially oxidized to acetaldehyde (Fig. 2) by one of three pathways (Fig. 3) (Lieber, 2005; Rajendram et al., 2016a):

1. Alcohol dehydrogenase (ADH)–cytosol
2. Microsomal ethanol oxidizing system (MEOS)–endoplasmic reticulum
3. Catalase–peroxisomes

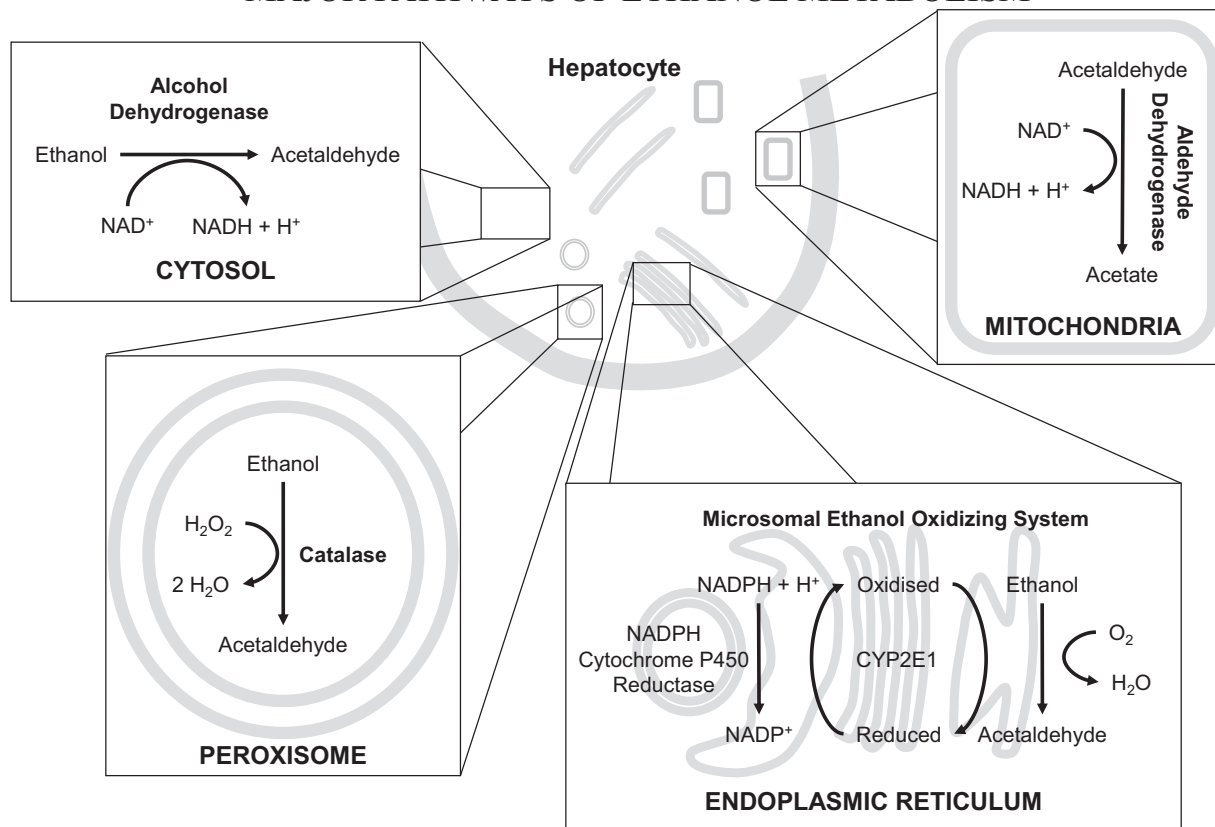

## Alcohol dehydrogenase

The oxidation of ethanol is coupled to the reduction of nicotinamide adenine dinucleotide (NAD<sup>+</sup>) to NADH by ADH (Kwo and Crabb, 2002; Kalant, 2004; Höög and Ostberg, 2011). This enzyme has a wide range of substrates and performs several important functions, including dehydrogenation of steroids and oxidation of fatty acids (Kwo and Crabb, 2002).

**Fig. 2** Chemical structures of acetaldehyde and acetate. Chemical structures of acetaldehyde and acetate, the products of ethanol metabolism. Acetaldehyde and acetic acid/acetate are the current preferred or common names for these chemicals. However, some texts may use their systematic names, i.e., ethanal and ethanoic acid, respectively.

## MAJOR PATHWAYS OF ETHANOL METABOLISM

**Fig. 3** Pathways of ethanol metabolism. This figure illustrates the most important enzyme pathways that oxidize ethanol to acetaldehyde and acetate. Adapted from [Rajendram et al. \(2013\)](#).

### Alcohol dehydrogenase isoenzymes

ADH is a zinc metalloprotein with at least five different isoenzyme classes ([Kwo and Crabb, 2002](#); [Edenberg, 2007](#)). These isoenzymes are generated by the dimerization of eight different subunits ([Kwo and Crabb, 2002](#)). There are at least seven genes which encode these isoenzymes of ADH ([Wang et al., 2012](#)). Class 1 isoenzymes generally require a low concentration of ethanol to achieve “half-maximal activity” (low  $K_m$ ), whereas class 2 isoenzymes have a relatively high  $K_m$  ([Kwo and Crabb, 2002](#)). Class 3 ADH has a low affinity for ethanol and does not participate in the hepatic oxidation of ethanol ([Lieber, 2005](#)). Class 4 ADH is found in the human stomach ([Moreno and Pares, 1991](#); [Stone et al., 1993](#); [Kwo and Crabb, 2002](#)) and class 5 ADH has been found in the liver and stomach ([Yasunami et al., 1991](#); [Kwo and Crabb, 2002](#)). Whereas the majority of ethanol metabolism occurs in the liver, gastric ADH is responsible for a small portion of ethanol oxidation. It is therefore important to note that the gastric ADH activity in women is less than that in men ([Frezza et al., 1990](#)). This may explain some (but not all) of the differences between the effects of alcohol on men and women.

### Catalase

Peroxisomal catalase, which requires the presence of hydrogen peroxide ( $H_2O_2$ ), is usually of little significance in the metabolism of ethanol ([Lieber, 2005](#)). Metabolism of ethanol by ADH inhibits catalase activity because  $H_2O_2$  production is inhibited by the reducing equivalents (NADH) produced by ADH ([Lieber, 2005](#)). However, metabolism of ethanol by catalase may be more significant if the other pathways for ethanol metabolism are inhibited, for example, by mitochondrial damage in a chronic alcoholic.

### Microsomal ethanol oxidizing system

Chronic administration of ethanol with nutritionally adequate diets increases clearance of ethanol from the blood. The MEOS has a higher  $K_m$  for ethanol ( $8\text{--}10\text{ mmol L}^{-1}$ ) than ADH ( $0.2\text{--}2.0\text{ mmol L}^{-1}$ ) so at low BEC, ADH is more important ([Lieber, 2005](#)).

However, unlike the other pathways, MEOS is highly inducible by chronic alcohol consumption (Lieber, 2005). Cytochrome P4502E1 (CYP2E1) is the most important ethanol metabolizing enzyme in the MEOS (Lieber, 2005). Chronic alcohol use is associated with a 4- to 10-fold increase of CYP2E1 due to increases in mRNA levels and rate of translation (Lieber, 2005).

When ethanol is metabolized by CYP2E1, free radicals are generated and acetaldehyde is produced (Tan et al., 2020). These highly reactive toxins deplete intracellular defenses against oxidative stress (e.g., glutathione) (Lieber, 2005; Konishi and Ishii, 2007). Hepatotoxicity occurs when these defenses are exhausted. The production of lipid hydroperoxides is accelerated by CYP2E1 activity. Lipid hydroperoxides contribute to the development of fatty liver disease and steatohepatitis (Kong et al., 2019). These diseases are commonly associated with obesity, type 2 diabetes, and hyperlipidemia as well as alcohol misuse.

Several commonly used medications are substrates for CYP2E1 (Konishi and Ishii, 2007). These include acetaminophen, diazepam and warfarin. Thus, the metabolism of these medications is increased when the expression of CYP2E1 is induced. This causes tolerance to these medications and reduces their efficacy (Konishi and Ishii, 2007). Induction of CYP2E1 also increases production of toxic metabolites such as, N-acetyl-p-benzoquinoneimine from acetaminophen (Yang and Beard, 2006). These toxins may compound ethanol-induced hepatotoxicity.

This cytochrome also has important roles in normal metabolism and homeostasis. CYP2E1 is involved in fatty acid oxidation and the diversion of ketones to gluconeogenesis (Lieber, 2005; Konishi and Ishii, 2007). The conversion of acetone to acetol is catalyzed by CYP2E1 (Bondoc et al., 1999). This acetol is further metabolized to methylglyoxal (Bondoc et al., 1999). Both methylglyoxal and acetol are involved in gluconeogenesis.

### Acetaldehyde metabolism

Humans' main source of exposure to acetaldehyde is their diet. Acetaldehyde is highly toxic but is rapidly converted to acetate. This conversion is catalyzed by aldehyde dehydrogenase (ALDH) and is accompanied by reduction of NAD<sup>+</sup> (Fig. 3). Like ADH, ALDH also has several isoenzymes (Kwo and Crabb, 2002). The most important of these isoenzymes are ALDH1, which is cytosolic, and ALDH2 which is present in mitochondria (Kwo and Crabb, 2002). The presence of ALDH in most tissues (for example in skeletal muscle) may reduce the toxicity of acetaldehyde.

There are several polymorphisms of ALDH2. The ALDH2\*2 allele, for example, encodes an inactive form of ALDH (Edenberg, 2007; Wang et al., 2012). Furthermore, this allele's expression is so dominant that there is virtually no detectable ALDH2 activity even in heterozygotes. While Europeans and Africans rarely have this allele, the ALDH2\*2 allele is often found in those of east Asian origin (for example, Japan, China) (Edenberg, 2007; Wang et al., 2012). The enzyme produced on translation of the ALDH2\*2 allele does not contribute to acetaldehyde metabolism.

Those who express the ALDH2\*2 allele can be subjected to the toxic effects of acetaldehyde by consuming just small amounts of alcohol (Peng et al., 2002). When individuals with this form of ALDH ingest ethanol the plasma concentration of acetaldehyde spikes sharply. This induces unpleasant sensations that probably reduce the risk of alcohol dependence (Peng et al., 2002). These sensations include nausea, facial flushing (see below for the section on facial flushing) and an increase in the heart rate. This is similar to the disulfiram reaction due to the rise of acetaldehyde after inhibition of ALDH (Edenberg, 2007). Disulfiram is used therapeutically to encourage abstinence in alcohol rehabilitation programs. The aversive effects of acetaldehyde may reduce the development of alcoholism and the incidence of cirrhosis in "flushers" (Edenberg, 2007; Wang et al., 2012).

In alcoholics, the oxidation of ethanol is increased by induction of MEOS. However, the capacity of mitochondria to oxidize acetaldehyde is reduced. Hepatic acetaldehyde therefore increases with chronic ethanol consumption (Di Padova et al., 1987). A significant rise in the acetaldehyde concentration of hepatic venous blood matches the high tissue levels of acetaldehyde.

### Metabolism of acetate

Acetaldehyde is converted to acetate by ALDH. In non-fasting humans, serum acetate concentrations are usually under 0.2 mmol/L (Ballard, 1972). However, after consumption of alcohol, serum acetate may increase more than 20 times above this baseline concentration (Cornier, 2004). Serum acetate concentrations may also be increased by fasting (i.e., starvation ketosis) and insulin deficiency (i.e., type 1 diabetes). The principles of acetate metabolism are not well described. However, the current understanding has been reviewed by Cornier (2004), Rajendram et al. (2016a) and Bose et al. (2019).

The metabolism of acetate is clearly very important to several homeostatic pathways and functions in cells' cytosol, mitochondria, and nuclei (Bose et al., 2019). Dysregulation of the metabolism of acetate and acetyl-CoA is associated with several diseases including alcoholic hepatitis (Kendrick et al., 2010; Bose et al., 2019).

### Nonoxidative metabolism of alcohol

Non-oxidative metabolism of alcohol, which results in formation of ethyl esters from fatty acids occurs in several organs which lack an oxidative system to metabolize alcohol (e.g., pancreas, heart, and adipose tissue) (Heier et al., 2016). These organs often develop alcohol-induced disease so fatty acid ethyl esters may play a role in the pathogenesis of the lesions induced by alcohol consumption

(Heier et al., 2016). The nonoxidative metabolism of ethanol may be more significant if the other pathways for ethanol metabolism are overwhelmed or inhibited.

### Kinetics of ethanol elimination in vivo

Initially, it was believed that the process of ethanol elimination always followed zero-order kinetics. That is to say, the rate of elimination of ethanol is always constant and does not vary with the concentration of ethanol (Norberg et al., 2003). Indeed, the metabolism of ethanol does usually follow zero order kinetics because the  $K_m$  of most ADH isozymes for ethanol is only about 1 mmol/L. Thus, ADH can be saturated even at relatively low ethanol concentrations. When ADH is saturated the rate of ethanol elimination then proceeds at maximal velocity and is then independent of concentration (Norberg et al., 2003).

However, concentration-dependent ethanol metabolism has been observed in some studies of the elimination of alcohol (Ramchandani et al., 2001). There are several possible explanations for this. If ADH is not saturated the rate of elimination of ethanol will not be constant. At low ethanol concentrations its elimination follows Michaelis-Menten kinetics. In that setting, the ethanol concentration and the kinetic constants  $K_m$  and  $V_{max}$  determine the rate of elimination (Matsumoto and Fukui, 2002). Furthermore, because the  $K_m$  of CYP2E1 and some isoenzymes of ADH for alcohol is high, the elimination of ethanol may remain concentration-dependent even at high BEC. Regardless, because of the intermittent concentration dependence of ethanol metabolism, a single specific rate of alcohol metabolism cannot be defined.

### Genetics of ethanol metabolism

Single nucleotide polymorphisms (SNPs) in the genes encoding ADH influence the translated enzymes' characteristics (Wang et al., 2012). The ADH polymorphisms vary between racial subgroups. There are three known polymorphisms in the ADH1B gene and two in the ADH1C gene. The ADH1B\*1 allele encodes the  $\beta 1$  subunit of ADH (Edenberg, 2007; Wang et al., 2012). This is the reference allele for ADH1 (Edenberg, 2007; Wang et al., 2012). The enzyme produced on translation of the ADH1B\*1 allele has arginine at positions 48 and 370. The ADH1B\*2 allele results in the production of an ADH enzyme subunit which has histidine in position 48 ( $\beta 2$ ). The ADH1B\*3 allele produces an ADH enzyme subunit with cysteine in position 370 ( $\beta 3$ ). These seemingly insignificant differences in amino acids have profound effects on  $NAD^+$  binding (Edenberg, 2007; Wang et al., 2012).

The ADH1B\*2 allele is common in Asians and the ADH1B\*3 allele is common in Africans (Zintzaras et al., 2006; Edenberg, 2007; Wang et al., 2012). Yet, individual studies of the polymorphisms of ADH2, ADH3, CYP2E1 and ALDH2 failed to conclusively identify any associations with alcohol misuse or toxicity. However, a large meta-analysis suggested that the risk of alcohol misuse is increased by the ADH2\*1 and ADH3\*2 alleles, or the ALDH2\*1 allele (Zintzaras et al., 2006). As ADH2\*1 and ADH3\*2 are less active forms of ADH and ALDH2\*1 is very active; these polymorphisms prevent acetaldehyde from accumulating. Rapid clearance of acetaldehyde by ALDH2\*1 also reduces the risk of alcoholic liver disease. On the other hand, neither ADH2 nor the ADH3 polymorphisms are implicated in alcoholic liver disease (Zintzaras et al., 2006). The risk of alcohol misuse or alcoholic liver disease is influenced by CYP2E1 polymorphism (Zintzaras et al., 2006).

Research in this field is progressing rapidly, but currently is still in its infancy. Alcohol misuse has been associated with select polymorphisms in the genes encoding enzymes that metabolize ethanol (e.g., ADH1B) has been identified by individual genome-wide association studies (GWAS; Lai et al., 2019). However, the findings of GWAS on other polymorphic loci have been inconsistent (Lai et al., 2019). This may be because the symptoms of alcohol misuse and ethanol toxicity are heterogeneous (Lai et al., 2019).

Considerable effort is still required to tease out the nature of the relationships between alcohol-induced disease and these polymorphisms. Regardless, it is already clear that the expression of these polymorphic genes has significant impact on alcohol metabolism and therefore blood ethanol concentration.

### Blood ethanol concentration

The relationship between BEC and the effects of alcohol is complex and varies between individuals and with patterns of drinking. Many of the effects correlate with the peak concentration of ethanol in the blood and organs during a drinking session. Other effects are due to products of metabolism and the total dose of ethanol ingested over a period of time. These two considerations are not entirely separable because the ethanol concentration during a session may determine which of its metabolic pathways are dominant.

It is of considerable clinical interest to understand what factors increase the probability of higher maximum ethanol concentrations for any given level of consumption.

## Factors affecting blood ethanol concentration

Ethanol has a low lipid: water partition coefficient. Thus, differences in body composition (i.e., fat and water content) will influence the differences between the BEC of drinkers who ingested the same dose of ethanol per kg body weight (Marshall et al., 1983; Goist and Sutker, 1985; Smith et al., 1993). This is relevant to gender differences in BEC.

## Gender differences in blood ethanol concentration

Women achieve higher peak BEC than men given the same dose of ethanol per kilogram of body weight (Marshall et al., 1983; Goist and Sutker, 1985; Smith et al., 1993). Total body water (TBW) strongly influences ethanol's volume of distribution (Marshall et al., 1983). Because the bodies of women contain a greater proportion of fat, it is not surprising that the BEC is higher in women. Moreover, the differences in the BEC of men and women disappears if ethanol is dosed by TBW rather than body weight (Goist and Sutker, 1985). However, the gender differences in the gastric metabolism of ethanol described above may also be relevant. Women have a lower rate of first-pass metabolism compared to men when given high concentrations of alcohol (Baraona et al., 2001).

## Period over which the alcohol is consumed

Rapid intake of alcohol increases the concentration of ethanol in the stomach and small intestine. The greater the concentration gradient, the faster the absorption of ethanol and therefore peak BEC. If alcohol is consumed and absorbed faster than the rate of oxidation, then BEC increases.

## Effects of food on blood ethanol concentration

Gastric emptying is delayed by food. Thus, eating flattens the increase in BEC seen when drinking alcohol on an empty stomach. The mean rate of clearance of ethanol from the blood increases by up to 50% after eating (Jones, 1993). Thus, drinking alcoholic beverages with or after food attenuates the peak BEC and reduces the area under the curve (AUC) when BEC is plotted against time (Fig. 4).

These facts can be illustrated by considering the observations of a study conducted by Jones and Jönsson (1994). In this study ten men were given a drink containing ethanol in the morning either immediately after consuming a standard meal or after fasting overnight (Jones and Jönsson, 1994). Jones and Jönsson measured the BEC in their subjects at several time points after they had consumed the alcoholic beverage.

After administration of  $0.80 \text{ g kg}^{-1}$  to fasted subjects, Jones and Jönsson (1994) found that the mean peak BEC was  $104 \text{ mg dL}^{-1}$  (standard deviation; SD  $14.5$ ;  $23.7 \text{ mmol/L}$  SD  $3.1$ ). The mean peak BEC was significantly lower if the same dose

**Fig. 4** Blood ethanol concentration curve after oral dosing of ethanol. Blood ethanol concentration curve after oral dosing of ethanol. This figure illustrates the possible trajectory of a subject's blood ethanol concentration after ingestion of  $0.8 \text{ g kg}^{-1}$  ethanol over 30 min either after an overnight fast (unbroken line) or after breakfast (broken line). The peak blood ethanol concentration and the area under the curve are reduced if ethanol is consumed with food (broken line).

of ethanol was taken after the overnight fast had been broken by a morning meal ( $67 \text{ mg dL}^{-1}$  SD  $9.5 \text{ mg dL}^{-1}$ ;  $14.4 \text{ mmol/L}$  SD  $2 \text{ mmol/L}$ ;  $p < 0.001$ ).

The mean AUC of the BEC time chart (0–6 h) was  $398 \text{ mg dL}^{-1} \times \text{h}$  (SD  $56 \text{ mg dL}^{-1} \times \text{h}$ ) in fasting subjects compared with  $241 \text{ mg dL}^{-1} \times \text{h}$  (SD  $34 \text{ mg dL}^{-1} \times \text{h}$ ) in those who drank after breakfast ( $p < 0.001$ ). The ethanol was metabolized approximately 2 h earlier if subjects drank before breaking their overnight fast (Jones and Jönsson, 1994).

The contributions of various nutrients to these effects have been studied, but small, often conflicting, differences have been found. The meal's caloric load seems to more relevant than specific nutritional content (Carbonnel et al., 1994).

However, food increases splanchnic blood flow which maintains the ethanol diffusion gradient in the small intestine (Kalant, 2004). Food-induced impairment of gastric emptying may be partially offset by faster absorption of ethanol in the duodenum (Kalant, 2004).

In animal studies liquid diets are often used to administer ethanol as well as other nutrients. It is, therefore, important to note that when ethanol is given in water, the AUC is greater than when a liquid diet is used to deliver with the same dose of ethanol (de Fiebre et al., 1994). The different blood ethanol profile could affect the expression of pathology in these models (Kalant, 2004).

## Beverage alcohol content and blood ethanol concentration

While the type of alcoholic drink (i.e., beer, wine or spirit) does not affect the BEC per se; the ethanol concentration of the beverage consumed (Table 4) does affect ethanol absorption and can, therefore, affect BEC (Roine et al., 1991, 1993). Absorption is fastest if the ethanol concentration is 10–30%. Under 10%, the low ethanol concentration in the GI tract reduces diffusion and the greater volume of liquid slows gastric emptying.

The concentration of ethanol in the GI tract also affects first-pass metabolism (FPM) (see below). Gastric ADH requires a high ethanol concentration for optimal activity. The ethanol concentration in the beverage consumed will therefore affect oxidation of ethanol to acetaldehyde (Roine et al., 1991). After ingestion of equivalent amounts of ethanol less FPM and higher blood levels occur after consumption of beer which has a low ethanol concentration than whisky which has a high ethanol concentration (Roine et al., 1993).

## First-pass metabolism of ethanol

The AUC is significantly lower after oral dosing (AUC<sub>oral</sub>) of ethanol than after intravenous (AUC<sub>iv</sub>) or intraperitoneal administration. The total dose of intravenously administered ethanol is available to the systemic circulation. The difference between AUC<sub>oral</sub> and AUC<sub>iv</sub> represents the fraction of the oral dose that was either not absorbed or metabolized before entering the systemic circulation FPM. The ratio of AUC<sub>oral</sub> to AUC<sub>iv</sub> reflects the oral bioavailability of ethanol.

The investigation of ethanol metabolism has primarily focused on the liver and its relationship to liver pathology. The role of the stomach in ethanol metabolism is controversial. However, several ADH isoenzymes are present in human gastric mucosa (Kwo and Crabb, 2002). This suggests that the stomach contributes to the FPM of ethanol (Moreno and Pares, 1991; Yasunami et al., 1991; Lieber, 2005). However, gastric metabolism could account for 5% of ethanol oxidation and 2–10% of ethanol is eliminated by urination, sweating, or breathing. The remaining ethanol undergoes hepatic metabolism.

Thus, up to 90% of all ethanol metabolism may be hepatic. However, several factors including ethnicity (Dohmen et al., 1996), gender (Frezza et al., 1990) and alcoholism (Di Padova et al., 1987) alter overall FPM. The observations that their effects on FPM correlate with their effects on gastric alcohol dehydrogenase (ADH) activity (Di Padova et al., 1987; Dohmen et al., 1996; Frezza et al., 1990) is further evidence for ethanol metabolism in the stomach.

The activity of gastric ADH is high. Its  $K_m$  is approximately  $40 \text{ mmol/L}$  (Kwo and Crabb, 2002). Thus, although, hepatic oxidation of ethanol cannot increase once ADH is saturated, gastric ADH can metabolize ethanol significantly at the high concentrations in the stomach. Thus, gastric ADH can protect the body somewhat if excessive amounts of ethanol are consumed. If gastric emptying

**Table 4** Alcohol content of selected beverages.

Beverage	Alcohol content		
	g/dL (%)	mmol/L	mol/L
Low-strength beers	3–4	650–870	0.65–0.87
High-strength beers	8–9	1740–1960	1.74–1.96
Wine	7–14	1520–3040	1.52–3.04
Brandy	35–45	7610–9780	7.61–9.78
Vodka	35–50	7610–10,870	7.61–10.87
Gin	35–50	7610–10,870	7.61–10.87
Whisky	35–75	7610–16,300	7.61–16.30

is delayed, prolonged contact with gastric ADH increases FPM of ethanol. Conversely, fasting which increases the speed of gastric emptying, reduces gastric FPM (Di Padova et al., 1987).

### Contribution of first-pass metabolism to overall ethanol metabolism

After absorption, ethanol is transported to the liver in the portal vein. Some is metabolized by the liver before reaching the systemic circulation. However, hepatic ADH is saturated at a BEC that may be achieved in an average-size adult after consumption of one or two UK units. If hepatic ADH is saturated by ethanol entering the liver from the systemic circulation via the hepatic artery, the ethanol in the portal blood must compete for ADH binding sites.

Thus, fractionally, hepatic FPM is greater when less alcohol is consumed. For example, the fractional FPM after consumption of 0.15 g ethanol kg bw<sup>-1</sup> will be greater than the fractional FPM after consumption of 0.3 g ethanol kg bw<sup>-1</sup> (Levitt, 2002). When large amounts of ethanol are consumed, proportionally, the pre-systemic metabolism is relatively insignificant in comparison to the systemic metabolism (Gentry et al., 1994; Crabb, 1997). However, when small doses of alcohol are administered, the contribution of FPM to overall ethanol metabolism is more important (Gentry et al., 1994; Crabb, 1997).

### Models of ethanol pharmacokinetics

Several attempts have been made to model the complex pharmacokinetics of ethanol (see Smith et al., 1993; Levitt, 2002). These pharmacokinetic models aim to predict, define and quantify ethanol's absorption and subsequent metabolism. For example, on computerized analysis of data from human subjects, Levitt (2002) found that the ethanol dose and the rate of gastric emptying are the main determinants of ethanol absorption and FPM.

When fasting subjects drink alcohol, ethanol is absorbed rapidly and the FPM was predicted to be small (Levitt, 2002). On the other hand, when alcohol is consumed with food, gastric emptying is delayed so the absorption of ethanol is slow. The FPM was also predicted to be less when more ethanol is consumed. It was predicted that the fractional FPM would be 36% after 0.15 g kg bw<sup>-1</sup> (10.5 g for a 70 kg man) but after 0.3 g kg bw<sup>-1</sup> (21 g for a 70 kg man) the model predicted that the fractional FPM would only be 7% (Levitt, 2002).

However, there are several pathways of ethanol metabolism, each of which has variable kinetics. So, the accuracy of these models is poor.

### Physiological effects of alcohol

Ethanol or the products of its metabolism affect nearly all cellular structures and functions.

### Effects of alcohol on the central nervous system

Ethanol generally decreases the activity of the central nervous system. In relation to alcohol, the most important neurotransmitters in the brain are glutamate, gamma-aminobutyric acid (GABA), dopamine, and serotonin.

Glutamate is the major excitatory neurotransmitter in the brain. Ethanol inhibits the N-methyl-D-aspartate (NMDA) subset of glutamate receptors (Abrahao et al., 2017). Ethanol thereby reduces the excitatory effects of glutamate. GABA is the major inhibitory neurotransmitter in the brain. Alcohol facilitates the action of the GABA-a receptor, increasing inhibition (Abrahao et al., 2017). Changes to these receptors seem to be important in the development of tolerance of and dependence on alcohol (Abrahao et al., 2017).

Dopamine is involved in the rewarding aspects of alcohol consumption (Abrahao et al., 2017). Enjoyable activities such as eating or use of other recreational drugs also release dopamine in the nucleus accumbens of the brain. Serotonin is also involved in the reward processes and may be important in encouraging alcohol use.

The most obvious effects of ethanol intoxication on the central nervous system begin with behavior modification (e.g., cheerfulness, impaired judgment, and loss of inhibitions; Morgan and Ritson, 2003; Abrahao et al., 2017). These excitatory effects result from the disinhibition described previously (inhibition of cells in the brain that are usually inhibitory).

As a result of these effects, it is well recognized that operating vehicles such as cars or heavy machinery under the influence of ethanol is unsafe. However, the BEC after consumption of a specific amount of ethanol and the impairment caused by a specific BEC vary significantly between individuals (Morgan and Ritson, 2003; Abrahao et al., 2017). Despite this variation, BEC is used to define intoxication and provide a rough measure of impairment for legal purposes (Morgan and Ritson, 2003; World Health Organization, 2018) because it is an objective measurement that is difficult to contest.

Most countries have set maximum legally permissible BEC levels for drivers to reduce harm from "drink driving". Governments define these levels after reviewing the available evidence. However, the definition of what is safe or acceptable varies between countries (Table 5; World Health Organization, 2018). These BEC thresholds range from zero tolerance (0.0 mg mL<sup>-1</sup>) to 1.0 mg mL<sup>-1</sup>.

**Table 5** Legal limits of blood ethanol concentrations for the general population to drive.<sup>a</sup>

Legal limit <sup>b</sup>	Blood ethanol concentration	
	mg/dL	mmol/L
The Czech Republic, Uruguay, and Hungary	0	0
Norway and Sweden	20	4.3
Japan and Montenegro	30	6.45
France, Germany, Italy, and Australia	50	11
United States, and Canada	80	17
Palau	100	22

<sup>a</sup>Ethanol impairs judgment and coordination. It is well recognized that driving under the influence of ethanol is unsafe. However, the definition of what is safe or acceptable varies between countries and can change as a result of social, political, or scientific influences. Moreover, many countries have lower legal blood ethanol levels for professional drivers than the general population.

<sup>b</sup>Legislation regarding legal limits of blood ethanol for driving may change.

Data derived from the [World Health Organization \(2018\)](#).

Some countries are considering the potential social benefits of lowering BEC limits. However, opponents cite factors such as the drinking culture, convenience, the unpalatability of tighter legislation and the impact on the alcohol industry.

The effects of ethanol are dose dependent ([Table 6](#); [Morgan and Ritson, 2003](#); [Abrahao et al., 2017](#)) and further intake causes agitation, slurred speech, memory loss, double vision, and loss of coordination ([Morgan and Ritson, 2003](#); [Abrahao et al., 2017](#)). This may progress to reduce level of consciousness, and induce respiratory depression with loss of airway protective reflexes, with danger of aspiration, suffocation, and death ([Morgan and Ritson, 2003](#); [Abrahao et al., 2017](#)).

This sequence of events is particularly relevant in the hospital setting, where patients may present intoxicated with a reduced level of consciousness. It is difficult to determine whether there is coexisting pathology such as an extradural hematoma or overdose of other drugs in addition to ethanol. Although measurement of BEC is helpful ([Table 6](#)), it is safest to assume that alcohol is not responsible for any disturbance in consciousness and to search for another cause.

## Neuroendocrine effects of alcohol

Alcohol activates the sympathetic nervous system, increasing circulating catecholamines from the adrenal medulla. Hypothalamic-pituitary stimulation results in increased circulating cortisol from the adrenal cortex and can, rarely, cause a pseudo-Cushing's syndrome with typical moon-shaped face, truncal obesity, and muscle weakness ([Bessemmer et al., 2011](#); [Rachdaoui and Sarkar, 2017](#)). Alcoholics with pseudoCushing's show many of the biochemical features of Cushing's syndrome, including failure to suppress cortisol with a 48 h low-dose dexamethasone suppression test ([Bessemmer et al., 2011](#)).

Ethanol affects hypothalamic osmoreceptors, reducing vasopressin release ([Rachdaoui and Sarkar, 2017](#)). This increases salt and water excretion from the kidney, causing polyuria ([Döring et al., 2003](#)). Significant dehydration may result particularly with consumption of spirits containing high concentrations of ethanol and little water. Loss of hypothalamic neurons (which secrete vasopressin) has also been described in chronic alcoholics, suggesting long-term consequences for fluid balance ([Döring et al., 2003](#)). Plasma atrial natriuretic peptide, increased by alcohol consumption, may also increase diuresis and resultant dehydration ([Döring et al., 2003](#)).

Alcoholism also affects the hypothalamic-pituitary-gonadal axis ([Rachdaoui and Sarkar, 2017](#)). These effects are further exacerbated by alcoholic liver disease ([Rachdaoui and Sarkar, 2017](#)). Testosterone is usually decreased in men, but it may increase in women. Estradiol is increased in men and women, and it increases as hepatic dysfunction deteriorates ([Rachdaoui and Sarkar, 2017](#)).

In women, the hormonal changes may reduce libido, disrupt menstruation, or even induce premature menopause ([Rachdaoui and Sarkar, 2017](#)). Sexual dysfunction is also common in men with reduced libido and impotence ([Rachdaoui and Sarkar, 2017](#)). Fertility may also be reduced, with decreased sperm counts and motility ([Rachdaoui and Sarkar, 2017](#)).

## Effects of alcohol on muscle

Myopathy is common, affecting up to two-thirds of all alcoholics ([Preedy et al., 2001](#); [Preedy and Watson, 2004](#); [Simon et al., 2017](#)). It is characterized by wasting, weakness, and myalgia and improves with abstinence ([Preedy et al., 2001](#); [Simon et al., 2017](#)). Histology correlates with symptoms and shows selective atrophy of type II muscle fibers ([Preedy et al., 2001](#)). Ethanol causes

**Table 6** Relationship between amount of ethanol consumed, blood ethanol concentration (BEC) and effect of ethanol on the central nervous system.

<i>Alcohol consumed<sup>a</sup></i> (UK units)	<i>Possible BEC</i>	<i>Effect</i>
1–5	10–50 mg/dL 2–11 mmol/L	No obvious change in behavior
2–7	30–100 mg/dL 7–22 mmol/L <b>Euphoria</b> <b>Sociability</b>	Increased self-confidence; loss of inhibitions Impaired judgment, attention, and control Mild sensorimotor impairment, delayed reaction times Legal limits for driving generally fall within this range (see <a href="#">Table 5</a> )
8–15	90–250 mg/dL 20–54 mmol/L	Loss of critical judgment Impairment of perception, memory, and comprehension Reduced visual acuity Reduced coordination, impaired balance Drowsiness
11–20	180–300 mg/dL 39–65 mmol/L  <b>Confusion</b>	Disorientation Exaggerated emotional states Disturbances of vision and perception of color, form, motion, and depth Increased pain threshold Further reduction of coordination, staggering gait, slurred speech
15–25	250–400 mg/dL 54–87 mmol/L  <b>Stupor</b>	Loss of motor functions Markedly reduced response to stimuli Marked loss of coordination, inability to stand/walk Incontinence Impaired consciousness
22–30	350–500 mg/dL 76–108 mmol/L  <b>Coma</b>	Unconsciousness Reduced or abolished reflexes Incontinence Cardiovascular and respiratory depression (death possible)
38	>600 mg/dL >130 mmol/L <b>Death</b>	Respiratory arrest

<sup>a</sup>Approximate amounts of alcohol required by a 70 kg male to produce the corresponding blood ethanol concentration (BEC) and intoxicating effects of ethanol. One UK unit of alcohol contains 8 g of ethanol. It should be noted that these theoretical data are provided for illustrative purposes only. The BEC and the effects after consumption of ethanol are dependent on several factors and varies significantly between individuals.

Adapted with permission from [Morgan and Ritson \(2003\)](#).

a reduction in muscle protein and ribonucleic acid content ([Preedy et al., 2001](#)). The underlying mechanism is unclear, but rates of muscle protein synthesis are reduced, whereas protein degradation is either unaffected or inhibited ([Preedy et al., 2001](#)). Attention has focused on the role of acetaldehyde adducts and free radicals in the pathogenesis of alcoholic myopathy ([Preedy et al., 2001](#); [Simon et al., 2017](#)).

## Alcohol and nutrition

The nutritional status of alcoholics is often impaired ([Rajendram and Preedy, 2008](#)). Some of the pathophysiological changes seen in alcoholics are direct consequences of malnutrition ([Rajendram and Preedy, 2008](#)). However, in the 1960s and 70s, Charles Lieber demonstrated that many alcohol-induced pathologies, including alcoholic hepatitis, cirrhosis, and myopathy, are reproducible in animals fed a nutritionally adequate diet ([Lieber et al., 1975](#)). Consequently, the concept that all alcohol-induced pathologies are due to nutritional deficiencies is outdated and incorrect.

Myopathy is a direct consequence of alcohol or acetaldehyde on muscle and is not necessarily associated with malnutrition ([Preedy et al., 2001](#); [Preedy and Watson, 2004](#)). Assessment of nutritional status in chronic alcoholics using anthropometric measures (e.g., limb circumference and muscle mass) may be misleading in the presence of myopathy ([Rajendram and Preedy, 2008](#)).

Acute or chronic ethanol administration impairs the absorption of several nutrients, including glucose, amino acids, biotin, folate, and ascorbic acid ([Rajendram and Preedy, 2008](#)). There is no strong evidence that alcohol impairs absorption of magnesium, riboflavin, or pyridoxine, so these deficiencies are probably due to poor intakes. Hepatogastrointestinal damage (e.g., villous injury, bacterial overgrowth of the intestine, pancreatic damage, or cholestasis) may impair the absorption of some nutrients such as the

fat-soluble vitamins (A, D, E, and K) (Rajendram and Preedy, 2008). In contrast, iron stores may be adequate as absorption can be increased (Rajendram and Preedy, 2008; Ribot-Hernández et al., 2020).

### Effects of alcohol on the cardiovascular system

Alcohol affects both the heart and the peripheral vasculature. Acutely, alcohol causes peripheral vasodilatation, giving a false sensation of warmth that can be dangerous. Heat loss is rapid in cold weather or when swimming, but reduced awareness leaves people vulnerable to hypothermia. The main adverse effect of acute alcohol on the cardiovascular system is the induction of arrhythmias i.e., “Holiday Heart” (Piano, 2017). These are often harmless and experienced as palpitations but can rarely be fatal (Piano, 2017). Chronic ethanol consumption can cause systemic hypertension and congestive cardiomyopathy (Piano, 2017). Alcoholic cardiomyopathy accounts for up to one-third of dilated cardiomyopathies but may improve with abstinence or progress to death (Piano, 2017).

The potential for beneficial, cardioprotective effects with alcohol consumption have been broadcast widely (Wood et al., 2018). This observation was based on population studies of mortality due to ischemic heart disease, case-control studies, and animal experiments (Renaud and de Lorgeril, 1992; Wood et al., 2018). However, there is no evidence from randomized controlled trials. The apparent protective effect of alcohol may therefore result from confounding factors. For example, the diets of drinkers are different from those of nondrinkers. Even the diets of beer drinkers are different from those of wine drinkers. Furthermore, on the population level, the burden of alcohol-induced morbidity and mortality far outweighs any possible cardiovascular benefit (Department of Health, 2016; Wood et al., 2018).

### Effects of alcohol on liver function

Fundamental to the effects of ethanol is the liver, where the majority of ethanol metabolism occurs (Utne and Winkler, 1980). Ethanol displaces many of the substrates usually metabolized in the liver. Metabolism of ethanol by ADH in the liver generates reducing equivalents (Kwo and Crabb, 2002; Höög and Ostberg, 2011). ALDH also generates NADH with conversion of acetaldehyde to acetate (Kwo and Crabb, 2002). The NADH:NAD<sup>+</sup> ratio is increased, with a corresponding increase in the lactate:pyruvate ratio (McGuire et al., 2006). If lactic acidosis combines with a  $\beta$ -hydroxybutyrate predominant ketoacidosis, the blood pH can fall to 7.1 and hypoglycemia may occur (McGuire et al., 2006). Severe ketoacidosis and hypoglycemia can cause permanent brain damage (McGuire et al., 2006). However, in general, the prognosis of alcohol-induced acidosis is good. Ketosis also reduces the renal capacity for urate excretion (Yamamoto et al., 2005). Hyperuricemia is further exacerbated by alcohol-induced ketosis and acetate-mediated purine generation (Yamamoto et al., 2005). Hyperuricemia explains, at least in part, the clinical observation that alcohol misuse can precipitate gout.

The excess NADH is reported to promote fatty acid synthesis and inhibits lipid oxidation in the mitochondria, resulting in fat accumulation (Kong et al., 2019). Fatty changes within the liver are usually asymptomatic but can be seen on ultrasound or computed tomography scanning, and they are associated with abnormal liver toxicity tests (e.g., raised activities of serum  $\gamma$ -glutamyl transferase, aspartate aminotransferase, and alanine transaminases) (Kong et al., 2019). The supposition that most of the hepatic damage in alcoholism is due to increases in the NADH:NAD ratio per se is somewhat outdated. Now, molecular and cellular processes in response to alcohol, and acetaldehyde toxicity, have been shown to be major contributors to the disease process (Rajendram et al., 2016b; Kong et al., 2019).

Progression to alcoholic steatohepatitis involves invasion of the liver by neutrophils with hepatocyte injury (Kong et al., 2019). The injured tissue may release damage-associated molecular patterns (DAMPs). These DAMPs activate immune cells, promoting liver fibrosis and metaplasia (i.e., cancer) (Kong et al., 2019). Thus, continued alcohol consumption may lead to cirrhosis. However, not all alcoholics progress to cirrhosis. The reason for this is unclear. It has been suggested that genetic factors and differences in immune response may play a role.

In alcoholic cirrhosis there is fibrocollagenous deposition, with scarring and disruption of surrounding hepatic architecture. There is ongoing necrosis with concurrent regeneration. Alcoholic cirrhosis is classically said to be micronodular, but often a mixed pattern is present. The underlying pathological mechanisms are complex and are the subject of debate. Induction of the MEOS and oxidation of ethanol by catalase result in free radical production (Halsted and Medici, 2012). Glutathione (a free radical scavenger) is reduced in alcoholics, impairing the ability to dispose of free radicals (Halsted and Medici, 2012). Mitochondrial damage occurs, limiting their capacity to oxidize fatty acids. Peroxisomal oxidation of fatty acids further increases free radical production. These changes eventually result in hepatocyte necrosis, and inflammation and fibrosis ensue. Acetaldehyde also contributes by promoting collagen synthesis and fibrosis (Rajendram et al., 2016b; Kong et al., 2019).

### Effects of acetaldehyde

Acetaldehyde is highly toxic and can bind cellular constituents (e.g., proteins including CYP2E1, lipids, and nucleic acids) to produce harmful acetaldehyde adducts (Rajendram et al., 2016b). Adduct formation changes the structure and the biochemical

properties of the affected molecules (Rajendram et al., 2016b). The new structures may be recognized as foreign antigens by the immune system and initiate a damaging response.

Adduct formation leads to retention of protein within hepatocytes, contributing to the hepatomegaly, and several toxic manifestations, including impairment of antioxidant mechanisms (e.g., decreased glutathione (GSH); Rajendram et al., 2016b). Acetaldehyde thereby promotes free radical-mediated toxicity and lipid peroxidation (Rajendram et al., 2016b). Binding of acetaldehyde with cysteine (one of the three amino acids that comprise GSH) or GSH also reduces liver GSH content (Rajendram et al., 2016b). Acute ethanol administration inhibits GSH synthesis and increases losses from the liver (Rajendram et al., 2016b). Furthermore, mitochondrial GSH is selectively depleted and this may contribute to the marked disruption of mitochondria in alcoholic cirrhosis (Rajendram et al., 2016b).

## Effects of acetate

The role of acetate in alcohol-induced pathology is not well understood. The uptake and utilization of acetate by tissues depend on the activity of acetyl-CoA synthetase (Cornier, 2004; Rajendram et al., 2016a; Bose et al., 2019). Acetyl-CoA and adenosine are produced from the metabolism of acetate. Acetate crosses the blood–brain barrier easily and is actively metabolized in the brain (Cornier, 2004; Rajendram et al., 2016a; Bose et al., 2019). Many of the central nervous system depressant effects of ethanol may be blocked by adenosine receptor blockers. Thus, acetate and adenosine may be important in the intoxicating effects of ethanol.

Ethanol increases portal blood flow, mainly by increasing GI tract blood flow. This effect is reproduced by acetate. Acetate also increases coronary blood flow, myocardial contractility, and cardiac output. Acetate inhibits lipolysis in adipose tissue and promotes steatosis in the liver. The reduced circulating free fatty acids (a source of energy for many tissues) may have significant metabolic consequences. Thus, some of the effects of alcohol may be due to acetate, though this area remains under explored.

## Conclusion

The second most commonly used recreational drug worldwide; ethanol, can affect the physiology of every organ. When a beverage containing ethanol is consumed the ethanol is rapidly absorbed via the upper gastrointestinal tract. Ethanol is initially oxidized to acetaldehyde via one of three major enzyme pathways. This highly toxic metabolite is further oxidized to acetate. Any ethanol remaining in the blood after FPM is rapidly distributed to the organs. Ethanol and the products of its metabolism affect nearly every cellular structure or function. The physiological effects of ethanol correlate with the blood ethanol concentration after drinking an alcoholic beverage. However, the relationship between the amount of ethanol ingested and its acute, physiological effects are complex. Several factors are relevant including gender, body composition and the rate of gastric emptying. Recent GWAS have investigated polymorphisms in the enzyme systems that metabolize ethanol. However, further studies are required to understand the interplay between an individual's alcohol intake, their blood ethanol concentration and the resulting physiological effects of ethanol.

### Key points

- Metabolism of ethanol provides  $7.1 \text{ kcal g}^{-1}$
- A significant calorific load can be obtained from alcohol intake.
- In alcohol misusers, ethanol can displace dietary macro- and micronutrients, damage several organ systems and increase the risk of several cancers
- The relationship between ethanol intake and mortality consists of many, distinct, opposing, dose–response curves rather than a single J-shaped curve.

### Glossary

**Alcoholic liver disease** This is characterized by “fatty liver” i.e., (steatosis; increased fat in the liver), inflammation, necrosis (death of liver cells), and fibrosis (scarring that leads to cirrhosis). It is most common in chronic alcohol misusers.

**Chronic alcohol misuse** Long-standing alcohol misuse. Excessive ethanol intake is typically daily may but may be episodic (e.g., at weekends).

**Standard Drink** A unit of ethanol consumption also known as a “unit of alcohol.” In the United States of America (USA) a standard drink contains 14 g ethanol but the definition varies internationally. It is usually 12–15 g, as found in 12 oz of beer, 1.2 oz of spirits, and 4 oz of wine. Note that the actual drinks people pour generally contain more ethanol than standard drinks.

**Moderate drinking** Up to 2 drinks per day for men but 1 drink per day for women.

**Nutritional consequences of alcohol misuse** Alcohol intake and the and alcohol-induced disease result in weight loss, protein malnutrition and deficiencies of several micronutrients (e.g., vitamin A, thiamine, pyridoxine, folate, vitamin B12, vitamin D, zinc and iron).

**Risks of chronic alcohol misuse** Liver disease, chronic pancreatitis, heart disease, myopathy, anemia, and cognitive disorders.

## Introduction

Ethanol is a highly addictive nutritional toxin. Its use is so ubiquitous that “drinking” usually describes consumption of beverages containing ethanol and “alcohol” and “ethanol” are effectively synonyms. The terms “standard drink” and “unit of alcohol” are also synonymous, but their definitions vary between countries. For example, in the United States of America (USA) a standard drink contains 14 g ethanol, while in the United Kingdom a unit of alcohol contains 8 g ethanol (Rajendram and Preedy, 2008). This may be confusing to the general public and complicates international comparisons of research and guidelines for “responsible” use of ethanol. So, for simplicity all references to standard drinks in this article will be based on the definition used in the USA.

The diet of active adult men should provide circa  $11.7 \text{ MJ day}^{-1}$  ( $2800 \text{ kcal day}^{-1}$ ) while active adult women require circa  $10 \text{ MJ day}^{-1}$  ( $2400 \text{ kcal day}^{-1}$ ; USA Department of Health and Human Services and USA Department of Agriculture, 2005). While the metabolism of ethanol provides  $29 \text{ kJ g}^{-1}$  ( $7.1 \text{ kcal g}^{-1}$ ), only miniscule amounts of other nutrients (e.g., proteins, vitamins, and minerals) are present (Rajendram and Preedy, 2008).

Light drinkers consuming 1 standard drink per day obtain  $406 \text{ kJ day}^{-1}$  ( $99.4 \text{ kcal day}^{-1}$ ) from ethanol alone. Furthermore, actual alcoholic beverages generally contain more ethanol than standard drinks. Thus, a significant calorific load can be obtained from alcohol intake. These additional calories can cause truncal obesity even in those who do not misuse alcohol (Tremblay et al., 1995).

Consuming 20 units of alcohol per week provides circa  $2000 \text{ kcal week}^{-1}$  from ethanol alone. As a result of the high energy content of alcoholic beverages or because of associated socioeconomic factors and medical disorders, heavy drinkers often replace a substantial proportion of nutrient-derived calories with alcohol (Suter, 2001).

Moreover, consumed in excess, ethanol can displace dietary macro- and micronutrients and damages several organ systems (Rajendram and Preedy, 2008). Alcohol misuse contributes to generalized malnutrition (Perlow et al., 1977; Suter, 2001; Morgan and Ritson, 2003). It affects the availability and metabolism of both water- and fat-soluble vitamins including folate, thiamine, pyridoxine, and vitamins B12, A and D (Wu et al., 1975; Majumdar et al., 1982; Kanazawa and Herbert, 1985; Rajendram and Preedy, 2008; Halseid and Medici, 2011; Malham et al., 2011; Clugston and Blaner, 2012). The presence of alcoholic liver disease (ALD) magnifies the effects of alcohol misuse on nutrition (Halsted, 2004; Lieber, 2004, 2005; Halseid and Medici, 2011). This article reviews the effects of alcohol consumption with a focus on the effects of ethanol intake on nutritional status in *Homo sapiens*.

## Effects of alcohol consumption on dietary intake

In the USA over 85% of those over 18 years old report that they have ever ingested ethanol (Substance Abuse and Mental Health Services Administration, 2019). Alcohol misuse is more common in young adults between 18 and 24 years of age than in any other age group (Substance Abuse and Mental Health Services Administration, 2019). While this group frequently present to hospital with complications of acute alcohol misuse (Hingson et al., 2009); organ damage as a result of chronic alcohol misuse generally manifests decades later.

Of those who ingest ethanol, most partake in moderation (Substance Abuse and Mental Health Services Administration, 2019). Moderate drinking can be defined as consuming no more than 2 standard drinks (i.e., units of alcohol) per day for men or 1 drink per day for women, where 1 standard drink contains 14 g of alcohol (USA Department of Agriculture and USA Department of Health and Human Services, 2020). Heavy drinking is defined as consuming more than 4 drinks on any given day per week for men or 3 drinks on any given day per week for women (National Institute on Alcohol Abuse and Alcoholism, 2021).

Chronic alcohol misusers are addicts who typically consume excessive amounts of alcohol on a daily basis. Binge drinkers are chronic alcohol misusers who episodically escalate their alcohol intake over weeks or months. Regardless of the style of heavy drinking, ethanol often displaces essential components from the diets of chronic alcohol misusers (Suter, 2001). Alcoholic beverages differ in their ethanol content, such that, wine contains approximately  $12 \text{ g } 100 \text{ mL}^{-1}$ , beer contains approximately  $4.5 \text{ g } 100 \text{ mL}^{-1}$  and spirits contain approximately  $40 \text{ g } 100 \text{ mL}^{-1}$ . Thus, the ethanol content of 4 oz of wine, 12 oz of beer and 1.2 oz of spirits are similar.

The effects on dietary intake depend on the amount of ethanol consumed each day and overall changes in eating habits. Although ethanol contains  $7.1 \text{ kcal g}^{-1}$ , its metabolism to acetaldehyde in the liver is rapid (rates up to  $50 \text{ g h}^{-1}$ ). None is stored as energy equivalents in the body. The metabolism of ethanol also affects fat and carbohydrate metabolism.

There are three main metabolic routes for the elimination of ethanol from the body (Rajendram et al., 2016; Kong et al., 2019). Alcohol dehydrogenase (ADH) is present in the cytosol of hepatocytes and metabolizes relatively low levels of alcohol that would be expected after moderate drinking (Rajendram et al., 2016). The metabolism of alcohol by ADH causes redox changes that contribute to hepatic lipid synthesis and reduce gluconeogenesis (Klop et al., 2013; Rajendram et al., 2016). Thus, even moderate

drinking can increase serum triglycerides and cause fatty liver (Klop et al., 2013). In the absence of dietary carbohydrate, excessive alcohol intake may result in hypoglycemia (i.e., low blood glucose levels). This can impair concentration and even consciousness.

The microsomal ethanol oxidizing system is the second group of enzymes involved in ethanol metabolism. The most important enzyme in this is cytochrome P450 2E1 (CYP2E1; Rajendram et al., 2016; Kong et al., 2019). The MEOS metabolizes alcohol at levels that may be generated by heavy drinking (Lieber, 2005; Rajendram et al., 2016). When metabolizing large amounts of ethanol, CYP2E1 utilizes adenosine triphosphate (ATP) “wasting” stored calories. This metabolic pathway, therefore, has the potential to cause weight loss.

Another form of ADH is present in the stomach (Rajendram et al., 2016). This is the first ethanol-metabolizing enzyme to encounter the alcohol contained in beverages. It accounts for approximately significantly more ethanol metabolism in men than in women (Baraona et al., 2001). This difference may explain why men’s tolerance of alcohol is much higher than that of women (Baraona et al., 2001).

## The complex relationship between alcohol consumption and adverse outcomes

Mortality increases progressively in those drinkers who consume more than 100 g week<sup>-1</sup> (Wood et al., 2018). Nevertheless, in 1992, Serge Renaud and Michel de Lorgeril reported the “French Paradox.” Despite similar diet and alcohol consumption; the cardiovascular mortality of the wine-drinking residents of the southern Mediterranean provinces of France is significantly lower than that in the northern provinces where wine is less frequently ingested (Table 1; Renaud and de Lorgeril, 1992). Subsequent population studies also identified increased mortality in abstainers. Thus, it is often suggested that the curve for alcohol-related mortality is J-shaped (Wood et al., 2018).

However, in 2018, an international study of almost 600,000 individuals who consume alcohol demonstrated that this concept oversimplifies the relationship between alcohol intake and cardiovascular disease risk (Wood et al., 2018). Higher alcohol intake was linearly associated with a higher risk of all types of stroke, coronary disease (except myocardial infarction), cardiac failure, and several other less common subtypes of cardiac disease (Wood et al., 2018). However, higher alcohol intake was associated with

<i>Minimal amount or duration of drinks per day Mechanism</i>		
<b>Benefits</b>		
Coronary disease protection	1–2 (women), 2–4 (men)	Flavonoid antioxidants
Cerebrovascular disease (nonhemorrhagic) protection		Elevated HDL lipoprotein reduced platelet adhesiveness
<b>Risks</b>		
Cancer	42 (women), 44 (men)	Unknown; higher risk in smoking alcohol misusers
<b>Oropharynx and esophagus</b>		
Breast (women)	42	Increases estrogen production
Colon	42 (women), 44 (men)	Initiation risk increases with low folate, proliferation risk increases with excessive folate
<b>Alcoholic liver disease</b>		
Fatty liver	42	Increased liver fat synthesis, decreased oxidation and export
Alcoholic hepatitis	43 (women) × 10 years 46 (men) × 15 years	Toxicity of alcohol metabolism Increased collagen synthesis
Alcoholic cirrhosis	43 (women) × 15 years 46 (men) × 20 years	
<b>Pancreas</b>		
Pancreatitis	B10 years	Acute inflammation of pancreas
Pancreatic insufficiency	B10–15 years	Loss of exocrine and endocrine pancreatic cells
Cardiomyopathy	Binge drinking	Mitochondrial damage of muscle cells or thiamine deficiency
<b>Neurological effects</b>		
Acute trauma, e.g., motor vehicle accidents	1–2 in social setting	Legal intoxication
Coma and death	10–20 in rapid succession	Severe toxicity
Withdrawal syndrome	Follows binge drinking	Neuronal hyperexcitability
Wernicke–Korsakoff syndrome	Unknown	Thiamine deficiency
Anemia	Unknown	Combination of iron, folate, and pyridoxal deficiencies

a lower risk of myocardial infarction. Furthermore, the threshold for lowest risk of all-cause mortality was about 100 g week<sup>-1</sup> (Wood et al., 2018).

Thus, this recent, large, international cohort study revealed that it is more likely that the relationship between ethanol intake and mortality consists of many, distinct, opposing, dose–response curves rather than a single J-shaped curve (Wood et al., 2018). It also called for reduction of all current recommendations for “responsible” alcohol intake to less than 100 g week<sup>-1</sup> (Wood et al., 2018).

The 1992 report describing the “French Paradox” attributed specific cardioprotective benefits to wine (Renaud and de Lorgeril, 1992). However, this was soon countered by in vitro data showing that the protective effect of wine on the oxidation of low-density lipoprotein could be mimicked by constitutive antioxidant flavonoids present in many fruits and vegetables (Zenebe et al., 2001). Another epidemiological study conducted by Holahan et al. (2012) concluded that, in comparison to non-wine drinkers, the lower mortality risk in wine drinkers could be due in large part to a better lifestyle (e.g., less smoking, more exercise, and better diet).

Any potential benefits of moderate drinking are confined to reductions in incidences of myocardial infarctions (Wood et al., 2018). Although red and white wine each contain protective antioxidant flavonoids, moderate amounts of alcohol may improve the circulating lipid profile by increasing levels of high-density lipoprotein and tissue plasminogen activator while reducing platelet function.

## The risks of alcohol misuse

Chronic alcohol misuse affects many different organ systems. These include the liver, pancreas, heart, skeletal muscle and brain. Alcohol misuse also increases the risk of certain cancers (Table 1). Although these risks are apparent among the citizens of the USA who misuse alcohol, their prevalence is generally no less in countries such as France, Italy, and Spain (GBD 2016 Alcohol Collaborators, 2018) where partaking of wine with meals is embedded into the culture. The organ damage from chronic alcohol misuse (e.g., chronic liver and pancreatic disease) may impair nutrient assimilation and metabolism. However, the organ damage is also exacerbated by nutrient deficiencies (e.g., thiamine deficiency can impair brain function). The specific effects of alcohol abuse on select organs are described below. This provides a background for consideration of specific effects of alcohol on nutrition.

## Alcoholic liver disease

Alcoholic liver disease (ALD) is one of the most common causes of mortality worldwide (GBD 2016 Alcohol Collaborators, 2018; Poznyak and Rekve, 2018). The pathogenesis of ALD is complex; several mechanisms have been implicated. Alcohol-induced translocation of bacterial lipopolysaccharide from the intestinal lumen through the portal vein initiates an inflammatory process in the liver (i.e., hepatitis) by activating tumor necrosis factor alpha (Kong et al., 2019). This cytokine promotes oxidative injury with necrosis of liver cells. It also has systemic effects including fever and anorexia with weight loss.

Several factors can initiate steatosis (i.e., increased lipid in the liver). These include the effects of alcohol on liver metabolism which promote lipid synthesis in hepatocytes. Other mechanisms reduce fatty acid oxidation and the export of lipid from the liver. Altered hepatic metabolism of methionine also contributes to the reduction of the antioxidant glutathione and apoptosis (i.e., cell death).

Fibrosis results from collagen synthesis by hepatic stellate cells (Kong et al., 2019). This is, in part, initiated by their incorporation of apoptotic liver cells as well as switching to collagen production. Of the three stages of ALD, fatty liver is related to the acute effects of alcohol on hepatic lipid metabolism. It is completely reversible with abstinence from alcohol (Kong et al., 2019). In contrast, alcoholic hepatitis usually occurs after a decade or more of chronic alcohol misuse. It is associated with steatosis and hepatitis (i.e., inflammation of the liver) with necrosis. It is associated with a high risk of mortality (approximately 40% within 6 months).

Alcoholic cirrhosis represents irreversible scarring of the liver secondary to fibrosis with loss of liver cells and function (Kong et al., 2019). It is usually preceded by alcoholic hepatitis. The scarring process greatly alters the circulation of blood through the liver in the sinusoids. It is associated with portal hypertension (i.e., increased blood pressure in the visceral (portal) circulation). As a result, blood flow is shunted away from the liver to other organs such as the esophagus.

The veins in these organs become dilated and tortuous (varicose). Potentially lethal complications of portal hypertension include hemorrhage due to rupture of esophageal varices and spontaneous bacterial peritonitis. Hepatic encephalopathy can also occur due to inadequate detoxification of waste products of metabolism (e.g., ammonia) in the visceral blood shunted around the scarred liver.

There is a clear dose response relationship between alcohol intake and ALD. The risk of developing alcoholic cirrhosis is dependent on the extent of exposure to alcohol regardless of the presence or absence of malnutrition (Lieber, 2004). However, while up to 95% of all chronic alcohol misusers develop fatty infiltration of the liver, only approximately 30% of heavy drinkers develop clinically significant ALD (Wood et al., 2018). This statistic indicates that genetic susceptibility is likely to be highly relevant in the pathogenesis of ALD (Wood et al., 2018).

## Pancreatitis and pancreatic insufficiency

Pancreatitis is less common in chronic alcohol misusers than ALD (Samokhvalov et al., 2015). Acute pancreatic inflammation is characterized by attacks of severe epigastric abdominal pain. Chronic pancreatitis occurs after multiple bouts of acute pancreatitis. Pancreatitis damages exocrine pancreatic cells that secrete digestive enzymes and the endocrine cells which secrete insulin and other hormones. Thus, pancreatic insufficiency is a feature of chronic pancreatitis. The pancreas is scarred and the pancreatic ducts are distorted and partially blocked. This further limits secretion and promotes recurrent episodes of acute inflammatory pancreatitis.

The pancreas produces proteases and lipases. These enzymes are required for protein and lipid digestion. Thus, destruction of the pancreas results in significant malabsorption of these major dietary constituents (Rasmussen et al., 2013). Patients with pancreatic insufficiency exhibit severe loss of muscle protein and body fat (Rasmussen et al., 2013). The increased excretion of fat with the feces causes steatorrhea (foul smelling feces that float). The absorption of fat-soluble vitamins is dependent on pancreatic lipase for solubilization of dietary fat. So, these patients are at risk of deficiencies of vitamins A, D, and E (Rasmussen et al., 2013). As insulin secretion is reduced Type 3c diabetes mellitus can also develop (Rasmussen et al., 2013).

## Heart

While the effects of alcohol on the heart are complex, they have been extensively investigated (Piano, 2017). While the risk of myocardial infarction may be decreased by moderate alcohol consumption, alcohol misuse can impair cardiac function (Piano, 2017). Episodic heavy drinking can cause arrhythmias with potential for sudden death ("holiday heart" syndrome; Piano, 2017). Chronic alcohol misusers are prone to left-sided heart failure secondary to mitochondrial dysfunction. This could be mediated by abnormal fatty acid metabolism in cardiac myocytes (Piano, 2017). A specific form of high-output heart failure, or "wet beriberi," is caused by thiamine deficiency. This is described in more detail in the Section on Micronutrient Deficiencies in Chronic Alcohol misuse.

## Neurological effects

Acute and chronic alcohol misuse have a broad range of adverse neurological effects. These can be broadly categorized as being directly to alcohol, secondary to ALD, or due to thiamine deficiency. The variable effects of alcohol on the brain are related to several factors including the duration and amount of drinking, the age when drinking started, malnutrition, genetic background, and family history of alcohol misuse (Sachdeva et al., 2016). The stages of acute alcohol toxicity worsen from legal intoxication with reduced reaction time and judgment (blood alcohol levels  $>0.08$  g dL<sup>-1</sup> that usually define legal intoxication), to coma and death ( $>0.35$  g dL<sup>-1</sup>) (Morgan and Ritson, 2003). Mild intoxication is common with social drinking (Morgan and Ritson, 2003). Yet, coma and death have been described in young men who consume excessive amounts of alcohol within a very short period of time (Hingson et al., 2009).

More common in inebriated pedestrians than drunk drivers; automobile accidents account for a large portion of alcohol-related mortality (GBD 2016 Alcohol Collaborators, 2018). Intoxication also causes falls and head trauma. Subdural hematoma presents with delayed but progressive loss of cognition and headaches but may cause death.

Chronic alcohol misusers are prone to symptoms of alcohol withdrawal. This is characterized by stages of tremulousness, seizures, and delirium tremens with hyperexcitability and hallucinations at any time up to 6 days from the last drink (Jesse et al., 2017). Delirium tremens is associated with progressive slowing of cerebral functions with stages of confusion, loss of cognition, and eventual coma and death (Jesse et al., 2017). Progressive impairment of cognition and judgment can also result from cerebral atrophy (Sachdeva et al., 2016). This generally occurs after years of heavy drinking but may also be exacerbated by thiamine deficiency (described in greater detail in the Section on Micronutrient Deficiencies in Chronic Alcohol Misuse; Sachdeva et al., 2016). These states of cognitive dysfunction are distinct from hepatic encephalopathy in chronic ALD (described above).

## Cancers

Chronic alcohol misusers are at increased risk of cancers of the oropharynx and esophagus, colon, and breast (Boffetta and Hashibe, 2006). The risk of oropharyngeal cancer is greatest when heavy smoking is combined with excessive daily alcohol intake. Increased risk of squamous cell cancer of the esophagus is also compounded by smoking and may be associated with deficiencies of vitamin A and zinc (Boffetta and Hashibe, 2006). Breast cancer in women may be mediated by increased estrogen production during heavy alcohol intake (Boffetta and Hashibe, 2006).

## Anemia

The causes of anemia in chronic alcohol misusers are legion. These include iron deficiency secondary to occult bleeding (e.g., episodic gastritis or bleeding from other sites of the gastrointestinal tract), folate deficiency from inadequate diet, malabsorption, and increased renal excretion of folic acid, and deficiency of pyridoxine (vitamin B6) due to abnormal effects on its metabolism

(Savage and Lindenbaum, 1986). Consequently, the bone marrow may demonstrate absent iron and mixtures of megaloblastosis from folate deficiency and sideroblastosis from pyridoxine deficiency (Savage and Lindenbaum, 1986).

## Effects of chronic alcohol misuse on nutritional status

### Body weight and energy balance

The effects of alcohol misuse on body weight depend on the timing and amount of alcohol consumption in relation to meals and on the presence or absence of organ damage, in particular, ALD (Table 2) (Halsted, 2004; Rajendram and Preedy, 2008; Halse and Medici, 2011). Although body weight is usually unaffected by moderate alcohol intake, chronic alcohol misusers who drink daily, substituting alcohol for other dietary constituents, lose weight as dietary alcohol is energy-neutral.

However, alcohol decreases control over eating. Thus, moderate drinkers on weight loss regimens who take alcohol with their meals are less likely to lose weight. At the same time, those who consume alcohol with high-fat meals are more likely to gain weight due to an acute effect of alcohol on reducing lipid metabolism and promoting the storage of fat (Tremblay et al., 1995; Feinman and Lieber, 1999).

Alcoholic liver disease has significant impact on body composition and energy balance (Halsted, 2004; Lieber, 2004). Large multicenter studies, demonstrate universal evidence of protein-calorie malnutrition in patients with alcoholic hepatitis (Fung and Pyrsopoulos, 2017). This is based on the physical findings of muscle wasting and edema, low levels of serum albumin and other visceral proteins, and decreased cell-mediated immunity (Fung and Pyrsopoulos, 2017). Their short- and long-term mortality is related to the severity of malnutrition (Fung and Pyrsopoulos, 2017).

Anorexia is a major cause of weight loss in ALD. Furthermore, active alcoholic hepatitis contributes to increased resting energy expenditure (Fung and Pyrsopoulos, 2017). However, resting energy expenditure is normal in stable alcoholic cirrhotic patients who are also typically underweight or malnourished in part due to preferential metabolism of endogenous fat stores. At the same time, the digestion of dietary fat and the absorption of fat-soluble vitamins A, D, E, and K are decreased in cirrhotics as secretion of bile salts and pancreatic enzymes is diminished (Rasmussen et al., 2013; Fung and Pyrsopoulos, 2017).

### Micronutrient deficiencies in chronic alcohol misuse

Chronic exposure to excessive amounts of ethanol is associated with deficiencies of several micronutrients. These include thiamine, folate, pyridoxine, vitamin A, vitamin D, zinc, and iron (Wu et al., 1975; Majumdar et al., 1982; Kanazawa and Herbert, 1985; Rajendram and Preedy, 2008; Halse and Medici, 2011; Malham et al., 2011; Clugston and Blaner, 2012; Skalny et al., 2018; Ribot-Hernández et al., 2020). The frequency of these deficiencies is increased in the presence of ALD. This decreases the numbers of hepatocytes available for storage of vitamins and metabolism. Many clinical signs of ALD are related to vitamin deficiencies.

### Thiamine deficiency

Low circulating levels of thiamine have been described in the majority of patients with alcoholic cirrhosis (Majumdar et al., 1982; Halsted, 2004; Chandrakumar et al., 2018). Thiamine pyrophosphate is a coenzyme in the intermediary metabolism of carbohydrates, in particular for transketolases that play a role in cardiac and neurological functions (Chandrakumar et al., 2018). Alcoholic beverages are essentially devoid of thiamine and acute exposure to alcohol decreases the activity of intestinal transporters required for thiamine absorption.

**Table 2** Effects of alcohol on body weight.

<i>Drinking behavior</i>	<i>Explanation</i>
<b>Moderate drinking</b>	
Reduce weight	Substitution of carbohydrate by alcohol; more likely in women
Increase weight	Decreased dietary restraint
<b>Heavy drinking</b>	
Reduce weight	Substitution of nonalcohol calories by alcohol calories, which are “wasted” during metabolism
Increase weight	Alcohol metabolism decreases lipid metabolism in the liver and promotes fat storage

Source: Reproduced from Halsted, C.H., 2006. Alcohol: effects of consumption on diet and nutritional status. In: Caballero, B., Allen, L., Prentice, A.M. (Eds.), *Encyclopedia of Human Nutrition*, second ed. Elsevier, Amsterdam, pp. 62–69.

The major neurological signs and symptoms of thiamine deficiency include peripheral neuropathy, partial paresis of ocular muscles, wide-based gait secondary to cerebellar lesions, cognitive defects, and severe memory loss (Chandrakumar et al., 2018). The presence of peripheral neuropathy is sometimes referred to as “dry beriberi.” The other symptoms constitute the Wernicke–Korsakoff syndrome. Although abnormal eye movements can be treated acutely by thiamine injections, the other complications are often permanent and contribute to the dementia that often afflicts alcohol misusers after years of drinking (Sachdeva et al., 2016; Chandrakumar et al., 2018).

“Wet beriberi” is a high-output cardiac failure that can also occur in thiamine-deficient alcohol misusers (Piano, 2017). It improves with thiamine in addition to conventional treatment for heart failure.

As endogenous thiamine is used during carbohydrate metabolism, acute symptoms can be precipitated by the administration of intravenous glucose to malnourished and marginally thiamine-deficient patients by depletion of remaining thiamine stores (Chandrakumar et al., 2018). This can be prevented by the intravenous addition of water-soluble vitamins including thiamine to malnourished chronic alcohol misusers who receive treatment for medical emergencies (Table 3).

## Folate deficiency

Folates, are a family of B vitamins with folic acid at its core. They are important in DNA synthesis and cell turnover and play a central role in methionine metabolism in the liver (Halsed and Medici, 2011). Originally recognized as a cause of megaloblastic anemia, the expanding known sequelae of folate deficiency are related to hyperhomocysteinemia (raised blood levels of homocysteine). These include increased risk of neural tube defects and other congenital abnormalities in newborns as well as altered cognition in the elderly people. Low serum folate levels in chronic alcohol misusers was common before grains were fortified with folate (Wu et al., 1975; Majumdar et al., 1982). There are no data on the incidence of folate deficiency in chronic alcohol misusers post-fortification.

Megaloblastic anemia, due to the negative effects of folate deficiency on DNA synthesis, has been described in approximately one-third of chronic alcohol misusers (Wu et al., 1975; Savage and Lindenbaum, 1986). Furthermore, folate deficiency may play a role in the pathogenesis of ALD by reducing hepatic levels of S-adenosylmethionine with consequent reduction in antioxidant glutathione and DNA methylation with resultant increased activation of genes relevant to alcoholic liver injury (Halsted and Medici, 2011).

There are multiple causes of folate deficiency in chronic alcohol misuse. All alcoholic beverages (except beer) are devoid of folate. The typical diet of the binge-drinking chronic alcohol misuser does not include fresh vegetable sources and fortified grains. Chronic alcohol misuse causes intestinal folate malabsorption, decreased liver folate uptake, and accelerated folate excretion in the urine (Halsted, 2004; Halsted and Medici, 2011). In addition, ALD decreases liver folate stores, so the time to development of folate deficiency with marginal diet is shortened (Halsted, 2004; Halsted and Medici, 2011).

**Table 3** Common micronutrient deficiencies in chronic alcohol misusers.

Deficiency	Cause	Effect
Thiamine	Poor diet Intestinal malabsorption	Peripheral neuropathy Wernicke–Korsakoff syndrome high-output heart failure megaloblastic anemia
Folate	Poor diet Intestinal malabsorption decreased liver storage increased urine excretion	Hyperhomocysteinemia and liver disease neural tube defect Altered cognition peripheral neuropathy sideroblastic anemia
Vitamin B <sub>6</sub>	Poor diet Displacement from circulating albumin promotes urine excretion	
Niacin	Poor diet	Pellagra with dermatitis, diarrhea, and dementia
Pantothenic acid	Poor diet	Paresthesias “burning feet” syndrome
Vitamin A	Malabsorption Increased biliary secretion	Night blindness May promote development of fibrosis in alcoholic liver disease calcium deficiency
Vitamin D	Malabsorption decreased sun exposure	Metabolic bone disease Night blindness
Zinc	Poor diet Increased urine excretion	Decreased taste Decreased immune function
Iron	Gastrointestinal bleeding	Anemia

## Vitamin B12 deficiency

The incidence of vitamin B12 deficiency in chronic alcohol misuse is undefined. This is because, while B12 is decreased in the liver of patients with ALD, serum levels may be normal or even increased (Kanazawa and Herbert, 1985; Halsted and Medici, 2011). The uptake and retention of vitamin B12 by damaged hepatocytes is reduced (Kanazawa and Herbert, 1985; Halsted and Medici, 2011). As vitamin B12 is a cofactor for methionine synthase, low hepatic vitamin B12 may contribute to abnormal liver methionine metabolism with hyperhomocysteinemia (Halsted and Medici, 2011).

## Pyridoxine deficiency

Pyridoxine (vitamin B6) is required for transamination. This is necessary for the elimination of homocysteine (Halsted and Medici, 2011). Pyridoxine deficiency in chronic alcohol misuse occurs because pyridoxal phosphate is displaced from hepatic protein binding sites by acetaldehyde (Halsted and Medici, 2011). This increases its urinary excretion. Low serum levels of pyridoxal phosphate are common in chronic alcohol misusers (Halsted and Medici, 2011). Pyridoxine deficiency manifests with peripheral neuropathy and sideroblastic anemia. In alcoholic hepatitis, measurements of serum alanine transaminase (ALT) activity is disproportionately low compared with aspartate transaminase (AST), as pyridoxine is required for ALT activity.

## Deficiencies of fat-soluble vitamins (A and D)

Chronic alcohol misusers are at increased risk of metabolic bone disease due to vitamin D deficiency and the resulting calcium insufficiency. Alcoholic liver disease increases the risk of low circulating levels of 25-hydroxy vitamin D (Malham et al., 2011). This deficiency is multifactorial in etiology. While malabsorption of fat-soluble vitamins due to biliary dysfunction is relevant, other factors include impaired hydroxylation of vitamin D by the liver, poor diet, and impaired production in the skin (Malham et al., 2011).

Serum levels of vitamin A are usually normal in chronic alcohol misusers in the absence of organ dysfunction (Clugson and Blaner, 2012). However, liver retinoids progressively fall as ALD progresses (Clugson and Blaner, 2012). This reduction in hepatic retinoids occurs independent of intake and malabsorption is not a key player in its etiology (Clugson and Blaner, 2012). Other possible explanations include reduced hepatic uptake of retinoids from chylomicrons and reduced retinol transfer and storage (Clugson and Blaner, 2012).

Complications of vitamin A deficiency include night blindness and increased risk of several cancers (Clugson and Blaner, 2012). However, it is important to note that patients with ALD are very susceptible to hepatotoxicity from vitamin A. Thus, it has not yet been clarified whether supplementation of vitamin A is beneficial in this cohort (Clugson and Blaner, 2012).

## Zinc deficiency

Zinc is a cofactor for many enzymes including retinol dehydrogenase. It is stored in the pancreas, in the circulation is mainly bound to albumin. Chronic alcohol misusers are frequently zinc deficient (Skalny et al., 2018). This is due to poor diet, pancreatic deficiency, and increased urine excretion because of hypoalbuminemia. The consequences of zinc deficiency include impaired cellular immunity. So, its deficiency may contribute to increased risk of infections in alcohol misusers (Skalny et al., 2018). Furthermore, zinc concentrations may reflect alcohol-induced metabolic dysfunction and supplementation should be considered in the treatment of alcohol-induced disease (Skalny et al., 2018).

## Iron deficiency

Chronic alcohol misusers are often iron deficient but may also be iron overloaded. Iron deficiency may result from gastrointestinal bleeding, typically due to alcoholic gastritis or esophageal tears from frequent retching and vomiting, or from rupture of esophageal varices in patients with cirrhosis and portal hypertension. The major consequence of iron deficiency is anemia (Savage and Lindenbaum, 1986). This may be compounded by the concurrent effects of folate and pyridoxine deficiencies (Savage and Lindenbaum, 1986). On the other hand, hepatic iron content is increased by ethanol (Ribot-Hernández et al., 2020). The oxidant effects of iron in the liver stimulates synthesis of ferritin and activates stellate cells (Ribot-Hernández et al., 2020). This promotes inflammation and fibrosis, worsening ALD (Ribot-Hernández et al., 2020). Yet, while albumin and transferrin saturation index are independently related to mortality in this cohort, serum iron and ferritin are not (Ribot-Hernández et al., 2020).

## Conclusion

The relationship between alcohol intake, nutritional status and alcohol-induced disease is complex. The calorific value of alcohol is high and can induce primary malnutrition in alcoholics by displacement of other nutrients from the diet. Secondary malnutrition

may result from the toxic effects of ethanol on several organs involved in the absorption and metabolism of micro- and macronutrients (Rajendram and Preedy, 2008). The ethanol-induced reduction of dietary intake, maldigestion and malabsorption often results in deficiency of one or more nutrients in alcohol misusers (Rajendram and Preedy, 2008). However, the effects of ethanol on nutrient metabolism affect even those alcoholics who are not malnourished, resulting, for example, in impaired protein synthesis (Rajendram and Preedy, 2008).

The investigation of the relationship between ethanol and nutrition has traditionally been hypothesis-driven. Importantly, this methodology has elucidated that some processes are not affected by either acute or chronic alcohol exposure. While hypothesis-driven research is clearly important, the application of holistic, or “omic,” technologies could rapidly highlight significant pathways, processes or products (Rajendram and Preedy, 2008). In particular, genomics, proteomics and metabolomics could identify thousands of molecular and cellular targets involved in the interaction between ethanol, the nutritional status of alcohol misusers and alcohol-induced disease.

Until this complex relationship is better defined, while it is sensible to encourage alcohol misusers to consume balanced diets; the most important nutritional intervention is to encourage and maintain abstinence.

## Introduction

Beverages, usually excluding drinking water, are referred to as fluids which are prepared for human consumption. In this article, we focus on nonalcoholic beverages. Water and alcohol are reviewed in other articles. For clarification, definitions for different beverage categories and other terminologies that are discussed in this article are provided in [Table 1](#).

In history, water and breast milk are the only beverages that were consumed by humans until 11,000 and 12,000 years ago. It is believed that other beverages appeared in the human diet no more than 11,000 years ago. [Fig. 1](#) provides a timeline of when major beverages entered the human food chain ([Popkin, 2010](#)). With industrialization, more and more beverages have been produced and introduced into the human diet. Today, beverages are playing very important roles in the human diet and health.

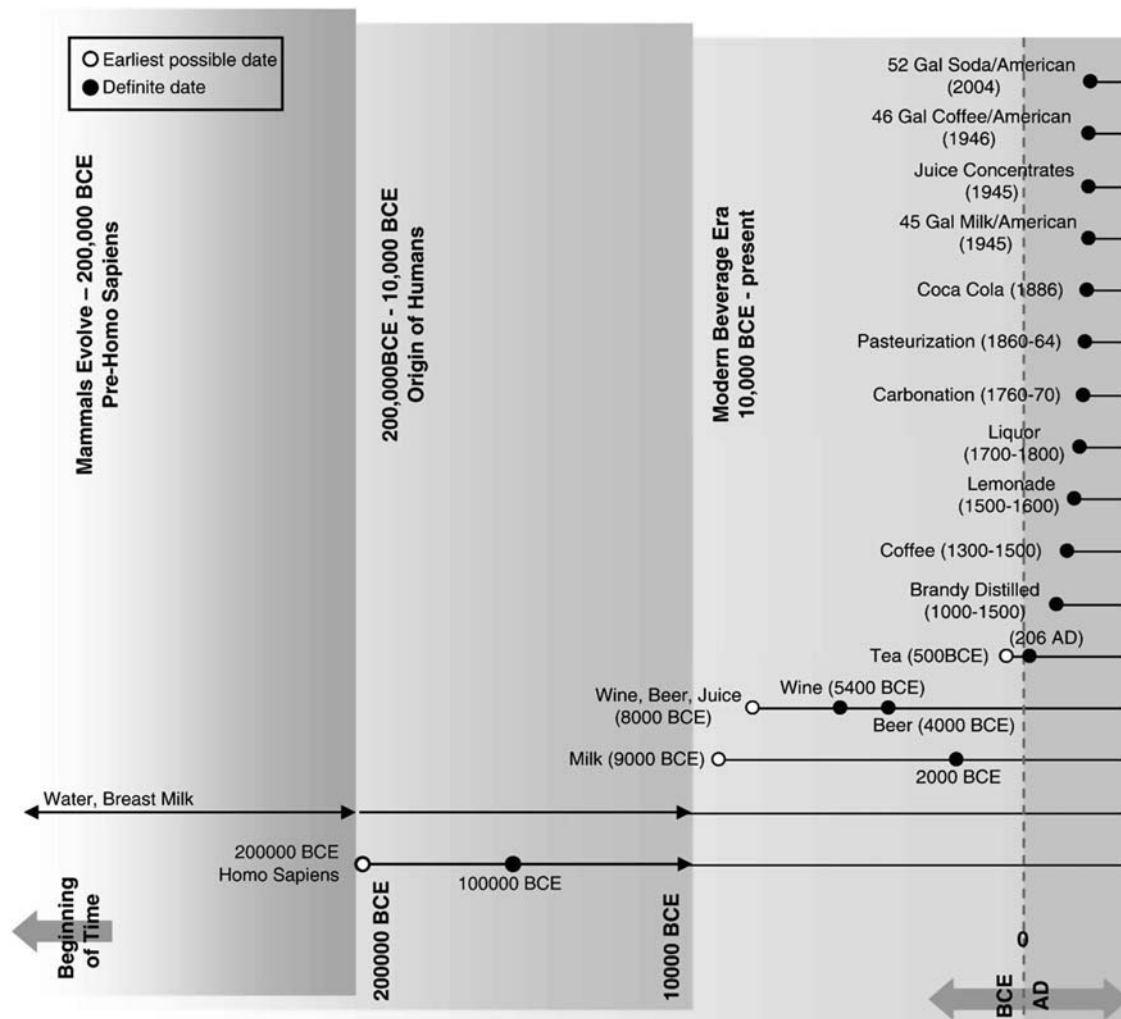

Currently, a large proportion of the world's population is consuming a significant amount of beverages on a daily basis. Globally, the consumption of packed beverages in 2019 was about 224 billion liters for carbonated soft drinks, 260 billion liters for milk and dairy drinks, and 86 billion liters for fruit and vegetable juice. In the United States (US), water accounted for 51% of total nonalcoholic beverage consumption among adults on a given day, followed by coffee (15%), sugar-sweetened beverages (10%), tea (9%), fruit beverages (6%), milk (5%), and diet beverages (4%) based a national survey. Beverages share the same feature as fluids but vary tremendously in their energy content and nutrient composition. The nutrient composition of commonly consumed beverages is provided in [Table 2](#). Given current consumption levels, these beverages could contribute significant amounts of calories as well as sugars, caffeine, and several other vitamins and minerals to our diet. In 2015–2016, beverages provided about 17% of total calories, 50% of added sugar intake, 1/3 of vitamin C intake (60% from 100% juice), and 4/1 of calcium (80% from milk) intake for the general American population. Sugar-sweetened beverages are the leading source of added sugars and calories in the Americans' diet, responsible for 1/3 of the total added sugar consumed by Americans. In 2011–2014, 63% of youth and 49% of adults drank sugar-sweetened beverages on a given day. On average, US youth consume 143 calories and US adults consume 145 calories from sugar-sweetened beverages on a given day. The United Kingdom (UK) and many other developed countries are heading in the same direction.

Beverages are important sources of fluids in our diet. There is no doubt that we need fluid to provide adequate water for maintaining normal physiological function and metabolic homeostasis of the human body. It has been estimated that about 20% of the water we need is derived from food, and the other 80% comes from drinking water and beverages. One fundamental question we should ask is: In addition to fluids, do adults need beverages to provide energy and other nutrients? The answer is no. Historically, adults consumed predominantly water which provided no calories. Scientifically, no evidence suggests that a healthy diet for adults relies on beverages to provide energy or other nutrients. Drinking water can provide the fluids our body needs as long as we maintain a healthy, balanced diet.

One of the major concerns regarding such a large amount of calories from beverages is that beverages are less satiating than solid foods. Evidence suggests that compensation of energy consumed in a liquid form (liquid calories) may be less complete than energy consumed in a solid form in humans. In other words, consumption of calorie-rich beverages does not reduce the intake of solid foods proportionally to maintain the energy balance. Therefore, when a large amount of calorie-rich beverages are consumed,

**Table 1** Definitions of beverages.

<i>Liquid calories</i>	<i>All calories derived from beverages</i>
Fruit drinks	Sugar-sweetened drink with a small percentage of fruit juice or juice flavoring
100% juices	Beverages composed exclusively of liquids extracted from fruits and vegetables with no added caloric sweeteners
Milk	A translucent white liquid produced by the mammary glands of mammals.
100% juices	Beverages composed exclusively of liquids extracted from fruits and vegetables with no added caloric sweeteners or flavorings
Soft drinks	Non-alcoholic carbonated beverages containing caloric and artificial sweeteners, including regular soft drinks and diet soft drinks
Diet beverages (diet soft drinks)	Carbonated or non-carbonated beverages sweetened with artificial sweeteners
Sugar-sweetened beverages (regular soft drinks)	Carbonated or non-carbonated beverages containing added caloric sweeteners
Added caloric sweeteners	All composite sugars added to foods and beverages during production and processing, including sucrose, high-fructose corn syrup, honey, molasses, and other syrups.
Artificial sweeteners	Synthetic food additives that have sweet taste but no or less energy content

**Fig. 1** Beverage history timeline. Adapted with permission from Fig. 1 in Popkin, B.M., 2010. Patterns of Beverage Use Across the Lifecycle.

the total calorie intake will increase, which may result in weight gain and other health issues over time. In addition, high consumption of soft drinks is linked with less healthy behaviors. For example, the frequent consumers of soft drinks are more likely to be smokers, don't get enough sleep, don't exercise much, eat fast food often, and don't eat fruit regularly. Among adolescents who frequently drink soft drinks also have more screen time, including televisions, cell phones, computers, and video games.

In the following sections, we will provide a review of the relative nutritional and health benefits and risks of various beverage categories. The beverage categories reviewed in this article are ordered according to their health benefits (from the relatively healthy to unhealthy) based on current scientific evidence.

## Coffee and tea

### Tea

Tea has been widely consumed in many countries and regions for a long period of time. The origin of tea drinking can be traced back as early as around 500 BC in China. Tea remained a primarily Chinese beverage until the 17th century when Europeans started trading for teas and introducing them to a broader market. In 1908, teabags were invented in the US, which largely increased the convenience of tea consumption.

Tea is traditionally prepared by adding tea leaves to boiling water. The tea leaves are leaves, leaf buds, or internodes of the *Camellia sinensis* plant. According to how the tea leaves are produced and processed, tea can be classified into six major varieties: green tea (unwilted and unoxidized), yellow tea (unwilted and unoxidized, but allowed to be yellow), white tea (wilted and unoxidized), Oolong tea (wilted, bruised, and partially oxidized), black tea (wilted, crushed, and fully oxidized), and Pu-erh tea (fully

fermented and composted). Worldwide, the most popular consumed tea is black tea which accounts for 78% of all tea consumed, followed by green tea (20%). Other types of tea are only consumed in very small amounts or only by particular populations. While black tea is mostly consumed in the Western countries, green tea is consumed primarily in Southeastern countries like China and Japan. In the US, 21% of adults are tea consumers. Tea leaves contain more than 700 bioactive compounds, including flavanoids (primarily catechins), amino acids, vitamins (C, E, and K), caffeine, and polysaccharides. Many of these compounds are antioxidants. For instance, the Oxygen Radical Absorbance Capacity (ORAC) is 1253  $\mu\text{molTE}/100\text{ g}$  for green tea and 1128  $\mu\text{molTE}/100\text{ g}$  for black tea.

Because of tea's rich contents of many bioactive compounds, numerous studies have investigated the health benefits of tea consumption, particularly on its role in the prevention of cancer and cardiovascular diseases (CVD). The beneficial effects of tea consumption on cancer and CVD have been shown in animal models. Recent meta-analyses of human observational studies also suggest that higher consumption of tea is associated with a lower risk of cancer, but the benefits may be site-specific. The inverse association was observed for lung, liver, gastric, biliary tract, breast, ovarian, prostatic, and oral cancer, but not for pancreatic and bladder cancer (Filippini et al., 2020). Results from the human experimental studies on cancer prevention and treatment remain inconclusive. For example, three randomized controlled trials (RCT, a study design with the highest research rigorous) conducted in men with high-risk of prostate cancer have suggested a decreased risk but the effect size varied substantially across studies. Also, no effect was found on the prevention of non-melanoma skin cancer with each consumption. The potential therapeutic effect of epigallocatechin-3-gallate (EGCG), an active compound of green tea, has been investigated. Although promising, the levels of EGCG in some experimental studies are too high to be reached by consuming brewed tea. In addition, the EGCG has poor bioavailability and can be eliminated from the human body quickly after intake, which limits the use of this compound as a treatment option for cancer. Several observational studies also investigated the association of tea consumption with CVD risk or CVD mortality; however, the results are inconsistent across populations. Studies that reported an inverse association were mainly conducted in Japanese and Chinese populations. Possible explanations on tea's CVD protective effect could be related to its impact on reducing serum total or low-density lipoprotein (LDL)-cholesterol, triglyceride, and coronary vessel function. Several observational studies also reported that higher tea consumption was associated with a lower risk of depression and cognitive disorders. Tea consumption may also enhance the innate immunity, increase bone density, promote weight loss, improve glucose metabolism,

and reduce kidney stones. However, data on these health benefits of tea consumption are still limited. Most observed health benefits of tea are modest and at the consumption levels of 3–4 cups per day, particularly from the green tea.

## Coffee

Coffee is one of the most popular beverages consumed worldwide. Coffee consumption originated in Africa around the ninth century. Early coffee was probably made using green (unroasted) coffee beans. The modern form of coffee (roasted, grounded, and brewed) likely appeared in Yemen in the late 14th century. By the 16th century, coffee had reached rest of the Middle East, and from there, spread to Italy and to the rest of Europe. Europeans began to add honey and milk to their coffee and vastly expanded the techniques for coffee brewing. In 1907, instant coffee was invented by preparing (freeze-drying or spray-drying) the soluble powder from brewed coffee beans. It rapidly gained popularity because of its convenience.

The most important bioactive compound in coffee is caffeine. A cup of coffee (7–8 oz), depending on the variety of coffee beans and brewed methods, may contain 80–175 mg of caffeine. The caffeine content in decaffeinated coffee is largely reduced to about 2–4 mg per cup. Coffee contains over 1000 bioactive compounds and is also a good resource of antioxidants. Both caffeinated and decaffeinated versions appear to have similar antioxidant levels. Vitamins and minerals that can be found in coffee include folate, vitamin K, pantothenic acid, riboflavin, calcium, magnesium, and manganese. Plain coffee contains only a trace amount of proteins and carbohydrates. The calories in coffee without any additives are only 2–3 kcal per cup. However, adding milk, cream, or sugar to coffee significantly increases the levels of calories as well as proteins, fats, and carbohydrate.

The stimulant effect of coffee is mainly due to its caffeine content. Human metabolic studies have found that caffeine ingestion acutely induces cardiac arrhythmias and increases plasma renin activity, catecholamine concentrations, and blood pressure. Numerous studies have been conducted to understand the long-term health effects of coffee consumption (van Dam et al., 2020). The relationship between coffee intake and cancer has been investigated for decades because of the potential cancer prevention effect of its main compounds such as caffeine, caffeic acid, and chlorogenic acid. Many meta-analyses, based on observational studies, have reported an inverse association between coffee consumption and the risk of liver, colorectum, colon, breast, prostate, oral, and endometrial cancer, but not of pancreatic, gastric or biliary tract cancer.

Many observational studies and several meta-analyses also examined the association between coffee consumption and CVD risk, including coronary heart disease (CHD), stroke, and heart failure. Up to date, there is no strong evidence to suggest that a higher intake of coffee or caffeine is associated with an increased risk of CVD. In a recent meta-analysis of 40 studies, a non-linear, inverse association was reported of coffee consumption with all-cause and CVD mortality, with the lowest risk at the intake of 2.5–3.5 cups per day (Kim et al., 2019). The inverse association between coffee consumption and CVD remained in subgroup analyses stratified by age, overweight status, alcohol drinking, smoking status, and caffeine content of coffee. A large prospective study of a half million people from the UK Biobank cohort also found an inverse association of coffee drinking with all-cause mortality and the results were the same when stratified by genetic polymorphisms affecting caffeine metabolism. On the other hand, coffee consumption has been related to several CVD risk factors such as serum lipids and blood pressure in the meta-analysis of RCTs. Coffee intake, especially unfiltered coffee, increases the plasma total and LDL-cholesterols and triglycerides. It is worthy to note that these RCTs were conducted only in Western countries with a mean duration of 45 days. Studies examining the long-term effects and in other populations are lacking. The cholesterol-raising effects may be related to the diterpenes cafestol and kahweol in coffee. Since diterpenes cafestol and kahweol can be trapped by paper filters, their concentrations are higher in boiled and espresso than in filtered coffee. Caffeine also has a well-known acute pressor effect. However, tolerance to the caffeine-induced pressor effect develops in habitual coffee drinkers. In addition, ingredients other than caffeine may also have blood pressure control effects. A meta-analysis of RCTs that longer than a week suggests that coffee consumption has no effect on blood pressure or risk of hypertension. Therefore, the long-term effect of habitual coffee consumption on blood pressure is still unclear.

Studies have consistently linked higher coffee consumption to a lower risk of type 2 diabetes. It has been suggested that compounds other than caffeine may contribute to such benefits. High coffee and caffeine intake were also associated with a reduced risk of Parkinson's disease in men, but not in women, which may be due to the modifying effect of estrogen. The relationships between coffee consumption and risk of other cognitive disorders (i.e., Alzheimer's disease, dementia, cognitive decline, and cognitive impairment) were reported as a "J-shaped" in a meta-analysis with the lowest risk at a daily consumption level of 1–2 cups of coffee. Similarly, a "J-shaped" relationship was also reported from a meta-analysis that examined the association between coffee consumption and risk of depression with the lowest risk at consumption of 1.5–2 cups per day.

There are concerns that coffee intake may be harmful to bone health. Animal studies have found that caffeine could increase urinary calcium excretion and decrease intestinal calcium absorption with a net result of a negative calcium balance. One meta-analysis of 10 prospective observational studies in humans found that a higher intake of coffee was associated with an increased risk of fracture, especially for women. However, a randomized cross-over study in women found that there was no difference in calcium balance between the moderate intake of caffeine (400 mg/day) and the placebo group for up to 19 days. Therefore, the current evidence on coffee consumption and bone health is inconclusive. Coffee consumption during pregnancy has raised some concerns regarding fetal health, mainly due to its caffeine content (Jahanfar and Jaafar, 2015). Several meta-analyses have reported that higher maternal caffeine intake during pregnancy was associated with a higher risk of pregnancy loss, low birth weight, and small for gestational age; however, the results are mixed for preterm birth. The adverse birth outcomes reported from observational studies are generally modest with the caffeine intake lower than 150 mg (e.g., 1–2 cups of coffee). Up to date, only one RCT was conducted among over 1000 Danish women to test whether the reduction in coffee intake during

pregnancy can decrease the risk of adverse birth outcomes. This trial found that there was no effect on birth weight and length of gestation between women who consumed decaffeinated instant coffee and caffeinated instant coffee (the mean caffeine difference was approximately 180 mg). Based on the available evidence, pregnant women are recommended to limit their caffeine intake to less than 200 mg per day. Pregnant women should be aware that caffeine can also be obtained from other beverages such as tea and soft drinks (See [Table 2](#)).

No safety limits of caffeine intake have been established for young children. There are some concerns about the potential adverse health effects of caffeine for this age group. Therefore, coffee and tea should be avoided for children younger than age 2.

## Milk

### Animal milk

Animal milk may have been consumed by humans since 2000 BC or even earlier. Later, the development of pasteurization largely enhanced the safety of milk consumption and expanded the market of milk trading. By the 1930s, most milk consumed in the UK and US was pasteurized. Milk consumption in the US peaked in the 1940s and has fallen steadily since then, probably due to the competition from other beverages, such as soft drinks.

Today, cow's milk is produced on an industrial scale and is the most commonly consumed form of milk. Milk and milk products are rich in many vitamins and minerals, including calcium, selenium, phosphorus, vitamin A, D (due to fortification), B2 (riboflavin), B5 (pantothenic acid), and B12 (cobalamin). Lactose, a disaccharide, is the dominant carbohydrate contained in plain milk (12–13 g/cup) and gives milk a slightly sweet taste. Interestingly, only certain human populations maintain the ability to digest lactose into adulthood. Some individuals cannot produce sufficient lactase, an enzyme to help absorb the lactose, and, therefore, may suffer intestinal gas, cramps, bloating and diarrhea when drinking milks. This is usually called "lactose intolerance" and it is more common among Asians, Africans, and Native Americans but less common among Caucasians. Processed cow milk contains about 8 g of proteins per cup. The fat content of milk varies by type of milk. A cup of whole milk (3.3% fat) contains about 8 g of fat, whereas reduced-fat (2% fat), low fat (1% fat), and skim milk contain 4.8, 2.4 and 0.2 g of fat, respectively. The majority of milk fats (57% for whole milk) are saturated fatty acids. For this reason, whole milk contributes significantly to the saturated fat intake for Americans and many other populations. Therefore, low-fat or skim milk are recommended instead of whole milk.

For children and adolescents, milk is an excellent source of calcium, vitamin D, and high-quality proteins. For adults, low fat and skim milks can contribute to a healthy diet, but are not essential. Both beneficial and detrimental health effects have been observed from milk consumption. Since milk is an important source for calcium and vitamin D, milk consumption can be beneficial for bone health, particularly among children and adolescents. A positive association between milk consumption and bone mineral density has been consistently reported by both human observational studies and RCTs. However, meta-analyses of observational studies have found that there is no clear pattern of association of milk intake with fractures, and findings from randomized trials are lacking. Some studies have shown that a higher intake of milk was associated with a reduced risk of metabolic syndrome, hypertension, and CVD, but the evidence is still inconclusive. Recent two meta-analyses concluded that there is no association between milk consumption and CVD risk, including CHD and stroke (both ischemic and hemorrhagic stroke) ([Fontecha et al., 2019](#)). A recent meta-analysis found an inverse association of fermented dairy consumption (including sour milk products, cheese, or yogurt) with mortality and CVD risk. Fermented milk is produced from fresh milk by the addition of bacterial cultures to initiate the fermentation process. As a result, fermented milk may impact human health through its influence on the gut microbiome.

The role of milk on weight control has been suggested by some studies but not others. It has been hypothesized that milk's effect on weight regulation is attributed to its high calcium content. High calcium intake may regulate body adiposity through plasma parathyroid hormone and  $25(\text{OH})_2 \text{D}_3$  by repartitioning dietary energy from adipose tissues to lean body mass and increasing thermogenesis. However, it is unlikely that increasing milk consumption can be an option for weight loss without a substantial reduction in total caloric intake.

The most important health concern of milk consumption among adults comes from cancer. Several studies have reported that a higher intake of milk was associated with an elevated risk of prostate cancer in men, and breast and ovarian cancers in women. It is speculated that such detrimental effects may be related to the high level of insulin-like growth factor I (IGF-1) in cow milk. IGF-1 has been linked with increased cell proliferation and inhibition of apoptosis, and thus has been associated with cancer risk. Dairy producers have been injecting growth hormones into cows to increase milk production, which results in an increased concentration of IGF-1 in the milk. The 2018 World Cancer Research Fund (WCRF) report concluded there is no strong evidence to conclude the relationship between the consumption of dairy products (including milk) and the risk of cancer ([World Cancer Research Fund International](#)). The evidence is divergent between cancer sites: consumption of dairy products may decrease the risk of colorectal cancer, but increase the risk of prostate cancer.

### Soy milk

Soy milk is an aqueous extraction of soybeans and has a milk-like appearance. Soy milk is traditionally produced by soaking the soybeans and grinding them with water. The resulting slurry is brought to heat at a boiling point for 15–20 min, followed by filtration to remove the insoluble residues (soy pulp). Soy milk was originally consumed in China and the oldest evidence can be traced to around 25–220 AD. Soy milk is widely consumed in China and other Asian countries such as Japan, Malaysia, and Singapore. The

drink is slowly getting popular in Western countries. Soy milk has a comparable amount of protein as cow milk, but very little saturated fat and no cholesterol. Unlike cow milk, soy milk does not contain lactose. Therefore, soy milk is safe for people with lactose intolerance. For the above reasons, soy milk is considered a healthy alternative to cow milk for children, adolescents, and adults. However, soy milk only provides about the 75% of calcium bioavailability from cow milk and cannot be legally fortified with vitamin D.

Both cow milk and soy milk should not be consumed by infants as a replacement of human milk or infant formula before age of 12 months. Unsweetened cow milk or soy milk can be consumed by children after age of 12 months to help meet calcium, potassium, vitamin D, and protein needs.

### **100% fruit or vegetable juice**

Juices are the liquids extracted from fruits or vegetables. Juices can be prepared by mechanically squeezing or mashing fresh fruits or vegetables. While the early history of juice consumption is not well documented, lemonade appeared during the 16th century in Italy and was considered the pioneer of modern juice. Important technologies in the juice industry happened in the past 100 years, including the use of pasteurization and the introduction of juice concentration.

#### **Fruit juice**

Sometimes, the labels of commercial fruit juices may be misleading. In the US and several other countries, fruit juice can only be legally used to describe a product that is 100% pure fruit juice. According US Food and Drug Administration (FDA), juices reconstituted from concentrate must be labeled that the product is reconstituted from concentrate. Beverages that contain less than 100% and more than 0% fruit juice should be called fruit beverages, fruit cocktails, fruit drinks, or juice drinks. Most of such juice products should be considered as sugar-sweetened beverages because they are mainly composed of water and added sugar.

Fruit juice consumption has increased in recent years, probably due to the public perception of juices as a natural source of many nutrients. Fruit juices provide most of the nutrients of their natural source, including vitamins (A, C, folate, etc.), minerals (calcium, potassium, and magnesium), and other phytochemicals. However, they have relatively higher energy content and lower fiber levels compared to whole fruits (many commercial juices are filtered to remove the fibers or pulps). Carbohydrates, including sucrose, fructose, glucose, and sorbitol, are the most prevalent nutrient in juice. The carbohydrate concentration varies from 26 g/cup (8 oz) to more than 38 g/cup, depending on the type of juices. Juices fortified with calcium have approximately the same calcium content as milk but lack other nutrients present in milk. Some juices have high contents of vitamin A, C, and flavonoids, and certain types of juices are fortified with vitamin D, which may provide beneficial health effects. However, the high energy and sugar contents in fruit juices may contribute to excessive energy intake ([American Academy of Pediatrics, 2001](#)). Studies have linked excessive intake of fruit juice to the risk of obesity and type 2 diabetes, but results are still mixed. Nevertheless, fruit juice offers no nutritional advantage over whole fruit, particularly for healthy adults. Consumption of whole fruits should be encouraged to meet individuals' nutrient needs and energy balance.

#### **Vegetable juice**

Vegetable juices, such as tomato and multi-vegetable juices, are getting more and more popular in many countries. In general, vegetable juice has fewer calories and sugars than fruit juice and can be considered as a healthy alternative to fruit juice. However, commercial vegetable juices usually contain a considerable amount of sodium. As with fruit juices, whole vegetables, rather than vegetable juices, should be encouraged.

100% fruit or vegetable juices should not be offered to infants before age of 12 months. After 12 months, 100% fruit juice can be added but is not necessary if children can eat the whole fruit. If children drink 100% fruit juice, the consumption should be limited to 4 ounces per day. Any juices that contain added sugars should be avoided for children at any age.

#### **Soft drinks**

Soft drinks are usually referred to as nonalcoholic beverages typically containing water, sweeteners, and some flavorings. Sometimes, they are also called pops, soda, or fizzy drinks. They are called "soft" is in contrast to "hard" drinks which are generally referred to drinks with significant alcohol content. Many of these beverages are carbonated and sweetened with either sugar or high-fructose corn syrup (HFCS). Some of them may contain a small proportion of additional ingredients such as fruit juice or alcohol. If alcohol is added to a beverage, the content must be less than 0.5% of the total volume if the beverage is to be considered as a non-alcoholic beverage. Widely, soft drinks include cola, lemonade, iced tea (usually sweet), sports drinks, fruit drinks, fruit punch, and root beer (non-alcoholic form). Carbonated water (also called sparkling water, seltzer, or fizzy water) which contains carbon dioxide gas and flavorings, as well as smart water (distilled water with added electrolytes), fruit water (distilled water with

zero-calorie fruit flavorings), and vitamin water (distilled water with vitamins and flavorings) are usually classified between the soft drinks and plain drinking water.

The history of soft drinks can be traced back to the 1760s when carbonation techniques were developed. The original purpose was to produce beverages similar to naturally occurring mineral water. Back then, no sugars or artificial flavorings were added to these beverages. It is unclear when and by whom sweeteners and/or flavorings were added to the carbonated waters. In 1886, J.S. Pemberton, an Atlanta pharmacist, combined kola (a caffeinated nut from Africa) with coca (a parent plant of cocaine from South America) to create Coca-Cola, which is considered a landmark event in the history of soft drinks. In the following section, we divided soft drinks into 2 major categories based on whether they are sweetened with added caloric sweeteners (sugars or HFCSs) or non-caloric artificial sweeteners (NAS).

### Diet beverages

Diet beverages (diet soft drinks) are carbonated or non-carbonated beverages sweetened with NAS that provide less than 1 kcal in one serving. Currently, 5 artificial sweeteners (saccharin, acesulfame, aspartame, neotame, and sucralose) have US FDA approval. Beverages sweetened with these artificial sweeteners are considered to be safe. In the past several decades, there is an increasing trend in consumption of diet beverages worldwide, likely due to the increased concern regarding the adverse effects of added sugars. In the US, 19% of children and 31% of adults in the US consume diet beverages on a daily basis.

Diet beverages are preferable to sugar-sweetened beverages because they provide water and sweetness but no calories. Randomized interventions have shown that drinking diet beverages was more favorable for weight management compared to drinking sugar-sweetened beverages. However, evidence is emerging to suggest that long-term consumption of these sweet beverages may increase people's desire for sweetness, resulting in increased intake of other sweet foods and beverages. NAS are hundreds to thousands of times sweeter than sugars. Individuals who habitually consume NAS may find less intensely sweet or unsweet foods unpalatable. In addition, diet beverages have a high degree of sweetness but no calories, which might produce a dissociation between sweet taste and calorie intake. One concern is that the dissociation of these physiological events might disrupt the hormonal and neurobehavioral pathways regulating hunger and satiety, potentially leading to seeking and consuming more palatable foods. Recent data also suggested that consumption of NAS could alert the microbial metabolic pathways that are linked to glucose intolerance in mice. A few small RCTs have reported an increase in insulin levels following the consumption of diet beverages or NAS in humans. Results from human observational studies on the relationship of long-term consumption of diet beverages with the risk of CHD, stroke, and death are highly inconsistent ([Mossavar-Rahmani et al., 2019](#)). These new data clearly called a need for large studies with rigorous design to determine the role of diet beverages and NAS in metabolic health, particularly for habitual consumption and for different types of NAS.

### Sugar-sweetened beverages

Sugar-sweetened beverages (regular soft drinks) include carbonated and noncarbonated beverages which are usually sweetened with HFCS or sucrose. These beverages have relatively high calorie and sugar contents, but no or a very small amount of other nutrients. Higher intake of sugar-sweetened beverages has been consistently associated with higher energy intake and increased risk of dental caries, obesity, type 2 diabetes, metabolic syndrome, hypertension, CVDs, gout, and cancer in several populations. Consumption of sugar-sweetened beverages was also positively associated with CVD and cancer mortality, independent of other dietary and lifestyle factors ([Malik et al., 2019](#)). Several RCTs have shown that reducing sugar-sweetened beverage consumption might result in significant weight loss and blood pressure reduction. It has been proposed that sugar-sweetened beverages contribute to weight gain because of their high sugar content and incomplete energy compensation. Fructose from sucrose or HFCS may also increase blood pressure and promote the accumulation of visceral adiposity through the increase of hepatic de novo lipogenesis. In addition, consuming a large amount of sugar-sweetened beverages can contribute to a high glycemic load diet by providing a large amount of rapidly absorbable sugars, leading to insulin resistance, chronic inflammation, and possibly impaired  $\beta$ -cell function. Therefore, high sugar-sweetened beverage consumption may increase type 2 diabetes and cardiovascular risk independently of obesity. Recent meta-analyses also reported that a higher intake of sugar-sweetened beverages was associated with a higher risk of fracture in children and lower bone mineral density in adults. Sugar-sweetened beverages, thus, should be consumed as less as possible.

### Summary

In summary, the primary purpose of drinking beverages is to provide fluids rather than calories or other nutrients. Beverages with more nutritional values but few calories and sugars can be consumed to meet our body's requirement for fluids. In general, beverages should provide less than 10% of total energy for healthy adults. By considering the energy density, nutrient density, and health benefits/risks linked with each beverage category, unsweetened tea and coffee are mostly recommended for adults, followed by low-fat and skim milk, and 100% fruit and vegetable juices. Soft drinks, both diet and sugar-sweetened beverages, are not necessary for a healthy diet and should be avoided. Special populations such as children and pregnant women may have additional

considerations when choosing beverages. No beverages should be consumed by infants before 12 months of age. Beverages that contain high levels of caffeine should be avoided for children and pregnant women.

## Key points

- Biofortification, or nutrient enrichment, of staple food crops, is the process of increasing the density of vitamins and minerals in widely consumed food crops through plant breeding or agronomic means.
- Nutrient retention in the biofortified food following storage, processing, and cooking, nutrient bioavailability compares favorably to non-biofortified foods suggesting potential for impact. Efficacy is well demonstrated, but less is known about factors determining effectiveness, including gene and environment interactions and use and re-use of seeds.
- There is a need to generate evidence on the effectiveness of biofortification in real-world settings, explore and test innovative market delivery models, and ensure coherent policies are in place that create an enabling environment for biofortification.

## Glossary

**Agronomy** Refers to the application of mineral enriched fertilizers to the soil or plant leaves to increase the micronutrient content of the resulting edible crop

**(Nutrient) Bioaccessibility** Is defined as the amount of an ingested nutrient that is available for absorption (released from the food matrix) in the gut after digestion. It is often considered a subset of bioavailability

**(Nutrient) Bioavailability** Refers to the proportion of an ingested nutrient that reaches the systemic circulation and the specific sites where it can exert its biological action. It is also referred to as absorbability

**Biofortification** Refers to the process of increasing the micronutrient content and/or bioavailability of micronutrients in crops through conventional plant breeding techniques. Several commonly consumed foods have been developed and shown to be

effective for improving micronutrient intakes, including iron-rich beans and millet, and vitamin A-rich sweet potato, maize, and cassava

**Conventional plant breeding** Refers to the cross-pollination of two genetically closely related plants to increase desirable characteristics. These characteristics include yields as well as micronutrient levels among others

**Micronutrient** Is a general term that refers to all vitamins (e.g., vitamin A, B vitamins such as folate, and vitamin D) and minerals (e.g., zinc, iron) that are required in small amounts for a range of different processes in the body, including the healthy functioning of all organ systems, growth, development, and health. An essential micronutrient is one that must be obtained from the diet because the body cannot produce it or does so in quantities insufficient to meet needs

**Staple foods** Refers to a food that makes up the dominant part of a population's diet. Food staples are eaten regularly—even daily—and usually in large quantities such that they contribute a major proportion of a person's energy and nutritional needs. They commonly include cereals, starchy roots, tubers, and legumes, and often extend to include vegetable oils, salt, and sugar

## Introduction

Biofortification (also known as nutrient enrichment) is a public health intervention in which the density of vitamins and minerals in a widely consumed crop is increased through agricultural means as a strategy to increase regular consumption of nutrients, thus decreasing risk of micronutrient deficiencies, particularly in low- and middle-income countries. Several processes are used to achieve biofortification, and these include conventional breeding, transgenic techniques, and agronomic approaches (Bouis, 2018). These are presented in detail in an earlier edition of this article (Hotz, 2013). The dominant method of enrichment of crops is through the use of conventional plant breeding, which applies the same basic techniques as used to breed plants with improved agronomic traits, such as increased yield or pest resistance (Hotz, 2013). Furthermore, conventional plant breeding does not encounter the same regulatory and acceptability barriers as transgenic approaches. In this article we present an overview of the history and current progress of biofortification, summarize the evidence on the efficacy and effectiveness of biofortified crops to improve micronutrient status and functional outcomes, and discuss the key elements necessary to maximize potential for impact of biofortification with a focus on conventionally bred biofortified crops.

## Overview of biofortification

### History and progress

The main objective of plant breeding—which is the most predominant form of biofortification—has historically been to improve farm productivity, usually by developing crops with higher yields, greater resilience to drought, and resistance to pests. This strategy, which is the primary focus of this article, takes advantage of the considerable genetic variation in crop species and entails crossing varieties with various traits in a bid to develop a variety with desirable characteristics. Agricultural research stations and smallholder farmers alike have used this technique to isolate desired traits. In comparison, transgenic approaches entail the introduction of new genes derived from another species to the target plant species. An example of this technique in practice is Golden Rice, in which genes from bacteria were introduced to trigger production of  $\beta$ -carotene in rice grain endoplasm (Beyer et al., 2002). Agronomic methods include the application of mineral (e.g., zinc or iron) micronutrient fertilizers to soils or plant leaves (foliar) to increase micronutrient contents in edible parts of crops (de Valença et al., 2017).

Biofortification using convention plant breeding began in the 1990s when it was in essence prompted by Howarth Bouis suggesting that dietary quality was just as important as quantity and that crops could “fortify themselves” with micronutrients to address the “hidden hunger” of micronutrient deficiencies. He posited three questions (Bouis, 2003):

1. “Can commonly eaten food staple crops be developed that fortify their seeds with essential minerals and vitamins?”
2. Can farmers be induced to grow such varieties?
3. If so, would this result in a marked improvement in human nutrition at a lower cost than existing nutrition interventions?”

Over the next decade scientists at the Consultative Group on International Agricultural Research (CGIAR) worked to provide proof of concept and evidence of the viability of this concept. This culminated in the establishment of HarvestPlus: the Biofortification Challenge Program in 2003 (Pfeiffer and McClafferty, 2007). Later renamed HarvestPlus, this international consortium of researchers and implementers has led, in collaboration with other CGIAR programs such as the International Potato Center (CIP), agricultural and biotechnology research, food science and nutritional research, economic and policy impact research, and direct programs delivering biofortified crops through the seed and agricultural inputs supply system to farmers. To date, more than 340 biofortified varieties of 12 crops have been released in 40 countries (Council for Agricultural Science and Technology (CAST), 2020).

The value proposition of biofortification is threefold. First, it has the potential for cost-effectiveness in the long-term by increasing regular consumption of essential nutrients (Bouis, 2003). This is predicated on initial development and dissemination having been completed and commercialization achieved, after which recurring costs are estimated to be low. Recent evidence on this is detailed in a comprehensive report of the Council for Agricultural Science and Technology (Council for Agricultural Science and Technology (CAST), 2020). Second, biofortification has the inherent ability to reach rural populations who rely heavily on locally-produced staple foods and are at greater risk of micronutrient deficiencies—and thus have the greatest potential to benefit. This population segment may also have limited access to a high variety of nutrient-rich foods and to industrially fortified foods from markets (that is, those to which micronutrients are added during processing), leaving them at additional risk and unreached by other population-based micronutrient deficiency mitigation programs. Third, it has potential for sustainability as once planting material is obtained, it can be saved, recycled, and shared with other farmers.

On the left side of the ledger are a few notable disadvantages. Mainly, biofortification can only provide modest additional amounts of micronutrients compared to supplements and, in some cases, industrially fortified foods; therefore, potential for impact may be modest. We provide more detail on target nutrient profiles in the next section. Another limitation that relates to delivery and timeliness in the time required to develop a viable, stable crop, which can take up to 6–8 years. This results in less flexibility to adjust nutrient contents and/or combinations over time. As a result, biofortification is considered a complementary strategy to other micronutrient deficiency strategies (e.g., industrial food fortification, supplementation, and promotion of a diverse diet).

### Target foods and nutrients

A diet that provides an adequate and consistent supply of essential micronutrients is out of the reach for many of the world's poor due to the relatively higher cost of nutrient dense foods and their availability in some regions. This explains the high prevalence and recalcitrance of micronutrient deficiencies and their harmful effects on morbidity and mortality. The fundamental premise of biofortification is therefore that enhancing the micronutrient content of energy rich commonly consumed foods, on which resource-constrained people often rely, can contribute to intakes and concomitant reductions in micronutrient malnutrition. The first step to achieving this goal is for plant breeders to identify plant varieties with high micronutrient content that can be bred into local varieties.

Such research has been largely successful in identifying nutrient rich varieties of the world's most important staple food crops, including maize, rice, wheat, cassava, potato, sweet potato, common beans, pearl millet, sorghum, and banana/plantain. Efforts have been mainly focused on increasing the content of provitamin A carotenoids, iron, and zinc (Pfeiffer and McClafferty, 2007) likely due to the high prevalence of deficiencies associated with these micronutrients in low- and middle-income countries.

It is important to note that a wider range of nutritional components are also being considered for biofortification (Council for Agricultural Science and Technology (CAST), 2020). This includes other minerals (i.e., calcium, iodine, magnesium, selenium), vitamins (i.e., vitamins C, E, folate), non-provitamin A carotenoids (i.e., lutein, lycopene), protein and protein quality, essential amino acids, fatty acids, other secondary nutritional components such as flavonoids, and probiotic compounds (i.e., inulin and other fructans). So, the research agenda is more expansive and ongoing.

In addition to addressing the inherent nutrient content of foods, biofortification has considered the presence of antinutritive compounds. Cereal grains tend to have a high content of phytate, a phosphorus storage compound found within the hulls and kernels of these seeds that has a strong binding affinity to dietary minerals such as calcium, iron and zinc, inhibiting their absorption in the small intestine. As a secondary strategy, biofortification research has therefore sought also to improve mineral bioavailability from cereals by targeting reductions in the phytate content or increases in phytase activity in the grain to reduce the inhibitory effect of phytate. The focus on high yield crops is important to note as it makes biofortified crops appealing to farmers and value chain actors.

To date, there are several examples of biofortified staple food crops under production using conventional plant breeding (Table 1). Some of these traits are visible, e.g., vitamin A biofortified staple food crops are often yellow or orange because of the  $\beta$ -carotene. While others are invisible, e.g., high iron beans look like conventional varieties.

Minimum breeding target levels for increased micronutrient contents are estimated during the development stage (Pfeiffer and McClafferty, 2007). Breeding targets are set based on micronutrient needs and usual daily quantities consumed of the staple crop by non-pregnant, non-lactating women of reproductive age and children 1–6 years of age and account for any micronutrient losses during storage, processing and/or cooking and the fractional absorption of the micronutrient content. These population groups are selected as they are at greatest risk of micronutrient deficiencies and thus the targets of most micronutrient interventions. Considering this, most biofortified staple food crops aim to provide an additional 20–100% of the micronutrient requirements for women and children compared to conventional crops (Table 1).

Current varieties of biofortified staple crops developed through conventional plant breeding focus on single nutrients. This can be considered a limitation because many population segments in low- and middle-income countries suffer from a range of co-existing micronutrient deficiencies and therefore combining micronutrients in the same staple food (also known as multi-biofortification) would be advantageous to tackling this problem. Some examples of this have been developed, such as

**Table 1** Target nutrient levels and estimates of contribution to the estimated average requirement (EAR)<sup>a</sup> of biofortified staple crops developed by conventional breeding.

Crop	Nutrient	Target increment provided by biofortification	Estimated proportion of the EAR provided for non-pregnant, non-lactating women		Estimated proportion of the EAR provided for children, 1–6 years old	
			Before biofortification	After biofortification	Before biofortification	After biofortification
Beans	Iron	+44 ppm	45%	90%	40%	75%
Pearl millet	Iron	+30 ppm	50%	85%	45%	75%
Sweet potato	Pro-vitamin A	+70 ppm	0%	>100%	0%	>100%
Cassava	Pro-vitamin A	+15 ppm	0%	>100%	0%	95%
Maize	Pro-vitamin A	+15 ppm	0%	55%	0%	60%
	Zinc	+12 ppm	45%	65%	55%	80%
Rice	Zinc	+12 ppm	40%	70%	40%	70%
Wheat	Zinc	+12 ppm	35%	55%	20%	25%

<sup>a</sup>Rounded to nearest 5%.Source: <https://www.harvestplus.org/content/estimated-average-requirements-provided-biofortification>.

multi-vitamin corn in South Africa that contains both provitamin A and folate; however, it was developed using transgenic techniques. Whether or not it is feasible to target multiples nutrients simultaneously through conventional plant breeding has yet to be determined.

### The potential of biofortification to improve micronutrient status

The extent to which biofortification can impact micronutrient status and health outcomes at scale is influenced by several factors, which include the presence of nutrient deficiency in the target population (i.e., the need), usual intake of the major staple food or foods (i.e., the opportunity), nutrient retention in the biofortified food following storage, processing, and cooking, nutrient bioavailability, and the efficacy of the biofortified food to improve nutrient status when consumed under controlled conditions. Taken together, the latter influences (retention, bioavailability, efficacy) relate to efficiency, and we tackle them sequentially.

#### Nutrient retention

A major role of the food matrix is to trap the nutrients within cells or subcellular compartments and provide constituents that interact chemically with specific nutrients to either encourage or delay their release, leading to their classification as absorption promoters and inhibitors. Because biofortified crops are subjected to periods of storage, transportation, processing, and cooking or other forms of preparation (e.g., fermentation), the extent to which nutrients are retained is worth considering as the effects differ by food processing technique and micronutrient (Table 2).

#### Minerals: zinc and iron

The lower proportions of iron and zinc retained (i.e., 20–60%) following milling of cereal grains for refinement is concerning. Grains, such as wheat, are often dehulled and milled to produce a flour, which, because a large proportion of minerals occur in the outer aleurone layers, can result in significant reductions of minerals like zinc (Díaz-Gómez et al., 2017). When it comes to cooking, the retention of minerals in plant-based staple foods following typical household cooking methods is generally quite high, with ≥90–95% of iron and zinc retained after cooking of cereal grains, roots, and tubers and ≥75% retained in boiled legumes. Minerals are heat-stable, although it is plausible that losses can occur due to leaching. However, the extent to which retention of minerals after cooking will differ in mineral-biofortified staple food crops is not yet determined. On the other hand, heating can soften the cell walls and remove inhibitors thereby enhancing the bioaccessibility of zinc in particular (Díaz-Gómez et al., 2017).

**Table 2** Effects of processing on the micronutrient content of food.

	<i>Carotenoids</i>	<i>Iron and zinc</i>
Drying	Can reduce carotenoid levels but this depends on the drying method, the temperature/time combination.	Not applicable.
Dehulling	Not applicable.	Significant quantities of minerals can be lost, up to 50% of the iron in some grains. Reduces the level of inhibitors that prevent mineral uptake.
Milling	Increases carotenoid bioavailability because the food particle size is reduced.	Degrades the cell wall, allowing minerals to interact with other components. Iron, zinc and phytate levels are reduced by milling, but the remaining iron and zinc is more bioavailable.
Fermentation	Does not usually affect carotenoid retention.	Can degrade phytate through the action of microbial phytases.
Heating	Exposure to light and heating can result in the loss of provitamin A activity.	Minerals are heat stable. Can enhance mineral absorption by softening the cell walls and removing inhibitors.

Adapted from Díaz-Gómez et al. (2017).

### Vitamin A

Nutrient retention is a greater consideration for biofortification with vitamins, particularly provitamin A carotenoids as they are more susceptible to exposure to heat, light, and oxygen. As such, retention during the postharvest storage (with respect to the duration and conditions) of the biofortified food must be considered. In orange sweet potato, the retention of  $\beta$ -carotene averages 84% after boiling and 77% after steaming, which are the most common cooking methods (Hotz, 2013). In biofortified orange maize, retention of  $\beta$ -carotene was ~75% in porridge cooked from fermented or unfermented, wet, milled flour. Retention of  $\beta$ -carotene after drying of sweet potato or cassava to make flour or chips is moderate, but dramatic degradation occurs during storage of these dried products over weeks or months.

### Nutrient bioavailability

Not all the retained nutrient is absorbed by the body and used in the physiological functions for which they are needed due to two interrelated characteristics. One is bioavailability (also called absorbability), which refers to the proportion of an ingested nutrient that reaches the systemic circulation and specific sites where it can exert its biological action. Bioaccessibility is often considered a subset of bioavailability and is defined as the amount of an ingested nutrient that is available for absorption (i.e., released from the food matrix) in the gut after digestion. The bioaccessibility and overall bioavailability of nutrients from specific foods is determined by the food matrix, the chemical form as well as the physical location of the nutrient, and the presence or absence of other food factors that inhibit or promote the bioavailability of a nutrient. Because traits often interact, it is possible that the process of biofortification will result in concomitant changes in these or other properties that may alter the relative bioavailability of the additional nutrient.

### Minerals: zinc and iron

The bioavailability of iron and zinc is influenced in general by the presence of antinutrients such as phytate. Although levels of phytate can be reduced through plant breeding, this needs to be counterbalanced against the potential implication that decreasing them too much may compromise the benefits of phytates to plants (La Frano et al., 2014). Studies have been conducted using low-phytic acid mutant maize with ~60% less phytic acid content than the wild type (Mazariegos et al., 2006). Controlled laboratory studies measured large increases in calcium, iron, and zinc bioavailability. However, when this maize was incorporated into typical diets of Guatemalan children in a community-based study, phytic acid in the total diet was reduced by only 25–30% and no significant improvement in zinc bioavailability was observed (Mazariegos et al., 2006). The difference in results highlights the importance of conducting these kinds of studies under realistic dietary conditions.

There is a general indication that iron biofortification of grains will not modify the relative bioavailability of additional iron from that of intrinsic (i.e., pre-existing) iron. Ferritin is an iron storage protein in plants, and transgenic rice and wheat with increased grain ferritin have increased grain iron content. Several studies indicate that iron from ferritin is as well absorbed as iron from exogenous ferrous sulfate and that zinc biofortified rice and wheat have similar bioavailability when compared to varieties that are industrially fortified with zinc. For example, human studies found that bioavailability for iron (2.6–9.0%) and zinc (17–20%) from biofortified crops were consistent with the results of studies in non-biofortified plants (La Frano et al., 2014).

### Vitamin A/provitamin A

Food related factors affecting the efficiency of absorption and conversion of dietary provitamin A to retinol include the type of provitamin A carotenoid (i.e.,  $\alpha$ -carotene,  $\beta$ -carotene,  $\beta$ -cryptoxanthin), its isomeric form (i.e., *trans*-, *cis*-), and the food matrix. In contrast to minerals, the bioconversion of  $\beta$ -carotene to retinol in the provitamin A biofortified crops, which varied from 2.8:1

to 6.5:1, was more efficient than the average bioconversion of 12:1 estimated for nonbiofortified foods (La Frano et al., 2014). The amount of provitamin A ingested ( $\mu\text{g}$ ) that is required to produce 1  $\mu\text{g}$  retinol is expressed as the retinol equivalency ratio, and this varies by food type. The order of increasing efficiency of conversion to retinol, or decreasing ratios, is: green or yellow vegetables  $\ll$  orange fruits, vegetables, or sweet potato  $\ll$  yellow or orange biofortified cereal grains (Hotz, 2013). Studies using animal and in vitro models also indicate that  $\beta$ -carotene in biofortified cassava is well absorbed and as efficiently converted to retinol as  $\beta$ -carotene from biofortified maize and rice (La Frano et al., 2014). These results support the potential for provitamin A-biofortified staple foods to serve as important sources of vitamin A.

### **Efficacy**

Another critical assumption of linking biofortification to its intended goal is that the nutritional efficacy of a biofortified crop must be established. The extent to which various biofortified staple crops can improve nutrient status and/or functional outcomes among women and children has been demonstrated under controlled settings. We summarize this evidence below (references to studies mentioned in this section can be found in (Council for Agricultural Science and Technology (CAST), 2020) except where noted). It is important to note however that, when moving from controlled to real-world settings, there is a need to additionally consider the different factors affecting nutrient absorption and utilization, including processing, cooking methods, and storage as described above that will vary in uncontrolled settings.

#### **Iron enriched crops**

Three of four efficacy studies completed for iron biofortified crops observed positive effects on iron status. In the Philippines, iron rice improved iron stores among non-anemic women. In Rwanda, iron biofortified beans improved iron status among women. In India, iron pearl millet improved iron status among school children. Conversely, in Mexico, iron biofortified beans had no significant effect on iron status compared to conventional beans among school children 12–16 years. Further meta-analyses of the first three studies have demonstrated that consumption of iron biofortified foods resulted in significantly increased serum ferritin concentrations and total body iron compared to controls and that the greatest effects were seen among individuals who were iron deficient at baseline and thus had the greatest potential to benefit.

Positive effects of iron biofortified crops on functional outcomes, such as cognitive and physical performance, have also been demonstrated. In Rwanda, iron biofortified beans increased physical work efficiency and improved cognitive performance among women. In India, iron biofortified pearl millet increased measures of physical activity and improved cognitive performance among school children 12–16 years.

#### **Provitamin A enriched crops**

The efficacy of the various vitamin A biofortified crops on vitamin A status and some functional outcomes has been demonstrated across different countries and populations. Provitamin A orange sweet potato improved vitamin A status in South Africa and vitamin A intakes and serum retinol concentrations in Mozambique among children. In Bangladesh, orange sweet potato increased plasma  $\beta$ -carotene concentrations but not vitamin A status among women with low initial vitamin A status; nor did it increase breast milk vitamin A concentrations among lactating women. Orange sweet potato has also been shown to reduce diarrhea prevalence and duration among children under 3 years in Mozambique.

Provitamin A maize has been demonstrated to significantly improve serum beta-carotene concentrations, total body stores of vitamin A compared to conventional maize as well as increased pupillary responsiveness among children in Zambia. Additionally, biofortified maize improved retinol concentration in breast milk among Zambian women. Biofortified maize has also been shown to be an effective, bioavailable source of vitamin A among men and women.

Provitamin A yellow cassava increased serum retinol and  $\beta$ -carotene concentration, markers of vitamin A status, among children 5–13 years in Kenya and improved serum retinol among preschool children in Nigeria (Afolami et al., 2021).

#### **Zinc enriched crops**

For zinc, only a few efficacy studies have been conducted to date. In India, high zinc biofortified wheat had no significant effect on zinc status compared to low zinc wheat among women of reproductive age and children 4–6 years, but this may have been due to small differences in zinc levels between the two wheat varieties (30 ppm vs. 20 ppm) and the limited duration of the intervention (6 months). However, a significant reduction in days with pneumonia and vomiting among children and fever among women was observed in the high zinc group. A randomized-controlled trial is currently in progress in Pakistan to examine the impact of zinc biofortified wheat on zinc status and functional outcomes among adolescent girls and children (Lowe et al., 2020). More data are needed to provide definitive evidence.

### **Effectiveness**

Evidence on the effectiveness of biofortified staple food crops to improve population-level nutritional status in real-world settings is limited (references to studies mentioned in this section can be found in (Council for Agricultural Science and Technology (CAST), 2020) except where noted). To date, two randomized controlled effectiveness trials have been conducted for provitamin A orange sweet potato. In Uganda, farming households were randomized to an intensive or reduced intervention program over 2 years that

was aimed at increasing the production and consumption of orange sweet potato. Consumption of orange sweet potato was associated with increased vitamin A intakes among children 3–5 years and women and improved vitamin A status (serum retinol concentrations) among children compared with controls. A similar study in Mozambique compared low intensity (1 year) and high intensity (3 years) intervention groups with controls and found increased vitamin A intakes among women and children in both groups compared to controls (with no difference between intervention groups). The lack of evidence on real-world impact is largely due to the nascency of the intervention and the fact that many crops have not yet been scaled up such that it would be feasible to assess impact at a population-level.

In addition to effectiveness, it is important to understand acceptance and adoption of biofortified crops as these are factors that determine their consumption and ultimately effectiveness. Evidence from a systematic review of acceptance and adoption of biofortified crops (which included sweet potato, maize, rice, and pearl millet) in low- and middle-income countries found good overall acceptance of biofortified crops and that sensory changes (such as color) were not barriers to acceptance (Talsma et al., 2017). Additionally, the most importance determinants of acceptance and adoption were availability and information on health benefits of the biofortified crops.

### Achieving potential for impact

Clearly, biofortification is a food-based approach that holds promise for cost-effective impacts on micronutrient, health, and functional outcomes. For biofortification to achieve its potential for impact, scale up, and sustainability, there is a need to identify or build on cost-effective delivery strategies. Such strategies need to be grounded in the three interrelated elements of (1) supply, (2) demand, and (3) an enabling policy environment.

Considering the goal of reaching the rural poor, current delivery models have focused with good reason on farmers. To unpack the sequence, the program pathway moves from specialized seeds bred by plant specialists, to seeds then multiplied and released by seed companies, to agricultural production by farmers, to farmers allocating some of their production for home consumption. With few published exceptions (Kangile et al., 2021), there has been less focus on getting the biofortified foods in the commercial markets. As suggested by Kangile in their study of orange sweet potato (Kangile et al., 2021), we posit that a transition from farmer to commercial market models is needed to achieve potential impact, scale up, and sustainability and additionally to reduce/eliminate the need for donor funding. This will require four conditions to be met. First, a sufficient supply of biofortified seed that is accessible and desirable to farmers. Second, the traceability of the biofortified seed through initial supply chain (as described above) and then through the rest of the food supply chain (i.e., storage and distribution, processing, packaging and distribution, retail, and markets). This is needed to signal nutritional value and consequently demand by value chain actors but is easier for crops with visible traits than those with invisible traits. Third, incentive/motivation for processors to take up the biofortified food over conventional varieties (e.g., price). A critical consideration for example is how prices for biofortified crop varieties compare to those for conventional varieties, since these will determine affordability of the biofortified staple crops and food products, and similarly influence demand from consumers - the fourth condition.

This having been said, the considerable advocacy that HarvestPlus and its partners have deployed to promote investment in biofortification and adoption by countries has contributed to the release of biofortified crops in at least 22 African countries (Covic et al., 2017). Biofortification is an intervention, but is there a need for policy processes and coordination at the level needed for more intensive, and we would suggest disruptive, interventions? There has been considerable progress in integrating biofortification into regional and national policies as evidenced by some national nutrition strategies that include biofortification (e.g., Bangladesh, Malawi, Nigeria, Pakistan, Tanzania, and Uganda) and a greater number that include biofortified crops in national agriculture and nutrition plans (Bouis, 2018).

### Conclusion

By enriching the micronutrient content in staples foods that are consumed by those most at-risk of micronutrient deficiencies, biofortification has the potential to be a part of the solution to the persistent problem of micronutrient deficiencies affecting many low- and middle-income countries. Significant progress in crop development and research on nutrient retention, bioavailability, and efficacy of biofortified foods has been made over the past two decades.

At the household level, the value of biofortified crops can be realized by combining the adoption of biofortified varieties by smallholder farmers and procurement of biofortified foods and ingredients by consumers with the most appropriate food preparation and cooking methods that maximize the bioavailability of different nutrients. The fact that selection of varieties also focuses on high yield or resilience co-factors helps acceptance and adoption across the value chain. Moving forward there is a need to generate evidence on the effectiveness of biofortification in real-world settings, explore and test innovative market delivery models, and ensure coherent policies are in place that create an enabling environment for biofortification.

## Key points

- Worldwide cereals grains are staple foods that provide a large proportion of energy, carbohydrates, proteins in the human diet
- Wheat, maize and rice are the three most highly produced and consumed cereal grains
- All cereal grains go through some level of processing that determines the quantity and quality of nutrients ingested
- Different varieties of cereals and cereal-based food products when routinely consumed are associated with various health outcomes

## Introduction

The edible monocotyledonous seeds from grasses, both cultivated and wild, of the *Poaceae* or *Gramineae* family are termed cereal grains. The term cereal originated from the word “Ceres”, the ancient Roman god of agriculture. Cereals have served as the primary staple food for human beings from ancient times ensuring food security. Its consumption contributes to approximately 50% of

caloric intake (Food and Agricultural Organization, 2016, 2020). Not only are over half of the cereals produced used for human consumption, but they are also used for consumption by livestock, poultry, and other birds. Further, they are the primary source for production of alcohol.

From an evolutionary perspective, cereal grains were ingested long before domestication of crops when humans were hunter-gatherers. The realization that cereal grains can be stored and used as a safe reliable food source may have served as a stimulus for humans to dwell close to where cereal crops were cultivated and become an agrarian society. Cereal grains were preferred as a source of food mainly because of the possibility of longer storage periods and the preservation of available nutrients in the grain compared to perishable foods (Wrigley, 2017b). Historically, domestication of maize first occurred in Mexico or Central America, wheat in the Far East and rice in China (Awika, 2011). Processing and cooking of cereals too probably began as early as 105,000 years ago when cereal-based snacks were eaten. Evidence from Africa where residues of grass seeds, mainly sorghum was found on implements were suggestive of the use of some form of processing technique to make the cereal grains conducive to consumption (Thielecke et al., 2020; Curry, 2021).

Cereals crops are the dominant agricultural produce grown over 60% of cultivable land available worldwide (Koehler and Weiser, 2013). There are several cultivars of each type of cereal grain with cultivation dependent on climate, temperature, availability of water, soil conditions prevailing in each region, apart from other cultural and economic factors (Awika, 2011).

A large proportion of food energy, protein, some of the B complex vitamins and minerals is contributed by cereals in human diets mainly because of the quantity of cereals consumed. The developing world relies more on cereal foods for their nutritional needs compared to the developed countries (Awika, 2011; Wrigley, 2017b). With the advent of processing and further advances in technology especially over the last century, changes in the form of consumption of cereals has occurred.

## Types of cereal grains

Global production and consumption of cereals are largely dominated by wheat, maize and rice followed by sorghum, barley, oats, rye, millets, and other cereals. Within each species of cereal grains, diverse varieties exist due to breeding for improvement of agro-nomic, technological, and nutritional properties. Some cereals are also termed coarse cereals. Coarse cereals exclude rice and wheat and refers to sorghum (*Sorghum vulgare*), maize (*Zea mays*), oats (*Avena sativa*), barley (*Hordeum vulgare*), buckwheat (*Fagopyrum esculentum*) and some millets species, namely pearl millet (*Pennisetum glaucum*), finger millets (*Eleusine coracana*), foxtail millets (*Setaria italica*) and kodo millet (*Paspalum setaceum*), etc (Fu et al., 2020). Pseudo cereals are dicotyledenous grains resembling cereals but not part of the Gramineae family. Buckwheat (*Polygonaceae*), amaranth (*Amaranthaceae*), chia (*Salvia hispanica*) and quinoa (*Chenopodium quinoa*) are the commonly consumed varieties of pseudo cereals. They are used as grains or ground into flour (Békés et al., 2017). The cereal species and the region of cultivation are provided in Table 1.

Generally, all cereals grains are harvested only once annually. Maize, rice, sorghum and millets are tropical grasses grown in regions with temperate climates under frost free conditions, while wheat, rye, barley, and oats are grown in regions with a moderate climate during cooler seasons. Cereals such as sorghum and millets can adapt in arid conditions and are tolerant to drought (Awika, 2011; Koehler and Weiser, 2013).

**Table 1** Cereal species.

Type	Sub-family	Genus and species mainly used	Region grown
<b>Cereals</b>			
Barley	Pooideae	<i>Hordeum vulgare</i>	Arctic and semi-arid zones
Rye	Pooideae	<i>Secale cereale</i>	Arctic zone, temperate zone
Wheat (common, bread)	Pooideae	<i>Triticum aestivum</i>	Temperate zones
Wheat (durum)	Pooideae	<i>Triticum durum</i>	Temperate zones
Triticale		×Triticosecale sp.	Arctic zone, temperate zone
Oats	Pooideae	<i>Avena sativa</i>	Temperate and sub-tropical zone
Maize (corn)	Andropogonoideae	<i>Zea mays</i>	Tropical, subtropical, temperate
Sorghum	Andropogonoideae	<i>Sorghum bicolor</i>	Tropical, sub-tropical regions
Millets (proso, pearl. Foxtail)	Panicoideae	<i>Pennisetum</i>	Tropical, subtropical, semi-arid
Millets (finger millet, teff)	Cynodonteae	<i>Eleusine coracana</i>	Tropical, subtropical, semi-arid
Rice	Oryzoideae	<i>Oryza sativa</i>	Tropical, subtropical
<b>Pseudocereals</b>			
Amaranth	Amaranthaceae	Amaranth caudatus; amaranth cruentus; amaranth hypochondriacus	Tropical, subtropical
Buckwheat	Polygonaceae	<i>Fagopyrum esculentum</i>	Tropical, high altitude
Quinoa	Chenopodiaceae	<i>Chenopodium quinoa</i>	Tropical, subtropical, temperate

Wheat, rye and barley are from the sub family Pooideae, tribus Triticeae, with oats being distantly related under the same sub-family. In evolutionary terms, rice, maize or corn, sorghum and millets are from a different species (Koehler and Weiser, 2013).

## Maize

Maize (*Zea mays*) also called as corn in some countries, is largely grown and consumed as a staple in Africa and North and South America. It grows in warmer climates and regions with adequate rainfall and is generally sown in spring and harvested in summer (Awika, 2011). The use of maize as food is projected to increase primarily in Sub-Saharan Africa where population growth is expected to rise. Maize grown across the world are of different colors (white, yellow, red, black). The maize grown in Africa and Central America are mostly white, while that grown in the United States of America are both white and yellow (Ranum et al., 2014). Maize, particularly white maize, will remain an important staple, accounting for about a quarter of total caloric intake of the world.

## Wheat

Wheat of the *Triticum* family, is the second most largely produced cereal in the world (OECD/FAO, 2021). It is mainly grown in the temperate zones and adapts itself to different agro-climatic conditions. Of the manifold species grown, the main commercial varieties grown are *T. aestivum* subspecies Vulgare and the hard wheat *T. durum*. Over 90% of wheat grown is *T. aestivum*. These are varieties that can be easily threshed. Wheat grows in a wide range of environments from low to high water availability and wide-ranging temperatures. Wheat grows in temperate regions both in winter and summer and is the predominant staple in North Africa and West and Central Asia although populations across the world ingest them (McKevith, 2004; Uthayakumaran and Wrigley, 2017).

## Rice

Rice (*Oryza Sativa*) is consumed by over 65% of the population largely in Asia followed by Latin America. Most rice is produced in Asia, with over half of the world's production from China and India (OECD/FAO, 2021). Rice, the major staple food in Asia. It is cultivated in standing water (approximately 5–10 cm depth) in tropical and subtropical climates and sometimes, on dry uplands (MacEvilly, 2003; OECD/FAO, 2021). The average estimated per capita consumption per year between the years 2018–2020 was highest in Asia (77.2 kg) followed by Latin America and Caribbean (28.0 kg), Africa (27.4 kg), Europe (20.7 kg), Oceania (13.5 kg) and North America (6.3 kg) (OECD/FAO, 2021). Rice is generally grown in warmer tropical and sub-tropical regions with high rainfall and requires a lot of water for production and hence production is highest in Asia. However, some varieties also thrive in temperate regions (Fitzgerald, 2017b). Wild rice is unrelated to rice but has a higher protein content than rice. It is from a North American plant *Zizania aquatica* which is both difficult to harvest and more expensive compared to other grains (McKevith, 2004).

## Millets

Millets are small, grained cereals belonging to a separate sub family *Panicoidacea* and since ancient times have been used by mankind in Asia and Africa (Belitz and Grosch, 2009). Pearl millet (*Pennisetum glaucum*), finger millet (*Eleusine coracana*), little millet (*Panicum sumatrense*), Italian or foxtail millet (*Setaria italica*), barnyard millet (*Echinochloa crusgalli*), proso or common millet (*Panicum miliaceum*) and kodo millet (*Paspalum scrobiculatum*) are the millets most consumed. Most millets are grown in the tropical and sub-tropical regions, while some are grown in the temperate regions. Millets form the staple food of populations inhabiting the arid and semi-arid tropics of the world and serve as food in most of the Asian and African countries and parts of Europe (MacEvilly, 2003; Taylor and Duodu, 2017). The ability of millets to adapt to extreme ecological conditions particularly in dry lands and other nutritional attributes makes it a sustainable crop for the future (Bandyopadhyay et al., 2017).

## Barley

Barley (*Hordeum vulgare*) grows mainly in the colder regions and is thus largely grown in northern Europe, United States of America and Canada. Nevertheless, being a versatile crop, with a short period for growth, it adapts to a wide range of environments and geographical locations. The crop is tolerant to drought and saline soil, too (Gyöfi, 2017). Barley is used as animal and human feed and to produce alcoholic beverages, but most barley is mainly malted and consumed. It is consumed as food in a few countries in Europe, and the Middle and Far East (McKevith, 2004; Gyöfi, 2017).

## Sorghum

Sorghum (*Sorghum bicolor*) is a crop grown in tropical and subtropical regions with 90% grown in Africa and Asia. It is the staple food in Africa and some parts of Asia and the Middle East (Leff et al., 2004; McKevith, 2004). Sorghum produced in North and Central America, South America and Oceania are primarily used for animal feeds (McKevith, 2004). It grows in warm climates and cannot tolerate low temperatures. Sorghum is both a pest and disease resistant crop.

## Oats

Oats (*Avena sativa*) is a grass grown annually in cold regions. A small quantity that is produced is used for human consumption while most is used as animal feed and for other purposes (McKevith, 2004; Butt et al., 2008).

## Rye

Rye (*Secale cereale*) is grown mainly in the colder regions, in high altitudes and semi-arid regions and is a winter crop (MacEvilly, 2003; McKevith, 2004; Wrigley and Bushuk, 2017). The principal use of the crop is as food and as a forage crop. Most rye is produced in Russia, the European countries of Poland, Germany and the Scandinavian countries and Canada where rye bread is mainly prepared (McKevith, 2004; Wrigley and Bushuk, 2017).

## Triticale

A hybrid of durum wheat and rye is Triticale (x Triticosecale). The hybrid variety was developed for the purpose of integrating the agronomic properties of growth of rye in winter and poor soil conditions and the baking qualities of wheat (Wrigley and Bushuk, 2017).

## Production and consumption of cereal grains

Cereals are produced in about 50% of the world's harvested area, of which wheat constitutes 14% of the global crop area. Among cereal grains, 40% of wheat is produced in China, India and the Russian federation, 65% of maize in the United States of America, China and Brazil and about 60% of rice in China, India and Indonesia (Food and Agricultural Organization, 2020). The current figure for production of cereal grains is 2817.2 million tonnes (Food and Agricultural Organization, 2021). (<http://www.fao.org/worldfoodsituation/csdb/en/>). The highest produced cereal grain is maize, followed by wheat, rice and other coarse grains (Fig. 1). Rice and maize are predominantly produced in the developing countries (Table 2).

Cereal grains have evolved from being the main or sole purpose of cultivation as food to being utilized for other purposes. Of the total cereal grains produced about 50% are utilized as human food. 35–40% as animal feed, and the rest as raw material for biofuels or other uses like for production of starch and related substances, malting and for production of alcoholic beverages. These proportions vary across different cereal grains and across countries. About 90% of rice grown is consumed as human food in the regions produced, except in some countries in Europe where it is primarily used as animal feed. The primary usage of oats is as human food in Britain and Brazil, but as animal feed in other parts of the world. A large proportion of most coarse grains produced, except for millets are used as animal feeds and for industrial purposes (Batey, 2017; OECD/FAO, 2021). In countries such as Mexico, most of the maize or corn produced is consumed as food, whereas, in the United States of America, a large proportion is processed industrially for starch and oil production (Wrigley, 2017b) although it is also used for the manufacture of glucose, beer and alcohol. The consumption in the various regions indicate that the per capita food consumption of maize is the highest in Latin America and Africa, wheat in Europe, Rice in Asia and other coarse grains in Africa (Table 3).

Growth in feed use of cereals is expected to continue exceeding the rate of expansion for food use. Feed use of cereals is projected to grow at 1.2% p.a. over the coming decade as livestock production expands and intensifies in low and middle-income countries, compared to a projected growth of 1% per annum for food use (OECD/FAO, 2021).

Production of cereals is likely to be significantly affected by temperature and carbon-dioxide emissions. An increase in carbon dioxide emissions is likely to increase temperatures and absolute humidity which in turn affects the soil's moisture content and the duration of the growing season. The higher temperatures are likely to accelerate crop maturity and result in water stress due to rise in temperature. Therefore, there can be lesser yields of cereals such as barley, wheat and oats. However, the increase in water stress may

**Fig. 1** Production of major cereals.

be beneficial for cereal crop yields of maize and sorghum. Decreased rainfall particularly in the African and Asian countries due to climate change with magnitude and timing of rainfall being affected can contribute to change in crop yields (Grace et al., 2019).

Sustainable cereal production is being encouraged in farming systems by adopting save and grow methods of conservation agriculture practices, improvement of soil health, improvement of yields and diversification of crops and efficiency in water and pest management (Food and Agricultural Organization, 2016). For example, across the world, wheat farmers grow legumes through crop rotation. This ensures nitrogen fixation of the soil and improves wheat yields. In South and Southeast Asian countries, rice farmers grow high yielding hybrid maize which require less water in the dry season (Food and Agricultural Organization, 2016).

The consumption of cereals is likely to be underestimated since direct consumption of cereals rather than indirect consumption from products such as corn-based sweeteners which provide additional food energy are not considered for per capita consumption (Awika, 2011). Maize is one of the most important commodities used as animal feed (Fig. 2). Since the early 2000s, demand in Asian middle-income countries have fueled the drive for production of biofuels from cereals. This increase has been due to the implementation of policies with three main objectives that is, support countries' commitments to reduce their carbon dioxide (CO<sub>2</sub>) emissions, reduce the dependency on imported fossil fuels and create additional demand for feedstock crops to support domestic producers (OECD/FAO, 2021).

## Structure of cereal grains

Botanically, a cereal grain is referred to as a kernel or caryopsis. Caryopsis refers to a single seeded indehiscent fruit where the pericarp or fruit coat is fused with the seed coat. Although cereal grains may be taxonomically uniform, between and within the same species of cereals, their morphology and composition vary and this determines their utilization (Koehler and Weiser, 2013; Wrigley, 2017a). The size and weight of the grain varies from large, with maize having the highest weight of about 350 mg to the small, seeded millets which are about 9 mg in weight (Koehler and Weiser, 2013). Apart from the kind of cereal, the cultivar and the technique for crop production determines the kernel size (weight in gram per 1000 kernels) (Belitz and Grosch, 2009).

**Fig. 2** Consumption of major cereals. Source: [OECD-FAO \(2021\)](#).

All grains have an outer protective hard inedible hull or husk or chaff ([Slavin, 2004](#); [Jones et al., 2015](#)). Beneath the hull, all cereal grains consist of 3 parts, that is the seed coat, embryo (germ) and endosperm characteristic to each species. The embryo is separated from the endosperm by the scutellum which during germination mobilizes the reserves of food. The seed coat is the thick-walled outer structure and consists of the outer wall called the pericarp, followed by a semipermeable layer, testa and then a permeable layer of thick-walled cells, the aleurone, altogether called the bran. The endosperm is covered by the aleurone layer, either by a single layer as in wheat, maize, rye, oats and sorghum or by three layers as in rice and barley ([McKevith, 2004](#)).

Cereal grains have a moisture content of 11–14%, 56–74% carbohydrates, 8–11% of proteins, 2–4% lipids, and 1–3% minerals ([Koehler and Weiser, 2013](#)). The seedcoat mainly contains about 2–13% fiber, cellulose, hemicellulose, proteins and lignins. The embryo contains protein, minerals, fat. The endosperm contains about 70–80% starch, and some amounts of protein ([Koehler and Weiser, 2013](#); [McKevith, 2004](#)).

Wheat grains are ovoid in shape. The kernel is classified by color, that is, red or white, soft or hard and winter or spring. Compared to other cereal kernels, the seed and the embryo of maize (10–13%) of grain are the largest ([Wrigley, 2017a](#)).

### Post-harvest storage of cereal grains

Before cereal grains are processed, they are stored at the farm or at a collection center. Prior to storage, the kernels need to be dried either through natural (wind/solar) or mechanical drying mechanisms. Drying minimizes the nutrient losses. Post-harvest losses because of mold spoilage, infestation by pests and germination of the grain due to the moisture content present in the grain, affect grain quality. A higher moisture content during storage and microbial amylases results in breakdown of starch affecting quality. Oxidation of unsaturated acids can result in rancidity and flavor can be affected ([McKevith, 2004](#)).

Rice is harvested as paddy, wherein the caryopsis is within the hull which provides protection against insects, pests and adverse climatic conditions ([Fitzgerald, 2017a](#)).

### Processing of cereal grains

Some form of processing is required before cereal grains can be consumed to render the indigestible carbohydrate digestible and to increase palatability. Even before domestication of cereals, processes such as cooking, sprouting, pounding, grinding or milling, and fermentation were employed ([Dietrich et al., 2019](#); [Hübner and Arendt, 2013](#)). From the early days, cracking, flattening, grinding, and milling were done using rudimentary tools ([Curry, 2021](#); [Jones et al., 2016](#)). By milling, cereal grains are rendered esculent by removal of the husk and sometimes the bran, and if required, ground into flour of varying particle size. The level of milling determines the level of nutrients removed ([Oghbaei and Prakash, 2016](#)).

Traditional methods of cooking used are soaking and germination of whole cereals. In some instances, kernels are soaked and then cooked in its whole form. This removes some of the toxins or bitter components and some antinutrients and increase nutrient availability, importantly for maize. These processes permit water to enter the kernel ([Jones et al., 2016](#)). Processing has evolved over the years to improve the life and retard the growth of microbes and toxins, increase nutrient availability, improve the sensory characteristics and functional properties, for convenience, and to reduce waste and any losses ([Thielecke et al., 2020](#)).

Between harvest and consumption, all cereals undergo a series of processes, starting from preparing the harvested grain for storage (threshing, winnowing, drying to reduce moisture content), primary processing to clean, sort and remove the inedible

husk by milling, pounding, grinding, tempering, parboiling, soaking, drying, sieving etc and finally secondary processing through fermentation or thermal treatment (baking, puffing, flaking, roasting, frying and extrusion) for utilization of cereal grains in the form of whole grains, flakes or flour (Tiwari and Pojić, 2020; Thielecke et al., 2020). Whole grains are consumed whole or intact, cracked or flaked but with the endosperm, germ and bran present in the same proportions as the original grain composition. With rapid advances in technology recombining the various components of grain, that is, bran, the heat-treated germ, and the milled white flour in different proportions compared to the intact grain (25%, 50%, 75%, or 100% of the germ and aleurone layer) is possible (Jones et al., 2016; Swaminathan et al., 2021). Rice grains are usually milled only after a storage period of at least 3–4 months so that the milled rice can expand more during cooking (McKevith, 2004).

## Milling

There are slight variations in the way different cereals are milled. But in general, most grains undergo the process of grinding, sifting, separation of fractions and regrinding (McKevith, 2004). Both dry and wet milling techniques are used. For maize, dry milling is used for producing grits, flour, and corn germ, while wet milling is used for starch production, dextrose and syrups for use in food (Slavin et al., 2000; Gyöfi, 2017). Traditional methods use mortar and pestle or stones for grinding into flour and this removes the outer layer but retains the germ, while the modern methods strip the maize grains of the germ too and make them more refined (Slavin et al., 2000). As rye has a softer kernel than wheat, the wet milling technique is used (McKevith, 2004). Wet milling is done in cereals to toughen the pericarp and germ so that they do not break during milling.

The type and level of processing further determines the quantity and quality of nutrients consumed and varies with the type of cereal grain (Oghbaei and Prakash, 2016; Thielecke et al., 2020). The outer layers of a grain are rich in antinutrients, and these are removed by dehulling. Heat treatments not only gelatinize starch but also help improve storage stability and may aid in retaining nutrients such as vitamin E by the inactivation of some enzymes, thus preventing rancidity (Oghbaei and Prakash, 2016). A distinction exists between processing and refining. Generally, if the different parts of the kernel remain as per the original ratio, they are said to be processed. However, in refined grains, the outer husk, bran and germ are removed by milling (Jones et al., 2016). In the case of rice paddy, the nutrients lost depends on the degree of polishing it undergoes (Oghbaei and Prakash, 2016). Paddy is dehulled and separated as brown rice and bran, after which to produce white rice, whitening or pearling and polishing are done. Barley undergoes dehulling and pearling to produce pearl barley, flaked or milled into barley flour (Slavin et al., 2000; McKevith, 2004).

After the grain is crushed during milling, the milled grain is separated by particle size into different milling streams and then crushed further depending on the type of grain required (Borneo and León, 2012; Jones et al., 2016; Oghbaei and Prakash, 2016). If the whole grain is directly made into flour it will result in whole grain flour or meal which are termed as flour with high extraction rates of 90%, indicating a high proportion of the whole grain in the flour. However differential milling is also done to separate the fractions as for example in wheat where through roller milling refined wheat flour, bran, germ, semolina etc. can be obtained. Low extraction flours have less than 75% of the whole grain and are considered as refined grains mostly consisting of the endosperm and miniscule amounts of bran. Thus, refined grains have less of vitamins, minerals, fiber and bioactive compounds than whole grain flours, and this loss may be mitigated by adding the nutrients lost during milling by enrichment of the flour. The nutrients usually added are dependent on the type of cereal flour and the needs of the specific population consuming the flour. The nutrients that can be added are thiamine, riboflavin, niacin, pyridoxine and iron, but not fiber. On the other hand, flours can be fortified by either adding nutrients more than the quantity originally present in the grain or by adding a nutrient not present, as for example the addition of folic acid (Jones et al., 2016; Oghbaei and Prakash, 2016). Rye is milled into flour with different extraction rates for production of soft rye breads, coarse rye meal for preparation of hard breads and rye flakes for breakfast cereals (Slavin et al., 2000).

The embryo and aleurone comprise only 10% of the dry weight of the grain and is usually removed by milling in wheat, polishing in rice, pearling in barley or decortication in sorghum, before it is consumed by humans. The concentration of fiber, protein, vitamins and minerals decrease from the outer bran layer to the inner part of the seed and depends on the extent to which the different fractions of the grain are removed and the type of cereal grain. The milling of wheat to white flour results in a decrease of 27% thiamine, 20% niacin and 19% riboflavin. Further bleaching removes nearly 98% of vitamin E (MacEvilly, 2003). During milling mechanical changes to the starch occur that can increase the level of enzyme activity which is beneficial in bread making. The extent to which this change occurs is dependent on the quality of the grain and the type of milling done. Denaturation of protein is likely due to high heat treatment during milling resulting in lower gluten yield and decreased absorption of water in the flour (McKevith, 2004).

## Germination

Germination and malting (germination under controlled conditions) are techniques that have been used since ancient times and not only change the taste, flavor and appearance of the grain, but also improve the nutrient content while decreasing the amount of antinutrients present thus improving the digestibility and availability of nutrients (Hübner and Arendt, 2013; Oghbaei and Prakash, 2016).

### Heat treatment

Heat treatment such as boiling, baking, frying and extrusion of cereal-based foods can cause losses in some vitamins. Antioxidant activities increase by processes such as baking or toasting by the browning reaction due to the Maillard reaction wherein reducing sugars interact with amino acids. Some heat treatments hydrolyse the phytates and thus increase the availability of iron, calcium and zinc (McKevith, 2004). Wheat is used to make a variety of food products such as biscuits, cookies, cakes, pasta, noodles, bread and many more. With globalization, wheat products such as ready to eat cereals and bread are now eaten across the world (Thielecke et al., 2020). The process of extrusion, a heat treatment where a shaped product is extruded through a screw press under heat is used for manufacturing products such as pasta, noodles and ready-to-eat breakfast cereals (McKevith, 2004). Among maize products, popcorn prepared using intense heat is an intact whole grain (Slavin et al., 2000).

### Fermentation and parboiling

Fermentation of several cereal products such as bread, maize, rice etc. are used in various regions. The carbon-di-oxide produced during fermentation increases the volume of the dough. Protein digestibility is improved by bacterially produced lysine and bioavailability of minerals are increased probably by hydrolyzation of phytates (McKevith, 2004).

Rice is also eaten parboiled, when unhusked rice is soaked for 4–5 h in water at a temperature of 65 °C, steamed under pressure and then dried and milled. Parboiling reduces the loss of nutrients by the movement of B vitamins and oil from the bran into the endosperm (McKevith, 2004).

### Nutrient composition of cereal grains

Cereal grains are eaten across the world in substantial quantities, thus providing the highest proportion of energy from food apart from proteins and micronutrients. Tables 4–7 provide the macronutrient, essential amino-acid contents, mineral and vitamin content per 100 g of cereal or cereal-based foods.

### Carbohydrates

Generally cereal grains contain about 60–80% carbohydrates, mainly as starch of which 70–75% is as amylopectin and the rest amylose. The proportion varies by the cereal grain especially in rice, maize, barley and sorghum. A higher proportion of amylase is associated with increased satiety, lower glycemic index, and insulin release. Among the cereals, those which are waxy cultivars have higher amylopectin. Apart from starch, non-starch polysaccharides (NSP), or dietary fiber, in the outer layers of the grain including arabinoxylans and beta glucans are also present (Koehler and Weiser, 2013; Wrigley, 2017a; Thielecke et al., 2020).

Both insoluble and soluble forms of NSP or dietary fiber are present; the insoluble dietary fiber contents are similar across cereals, but the soluble fraction differs (McKevith, 2004). A high content of dietary fiber is present in barley. Arabinoxylans are the principal water-soluble NSPs in wheat, rye and barley and beta glucans in oats. The beta-glucan content in oats makes it difficult to refine oats and it thus remains a whole grain (Fu et al., 2020).

## Proteins

A large proportion of the protein from the diet comes from cereal grains particularly in low- and middle-income countries. Protein ranges on an average from 7 to 12% of dry weight of cereals. The protein content present is dependent on the genotype, that is, cereal, species, variety, and the conditions during cultivation, which includes climate, soil and fertilization, especially that of nitrogen. The proteins are mainly concentrated in the germ and aleurone layer, although protein is distributed across the grain with the bran containing about 7% and the endosperm about 13% of the protein (Belitz and Grosch, 2009; Koehler and Weiser, 2013). Not only does it determine the nutritional value, but it also impacts the functional properties in food processing. Prolamins and globulins are the storage proteins present in varying amounts in cereal grains. Globulins are largely present in the embryo and the outer aleurone layer of the endosperm. In oats and rice, however, globulins which constitute 70–80% of the total protein, are the main endosperm storage protein fraction. In other cereals, prolamins constitute the major protein storage fraction in the

**Table 7** Vitamin content of cereals and pseudo-cereals (per 100 g).

Type	Thiamin (mg)	Riboflavin (mg)	Niacin (mg)	Pantothenic (mg)	Vitamin B6 (mg)	Total folate (μg)
<b>Cereals</b>						
Wheat (durum)	0.42	0.12	6.74	0.94	0.42	43

endosperm. Wheat flour contain the globulins gliadin and glutenin, which form the gluten fraction a factor that determines the end use quality (Wrigley, 2017b). Coarse cereals have a higher content of protein and a balanced amino acid profile (Fu et al., 2020).

The amino acid composition of the cultivar of cereal determines the quality of protein. Cereals are not only deficient in the essential amino acid lysine but also in threonine and specifically in maize, tryptophan too (Shewry and Halford, 2002; Belitz and Grosch, 2009). Lysine content is low in most cereals particularly in wheat, rye, barley, oats and corn. In oats protein content is higher than some of the other cereals like wheat but they have a higher arginine and lysine content, which improve the quality of protein (Slavin et al., 2000).

## Fats

Cereal grains in general contain a low level of lipids. Most of the lipids are present in the germ. Barley, rice, rye and wheat contain 1–3% lipids, corn 5–9% and oats 5–10% of the dry matter. The essential fatty acid linoleic acid is the main lipid present in grains (McKevith, 2004).

## Micronutrients

Micronutrients are mainly concentrated in the pericarp, germ and aleurone layer. About 45% of vitamins and minerals are present in the bran and germ components of the whole grain (Oghbaei and Prakash, 2016).

Cereals are a good source of potassium but contain a lower amount of sodium. Whole grains have a considerable amount of iron, magnesium and zinc and lower levels of trace elements such as selenium (rice has the highest content at 10–13 μg per 100 g), and the content is dependent on soil conditions. A high amount of calcium is found in finger millet and iron in barnyard millet (McKevith, 2004).

In general, B vitamins thiamine, riboflavin and niacin and vitamin E are present in cereal grains but do not contain vitamin B12 and C, and in most grains, vitamin A. Whole grain cereals and bran and the main dietary sources for vitamin E (Jones et al., 2016).

## Bioactive compounds

Bioactive substances such as fiber, vitamins, minerals and trace elements (vitamins B, E and folate, zinc, magnesium, selenium etc), phytochemicals (polyphenols, γ-oryzanol, carotenoids, phytic acid, alkyl resorcinols, phytosterols, inulin, B-glucans flavonoids etc) sulfur containing compounds and alpha linolenic acid, methyl donors and lipotrophes (for example betaine, choline, melatonin, etc) constitute 15% of the dry weight of whole grains, with about 52% and 24% concentrated in bran and embryo respectively (Fardet, 2013; Fu et al., 2020). Lignans, tocotrienols, phenolic compounds, and antinutrients including phytic acid, tannins, and enzyme inhibitors present in whole grains are associated with better health outcomes (Oghbaei and Prakash, 2016).

Among phytochemicals, small quantities of flavonoids and lignans (phytoestrogen) are present in cereals. The major contributor to the antioxidant activity of cereals are bound phytochemicals (McKevith, 2004).

## Anti-nutrient compounds

Some of the anti-nutrient compounds present in cereals are phytates, tannins and polyphenols. Phytates mainly reside in the germ of maize, the aleurone layer of wheat, and is uniformly distributed in millets (Tiwari and Pojić, 2020). Polyphenols and phytates are mainly found in the pericarp, seed coat and aleurone of the grain. When outer layers of the grain are removed there is a reduction in tannins, phytates and polyphenols which increases the digestibility of proteins and carbohydrates and availability of minerals. But these nutrients also have antioxidant properties (Oghbaei and Prakash, 2016).

Phytates form insoluble complexes with iron and calcium decreasing bioavailability. Tannins, phenolic compounds from the flavonoid group reduces protein digestibility by phenol-protein complexing, reduce palatability as flavor and color are affected. As tannins are mainly present in the outer layers, removal of these layers reduces the quantity of tannins in the cereal, but this results in loss of nutrients. In sorghum, the anti-nutrient effects can be mitigated by germination and treatment with calcium oxide, potassium carbonate, ammonium bicarbonate or sodium bicarbonate (McKevith, 2004).

Goitrogens, substances that decrease bioavailability of iodine or interfere within the thyroid hormone biosynthetic pathway, are present in pearl millet and barley, while trypsin inhibitors that reduce protein digestibility anti-nutritive compounds are present in pearl millet and rye, Heat treatment of the grain reduces these antinutrient contents (McKevith, 2004).

## Contaminants

Pests such as mites and weevils can affect cereal crops before and after harvesting and can produce unpleasant smells and tastes, decrease carbohydrate content while increasing the free fatty acid levels and reducing vitamin B levels of thiamine and riboflavin (McKevith, 2004). The mycotoxin, aflatoxin present in raw maize, rice, wheat and sorghum are harmful carcinogenic substances present in wheat and rice and corn (MacEvilly, 2003; Mousavi Khaneghah et al., 2018; Andrade and Caldas, 2015). Analysis of worldwide aflatoxin (s (AFB1, AFB2, AFG1, AFG2)) occurrence data has reported that rice, wheat, maize and sorghum consumption contributed to 41.6%, 35.4%, 21.2% and 1.8% of the total aflatoxin intake respectively (Andrade and Caldas, 2015). Aflatoxins are naturally present in cereals, but the presence of a substantial amount can cause harm (Andrade and Caldas, 2015). Rye and other temperate cereals can be affected by Ergot (*Claviceps purpurea*) and produces alkaloid toxins.

## Cereals grains and adverse health outcomes

### Gluten allergy

Some individuals are allergic to gluten, a protein present in cereals such as wheat, oats barley and rye. Glutenin and gliadin in wheat, avenin in oats, hordein in barley, and secalin in rye are the gluten compounds present leading to celiac disease (MacEvilly, 2003). It is precisely for this reason that gluten free sorghum, millets and pseudo cereals are considered safe options for individuals with gluten allergy.

### Association with non-communicable diseases

With rapid changes in technology in processing of cereal grains, there is a focus now on their association with some of the non-communicable diseases mainly through evidence from epidemiological studies. Higher intakes of fiber from cereal foods or a mix of whole grains and bran are associated with a lower risk of obesity, type 2 diabetes, cardiovascular disease and some cancers (Slavin et al., 2000; Cho et al., 2013; Fardet, 2013).

Coarse cereals contain betaglucons (or lichenins, a water-soluble fiber), polyphenols, phytosterols and fagopyritols and phytochemicals, such as phenolic acids, flavonoids, lignans, tocopherols and phytosterol which have anti-inflammatory properties and a beneficial effect on non-communicable diseases such as cardiovascular disease, diabetes and some cancers (Fu et al., 2020). Beta glucan in oats and the arginine and lysine content have been shown to have a cholesterol lowering effect, reduce the risk of heart disease and also promote weight control by enhancing the feeling of satiety (Slavin et al., 2000; Wrigley, 2017b; Fu et al., 2020). Carbohydrates in foods can be classified based on the extent to which they can be digested and absorbed and assimilated into the human body resulting in a post-prandial glucose response. The higher the glucose response, the higher will be the glycemic index of the food. Cereals are the principal sources of carbohydrate and therefore, the glycemic response of cereal-based foods are important. The starch present in the food matters. Amylose is slowly digested by the enzyme  $\alpha$ -amylases in the human duodenum, while amylopectin is rapidly digested mainly because its branched structure allows enzymatic hydrolysis at multiple sites. The ratio of the incremental area under the curve (AUC) on ingestion of a certain amount of carbohydrate from a test food, to the AUC in a reference food with similar amount of carbohydrate usually glucose or white bread is termed the glycemic index. A lower glycemic index in foods including cereals combined with high fiber diets can decrease post-prandial glucose and insulin responses and improve the lipid profile and better metabolic and health outcomes. The extent of fiber present further lowers the glycemic response and therefore cereal grains consumed whole are beneficial in preventing cardiovascular disease and diabetes. The presence of resistant starch also matters. More the resistant starch present, lower the digestion of the starch. The size, shape and crystallinity, amylose content, lipid, protein and phosphate content of the starch granule are important for this resistance. Physiologically, there is an increased production of the small chain fatty acids, butyrate, acetate and propionate in the large bowel due to fermentation of

the unabsorbed resistant starch by the gut microbiota, thereby improving gut health. This in turn increases the level of the gut hormones, glucagon-like peptide (GLP-1) and peptide YY (PYY) that regulate energy intake (Lafiandra et al., 2014).

Acrylamides formed during heat treatment such as baking and frying are quoted as potential carcinogen, but there is no convincing evidence to support this (McKevith, 2004).

## Conclusions

Cereal grains are the principal foods that provide a large proportion of energy, carbohydrate, protein and some vitamins and minerals in the diet. Wheat, maize and rice and the three most highly produced and consumed cereal grains. Other coarse cereals are ingested to a lesser extent but are important due to their nutritional properties. Processing enhances palatability and alters the nutrient content. Both traditional and technologically advanced techniques are used for processing cereal and cereal-based foods. There are potential benefits of consumption of cereal grains which is dependent on both the inherent property of the cereal and the level of processing. Apart from immunological disturbances, there are other adverse health outcomes due to consumption of cereal grains, particularly refined cereals that need to be addressed and tackled.

## Key points

- Dietary fiber comprises a range of food-borne polysaccharides that share the single physiological property of resistance to human digestive enzymes.
- These polysaccharides are confined to the intestinal lumen during digestion of food in the upper alimentary tract. Their presence influences digestion in ways that depend on their individual physical and chemical properties.
- After passage through the small intestine, undigested polysaccharides enter the colon, where they differ in their accessibility for fermentation by the colorectal microbiota.
- As a result of these various properties and effects, fiber influences metabolic processes throughout the body.
- Epidemiological evidence demonstrates that the inclusion of adequate levels of fiber in the diet is a protective factor in relation to metabolic, cardiovascular and gastrointestinal diseases.
- Future research should focus particularly on the metabolic and physiological effects of novel polysaccharides that may become increasingly important due to global trends in agricultural production, food supply and culinary practice.

## Introduction

In addition to digestible sugars, starch and protein, plant foods contain poorly digestible carbohydrate components that do not contribute to nutrition in the classical sense of providing macronutrients or other essential substances, but which are nevertheless important for human health. The existence of undigestible residues in plant foods, first described as *crude fiber*, was recognized early in the 20th century by some of the pioneers of scientific nutrition, including Atwater in the USA and Rubner in Germany. Later the British scientists McCance and Lawrence categorized the *available carbohydrates* present in plant-foods, which consist of starch and sugars, and the *unavailable carbohydrates*, which in cereal seeds consist mainly of cell wall polysaccharides that cannot be hydrolyzed by human digestive enzymes. During the middle years of the 20th century, TL Cleave and other medical scientists went on to develop the view that various chronic diseases of western society were caused by excessive consumption of highly refined

carbohydrates from which non-digestible cell wall material had been removed. The colonial medical officer Denis Burkitt became convinced from his own field observations that diets rich in unrefined carbohydrate foods protect rural African populations against gastrointestinal disorders, including diverticular disease, appendicitis and colorectal cancer. Contemporaneously, his colleague, the physician Hugh Trowell, argued that consumption of unrefined carbohydrates was protective against obesity, coronary heart disease and type 2 diabetes. Trowell proposed the umbrella term *dietary fiber* to describe “that portion of food which is derived from cellular walls of plants which are digested very poorly by human beings” (Trowell, 1972). The “dietary fiber hypothesis”, as it soon came to be known, has been developed and refined over subsequent decades, and it is now firmly established as a principle of human nutrition. This article explores the physiological mechanisms by which food components that, at least in the early stages of digestion, are unavailable for absorption and metabolism by the body, but can nevertheless be deemed essential for normal function and the prevention of disease.

## Definitions

Trowell’s early concept of dietary fiber was logical but chemically naive. Once the hypothesis began to be explored, it became increasingly obvious that a more precise definition of fiber was needed, together with a standardized method of analysis. However the diversity of human diets and the complexity of their carbohydrate constituents delayed these goals for many years. The available carbohydrates in plant foods are mainly those that function in the plant as energy stores. They consist of alpha-linked linear or branching glucose polysaccharides known collectively as *starches*, and the *sugars*, notably the monosaccharides glucose and fructose, and the disaccharide sucrose. The presence of alpha-linkages ensures that both sucrose and starch are readily hydrolyzed to monosaccharides by human digestive enzymes, and rapidly absorbed in the small intestine. In contrast, the structural carbohydrates of plant tissues consist of non-starch polysaccharides (NSP) containing a variety of saccharide units, including glucose, galactose, arabinose, xylose and uronic acids, joined by beta linkages, which are not hydrolyzed by human digestive enzymes. Cellulose, which is one of the most abundant components of this group, consists of polymers of 1–4 beta-linked glucose molecules, often with molecular weights of a million Daltons or more. Individual cellulose polymers are combined to form fibrils which, when embedded within a matrix of branching xylose, galactose and arabinose polymers, provide structural rigidity to the cell walls of undifferentiated parenchyma cells in fruits and vegetables. The walls of more specialized structural cells, and the vascular components in stem and leaf tissue, typically require the greater rigidity and mechanical strength provided by even higher levels of cellulose and other matrix polysaccharides; these structures are often toughened further by the deposition of lignin, a branching polymer of phenyl propane units. Pectins, and another class of beta-linked glucose polysaccharides, the beta-glucans present in the outer layers (bran) of cereal seeds such as oats and barley, have the important property of solubility in water. Some important sources and constituents of dietary fiber in human foods are summarized in Table 1.

## Analytical methods

Quantification of fiber in foods is essential for the compilation of food composition tables, for dietetic practice and for nutrition research, but the great diversity of substances classified as fiber leads to technical difficulties. The earliest methods for measuring the undigestible residues in animal feeds emerged in the 19th century. The approach was to remove the digestible components by chemical degradation, and then measure the residues by weighing. This *gravimetric* approach formed the basis of the crude-fiber procedure for food analysis, which was widely used until the 1970s. However, because the old analytical procedures typically employed strong acids and alkalis for the initial digestion step, many of the cell wall carbohydrates falling within the new concept of dietary fiber were broken down and lost. To address this problem, Southgate developed methods based on enzymatic hydrolysis of polysaccharides followed by colorimetric analysis of the constituent sugars. Using a distinctly different approach, Prosky and

**Table 1** Some important sources and constituents of dietary fiber in the human diet.

<i>Food source</i>	<i>Non-starch polysaccharides</i>	<i>Associated substances</i>
Fruits and vegetables	Cellulose, xyloglucans, pectic polysaccharides	Lignin, suberin, glycoproteins
Cereal grains	Cellulose, branched arabinoxylans, xyloglucans, beta-glucans, glucomannans	Lignin, and other phenolic esters
Leguminous seeds	Cellulose, xyloglucans, mannans, galactomannans, pectic substances	Oligosaccharides (verbascose, stachyose, inulin)
Manufactured foods	Galactomannan gums (guar gum, locust bean gum), beta-glucans (oat gum), pectins, alginates, carrageenans, modified cellulose gums (carboxymethyl cellulose, methyl cellulose)	

**Table 2** Total dietary fiber, non-starch polysaccharides (NSP) and resistant starch (RS) in some typical human foods, measured using two official AOAC methods and the Englyst method for resistant starch and NSP.

Food source	AOAC 991.43	AOAC 2009.01	Englyst method		
	Total dietary fiber	Total dietary fiber	Total RS	NSP	Total dietary fiber
Whole wheat cereal	11.1	12.1	1.0	7.5	10.8
Puffed rice cereal	2.3	3.2	0.5	1.1	2.2
Bread	5.9	7.2	2.1	2.9	6.1
Biscuit	3.2	3.0	0.2	2.1	4.0
Canned potato	10.3	13.6	5.4	6.1	11.1
Canned chick peas	22.7	22.5	6.9	11.4	19.8

Illustrative data selected from Englyst et al. (2013).

colleagues developed methods for the analysis of *total dietary fiber* (TDF) based on stepwise enzymatic hydrolysis and accurate weighing of the residue. This gravimetric approach was adopted for official methods of fiber analysis by the Association of Official Analytical Chemists (AOAC International). Though more physiologically relevant than the crude fiber methods, these new approaches allowed varying quantities of *resistant starch* (RS) to be in the final value for TDF. It is now recognized that RS is not merely an analytical artifact, but an important component of food, which does, to varying degrees, escape digestion in the human small intestine. To address this issue, Englyst and others developed analytical refinements to enable the physical separation of starch residues from *non-starch polysaccharides* (NSP). Though analytically more precise, these methods are also more complex and time-consuming than gravimetric methods. Some typical values for TDF and RS in processed foods are given in Table 2. In general, the AOAC and Englyst methods do give similar results for TDF, but in some foods a substantial proportion of this value is accounted for by RS.

For regulatory purposes most countries now use definitions of dietary fiber consistent with those agreed upon in 2009 by the food regulation arm of the World Health Organization, *Codex Alimentarius* (Codex Alimentarius, 2010). The definition states that: *Dietary fiber means carbohydrate polymers with ten or more monomeric units, which are not hydrolyzed by endogenous enzymes in the small intestine of human beings and belong to the following categories:*

- *Edible carbohydrate polymers naturally occurring in food as consumed.*
- *Carbohydrate polymers, which have been obtained from raw material in food by physical, enzymatic, or chemical means and which have been shown to have physiological effect of benefit to health by generally accepted scientific evidence to competent authorities,*
- *Synthetic carbohydrate polymers, which have been shown to have physiological effect of benefit to health by generally accepted scientific evidence to competent authorities.*

Thus, both RS and NSP are included in the modern definition of dietary fiber. It is left to national authorities to decide whether to include purified or synthetic polysaccharides with established health benefits, and oligosaccharides with degrees of polymerization between 3 and 9. The Codex Alimentarius Commission recommends several AOAC methods for analysis of dietary fiber. The more elaborate NSP method is also recognized as being appropriate for research purposes, where separation of NSP and RS and a full analysis of the monosaccharide composition of fiber may be required.

## Physiological effects

The modern definition of dietary fiber is convenient from a regulatory perspective but, given the diverse chemical and physical properties of the substances captured by the gravimetric approach to analysis, a single analytical value for TDF cannot predict the physiological properties or the health benefits of any particular food or diet. In this section the physiological effects of dietary fiber will be discussed in relation to the properties and behavior of its constituents at sequential locations along the digestive tract. However, for many components of dietary fiber, the metabolic consequences of their presence, and hence their effects on health, extend well beyond the gut.

## Dietary fiber in the upper alimentary tract

The human alimentary tract is essentially a tube extending from mouth to anus, although it is subdivided into anatomically distinct regions that function as separate organs. After ingestion food is conveyed progressively through the gut and physically disrupted by rhythmic contractions of the muscular walls (peristalsis). Hydrolysis of polymers occurs under the influence of digestive enzymes released into the lumen at the appropriate anatomical sites. The presence of dietary fiber influences digestion at each stage.

## Mouth and pharynx

The earliest steps in digestion begin in the mouth, where food particles are reduced in size by mastication, lubricated with saliva, and prepared for swallowing. Salivary amylase initiates the hydrolysis of starch at this stage. Intact cell walls confer three-dimensional structure on plant foods, they are an important determinant of texture, and they can influence the degree of mechanical breakdown that tissues undergo prior to swallowing. The rate at which starch is digested and absorbed from cubes of cooked potato has been shown to be slower when they are swallowed whole than when they are chewed. Thus, simple mechanical factors related to food texture can limit the rate at which glucose enters the circulation.

## Stomach

After passage from the mouth and through the esophagus, food accumulates in the stomach, where large fragments are further degraded by the activity of gastric smooth muscle and the effects of hydrochloric acid and proteolytic enzymes. The physical structure of fiber-rich complex carbohydrates modifies gastric digestion. For example, the persistence of intact cereal fragments in the stomach can delay starch digestion significantly, and soluble non-starch polysaccharides with high viscosity, such as pectin and guar gum, can slow the delivery of glucose solutions to the small intestine by delaying gastric emptying.

## Small intestine

The small intestine, and particularly the jejunum which accounts for about forty percent of its total length, is the main site of nutrient absorption. The semi-liquid products of gastric digestion are released into the duodenum and then propelled through the jejunum by peristaltic movements. Further hydrolysis of proteins, triglycerides and starch, catalyzed by pancreatic enzymes, proceeds rapidly within the jejunal lumen, but the final stages of digestion occur at the jejunal mucosa, under the influence of cell-surface enzymes. The products of hydrolysis are then absorbed into the circulation, along with water and electrolytes, through the epithelial cells of the mucosal villi. Waves of muscular activity ensure that the mixture of ingested fluids, gastric secretions and partially digested food is well stirred.

The presence of dietary fiber modifies the rate of nutrient digestion and absorption by various mechanisms. For example, the effects of intact cell walls have been investigated in cooked legume seeds and shown to delay the hydrolysis of starch by restricting the process of gelatinization, inhibiting the access of pancreatic amylase to starch granules, and perhaps by the physical binding of amylase. Soluble, viscous polysaccharides added as isolates to carbohydrate test-meals can also inhibit glucose absorption, but this effect is abolished if the viscosity is eliminated. In contrast to the barrier-effects of intact cell wall polysaccharides, which inhibit digestion, the importance of viscosity lies in the inhibition of transport, through suppression of convective stirring in the boundary layer immediately adjacent to the mucosal surface. The absorptive activity of the epithelial cells reduces the concentration of substrates in the fluid layer adjacent to the mucosal cells. To maintain rapid transport the absorbed substrates must be replaced by diffusion or, more efficiently, by physical stirring due to peristalsis; viscous forms of dietary fiber inhibit this latter process, thus slowing the delivery of glucose across the mucosa and into the circulation.

Prolonged consumption of viscous types of dietary fiber is associated with a reduction in plasma cholesterol levels in humans. Unlike the acute suppression of glucose absorption, the change in cholesterol metabolism is a chronic effect, but it probably also results from a suppression of mucosal transport, this time in the lower small intestine (ileum) where, as a crucial step in their entero-hepatic circulation, bile salts are reabsorbed. If this step is inhibited, bile salts can be lost to the feces; it is probable that a compensatory increase in bile-salt synthesis from endogenous cholesterol pools leads to the observed reduction in plasma cholesterol.

Dietary fiber also influences the rate of transit through the upper alimentary tract, but the importance of its physical properties in this context is complex and still poorly understood. Thus, although insoluble fiber (coarse wheat bran) added to a carbohydrate test-meal delays gastric emptying, the same material apparently accelerates the rate of transit through the small intestine. Some of the effects on motility probably reflect the ability of dietary fiber to modify the release of gastrointestinal peptide hormones. For example, addition of viscous fiber to test-meals inhibits insulin secretion, and the release of gut peptides, including glucagon-like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP), which both regulate the release of insulin and inhibit the motility of the upper gastrointestinal tract. The distal small intestinal mucosa also contains endocrine cells which, in response to the presence of nutrients in the gut lumen, secrete gastrointestinal regulatory peptides, including enteroglucagon, GLP-1 and PYY, into the circulation. Among other effects, these peptides inhibit gastric emptying, via the so-called *ileal brake*, a mechanism which may be important in appetite control. Thus, by slowing digestion and absorption in the upper small intestine, dietary fiber can displace nutrients to more distal regions of the small intestine and thereby activate this regulatory system. However, dietary fiber also exerts important effects on gut motility via endocrine mechanisms initiated in the large bowel.

## Physiological effects in the lower alimentary tract

Having escaped hydrolysis in the small intestine, the various polysaccharides that comprise dietary fiber enter the large bowel, where they encounter the complex array of carbohydrase enzymes expressed by the gut microbiota.

## Colon and rectum

Humans do not possess the enlarged cecum typical of herbivores, but the proximal colon is well adapted for bacterial colonization. It typically contains around 200 g of semi-liquid dietary residues, mucus and intestinal secretions, which provide ideal conditions for anaerobic fermentation, to the extent that the human large intestine is one of the richest known bacterial eco-systems. The dominant groups are gram-negative anaerobes of the genus *Bacteroides*, and gram-positive organisms including *bifidobacteria*, *eubacteria*, *lactobacilli*, and *clostridia*. The technical difficulty of culturing many of the anaerobic bacteria long delayed our understanding of the gut microbiome but, with the use of DNA sequencing technology and advanced bioinformatics, much of this complexity has been unlocked in recent years.

In contrast to the very limited enzymic repertoire of human saliva and pancreatic secretions, gut bacteria express a diverse array of enzymes capable of degrading many of the components of the plant cell wall. The microflora profit by gaining energy and substrates that are converted to bacterial mass, whereas the human host gains from the release of the short chain fatty acids (SCFA) acetate, propionate and butyrate, some of which are reabsorbed and utilized as a source of metabolic energy. Colorectal epithelial cells are adapted to utilize butyrate as their primary source of energy. Propionate is metabolized in the liver, but acetate enters the circulation and is used as an energy source by various peripheral tissues.

Despite the huge array of carbohydrase enzymes deployed by the gut microbiota, some polysaccharides, including both natural and chemically modified celluloses, and heavily lignified non-cellulose polysaccharides, remain resistant to gut bacterial fermentation, and serve only to contribute bulk and increased water-retention to the fecal mass. Wheat-bran is a familiar source of dietary fiber. It has long been recognized and recommended as *roughage* by dieticians for its mild laxative properties, and it is widely consumed in wholemeal breads and breakfast cereals. The resistance to bacterial fermentation of the lignified bran enables the material to retain much of its particulate structure in the fecal mass. The resulting matrix favors the retention of water, which adds to fecal bulk in the rectum, and softens the stool. All types of dietary fiber increase fecal bulk to some extent, but raw wheat bran is about five times more effective than more readily fermented polysaccharides such as pectin, beta-glucan and most types of RS.

Because of the varying fermentability of different components of dietary fiber, the precise contributions made by cell wall polysaccharides and RS to total human energy consumptions are difficult to quantify. For practical purposes a figure of 8.4 kJ/g (2.0 kcal/g) is considered a realistic approximation for the energy value of dietary fiber derived from mixed diets. This figure, which is half the energy value of glucose, has been endorsed by the Food and Agriculture Organization of the United Nations, but, as with all food energy factors, this is only an approximation. Indeed, the capacity to derive energy from fermentation of dietary fiber differs between individuals, presumably because of differences in the composition of the colonic microflora, and in the transit time, which determines the time available for fermentation in the large bowel.

Apart from their role as energy substrates, SCFA exert important metabolic effects on the host via their role as signaling molecules. The free fatty acid receptors FFAR2 and FFAR3 are G protein-coupled receptors expressed in gut epithelial cells, and in a variety of other tissues and organs, including those of the immune system. Thus, by stimulating the production and absorption of SCFA, fermentable components of dietary fiber may modulate important physiological pathways in distant tissues, including some related to immunity and inflammation. SCFA have also been shown to stimulate the release of the gut regulatory peptides GLP-1 and PYY from the L-cells of the colonic mucosa. It is hypothesized that through this mechanism the presence of fiber in the diet can modify energy metabolism via effects on upper bowel motility, and hence on satiety.

SCFA may also directly influence gene expression, both in the colorectal mucosa and in other tissues. Butyrate is a potent inhibitor of histone deacetylase (HDAC), a cellular enzyme that reduces acetylation of the histones of chromatin, thus modifying the interaction of gene transcription factors with their target sequences, and thereby altering gene-expression. This *epigenetic* mechanism may exert profound effects on the growth and functioning of cells, both in the gut mucosa, and in other organs including the heart. The consequences for human physiology and health are important subjects of ongoing research.

Because gut bacteria vary in their capacities to degrade different polysaccharides, certain components of dietary fiber can selectively favor the growth of bacteria specialized to utilize them. This so-called *prebiotic* effect is an important determinant of bacterial diversity in the human gut. The recognition of these effects has led some scientists recently to argue that the term *microbiota-accessible carbohydrates* (MAC) should be used to highlight the importance of fermentable components of fiber in relation to both the diversity and the metabolic activity in the gut microbiota. It is increasingly recognized that although all MAC are components of dietary fiber, not all dietary fiber provides MAC.

## Health outcomes attributable to dietary fiber

### Overweight and obesity

Several of the physiological effects of dietary fiber during digestion have the potential to increase satiety and cause a reduction in energy intake in humans. The average consumption of dietary fiber in the adult populations of high-income countries, including those of North America and Western Europe, is usually significantly lower than the 25 g–50 g per day widely recommended by bodies responsible for public health. Such populations tend also to have a high prevalence of overweight and obesity, but it is not clear that these associations provide evidence for a causal link. Epidemiological studies have shown that average consumption of dietary fiber is often inversely related to body-mass index, but given the complexity of self-selected human diets, and the difficulty of correcting for all the variables involved, it is very difficult to establish a causal mechanism at the population level.

Experimental evidence for a suppression of weight gain by dietary supplementation with, for example, pectin, has been obtained with rodent models and there is some support from human intervention trials. For example, [Reynolds et al. \(2019\)](#) conducted a meta-analysis of 27 controlled intervention trials in which the effect of a higher intake of dietary fiber on weight-gain was investigated and concluded that there was evidence for an approximately 37% reduction in weight-gain in the subjects consuming higher levels of fiber. The evidence for a similar effect of RS is, reportedly, less strong.

## Etiology and management of type 2 diabetes

Trowell's early work on dietary fiber led him to propose that both type 2 diabetes and insulin-dependent diabetes were largely diseases of fiber-depletion, caused in high-income countries by mechanized flour milling. His argument was that fiber-depleted starchy foods were diabetogenic and, conversely, that lightly processed high-fiber foods were protective. In the case of type 2 diabetes, subsequent epidemiological evidence provides circumstantial support for this hypothesis. For example, The UK Scientific Advisory Committee on Nutrition conducted a meta-analysis of eleven prospective epidemiological studies and observed a statistically significant protective effect of higher fiber consumption against type 2 diabetes, estimated to provide a 6% reduction in risk for every additional 7 g of fiber consumed per day. Another more recent systematic review of observational studies also demonstrated a reduction in risk of type 2 diabetes among higher consumers of fiber compared to lower consumers, which was estimated to result in a relative risk of 0.85 for every additional 8 g of fiber consumed.

Though the long-term consumption of insoluble cereal fiber is associated with a reduced risk of type-2 diabetes the reasons remain unclear. One early proposal was that because the presence of some types of fiber in carbohydrate foods slows the delivery of glucose to the bloodstream, the reduced demand for insulin would protect against impaired glucose metabolism. The rate at which digestion of a carbohydrate food increases blood glucose is expressed as a numerical quantity, the "glycemic index" (GI), which is determined empirically in human subjects. Despite its proven importance for diabetes management, the role of GI in the causation of type 2 diabetes remains controversial. There is some epidemiological evidence that high-GI diets are diabetogenic, but the dietary fiber content of foods is not a strong predictor of GI. Thus any protective effect of fiber may not be driven primarily by the regulation of intestinal glucose uptake. An alternative explanation is that, through its effects on the gut microbiota, fermentable fiber reduces systemic low-grade inflammation, which is an established risk-factor for insulin-resistance and other metabolic abnormalities. This hypothesis remains under investigation.

Whatever the precise role of fiber in the causation of type 2 diabetes, it is well established that increased fiber consumption is beneficial as a means of managing the condition. Many studies on postprandial glycemia have been conducted using soluble fiber supplements, including guar gum, beta-glucan and pectin, added to carbohydrate test-meals. Although wheat bran and other insoluble cell wall materials have little effect on glucose absorption viscous soluble polysaccharides do ([Jenkins et al., 1978](#)). This hypoglycaemic effect is among the physiological properties deemed appropriate to enable isolated or synthetic polysaccharides to be classified as dietary fiber for commercial purposes. Beyond these acute effects on glucose uptake, prolonged supplementation with viscous polysaccharides, including guar gum and beta-glucan, has been shown to improve long-term control of blood glucose in patients with type-2 diabetes.

## Cholesterol metabolism

As mentioned previously, consumption of guar gum and beta-glucan has been shown to reduce plasma cholesterol in humans. Dietary guidelines for patients with impaired glucose and cholesterol metabolism often recommend a high intake of carbohydrate foods rich in soluble fiber, although only a few common foods, such as oat products, contain significant quantities of soluble viscous polysaccharides. Most studies in which significant effects on plasma cholesterol are achieved use isolated polysaccharide supplements. One meta-analysis of randomized, controlled intervention trials of this type showed that oat beta-glucan reduced plasma cholesterol by 0.13 mmol/L total cholesterol for every 3 g soluble fiber consumed per day. Reductions of this magnitude are potentially beneficial to those with total plasma cholesterol levels in excess of the desirable upper limit of 5 mmol/L. Health claims relating to cholesterol metabolism are officially recognized for oat bran, and for isolated beta-glucan, by regulatory authorities in both Europe and the USA.

## Blood pressure

Observational studies on human populations indicate that higher fiber consumption is associated with lower systolic and diastolic blood pressure. However experimental research indicates that this does necessarily apply equally to all forms of fiber. For example, [Evans et al. \(2015\)](#) carried out a meta-analysis of 18 human intervention trials and observed a reduction in blood pressure in response to higher consumption of all fiber types combined (0.9 mmHg), but this was not statistically significant. Further analysis of the effects of specific fiber types indicated that supplementation with soluble fiber (beta-glucans) reduced systolic blood pressure by 2.9 mmHg (95% Confidence Interval 0.9–4.9 mmHg) and diastolic blood pressure by 1.5 mmHg (95% Confidence interval 0.2–2.7 mmHg) for every extra 4 g of beta glucans consumed. Although these effects seem modest, they are potentially significant

for public health. At the population level, a reduction of 2.0 mmHg in the average systolic blood pressure has been estimated to lead to reductions in annual mortality from coronary heart disease and stroke of 4% and 6% respectively.

## Cardiovascular disease

In addition to protective effects against risk factors for cardiovascular disease (CVD), including overweight, impaired glucose tolerance and hypertension, a high consumption of dietary fiber may be directly protective against stroke and coronary heart disease (CHD). [Pereira et al. \(2004\)](#) used pooled data from 10 prospective studies to conduct a systematic analysis of CHD and fiber intake in 91,058 men and 245,186 women. Food-frequency questionnaires were used to estimate intakes of TDF, and fiber from cereals, fruits and vegetables separately. Each 10 g increment in total dietary fiber intake was associated with a 14% reduction in risk of coronary events, and a 27% reduction in risk of death from CHD. A more recent metaanalysis of prospective cohort studies on dietary fiber intake and mortality from cardiovascular disease observed a dose-dependent protective effect such that the pooled relative risk for a 10 g increment in fiber intake was 0.91 (95% confidence interval 0.88–0.94). A similar relationship was observed for CHD in particular. No distinction was observed for any particular type or source of fiber, and no conclusions could be drawn as to mechanism. Total dietary fiber has recently been shown to be protective against ischemic stroke, in an analysis of a large cohort spanning nine European countries.

One possibility for the protective effect of dietary fiber against cardiovascular disease is that MAC modifies the metabolic activity of the gut microbiota and suppresses systemic low-grade inflammation and its adverse effects via increased production of SCFA. In a recent study, [Ma et al. \(2021\)](#) compared habitual dietary fiber intake, levels of the inflammation marker C-reactive protein (CRP) in plasma, and the composition of the gut microbiome in 307 healthy male volunteers. They observed a statistically significant relationship such that a higher intake of fiber was associated with a lower level of CRP and with consistent changes in the colorectal microbiome. Studies of this type do provide valuable evidence for the hypothesis that MAC influences systemic physiology by modulating the metabolism of the gut microbiome, but further research is needed to establish a full causal relationship between fiber intake and disease pathology. Most intervention studies using dietary fiber for primary prevention of CVD have been short-term investigations on risk-factors such as LDL cholesterol, rather than studies with disease as the endpoint of interest. There is a clear need for long-term, randomized intervention trials to explore the full potential of dietary fiber for the primary prevention of cardiovascular disease events.

## Diseases of the alimentary tract

### Constipation and diverticular disease

One of the earliest hypotheses for the health benefits of dietary fiber was the idea advanced by Denis Burkitt that undigested plant material provided high fecal bulk which, he proposed, was associated with an optimal rate of movement of stool through the large intestine during peristaltic contractions, lower intraluminal pressure and minimal straining at stool ([Burkitt, 1975](#)). In contrast, he argued, the low-fiber diets of western populations, led to both chronic constipation and age-related degenerative changes in the muscular wall of the colon. Burkitt based these conjectures largely on his own observations of bowel function and disease prevalence in the rural communities of Africa in which he had worked.

Chronic constipation is a relatively common complaint in western populations. It is defined as a condition in which patients regularly experience fewer than three bowel movements per week, with hard stools and a sense of incomplete evacuation or excessive straining. Epidemiological evidence from western populations suggests that higher intakes of dietary fiber are associated with a reduced incidence of constipation in the general population. A systematic review by [Suares and Ford \(2011\)](#) concluded that soluble fiber was probably effective as a treatment for chronic idiopathic constipation but found the evidence inconclusive for insoluble fiber. In routine medical practice, patients with chronic constipation may be advised to increase their consumption of foods rich in fiber, or they may be prescribed pharmaceutical preparations such as refined isphagula husk, derived from the seeds of *Plantago psyllium*.

Diverticulae are small inward protrusions of the mucosa, extending deep into the muscular wall of the colon, common in older age-groups in western populations. They are often symptomless, but if they become filled with impacted fecal material, they can enlarge and become inflamed; causing a condition termed *diverticulitis*, which is both painful and potentially serious. There is epidemiological evidence to support the hypothesis that a high intake of dietary fiber protects against diverticular disease in populations in the USA and Europe, but it is not known whether this is due to physical causes as envisaged by Burkitt, or to some unidentified effect acting via the colonic microbiota. Increased consumption of fiber is often recommended for the management of established disease, but the evidence base to support this advice remains relatively weak.

### Irritable bowel syndrome (IBS)

IBS is a poorly defined functional bowel disorder with a variety of symptoms, including abdominal pain, bloating, constipation or chronic diarrhea, with no established organic cause. Increased consumption of dietary fiber, either from high-fiber foods, or from supplements, is often recommended for the management of IBS but the clinical evidence for this is not strong. Various types of

dietary fiber have been used in the management of IBS but the most common have been wheat bran, which has a high fecal bulking capacity, and ispaghula, which is soluble, only partially fermentable and commonly prescribed as a mild laxative and stool-softener. The literature suggests that ispaghula is generally more effective than wheat bran in the treatment of IBS symptoms. However, given the diversity of IBS symptoms, and the multiple properties that characterize the various components of dietary fiber, a much more selective and personalized approach is probably needed for the rational use of fiber in IBS therapy.

### Colorectal cancer (CRC)

Colorectal carcinoma remains one of the most prevalent and potentially fatal cancers in industrialized countries, where the incidence is around five times higher than in the rural communities of many countries of Africa and southern Asia. Burkitt observed this disparity at first hand in Africa and proposed that diets rich in dietary fiber protect against CRC due to the stool bulking effects of undigested polysaccharides. His hypothesis, simply stated, was that Western dietary patterns, typically low in dietary fiber, caused prolonged exposure of the colonic mucosa to fecal carcinogens. Consistent with this hypothesis, Cummings et al. (1992) later showed a statistically significant inverse relationship between fecal mass and risk of CRC across a range of population groups. However, as with all observational studies, these data could only demonstrate an association, with no proof of a causal mechanism. Later epidemiological studies, often conducted within populations such as that of the USA where the range of intakes of dietary fiber is relatively limited, failed to confirm the hypothesis. For example, in a systematic review of cohort studies, Park et al. pooled the results of 13 investigations and showed that among those in the highest quintile of fiber consumption the risk of CRC was 16% lower than among those in the lowest quintile. However, when the data were adjusted for confounding factors. The protective association was reduced to 6% and became statistically non-significant. In contrast, strong evidence for a protective effect of fiber consumption against CRC emerged from the European Prospective Investigation of Cancer and Nutrition (EPIC) project, which is based on a cohort of approximately half a million individuals drawn from geographically and culturally distinct European populations with widely differing diets. Analysis of these data after 11 years of follow-up indicated that total dietary fiber intake was inversely associated with colorectal cancer (Murphy et al., 2012). The hazard ratio per 10 g/day increase in fiber intake was 0.87 (95% confidence interval: 0.79–0.96). A meta-analysis performed by the Scientific Advisory Committee on Nutrition (SACN) in the UK also identified a protective dose-response relationship between consumption of dietary fiber and CRC, and this was used as a criterion for the recommendation that the adult population of the UK should consume at least 30 g of dietary fiber per day. Further support for these findings and recommendations has come from more recent meta-analyses of prospective studies. The protective effects of fiber consumption against CRC are now generally acknowledged.

In most cases CRC develops from relatively common lesions of the colorectal mucosa called adenomatous polyps, a minority of which eventually develop into carcinoma. Polyps are frequently identified during endoscopy carried out for screening or diagnostic investigations and their removal is a routine preventative measure. If a high intake of fiber is protective against CRC, then it is reasonable to expect a similar protection against the development of polyps. A recent systematic review of epidemiological studies supports this conjecture (Nucci et al., 2021). It might also be expected that an increased consumption of fiber would reduce the risk of polyp recurrence after polypectomy. A review of intervention trials with different types of dietary fiber found no evidence to support this hypothesis, but the authors questioned the overall quality of the research to date and recommended longer trials using higher levels of fiber.

Although the original proposal of Burkitt that fiber intake reduces the risk of CRC appears to be correct, the mechanisms underlying the protective effect remain uncertain. The simple hypothesis that fiber reduces both the level and duration of exposure to carcinogens has not been disproved but it is unlikely to be the whole explanation. The development of CRC begins with a sequence of somatic mutations in the crypt cells of the colorectal mucosa, which drive abnormalities of gene expression during epithelial cell-proliferation and differentiation. These changes accumulate over decades and are probably caused both by local genetic damage from fecal mutagens and adverse metabolic drivers related to overweight, insulin-sensitivity and low physical activity. Higher consumption of dietary fiber probably protects against CRC through a variety of mechanisms, ranging from local effects on the colorectal epithelia, mediated via intraluminal fermentation products, to systemic effects, including the reduced risk of obesity and improved metabolic health.

### Conclusion

Although the founders of the dietary fiber hypothesis may have over-stated the role of inadequate fiber consumption as a cause of non-infectious diseases in western countries, the strength of their convictions, coupled with their pioneering observations on rural populations eating traditional diets, launched decades of experimental research and more robust epidemiology. The outcome has been a much deeper, though rather more nuanced understanding of the role of fiber in human health. There is probably no disease that can be attributed entirely to a deficiency of dietary fiber, and yet a surprising proportion of what the pioneers believed has turned out to be correct; the complex group of dietary constituents that we now call dietary fiber indisputably contributes to the maintenance of human health, though often through mechanisms that would have been beyond speculation in the mid 1960s. Despite this modern consensus, consumption of dietary fiber in most western countries continues to fall significantly below dietary recommendations. This problem may prove difficult to rectify as the human food chain evolves in response to global trends in agricultural production, food supply and culinary practice. With increasing prosperity, populations tend to rely more on manufactured,

often highly processed foods for a large fraction of their energy intake. In these circumstances a smaller proportion of fiber consumption will come from unprocessed plant foods, and more will need to be incorporated into diets in the form of isolated cell-wall polysaccharides, or as resistant starches, formed during food processing, or perhaps enriched in food products through the creation of novel varieties of starchy crops. To retain, or better still to maximize the benefits of fiber for human health, it will be essential to continue to explore the physiological effects of these substances, and their interactions with the microbiota. With a growing understanding of human molecular physiology, advances in bacterial genomic sequencing and increasingly sophisticated bioinformatics, we can be confident of continued progress.

### Key points

- The term “fatty acid” comprises a large group of biologically and structurally diverse molecules. The metabolism of these compounds is equally diverse.
- Fatty acids can be structural components of more complex lipids, including triacylglycerol and phospholipids. They can be degraded for energy production; conversely, fatty acids can be synthesized from carbohydrates for energy storage. Polyunsaturated fatty acids can be converted into signaling molecules such as oxylipins, and are constituents of endocannabinoids. Fatty acids can regulate protein function by reversible or irreversible covalent attachment.
- The objective of this article is to provide an overview of the major metabolic pathways in which fatty acids participate.

### Glossary

**Fatty acid** An aliphatic hydrocarbon chain terminating in a carboxylic acid function

**Fatty acid activation** Formation of fatty acyl-CoA *via* the attachment of coenzyme A to the fatty acid's carboxylic acid function *via* a thioester bond

**Fatty acid *de novo* synthesis** Synthesis of a saturated, 16-carbon fatty acid from precursors typically derived from carbohydrate metabolism

**$\beta$ -Oxidation** Energy-yielding cyclic process in which the hydrocarbon chain of a fatty acid is shortened, typically by two carbon atoms per cycle

**Protein acylation** The covalent modification of an amino acid residue in a protein by a fatty acid, most commonly a 14- or 16-carbon saturated fatty acid

### Introduction

Fatty acids (FAs) are hydrophobic molecules consisting of an aliphatic hydrocarbon chain terminating in a carboxylic acid moiety. Structurally, FAs are quite diverse. Although FAs containing 16–18 carbons are the most abundant in nature, the hydrocarbon chain can vary in length from two to more than 26 carbons. The carbon chain can be fully saturated, or contain one or more double bonds.

Ingestion of dietary fats and oils is a major source of FAs for humans and most other animals. In addition, many physiologically important FAs can be synthesized *de novo* from metabolites derived from the catabolism of sugars and proteins.

FAs in the human body serve two primary functions—they are an excellent source of metabolic energy, and they serve as building blocks for many diverse complex lipids. FAs are also precursors of bioactive molecules such as prostaglandins and other eicosanoids. An important covalent modification of proteins is the attachment of a 14- or 16-carbon FA. In addition, FAs and their coenzyme A derivatives have many metabolic regulatory roles.

### Fatty acid nomenclature conventions

In this article, FAs will be identified by their chain length, the number of double bonds present, and the position of the first double bond from the methyl end of the molecule. Thus 14:0 denotes a 14 carbon saturated FA, 16:1 $\omega$ 9 denotes a 16 carbon monounsaturated FA in which one double bond occurs nine carbons from the omega (methyl) end, and 20:4 $\omega$ 6 denotes a 20 carbon polyunsaturated FA in which the first of four double bonds is found six carbons from the methyl end. Unless otherwise noted, all double bonds are in the *cis* configuration and double bonds in polyunsaturated FAs are always separated by a single methylene ( $-\text{CH}_2-$ ) group. The carboxyl carbon of any FA is carbon-1. The adjacent carbon is referred to as either carbon-2 or the  $\alpha$ -carbon; the next is carbon-3 or the  $\beta$ -carbon, and so on. Some examples are shown in Fig. 1.

### Physical properties of fatty acids

FAs are aliphatic organic acids with the fundamental structure

$$\text{CH}_3-(\text{CH}_2)_n-\overset{\text{O}}{\parallel}\text{C}-\text{OH}$$

Where  $n$  can range from 0 to  $>26$ . Thus, FAs range from the shortest, acetic acid (2:0), to the very long-chain FAs containing 26 or more carbon atoms (e.g., 26:0). Although FAs with an odd number of carbon atoms exist in nature, most common FAs have an even number. The most abundant FAs found in human lipids, as well as in dietary lipids, are the long-chain FAs 16:0 (palmitic acid) and 18:1 $\omega$ 9 (oleic acid) (Fig. 1). The hydrophobic nature of the hydrocarbon chain of FAs containing more than eight carbons renders them quite insoluble in aqueous media. It has been estimated that for every two carbon increase in FA chain length, its solubility decreases 10 fold (Miura and Nonomura, 2019).

Owing to the poor solubility of the most abundant FAs, free (nonesterified) FAs are often found associated with binding or transport proteins (Schwenk et al., 2010; Xu et al., 2019). Serum albumin has at least six binding sites for FAs and is the primary transporter of these molecules through the bloodstream. Several low molecular weight intracellular FA binding proteins (FABPs) have also been identified. Free FAs can also associate with lipophilic cellular and organellar membranes; however, concentrations of these nonesterified compounds in membranes is typically very low.

### Fatty acid activation

FAs are generally nonreactive unless first “activated” in an ATP-dependent process by thioesterification to coenzyme A (CoA) (reviewed in Watkins, 1997). Activation is catalyzed by acyl-CoA synthetases (ACS; E.C. 6.2.1.x) *via* a bi uni uni bi ping-pong mechanism. In the first half-reaction, an acyl-adenylate intermediate is formed, with the release of inorganic pyrophosphate (PPi):

Pyrophosphatases rapidly cleave PPi, effectively preventing reversal of this reaction. In the second half-reaction, CoA displaces AMP to form the acyl-CoA:

The thioester bond between the acyl moiety and CoA is a high-energy bond that facilitates subsequent participation of the FA in metabolic pathways. Humans have more than 25 ACSs that differ in their tissue expression, subcellular location, and FA chain length preference.

### Mitochondrial fatty acid $\beta$ -oxidation

To recover their stored energy, FAs must be oxidized. Quantitatively, the most important energy-yielding degradation pathway is mitochondrial  $\beta$ -oxidation (Fig. 2) (reviewed in Houten et al., 2016). In the fed state, triacylglycerol in circulating lipoproteins

**Fig. 1** Fatty acid structure and nomenclature. (A) Chemical formula and carbon numbering system for a 16-carbon saturated FA (16:0). (B) Schematic representation of 16:0. (C) A monounsaturated FA, 18:1 $\omega$ 9, showing the double bond nine carbons from the methyl end (carbon 18). (D) The essential  $\omega$ 6 FA, 18:2 $\omega$ 6 (linoleic acid), where the first double bond is found six carbons from the methyl end. The two double bonds are separated by a methylene ( $-\text{CH}_2-$ ) group. (E) The essential  $\omega$ 3 FA, 18:3 $\omega$ 3 ( $\alpha$ -linolenic acid), where the first double bond is found three carbons from the methyl end. (F) Phytanic acid, a dietary  $\beta$ -methyl-branched-chain FA (3,7,11,15-tetramethyl 16:0). The methyl group on carbon-3 prevents this FA from degradation by  $\beta$ -oxidation. (G) Pristanic acid (2,6,10,14-tetramethyl 15:0) is the product of phytanic acid  $\alpha$ -oxidation, in which a single carbon (carbon 1) is lost. The methyl group on carbon-2 does not preclude subsequent degradation by  $\beta$ -oxidation.

delivers FAs to tissues; hydrolysis by lipoprotein lipases in the capillary endothelium releases FAs for cellular uptake. In the fasted state, FAs are released from triacylglycerol stored in adipocytes and delivered to tissues bound to serum albumin. Because of their hydrophobic nature, FAs can traverse the plasma membrane by simple diffusion; however, proteins such as CD36, GOT2, and SLC27A1-6 have also been proposed to play a role in membrane FA transport (Official Symbols for genes/proteins are shown in bold typeface throughout this article; other commonly used abbreviations are in normal typeface).

ACS activity toward long-chain FA substrates is present in the outer mitochondrial membrane. However, fatty acyl-CoAs do not readily traverse biological membranes such as the inner mitochondrial membrane. A highly sophisticated transport system has evolved that allows for tight regulation of FA entry into the mitochondrion (Fig. 2). Carnitine palmitoyl transferase 1 (CPT1), located on the inner aspect of the outer mitochondrial membrane, catalyzes a transesterification reaction: Fatty acyl-CoA + carnitine  $\rightarrow$  fatty acyl-carnitine + CoA-SH. Carnitine:acylcarnitine translocase (CACT; SLC25A20), located in the inner mitochondrial membrane, carries the fatty acyl-carnitine inside the mitochondrion in exchange for a free carnitine molecule.

**Fig. 2** Mitochondrial fatty acid  $\beta$ -oxidation pathway. Long-chain FAs are activated, converted to carnitine esters, transported across the inner mitochondrial membrane, and re-converted to their CoA thioester once in the mitochondrial matrix. Four sequential mitochondrial enzyme reactions shorten the fatty acyl-CoA by two carbons, which are released as acetyl-CoA. The shortened fatty acyl-CoA can undergo additional cycles of degradation until the entire carbon chain has been converted to acetyl-CoA units.  $\text{FADH}_2$  and  $\text{NADH}$ , produced in reactions 1 and 3, respectively, can enter the electron transport chain for ATP production. Acetyl-CoA enters the tricarboxylic acid (TCA) cycle, yielding additional  $\text{NADH}$  and  $\text{FADH}_2$  for ATP production. Mitochondrial  $\beta$ -oxidation is the primary pathway for recovering the energy stored as triacylglycerol, or “fat”.

CPT2, located inside the mitochondrion, then catalyzes the reversal of the CPT1 reaction. Thus the concerted actions of CPT1, CACT, and CPT2 effectively translocate fatty acyl-CoA across the inner mitochondrial membrane. Entry of FAs into the mitochondrion is tightly regulated primarily at the CPT1 step by malonyl-CoA. This intermediate in FA synthesis (see *Fatty acid de novo synthesis*, below) is a potent inhibitor of CPT1.

The entry of medium-chain FAs into the mitochondrial matrix does not utilize the carnitine pathway (Papamandjaris et al., 1998). These FAs can “flip-flop” across the inner mitochondrial membrane by simple diffusion. Medium-chain ACSs located in the matrix then activate them intramitochondrially. Thus, the subcellular location of the ACS responsible for activation of long-chain FAs (outer mitochondrial membrane) versus medium-chain FAs (mitochondrial matrix) dictates whether entry into the  $\beta$ -oxidation pathway is regulated (long-chain FA) or unregulated (medium-chain FA). The latter is of particular nutritional significance for newborns, as breast milk is rich in medium-chain FAs. Bypassing the regulated carnitine transport pathway allows for more rapid energy production.

The four primary enzyme activities of mitochondrial  $\beta$ -oxidation act on intramitochondrial fatty acyl-CoA by: (1) dehydrogenation (acyl-CoA dehydrogenase), (2) hydration (enoyl-CoA hydratase), (3) dehydrogenation (3-hydroxyacyl-CoA dehydrogenase), and (4) cleavage (3-oxoacyl-CoA thiolase). The products are fatty acyl-CoA that has been shortened by 2 carbons, acetyl-CoA,  $\text{FADH}_2$  (from reaction 1) and  $\text{NADH}$  (from reaction 3).  $\text{FADH}_2$  and  $\text{NADH}$  directly enter the electron transport chain, yielding approximately 5 ATP molecules. Acetyl-CoA can be further degraded to  $\text{CO}_2$  and water by the tricarboxylic acid cycle, yielding additional ATP molecules. Importantly, the entire  $\beta$ -oxidation process can be repeated multiple times using the shortened fatty acyl-CoA as substrate until the entire carbon skeleton of the FA has been degraded to 2-carbon acetyl-CoA units. Complete oxidation of one molecule of 16:0 ( $\beta$ -oxidation + tricarboxylic acid cycle) yields more than 160 ATP molecules.

Depending on the acyl chain length, the first enzymatic step of mitochondrial  $\beta$ -oxidation is carried out by either short-, medium-, or very long-chain acyl-CoA dehydrogenase (ACADS, ACADM, and ACADVL, respectively). Long-chain acyl-CoA dehydrogenase (ACADL) functions in rodents but not in humans. Instead, VLCAD acts on long-chain acyl-CoAs in most human tissues whereas another dehydrogenase, ACAD9, performs this function in brain. For medium-to long-chain fatty acyl-CoAs, the three subsequent  $\beta$ -oxidation reactions are catalyzed by mitochondrial trifunctional protein (HADHA), whereas three separate enzymes (ECHS1, HADH, and ACAA2) are needed for oxidation of short-chain acyl-CoAs. Genetic defects in essentially all of the mitochondrial  $\beta$ -oxidation enzymes, as well as the carnitine transport system, are known. If unrecognized, these FA oxidation disorders are often fatal, and are a recognized cause of sudden infant death syndrome (SIDS).

FAs with an odd number of carbons in their acyl chain are degraded in the same manner as even-chain FAs by the normal  $\beta$ -oxidation pathway. However, the final degradation product is the CoA derivative of the 3-carbon molecule, propionic acid. Propionyl-CoA can be metabolized to succinyl-CoA, which is a tricarboxylic acid cycle intermediate.  $\beta$ -Oxidation of unsaturated FAs requires participation of one or more ancillary enzymes, such as enoyl-CoA isomerase and 2,4-dienoyl-CoA reductase, to change the position and/or conformation of the double bond and thus allow degradation to go to completion.

Some tissues, for example skeletal muscle, completely oxidize FAs to  $\text{CO}_2$  and water. Others, for example liver, only partially oxidize FAs, using the acetyl-CoA product for biosynthetic needs. In particular, liver utilizes intramitochondrial acetyl-CoA for the synthesis of ketone bodies, acetoacetate, and  $\beta$ -hydroxybutyrate (Fig. 3) (Rui, 2014). Ketone bodies can be oxidized by all tissues except liver and provide an alternative fuel source during starvation. In particular, brain and nerve, which do not derive energy from FA oxidation, can oxidize ketone bodies. During prolonged starvation, increased ketone body utilization spares the brain's requirement for glucose.

### Peroxisomal fatty acid $\beta$ -oxidation

Like mitochondria, peroxisomes contain pathways for the  $\beta$ -oxidation of FAs that yield a chain-shortened FA-CoA, acetyl-CoA (or propionyl-CoA), NADH, and  $\text{FADH}_2$  (Fig. 4) (reviewed in Wanders, 2014, and Wanders et al., 2020). Unlike mitochondria, peroxisomes do not contain an electron transport chain or tricarboxylic acid cycle and thus FA degradation is not directly coupled to energy production. Typically, peroxisomes degrade FA substrates that cannot be catabolized in mitochondria. Peroxisomes are indispensable for the degradation of saturated very long-chain FAs (VLCFA; containing more than 22 carbon atoms), which are neurotoxic if allowed to accumulate. Detoxification *via* several cycles of peroxisomal  $\beta$ -oxidation decreases VLCFA chain-length to 8–10 carbons, after which they are converted to carnitine derivatives, exit peroxisomes, and translocate to the mitochondrion

**Fig. 3** Ketone body synthesis. In the mitochondrion of liver hepatocytes, acetyl-CoA derived from  $\beta$ -oxidation is converted to “ketone bodies”, primarily acetoacetate and  $\beta$ -hydroxybutyrate, rather than enter the tricarboxylic acid cycle. Two molecules of acetyl-CoA condense in a reversal of the last  $\beta$ -oxidation reaction (3-oxoacyl-CoA thiolase). The product, acetoacetyl-CoA, condenses with another molecule of acetyl-CoA, yielding  $\beta$ -hydroxy,  $\beta$ -methyl-glutaryl-CoA (HMG-CoA), a reaction catalyzed by HMG-CoA synthase. Cleavage of HMG-CoA by HMG-CoA lyase yields acetoacetate, regenerating one molecule of acetyl-CoA. Acetoacetate is reversibly reduced to  $\beta$ -hydroxybutyrate *via* the NAD-dependent enzyme  $\beta$ -hydroxybutyrate dehydrogenase. These ketone bodies can traverse the inner mitochondrial membrane, eventually reaching the bloodstream for ultimate utilization by brain and other tissues.

**Fig. 4** Peroxisomal fatty acid  $\beta$ -oxidation pathways. Although saturated long-chain FAs (LCFA) are preferentially degraded in mitochondria, saturated very long-chain FAs (VLCFA) and some LCFA are shortened by peroxisomal  $\beta$ -oxidation. Degradation of pristanic acid, the product of phytanic acid  $\alpha$ -oxidation, and the conversion of the cholesterol-derived 27-carbon bile acid precursors DHCA and THCA (di- and tri-hydroxycholestanic acids) to 24-carbon bile acids also require this pathway. Four enzymatic reactions serve to shorten the substrates by either two (LCFA, VLCFA) or three (pristanic acid, DHCA, THCA) carbons. The 2-methyl group of the latter substrates is shown in brackets.

for further catabolism. Degradation of xenobiotic fatty acyl-like compounds (e.g., sulfur-substituted FAs and many nonsteroidal anti-inflammatory drugs) also takes place in peroxisomes. Oxidation of dicarboxylic acids (from the diet or from  $\omega$ -oxidation) or 2-methyl-branched-chain FAs (from the diet or from  $\alpha$ -oxidation of phytanic acid) also occurs in peroxisomes.

FAs enter peroxisomes *via* a mechanism that is distinct from the mitochondrial CPT1/CACT/CPT2 pathway. Long- and very-long-chain ACSs are associated with peroxisomes, and it is currently thought that FAs are activated to their CoA derivatives before entry into the peroxisomal matrix. Homodimers of peroxisomal membrane transporter proteins ABCD1 and ABCD2 are believed to transport saturated and unsaturated VLCFA-CoAs, respectively, into the matrix, while ABCD3 homodimers are responsible for the translocation of CoA derivatives of phytanic acid, pristanic acid, dicarboxylic FAs, and bile acid precursors (Wanders et al., 2020). The basic reactions of peroxisomal  $\beta$ -oxidation resemble those found in mitochondria, but the peroxisomal and mitochondrial enzymes are distinct proteins (Fig. 4). In fact, peroxisomes contain two sets of  $\beta$ -oxidation enzymes that appear to function with distinct substrates.

The first step in the oxidation of straight-chain FAs, (e.g., VLCFAs), is catalyzed by acyl-CoA oxidase 1 (ACOX1) (Fig. 4). ACOX2 and ACOX3 catalyze this initial desaturation reaction for  $\alpha$ -methyl branched-chain substrates—bile acid precursors and pristanoyl-CoA, respectively (*see* FA  $\alpha$ -Oxidation). For all substrates, enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase activities are catalyzed mainly by d-bifunctional protein (HSD17B4), which contains both activities. For straight-chain substrates, peroxisomal 3-ketoacyl-CoA thiolase (ACAA1) catalyzes the final  $\beta$ -oxidation reaction, whereas SCPx thiolase (SCP2) catalyzes this step for pristanic acid and bile acid precursors. Peroxisomes also contain L-bifunctional protein (EHHADH), which is thought to contribute to straight-chain FA oxidation. Human deficiencies of ACOX1 and HSD17B4 are associated with significant morbidity and mortality.

The peroxisomal  $\beta$ -oxidation pathway also performs important biosynthetic roles. In the hepatic synthesis of bile acids from cholesterol, the aliphatic side chain, which resembles a 2-methyl-branched-chain FA, must be shortened. A single cycle of peroxisomal  $\beta$ -oxidation removes a three-carbon portion of the side chain (as propionyl-CoA), converting the 27-carbon bile acid precursors di- and tri-hydroxycholestanoic acids into the 24-carbon primary bile acids chenodeoxycholate and cholate, respectively. Furthermore, peroxisomal  $\beta$ -oxidation is required for synthesis of docosahexaenoic acid (DHA 22:6 $\omega$ 3) (see **Fatty acid unsaturation and the essential FAs**, below).

### Fatty acid $\alpha$ -oxidation and $\omega$ -oxidation

Other important FA catabolic pathways include  $\alpha$ -oxidation (reviewed in Wanders, 2014) and  $\omega$ -oxidation (reviewed in Miura, 2013). 3-Methyl-branched FAs, for example, phytanic acid (3,7,11,15-tetramethyl-16:0; **Fig. 1**), present in ruminant meats, fats, dairy products, and certain fish consumed in the diet, cannot be degraded by  $\beta$ -oxidation due to the methyl group on carbon-3. Shortening the FA chain by one-carbon ( $\alpha$ -oxidation; **Fig. 5**) effectively shifts the position of the methyl group to carbon-2, thereby allowing subsequent degradation *via*  $\beta$ -oxidation. Phytanic acid is first activated to phytanoyl-CoA, translocated into peroxisomes *via* ABCD3, and is then hydroxylated on the 2-carbon by phytanoyl-CoA 2-hydroxylase (PHYH). 2-Hydroxyphytanoyl-CoA lyase (HACL1) cleaves a one-carbon CoA derivative, formyl-CoA, yielding an aldehyde, pristanal. A splice variant of fatty aldehyde dehydrogenase (ALDH3H2) is thought to oxidize pristanal to pristanic acid (2,6,10,14-tetramethyl-15:0). Both  $\alpha$ -oxidation and pristanic acid  $\beta$ -oxidation occur in peroxisomes. Deficiency of PHYH is the primary cause of Refsum disease, a peripheral neuropathy, which, if untreated, causes cerebellar ataxia, retinitis pigmentosa, and deafness.

**Fig. 5** Peroxisomal phytanic acid  $\alpha$ -oxidation pathway. The dietary 3-methyl-branched FA, phytanic acid, is toxic if allowed to accumulate in tissues. Its 3-methyl group prevents degradation by  $\beta$ -oxidation; therefore, this FA is first shortened by one-carbon. Like the substrates for peroxisomal  $\beta$ -oxidation, the mechanism by which phytanic acid enters peroxisomes is not known. Activated phytanic acid is translocated into the peroxisomal matrix *via* ABCD3, after which it is hydroxylated on carbon-2. Cleavage between carbons 1 and 2 yields a one-carbon CoA compound, formyl-CoA, and an aldehyde, pristanal. After oxidation and re-activation to the CoA derivative, pristanoyl-CoA can be degraded by  $\beta$ -oxidation.

Like mitochondria, peroxisomes also require ancillary enzymes of FA metabolism. For unsaturated FA  $\beta$ -oxidation, enoyl-CoA isomerase and 2,4-dienoyl-CoA reductase are needed. In addition, the enzyme 2-methylacyl-CoA racemase (AMACR) is essential for proper metabolism of branched chain substrates. Methyl branches can be in either the R- or S-conformation, but ACOX2 and ACOX3 can oxidize only the S-conformers. AMACR catalyzes the interconversion of these isomers.

Another mechanism for degradation of FAs that cannot undergo  $\beta$ -oxidation is  $\omega$ -oxidation. In this process, the terminal methyl group of a FA chain is oxidized to a carboxylic acid *via* various cytochrome P450 isozymes in the endoplasmic reticulum. The resulting dicarboxylic acids are then degraded by  $\beta$ -oxidation from the  $\omega$ -end, primarily in peroxisomes.

### Fatty acid *de novo* synthesis

Much of our need for FAs as constituents of phospholipids and other complex lipids are met by the diet. In addition, lipogenic tissues are capable of the *de novo* synthesis of FAs (Fig. 6) (reviewed in Nguyen et al., 2008). These tissues include liver (hepatocytes), adipose tissue, and lactating mammary gland. Much of the FAs synthesized by all three tissues are incorporated into triacylglycerol. Hepatic synthesis is primarily for export to other tissues (in very low-density lipoproteins), whereas synthesis in adipocytes and mammary gland is for local storage. In several respects, the enzymatic reactions of FA synthesis are the converse of those in FA oxidation. However, there are key differences, which are summarized in Table 1.

**Fig. 6** Fatty acid biosynthesis. Cytoplasmic acetyl-CoA (AcCoA) is the primary substrate for *de novo* FA synthesis. This 2-carbon compound most commonly derives from the glycolytic degradation of glucose, and its formation is dependent on several reactions in mitochondria. The mitochondrial enzyme, pyruvate carboxylase, is found primarily in tissues that can synthesize FAs. AcCoA is converted to malonyl-CoA (MalCoA) by acetyl-CoA carboxylase. Using AcCoA as a primer, the FA synthase multienzyme complex carries out a series of reactions that elongate the growing FA by two carbons. In this process MalCoA condenses with AcCoA, yielding an enzyme-bound 4-carbon  $\beta$ -ketoacid that is reduced, dehydrated, and reduced again. The product is enzyme-bound 4:0. This process is repeated six more times, after which 16:0 is released from the complex. The reductive steps require NADPH, which is derived from enzyme reactions and pathways shown in gray.

**Table 1** Distinctions between fatty acid  $\beta$ -oxidation and fatty acid synthesis.

	<i>Fatty acid <math>\beta</math>-oxidation</i>	<i>Fatty acid synthesis</i>
Tissues with active pathway	Nearly all tissues except brain, nerve, and erythrocytes	Liver, adipose, lactating mammary gland
Subcellular location	Mitochondria	Cytoplasm
Redox cofactors	NAD, FAD	NADPH
Acyl group carrier	CoA	Enzyme-bound acyl carrier protein
Stereochemistry of 3-hydroxy intermediate	L-	D-

The carbon utilized for FA synthesis typically derives from the products of glycolysis (**Fig. 6**). Pyruvate enters the mitochondrion and becomes the substrate for two separate reactions. In one, pyruvate is decarboxylated *via* the pyruvate dehydrogenase complex, yielding acetyl-CoA. Lipogenic tissue mitochondria also contain pyruvate carboxylase, which converts pyruvate to the 4-carbon acid, oxaloacetate. Acetyl-CoA and oxaloacetate condense to form the 6-carbon acid, citrate. As citrate accumulates within the mitochondrion, it is exported via a transporter to the cytoplasm, where it is converted back to oxaloacetate plus acetyl-CoA in a reaction catalyzed by ATP citrate lyase (**ACLY**). Cytoplasmic acetyl-CoA is the fundamental building block for *de novo* synthesis of FAs.

The first enzyme unique to FA synthesis is acetyl-CoA carboxylase (**ACC1**), which converts the 2-carbon substrate, acetyl-CoA, into the 3-carbon product, malonyl-CoA. Citrate, in addition to being the precursor of cytoplasmic acetyl-CoA, also has a regulatory role. Citrate is an allosteric activator of acetyl-CoA carboxylase and serves as a signal that there is an ample carbon supply for FA synthesis. As mentioned, malonyl-CoA is a potent inhibitor of **CPT1**. Cytoplasmic malonyl-CoA levels are high when there is significant flux through glycolysis, indicative of a high cellular energy state. Under these conditions, entry of FAs into the mitochondrion (and subsequent  $\beta$ -oxidation) is prevented. Interestingly, there are two isoforms of acetyl-CoA carboxylase. **ACC1** is found in the above-named lipogenic tissues. **ACC2** is found in many tissues that are not capable of synthesizing FAs, for example, heart. It is thought that the primary role of the second isozyme is to regulate mitochondrial FA  $\beta$ -oxidation by synthesizing malonyl-CoA when cellular energy needs are being met by carbohydrate metabolism.

The subsequent reactions of cytoplasmic FA synthesis in humans are catalyzed by a multienzyme complex, fatty acid synthase (**FASN**). After binding of one molecule each of acetyl-CoA and malonyl-CoA to unique binding sites, a condensation reaction occurs in which  $\text{CO}_2$  is released, and an enzyme-bound 4-carbon 3-ketoacid is formed. Subsequent reactions include reduction, dehydration, and a second reduction. The intermediates produced in these reactions are similar to those seen in  $\beta$ -oxidation (**Fig. 2**), in reverse order. The product (enzyme-bound) is the saturated FA 4:0, which can then condense with another molecule of malonyl-CoA to start the process anew. After seven such cycles, the ultimate product, 16:0, is released from the complex.

The reductive steps in FA synthesis require NADPH, derived from two sources. Oxaloacetate produced by the **ACLY** reaction is converted to malate (*via* cytoplasmic malate dehydrogenase). Malic enzyme (**ME1**) then catalyzes the decarboxylation of malate to pyruvate, reducing  $\text{NADP}^+$  to NADPH in the process. Two reactions in the pentose phosphate pathway, glucose-6-phosphate dehydrogenase (**G6PD**) and 6-phosphogluconate dehydrogenase (**PGD**), also yield NADPH.

### Mitochondrial fatty acid synthesis

While the function of the cytoplasmic pathway for *de novo* synthesis of FAs is well-defined, the presence of a similar pathway in mitochondria remains somewhat enigmatic. Typically, metabolic pathways for the synthesis and degradation of a compound—in this case, FA—are not found in the same subcellular compartment. Nevertheless, there is ample evidence for a mitochondrial FA synthesis pathway (reviewed in [Kastaniotis et al., 2017](#)). Acetyl-CoA is abundant in mitochondria, but no acetyl-CoA carboxylase enzyme has been found in this organelle in humans. It has been speculated that mitochondrial propionyl-CoA carboxylase (**PCC**) can also accept acetyl-CoA as substrate, yielding malonyl-CoA. Alternatively, malonate entering mitochondria can be activated to malonyl-CoA *via* the acyl-CoA synthetase **ACSF3**.

Unlike cytoplasmic FA synthesis, most enzymes of the mitochondrial pathway are individual proteins rather than a multienzyme complex. The growing acyl chain is tethered to acyl carrier protein (**ACP**). A molecule of malonyl-CoA condenses with a primer acetyl-CoA *via* 3-ketoacyl-ACP synthase (**OXSM**), forming the 4-carbon 3-ketoacid. Subsequent reduction, dehydration, and second reduction steps are catalyzed by oxoacyl-ACP reductase (**CBR4**), 3-oxoacyl-ACP reductase (**HDT2**), and 2-Enoyl-ACP reductase (**MECR**), respectively. The resulting 4-carbon acyl-ACP can serve as primer for additional cycles to increase chain length. Both reductase enzymes utilize NADPH.

Research over several decades has uncovered some, but likely not all, functions for the mitochondrial FA synthesis pathway. One is the synthesis of lipoic acid, derived from the 8-carbon FA octanoic acid. Lipoic acid is a critical cofactor for carboxylase enzymes such as **ACC1**, **ACC2**, and **PCC**. Other functions include RNA processing, enzyme activity regulation, and control of mitochondrial gene expression.

### Fatty acid elongation

16:0 is the primary product synthesized by the *de novo* cytoplasmic FA synthesis pathway. Although 16:0 is an important FA, there is need to synthesize longer chain-length acids. Enzymes for elongation of FA have been found in endoplasmic reticulum membranes (reviewed in [Jakobsson et al., 2006](#)). Reactions involved in FA elongation are very similar to those of cytoplasmic FA synthesis. The

donor of the added carbon atoms is also malonyl-CoA, indicating that an active acetyl-CoA carboxylase is required for elongation. Whereas the four primary reactions of FA synthesis are found within the FASN multienzyme complex, individual proteins catalyze these reactions in FA elongation. Like FA synthesis, both reduction steps in FA elongation require NADPH.

The condensation reaction is thought to be rate-limiting, and is catalyzed by a family of very long-chain elongase enzymes (ELOVL1-7). ELOVL1, 3, 6, and 7 have been associated with elongation of saturated and monounsaturated FAs, whereas ELOVL2, 4, and 5 seem to prefer polyunsaturated FAs. The second reaction is catalyzed by 3-ketoacyl-CoA reductase (HSD17B12). No specific enzyme has been associated with the third (dehydratase) reaction. The last step is catalyzed by trans-2,3-enoyl-CoA reductase (TECR).

A minor pathway (in eukaryotes) for FA elongation is found in mitochondria. The donor of elongation units is acetyl-CoA, not malonyl-CoA, and the reduction reactions utilize NADH rather than NADPH. There is little knowledge of how FA elongation in either endoplasmic reticulum or mitochondria is regulated. However, the presence of different ELOVL isoforms suggests that each might direct its elongation product toward a specific metabolic fate.

## Fatty acid unsaturation and the essential FAs

Monounsaturated and polyunsaturated FAs are extraordinarily important in human health and nutrition. Thus, the ability to insert double bonds into the carbon skeleton of an FA is a vital metabolic function (reviewed in Lee et al., 2016). However, humans generally cannot insert a double bond closer than nine carbons from the methyl end of FAs. Thus, we are incapable of the *de novo* synthesis of two important classes of FAs, the  $\omega$ 3 FAs such as docosahexaenoic acid (22:6 $\omega$ 3) and the  $\omega$ 6 FAs such as arachidonic acid (20:4 $\omega$ 6). The  $\omega$ 3 FAs have proven health benefits, for example, in the prevention of coronary artery disease. 22:6 $\omega$ 3 has been shown to be important for normal development of brain and retina, leading some manufacturers to include this FA into their infant formula preparations. The  $\omega$ 6 FAs are important constituents of membrane lipids. 20:4 is also the precursor of prostaglandins and other bioactive eicosanoids. Because humans cannot synthesize these FAs *de novo*, we are dependent on the presence of at least some  $\omega$ 3 and some  $\omega$ 6 FAs in the diet. 18:2 $\omega$ 6 (linoleic acid) and 18:3 $\omega$ 3 ( $\alpha$ -linolenic acid) are the precursors of most biologically important  $\omega$ 3 and  $\omega$ 6 FAs; thus, they are referred to as essential FAs.

One of the most abundant FAs in humans is 18:1 $\omega$ 9 (oleic acid), produced by inserting a *cis*-double bond in 18:0 (stearic acid). The enzyme catalyzing this reaction, stearoyl-CoA desaturase (SCD1) (reviewed in Piccinin et al., 2019) is called a  $\Delta$ 9 desaturase because it inserts the double bond 9 carbons from the *carboxyl* carbon. Because oleic acid is so abundant, the importance of SCD1 in metabolism was initially overlooked. Oleic acid produced by SCD1 appears to be directed specifically toward triacylglycerol synthesis. SCD1 knockout mice have decreased adiposity. Furthermore, genetically obese, leptin-deficient (ob-/ob-) mice in which the SCD1 gene was also disrupted had significantly reduced body weight than did ob-/ob-mice, leading to the hypothesis that leptin regulates the synthesis of SCD1. Interestingly, dietary oleate seems to be more readily incorporated into lipids other than triacylglycerols, implying that the dietary pool and the SCD1-produced pool of this FA are metabolically distinct. Like the  $\omega$ 3 FAs, dietary ingestion of monounsaturated FAs like 18:1 $\omega$ 9 have been associated with benefits to cardiovascular health. Humans and nonhuman primates also express SCD5, an isozyme found primarily in brain and pancreas, whose physiological role may be distinct from that of SCD1. Potential functions proposed for SCD5 include regulation of neuronal differentiation, proliferation, and survival.

Humans are also capable of inserting *cis*-double bonds either five or six carbons from the carboxyl carbon of a FA ( $\Delta$ 5 desaturase and  $\Delta$ 6 desaturase activity, respectively). These activities, when combined with FA elongation pathways, form a powerful mechanism for synthesis of highly polyunsaturated FAs such as 20:4 $\omega$ 6 or 22:6 $\omega$ 3 from dietary essential FAs. The conversion of 18:3 $\omega$ 3 to 22:6 $\omega$ 3 also theoretically requires a  $\Delta$ 4 desaturase to insert the 6th double bond (in 22:5 $\omega$ 3); however, humans lack this enzyme. It is now believed that 22:5 $\omega$ 3 is elongated to 24:5 $\omega$ 3, converted to 24:6 $\omega$ 3 by  $\Delta$ 6 desaturase, and finally chain-shortened to 22:6 $\omega$ 3 by one cycle of peroxisomal  $\beta$ -oxidation.

## Fatty acids as components of complex lipids

FAs are important building blocks for various cellular complex lipids (Fig. 7) (reviewed in Nguyen et al., 2008). For simplicity, the pathways for incorporation of FAs into these lipids are outlined only briefly. In most cases, fatty acyl-CoA and not free FA participates in these biosynthetic reactions. Nearly all cells synthesize phospholipids, which are essential membrane constituents. Phospholipid synthesis takes place in the endoplasmic reticulum. It begins by fatty acylating the two free hydroxyl groups in  $\alpha$ -glycerophosphate, a triose derived from glycolytic intermediates, yielding phosphatidic acid. Various head groups (e.g., choline, ethanolamine, inositol, or serine) can then be linked to the phosphate group. For synthesis of triacylglycerol, this phosphate moiety is removed, yielding diacylglycerol, and a third fatty acyl group is esterified to the free hydroxyl group. Synthesis of plasmalogens (alkyl-acyl phospholipids), which comprise approximately 20% of membrane phospholipids, requires enzymes present in both peroxisomes and the endoplasmic reticulum. Plasmalogens are thought to be part of the cellular defense mechanism against oxidative injury.

Cholesteryl esters (ChE), in which an FA is esterified to the 3-hydroxyl group of cholesterol, are a transport and storage form of cholesterol. ChE are found in high concentrations in plasma low-density lipoproteins. Intracellular lipid droplets containing ChE

**Fig. 7** Fatty acids as components of complex lipids. FAs form the basis of most complex lipids. The part of the molecule derived from FAs is black, and the part derived from other sources is gray. For phospholipids and plasmalogens, R = choline, ethanolamine, inositol, serine, or similar head group.

are found in steroidogenic tissues and are a reservoir of cholesterol for steroid hormone synthesis. ChE most commonly contain 18:1 $\omega$ 9, which is activated to its CoA derivative before transfer to cholesterol by the enzyme acyl-CoA:cholesterol acyltransferase (SOAT1). ChE are also formed within lipoproteins by the transfer of a fatty acyl chain from phosphatidylcholine to cholesterol in a reaction catalyzed by lecithin:cholesterol acyltransferase (LCAT).

Synthesis of sphingolipids, which include sphingomyelin, ceramides, cerebroside, and gangliosides, begins by the condensation of palmitoyl-CoA (16:0-CoA) with serine. The amino group of serine is then acylated by a second fatty acyl-CoA to form ceramide; the chain length of the second FA can be variable. Transfer of phosphorylcholine (from phosphatidylcholine) to the hydroxyl group of ceramide yields sphingomyelin. Alternatively, sugars (from sugar nucleotide donors) are added to produce the cerebroside, gangliosides, and related lipids.

### Oxylipin synthesis

Highly unsaturated FA from both the  $\omega$ 6 and  $\omega$ 3 series can be converted to potent signaling molecules collectively referred to as oxylipins (reviewed in Christie and Harwood, 2020). As noted previously, humans are incapable of synthesizing *de novo* FAs

with double bonds in the  $\omega 6$  and  $\omega 3$  positions. Thus, oxylipins are derived from dietary lipids or are synthesized by elongation and unsaturation of essential FAs. The FA 20:4 $\omega 6$  (arachidonic acid; AA) is the precursor of most classic eicosanoids, which include the prostaglandins, leukotrienes, and thromboxanes. Like other FAs, cellular concentrations of unesterified AA are low. Conversion of AA to eicosanoids begins with an agonist-induced release of the FA from the sn-2 position of membrane phospholipids *via* the action of phospholipase A2. Unlike most reactions of FAs, free AA rather than its CoA derivative appears to be the substrate for eicosanoid synthesis.

Cyclooxygenases (COX1 and COX2) catalyze a complex, molecular O<sub>2</sub>-requiring reaction that convert AA to prostaglandin G2. This reaction involves carbon atoms in the middle of the acyl chain, rather than at the methyl carbon (such as occurs in  $\omega$ -oxidation) or the carboxyl carbon (such as occurs in nearly all other reactions of FAs). Prostaglandin G2 can subsequently be converted to other prostaglandins or to thromboxanes. As these compounds have potent biological effects, including mediation of inflammation, COX inhibitors form an important class of anti-inflammatory drugs. Free AA is also the primary substrate for the enzyme 5-lipoxygenase, which is the first step in the synthesis of leukotrienes, and for several cytochrome P450 oxidases, which lead to synthesis of hydroxyeicosatetraenoic acids (HETEs) and epoxyeicosatrienoic acids (EETs).

Important oxylipins are also derived from the highly unsaturated  $\omega 3$  FAs, 20:5 $\omega 3$  (eicosapentaenoic acid; EPA) and 22:6 $\omega 3$  (docosapentaenoic acid; DHA). Many of these oxylipins are involved in the resolution of inflammation, and have been collectively referred to as specialized pro-resolving mediators (SPM). Enzymes that act on AA can also act on EPA and DHA, including cyclooxygenases, lipoxygenases, and cytochrome P450 oxidases. Products of these reactions and downstream pathways include bioactive lipids such as protectins, resolvins, and maresins.

## Endocannabinoids

Research that identified receptors for the psychoactive ingredient in cannabis,  $\Delta^1$ -tetrahydrocannabinol, led to the discovery of endogenous ligands of these receptors, or endocannabinoids (reviewed in [Joshi and Onaivi, 2019](#); [Cristino et al. 2020](#)). Receptors are located not only in the brain, but throughout the body. The endocannabinoid system serves important roles in human reproduction and newborn growth, among other things. The endocannabinoids are FA-derived molecules, primarily anandamide (N-arachidonylethanolamine; AEA) and 2-arachidonoylglycerol (2-AG). The main pathway for AEA synthesis in brain begins with the action of an N-acyltransferase that links the carboxyl carbon of AA (released from membrane phospholipids) to the amino group of phosphatidylethanolamine, producing N-arachidonoyl phosphatidylethanolamine (NAPE). A NAPE-specific phospholipase D (NAPEPLD) cleaves this molecule, yielding AEA and phosphatidic acid. There are additional AEA synthesis pathways in the brain and other tissues. Degradation of AEA is rapid, and is catalyzed by fatty acid amide hydrolase (FAAH), which cleaves the carbon-nitrogen bond between AA and ethanolamine.

Phosphatidylinositol typically contain AA at the sn-2 position. Synthesis of 2-AG begins with the cleavage of phosphatidylinositol, producing diacylglycerol and phosphoinositol, by the enzyme phospholipase C (PLCG1). A specific diacylglycerol lipase (DAGLA/B) releases the FA (typically a saturated FA) from the sn-1 position, yielding 2-AG. Like AEA, 2-AG is rapidly inactivated *in vivo*. Monoacylglycerol lipase (MGLL) and other lipases cleave 2-AG, releasing AA from the glycerol backbone.

## Fatty acylation of proteins

Covalent modification of proteins is a more recently discovered role of FAs (reviewed in [Resh, 2016](#)). Fatty acylation of proteins frequently serves as a means of targeting or anchoring a protein to a membrane. Before attachment, all FAs must be activated to their CoA derivatives. Myristoylation, the addition of 14:0 to a protein, occurs at N-terminal glycine residues after removal of the initiator methionine. The consensus sequence for this modification is H<sub>2</sub>N-Met-Gly-X-X-X-Ser/Thr. The reaction, catalyzed by N-myristoyltransferase (NMT1, NMT2), is co-translational and irreversible. N-myristoyl-proteins include many signal transduction-associated proteins, for example, *src* and ADP-ribosylation factors (Arfs).

Palmitoylation, the addition of 16:0 to a protein, is also commonly observed. This modification occurs post-translationally and is reversible. Most often, palmitic acid is bound to the sulfhydryl side chain of cysteine residues. Both membrane-associated proteins and integral membrane proteins can be palmitoylated; examples include ion channels, caveolin, neurotransmitter receptors, wnt, and sonic hedgehog. Palmitoylation is catalyzed by members of the large family of palmitoyltransferases (ZDHHC1-22). Three protein palmitoylthioesterases (PPT1, PPT2, and LYPLA1) that catalyze depalmitoylation of proteins have been identified. Several proteins are modified with both an N-terminal 14:0 and an S-linked 16:0 elsewhere in the protein chain. Alpha-subunits of heterotrimeric G-proteins and endothelial nitric oxide synthase are examples of myristoylated/palmitoylated proteins. In addition to palmitoylation, the signaling protein wnt is modified on a serine residue by the monounsaturated FA, palmitoleic acid (C16:1 $\omega 7$ ), which is produced by the action of SCD1 on palmitoyl-CoA.

There are instances of acylation by FAs with chain length other than 14 or 16 carbons. Proteins modified by C8:0, C18:0, C18:1, and C20:4 have been reported. One nutritionally important example is the recently identified orexigenic peptide, ghrelin. The active form of this 28-amino acid peptide hormone has the medium-chain FA, C8:0, covalently esterified to the hydroxyl group of serine-3. Octanoylated ghrelin is believed to act at the level of the hypothalamus to stimulate appetite, perhaps *via* neuropeptide Y.

**Table 2** Vitamins associated with fatty acid metabolism.

<i>Vitamin</i>	<i>Active form</i>	<i>Enzymes</i>	<i>Pathways</i>
Pantothenic acid	CoA	Many enzymes	Most reactions involving FAs
Niacin	NAD, NADH, NADP, NADPH	Dehydrogenases; reductases	Many pathways, particularly $\beta$ -oxidation and FA synthesis and elongation
Riboflavin	FAD, FADH <sub>2</sub>	Oxidases	$\beta$ -Oxidation
Thiamine	Thiamine pyrophosphate	Pyruvate dehydrogenase complex; $\alpha$ -hydroxyphytanoyl-CoA lyase	FA synthesis from glucose; phytanic acid $\alpha$ -oxidation
Biotin	Biocytin	Acetyl-CoA carboxylase; pyruvate carboxylase	FA synthesis from glucose

### Vitamins and fatty acid metabolism

Several of the B-vitamins are essential for normal FA metabolism (Table 2). Pantothenic acid is a constituent of CoA, and is thus required for numerous reactions of FAs. Niacin and riboflavin are necessary for the synthesis of oxidized and reduced NAD(P) and FAD, respectively. These compounds play essential roles in FA oxidation, synthesis, and elongation. Biotin is a constituent of acetyl-CoA carboxylase and pyruvate carboxylase, and thiamine is required for activity of the pyruvate dehydrogenase complex; all three enzymes are involved in the synthesis of FAs from glucose.

### Regulation of fatty acid metabolism

Regulation of FA synthesis (see **Fatty acid *de novo* synthesis**) and  $\beta$ -oxidation (see **Mitochondrial fatty acid  $\beta$ -oxidation**) have already been discussed. More global regulatory mechanisms that deserve a brief mention include those mediated by insulin/glucagon, sterol regulatory element binding protein (SREBP)1c, and peroxisome proliferator-activated receptors (PPARs) (reviewed in [Nguyen et al., 2008](#); [Nakamura et al., 2014](#); [Rui, 2014](#)). In the fed and fasted states, control of fuel metabolism is mediated to a large extent by insulin and glucagon, respectively. Effects of glucagon are mediated *via* cAMP-dependent kinases. During fasting, increased blood glucagon levels promote release of free FAs from adipocyte triacylglycerol stores. In the liver and other tissues, glucagon promotes decreased flux through glycolysis, thereby decreasing the rate of *de novo* FA biosynthesis and increasing rates of mitochondrial  $\beta$ -oxidation and ketogenesis. In the fed state, insulin levels rise in response to increased blood glucose. Insulin's effects are mediated through activation of its receptor tyrosine kinase and are in general opposite to those of glucagon, stimulating glycolysis and FA synthesis while inhibiting FA degradation. Insulin and glucagon have both acute and long-term effects on FA metabolism.

SREBP1c (SREBF1) is a transcription factor thought to mediate the action of insulin in upregulating genes involved in FA synthesis such as ACC1 and FASN. PPAR $\gamma$  (PPARG) is a nuclear hormone receptor that, on activation by an as yet unknown ligand, activates genes involved in adipocyte differentiation and lipid storage. It has been hypothesized that activation of SREBP1c may contribute to generation of an endogenous PPAR $\gamma$  ligand.

Activation of PPAR $\alpha$  (PPARA) on the other hand increases rates of FA oxidation and ketogenesis. Endogenous ligands for this nuclear receptor are thought to include polyunsaturated FAs and branched-chain FAs. Both PPARs heterodimerize with the retinoid-X-receptor (RXR), and both receptors must be ligand-bound for transcriptional activation. Several mitochondrial and microsomal, as well as peroxisomal, genes associated with FA catabolism are upregulated *via* PPAR $\alpha$  stimulation.

### Summary

This article discusses the primary metabolic pathways in which fatty acids participate. The prerequisite for activation of fatty acids prior to metabolism is described. Multiple metabolic pathways for degradation and synthesis of fatty acids are explained. Fatty acid elongation and desaturation are described, as well as the incorporation of these molecules into complex lipids. The metabolic conversion of fatty acids into signaling molecules, as well as the participation of fatty acids in endocannabinoid synthesis, is discussed. Fatty acylation of proteins is mentioned. The article concludes with a brief synopsis of the regulation of fatty acid metabolism.

### Key points

- Provide the key aspects of high-quality food composition tables or databases
- Discuss the different sources of food composition data
- Present the pillars to assure that food composition data are generated, compiled and used correctly

## Introduction

Food composition data (FCD) play a key role in most nutrition related activities and should play an increasing role in agriculture when implementing nutrition-sensitive policies and programs. Undernutrition and micronutrient deficiencies persist in most countries, while overweight, obesity and dietary related non-communicable diseases are increasing. Many countries concentrate their efforts on supplementation or fortification, despite increasing criticism of their sustainability and effectiveness. Foods contain not only nutrients, but many other bio-active compounds with positive health effects, which supplements and fortificants cannot deliver. Thus, food-based approaches are on the rise and, for this type of intervention, FCD are key.

Over the last 40 years, progress in the availability and quality of food composition data has been realized, and much of this was achieved through INFOODS, the International Network of Food Data Systems, established in 1984 and coordinated since 1999 by the Food and Agriculture Organization of the United Nations (FAO). INFOODS and FAO have published, free of charge, many important guidelines and standards, training materials, a food composition database management system (FAO/INFOODS Compilation tool), and food composition tables and databases (FCT/FCDB), and have provided training and technical support to many countries. Other organizations, such as the European Food Information Resource Network (EuroFIR), established in 2005, complement these efforts. However, much is still to be done.

## What are food composition data and where to find them?

FCD provides information about the content of nutrients and other nutrition-relevant components in foods. These data are published in national, regional or global FCT/FCDB. They may comprise a range of components, such as edible portion, macronutrients, vitamins, minerals, bioactive components (e.g., flavonoids), as well as conversion factors and contributing components, to calculate the different nutrients and their fractions (e.g., pro-vitamin A carotenes and retinol for vitamin A calculation or different fatty acids to present saturated fatty acids). Excluded are contaminants and other food components of interest for food safety, called occurrence data.

FCD can vary significantly due to the natural or artificial differences in the nutrient content of foods. Natural differences are due to the environment, processing, biodiversity, storage, cooking methods, recipe or product formulation. Additionally, artificial differences may be introduced into data due to sampling design and collection, analytical methods and quality control used, calculation methods or definitions adopted for each food component.

The quality of FCTs/FCDBs are affected mainly by the sources of FCD such as quality, coverage and description of foods and components, and their documentation.

### Coverage of foods

An FCT/FCDB of sound quality should include foods as consumed by the population of interest, including raw and cooked foods, mixed dishes, manufactured and biodiverse foods.

Many FCTs/FCDBs include mainly raw foods, with a limited number of mixed dishes, biodiverse and branded or fortified foods. The lack of fortified foods in FCTs/FCDBs will result in an underestimation of the micronutrient intake for the population, particularly if these foods are highly consumed. In all countries, voluntarily fortified food products exist, and many countries have mandatory fortification of core foods. For instance, the intake for Dietary Folate Equivalents (DFE) was estimated for different regions of Brazil, where fortification with folic acid is mandatory for wheat and corn flours. The total average intake for DFE was up to 35% lower when a FCDB was used which was not adjusted according to the fortification practices in Brazil (Grande et al., 2019). Currently, 85 countries have mandatory fortification of wheat flour, meaning that the inclusion of fortified foods in the respective FCT/FCDB is of great importance (Global Fortification Data Exchange, 2021). As a rule, the more reported foods are unavailable in FCT/FCDB and would have to be matched to a similar food, the lower the quality of the nutrient intake estimations. This is not only true for fortified foods, as shown in the example, but also for biodiverse or cooked foods or recipes.

Dietary supplements also add significant amounts of nutrients and other ingredients to the diet, as in the USA, where 81% of the population over 55 years report using them regularly (Statista, 2021). There are some databases on dietary supplements using the labeling information, e.g., USA, INFOODS, but it is difficult to keep them up-to-date, to evaluate their quality and to present the data in a similar way as FCTs/FCDBs, i.e., using the same component identifiers (e.g., INFOODS tagnames) or principles. Their contributions to nutrient intake are, therefore, difficult to include in food consumption surveys.

### Food description, food group and food coding

The detail of food description has significant relevance for nutrient content and data quality. Foods not well described leave room for interpretation and errors in usage. The main descriptors that should be added to the food name are the cooking or preservation method, color, maturity stage, origin (e.g., type of animal, acquisition type or harvest season), part, edible/inedible portion, fortification or enrichment and biodiversity details (e.g., variety, breed or wild food). The more complete the food description the better, as nutrient content can differ greatly with different descriptions of the same food. For instance, if we find in a FCT a poor food description such as “meat” or “cassava” it is very difficult (or not feasible) to use the data, even if they were generated by high-quality analytical methods. The meat composition will depend on the type and part of the animal and cooking method. In the 2019 FAO/INFOODS FCT for Western Africa (Vincent et al., 2020), the protein content for “Beef meat, lean, ca. 5% fat, raw” is 22.5 g per 100 g edible portion on fresh weight basis (EP) while for “Beef meat, lean, ca. 5% fat, boiled (without salt), drained” it is 37.5 g per 100 g EP. For cassava, the part of the plant, cooking method and color affect the composition. In the same FCT, when we compare different plant parts, we can find that the dietary fiber content for “Cassava, tuber, white flesh, raw” is 3.7 g per 100 g EP while for “Cassava, leaves, fresh, raw” it is 7.9 g per 100 g EP. Moreover, the vitamin A content in retinol equivalents (RE) is very different due to tuber color: white raw cassava tuber contains 4 µg RE per 100 g EP while the yellow fleshed raw cassava contains 75 µg RE per 100 g EP. These examples demonstrate the importance of detailed food description. as the nutritional contents change drastically depending on their characteristics. An ambiguous food description is likely to introduce errors into food matching and therefore into nutrient intake estimations.

Some food description systems include the food grouping and/or food coding, such as the food classification and description system (FoodEx2) (European Food Safety Authority, 2015) or the LanguaL food classification system (Møller and Ireland, 2018). Food groups help to find the foods easily and to define certain quality checks at the food group level. Common food groups used are in Table 1.

In an FCT/FCDB, each food entry should have their own unique food code. Often, it is a combination of the food group and food entry within the food group. For example, in the FAO/INFOODS Food Composition Table for Western Africa (WAFCT 2019) (Vincent et al., 2020), “Millet, whole grain, raw” has the code 01\_015, where 01 indicates the food group “01 Cereals and their products” followed by the number of the food record.

### Component identification

A clear and complete component description is key for FDC and the quality of FCT/FCDB. A complete component description should cover both the component identification (e.g., expression, definition and analytical methods), units and denominator.

For some components, there are potential problems regarding component naming, due to differences in definitions and analytical methods. These “problematic components” are important for nutrition as they, unfortunately, may have different analytical

**Table 1** Common food groups used in FCT/FCDB.

<i>Food group name</i>
Cereals and their products
Starchy roots, tubers and their products
Legumes and their products
Vegetables and their products
Fruits and their products
Nuts, seeds and their products
Meat, poultry and their products
Eggs and their products
Fish and their products
Milk and their products
Fats and oils
Beverages
Miscellaneous
Soups and sauces

methods, expressions or calculations, yielding significantly different values. Such components include energy, protein, fat, carbohydrates, fiber, most vitamins (Vitamin A, D, E, D, C, B6, folate, niacin/niacin equivalent) and phytate. For these components, the user should carefully investigate which analytical method or definition is used in an FCT/FCDB (or another source) before utilizing their nutrient values.

To provide unambiguous and language-independent component descriptions, INFOODS developed the INFOODS food component identifiers in 1989 (Klensin et al., 1989), also known as tagnames. A list of tagnames is available at the INFOODS website (<http://www.fao.org/infoods/infoods/standards-guidelines/food-component-identifiers-tagnames/en/>). These have been updated and enlarged over the last decade, as new components are analyzed, or because of newly developed methods. Their use in FCT/FCDB is of upmost importance, as nutrient values will change significantly by tagname. Different tagnames exist if analytical methods, expressions or definitions generate significantly different nutrient values. The “problematic components” always have several tagnames. Luckily, most components have one tagname, meaning that existing analytical methods generate similar values and only one definition/expression exists. Tagnames are like unique codes or abbreviations according to a specific naming system that allows clear definition of components developed using the following main principles:

- Each time an analytical method, expression or calculation generates significantly different values, a new tagname should be created for the specific component. This ensures that values assigned to the same tagname are directly comparable. Only data with the same tagname are comparable and can be combined. Data with different tagnames are not comparable and should not be combined.
- Each chemical used for nutrition that is analyzed should have a specific tagname.
- The food component tagname scheme should reflect “nutrients,” not just chemistry.
- For unknown methods, or multiple empirical methods, the tagname with a hyphen is used (e.g., FIB-). This is to avoid the assignment of a specific tagname without knowing if it is the most appropriate one.

The tagname system must be robust and extensible to allow new tagnames to be added in the future, as information technology and nutrition science are rapidly developing fields. Some examples for different INFOODS tagnames, due to different definition or analytical method, are shown in Table 2.

Vitamin A may be calculated either as Retinol Equivalents (RE with tagname VITA) or as Retinol Activity Equivalents (RAE with tagname VITA\_RAE). In plant foods, they result in different values for the same carotenoid content. Thus, using RE or RAE in estimating nutrient intake would generate two significantly different figures.

FCD can also be presented with different units, such as g, mg, µg or international units, and with different denominators. In general, nutrient values in FCT/FCDB are expressed per 100 g edible portion on fresh weight basis (EP). Some use per 100 mL for beverages, per g of nitrogen for amino acids; or fatty acids may be expressed per 100 g EP or as a percentage of total fatty acids. Scientific articles often express data per 100 g edible portion on a dry matter basis (DM), or per 100 g fatty acids. These differences have great implications on the absolute value of the data. The importance of unit and denominator on the absolute values is exemplified in Table 3.

Users of FDC need to understand the importance of component description, unit, and denominator to calculate nutrient intake correctly. It is also key to verify that component definitions are the same between FCD and recommended daily intakes (RDI) to avoid errors in nutrient adequacy estimations.

### Coverage of components

FAO/INFOODS defined the minimum number of components to be included in FCT/FCDB as: Edible portion (Refuse), energy, water, protein, fat, available carbohydrates, dietary fiber, iron, zinc, calcium, vitamin A, vitamin C, vitamin B1, vitamin B2, vitamin B12, and folate. Many FCT/FCDB contain more than these components, while some FCT/FCDB do not include all of them.

**Table 2** Different INFOODS food component identifiers (tagnames) for carbohydrates, fiber and vitamin A.

Component	Analytical/determination method or definition	Tagname	Description
Carbohydrates	Total carbohydrates (includes fiber)	CHOCDF	Calculated by difference = $100 - (\text{water (g)} + \text{protein (g)} + \text{fat (g)} + \text{alcohol (g)} + \text{ash (g)})$
		CHOCSM	By summation, this value is the sum of analytical values of sugars, starch, oligosaccharides and dietary fiber
	Available carbohydrates (excludes fiber)	CHOAVLDF	Calculated by difference = $100 - (\text{water (g)} + \text{protein (g)} + \text{fat (g)} + \text{alcohol (g)} + \text{ash (g)} + (\text{dietary fiber}))$
		CHOAVL	By weight, this value is the sum of analytical values (anhydrous form) of sugars, starch and glycogen
		CHOAVLM	Monosaccharide equivalents, this value is the sum of analytical values (hydrous form) of sugars, starch and glycogen
Fiber	Total dietary fiber	FIBTG	Analyzed by AOAC Prosky method. It is a mixture of non-starch polysaccharides, lignin, resistant starch, resistant oligosaccharides, gum and waxes (most recommended definition)
	Non-starch polysaccharide	PSACNS/NSP	Also called Englyst fiber. This includes non-starch polysaccharides but excludes lignin, resistant starch and resistant oligosaccharides
	Southgate fiber	FIBTS	Mixture of non-starch polysaccharides, lignin and some resistant starch
	Fiber, determined by acid detergent method	FIBAD	This includes lignin, cellulose, some hemicellulose and some pectin
	Fiber, determined by neutral detergent method	FIBND	This includes lignin, cellulose, and insoluble hemicellulose
	Crude fiber	FIBC	It captures only fractions of lignin, cellulose and hemicellulose (obsolete and should not be used)
Vitamin A	Fiber, unknown or mixed methods	FIB-	
	Vitamin A, expressed in retinol equivalents (RE)	VITA	$VITA = \text{retinol } (\mu\text{g}) + 1/6 \text{ beta-carotene } (\mu\text{g}) + 1/12 \text{ other pro-vitamin A carotenoids } (\mu\text{g})$
	Vitamin A, expressed in retinol activity equivalents (RAE)	VITA_RAE	$VITA\_RAE = \text{retinol } (\mu\text{g}) + 1/12 \text{ beta-carotene } (\mu\text{g}) + 1/24 \text{ other pro-vitamin A carotenoids } (\mu\text{g})$
	Vitamin A, determined by bioassay	VITAA	No longer used in food composition tables and databases

Adapted from FAO/INFOODS e-Learning Course on Food Composition Data (FAO, 2013).

**Table 3** Examples of how different units and denominators can affect the absolute fat values in cream cheese.

Fat value	Unit	Denominator
34.2	g	100 g edible portion on fresh weight basis (EP)
34.2	%	100 g EP
342	g	1 kg EP
34,200	mg	100 g EP
75	g	100 g edible portion on a dry matter basis (water content = 54.4 g/100 g EP)
75	%	Of dry matter (34.2 g fat/45.6 g DM)
75	%	Fat in dry matter

Adapted from FAO/INFOODS e-Learning Course on Food Composition Data (FAO, 2013).

An example of how FCT/FCDB should identify components was taken from the FAO/INFOODS Food Composition Table for Western Africa (WAFCT 2019) (Table 4). In addition to such a table with the components, the FCT/FCDB should include detailed description of the nutrients, their calculation methods and details on the analytical methods.

### What are the sources of data for food composition tables and databases?

Analytical data should be the basis for FCT/FCDB. They should be generated using appropriate methods and quality standards published in scientific articles or laboratory reports. FCD generated through direct analysis, in which the values are a result of analysis carried out specifically for a certain FCT/FCDB are considered the highest quality data. In this approach, it is possible to collect representative samples across a country or region so that they accurately reflect the food supply. As this is costly, it is rarely done for most foods.

In general, FCD published in the scientific literature contain limited analytical data, with a short description of the analytical methods and quality control schemes and, sometimes, with sampling information. Many analyzed FCD, however, never get

**Table 4** Components, units, analytical/determination method/definition and corresponding INFOODS component identifier listed in the FAO/INFOODS Food Composition Table for Western Africa (WAFCT 2019), expressed per 100 g edible portion.

<i>Component</i>	<i>Unit</i>	<i>Analytical/determination method/definition</i>	<i>INFOODS component identifier (tagname)</i>
Edible portion 1	–	Edible portion coefficient: from as purchased to as described	EDIBLE1
Edible portion 2	–	Edible portion coefficient: from as described to as eaten	EDIBLE2
Sum of proximates (SOP)	G	=Water + protein + fat + available carbohydrates + ash + dietary fiber + alcohol	SOP
Energy	kJ, kcal	Calculated (see formula below)	ENERC
Water	g	Drying	WATER
Protein, total	g	Calculated by multiplying the nitrogen conversion factor (XN) times the analyzed total nitrogen (mainly Kjeldahl method)	PROTCNT
Fat, total or [fat by Soxhlet]	g	Mixed solvent extraction or [Soxhlet method with continuous extraction]	FAT of [FATCE]
Carbohydrates, available by difference	g	=100 – (water + protein + fat + ash + dietary fiber + alcohol)	CHOAVLDF
Fiber, total dietary or [crude fiber]	g	AOAC Prosky method (AOAC 991.43) or [Weende method]	FIBTG or [FIBC]
Alcohol	g	GLC or distillation	ALC
Ash	g	Gravimetric methods	ASH
Calcium	mg	AAS, ICP-MS	CA
Iron	mg	AAS, ICP-MS	FE
Magnesium	mg	AAS, ICP-MS	MG
Phosphorous	mg	AAS, ICP-MS	P
Potassium	mg	AAS, ICP-MS	K
Sodium	mg	AAS, ICP-MS	NA
Zinc	mg	AAS, ICP-MS	ZN
Copper	mg	AAS, ICP-MS	CU
Vitamin A (expressed in retinol equivalents)	µg	=Retinol + 1/6 beta-carotene equivalent	VITA
Vitamin A (expressed in retinol activity equivalents)	µg	=Retinol + 1/12 beta-carotene equivalent	VITA_RAE
Retinol	µg	HPLC	RETOL
Beta-carotene equivalents or [beta-carotene]	µg	=Beta-carotene + 1/2 alpha-carotene + 1/2 beta-cryptoxanthin	CARTBEQ or [CARTB]
Alpha-carotene	µg	HPLC	CARTA
Beta-carotene	µg	HPLC	CARTB
Beta-cryptoxanthin	µg	HPLC	CRYPXB
Vitamin D	µg	=Vitamin D <sub>2</sub> + Vitamin D <sub>3</sub> ; analyzed by HPLC	VITD
Vitamin E (expressed in alpha-tocopherol equivalent) or [alpha-tocopherol]	mg	=Alpha-tocopherol + 0.4 × beta-tocopherol + 0.1 × gamma-tocopherol + 0.01 × delta-tocotrienol; analyzed by HPLC	VITE or [TOCPHA]
Alpha-tocopherol	mg	HPLC	TOCPHA
Beta-tocopherol	mg	HPLC	TOCPHB
Gamma-tocopherol	mg	HPLC	TOCPHG
Delta-tocopherol	mg	HPLC	TOCPHD
Thiamin (vitamin B1)	mg	HPLC, microbiological	THIA
Riboflavin (vitamin B2)	mg	HPLC, microbiological	RIBF
Niacin equivalents or [niacin] (vitamin B3)	mg	=Niacin + 1/60 tryptophan	NIAEQ or [NIA]
Niacin	mg	HPLC, microbiological	NIA
Tryptophan	mg	Ion exchange chromatography	TRP
Vitamin B6	mg	HPLC, microbiological	VITB6C
Folic acid, fortificant	µg	HPLC	FOLAC
Folate, naturally occurring (food folate)	µg	Microbiological	FOLFD
Dietary folate equivalents	µg	=Food folate + 1.7 × folic acid	FOLDFE
Folate, total or [sum of folates] (vitamin B9)	µg	Microbiological determination or [HPLC]	FOL or [FOLSUM]
Vitamin B12	µg	HPLC, microbiological	VITB12
Vitamin C	mg	=Ascorbic acid + dehydro-ascorbic acid	VITC
Cholesterol	mg	HPLC	CHOLE
Fatty acid conversion factor	–	From literature sources	XFA
Fatty acids, total saturated	g	Calculated from FA profile	FASAT
Fatty acid, total monounsaturated	g	Calculated from FA profile	FAMS

**Table 4** Components, units, analytical/determination method/definition and corresponding INFOODS component identifier listed in the FAO/INFOODS Food Composition Table for Western Africa (WAFCT 2019), expressed per 100 g edible portion.—cont'd

<i>Component</i>	<i>Unit</i>	<i>Analytical/determination method/definition</i>	<i>INFOODS component identifier (tagname)</i>
Fatty acids, total polyunsaturated	g	Calculated from FA profile	FAPU
Linoleic acid	g	Calculated from FA profile	F18D2CN6
Alpha-linolenic acid	g	Calculated from FA profile	F18D3CN3
Phytate, total	mg	Phytate, total, calculated from phytate phosphorus by anion exchange method (AOAC 986.11) or [phytate, determined by direct precipitation] or [phytate, determined by indirect precipitation]	PHYTCPP or [PHYTCPPD] or [PHYTCPP1]
Inositol triphosphate (IP3)	mg	HPLC	IP3
Inositol tetraphosphate (IP4)	mg	HPLC	IP4
Inositol pentaphosphate (IP5)	mg	HPLC	IP5
Inositol hexaphosphate (IP6)	mg	HPLC	IP6
Nitrogen conversion factor	—	From literature sources	XN

AAS = Atomic absorption spectrophotometry, GLC = Gas liquid chromatography, HPLC = High performance liquid chromatography, ICP-MS = Inductively coupled plasma-mass spectrometry. Components were assigned to a secondary tagname if the preferred one was not available for a given food and the values was presented between square brackets ([ ]).

published outside the laboratory reports, as either the data owners consider them propriety data (mainly by food industry), do not have time to write a scientific article, or the data quality was too low for publication. FAO/INFOODS has published several global databases as repositories of analytical data (see <http://www.fao.org/infoods/infoods/tables-and-databases/faoinfoods-databases/en/>), such as the FAO/INFOODS Food Composition Database for Biodiversity (BioFoodComp), FAO/INFOODS Analytical Food Composition Database (AnFood), or the FAO/INFOODS/IZiNCG Global Food Composition Database for Phytate (PhyFoodComp), while EuroFIR published eBASIS (Bioactive Substances in Food Information Systems). When compiling analytical data from scientific articles or laboratory reports into the FAO/INFOODS databases, most could not be included because of missing data or imprecise documentation. A common error is an imprecise denominator, e.g., presenting data per 100 g—is this 100 g edible portion on fresh weight basis (EP), 100 g edible portion on dry matter basis (DM), 100 g total food (edible and inedible part) on fresh weight basis, 100 g of fatty acids or something else? Other main reasons for not including the analytical data are missing or imprecise units, poor data quality and/or description of foods, components, method—or missing water value (if data is expressed in dry matter). This is unfortunate and a waste of scarce funds for analysis. In many countries, high-quality analytical food composition data are still missing on commonly consumed foods, on underutilized and wild foods, and on the different varieties. They often include raw foods, but rarely different varieties (i.e., biodiversity) or indigenous foods, prepared or processed foods, recipes or branded foods. This represents a major challenge in most countries, as these latter foods represent the majority of foods consumed. Most of the published analytical compositional data are on macronutrients, some on minerals or bioactive components, but few include vitamins. Fiber is unfortunately often analyzed using the crude fiber method, which is unsuitable for human nutrition. Carbohydrates are rarely analyzed, but usually calculated by difference. Fortunately, total carbohydrates by difference (i.e., carbohydrates including dietary fibers) has been phased-out in most of the recently published food composition tables/databases (except e.g., the food composition database of the US Department of Agriculture).

Another source of FCD are nutrition label data. However, they are rarely analyzed, which means that nutrient values of manufactured products are often of lower quality in FCT/FCDB. Further, it seems that food companies calculate the nutrient content of complex foods (e.g., cornflakes, pizza, cakes) for the label by summing the nutrient values of the raw ingredients, without taking into account the weight loss during processing, which will result in a concentration of nutrients in the final product. This means that, in general, the nutrient contents on labels of complex foods are underestimated. These lower values could mean that the nutritional label holds lower than true values.

Because analytical data are incomplete, and analyses are costly and time-consuming, data in FCT/FCDB are largely imputed, calculated, presumed or borrowed from FCT/FCDB from other countries. Imputed data estimated based on similar foods (e.g., values for red beans used fill missing values for white beans). The accuracy of these values relies on good food composition knowledge and an understanding of the variation in the composition of foods by the data compiler. Calculated data are mainly used to estimate the composition of cooked foods, either single foods or mixed dishes. FCD for cooked foods and mixed dishes are commonly derived from recipe calculations. Appropriate calculations require complete recipe information (including the amount of each ingredient and the weight of the cooked recipe), application of nutrient retention factors to estimate the loss of nutrients, and yield factors to account for changes in water and/or fat during cooking. Detailed instruction on these calculations can be seen in lesson 5.2 Recipe calculation in the FAO/INFOODS e-Learning Course on Food Composition Data (FAO, 2013). Presumed zeros may be used in some cases, when a certain component is known to not exist in a food category; for example, alcohol in non-alcoholic beverages or cholesterol in plant-based products. Borrowed data from other countries are often the alternative used where local data are not available. These data need to be scrutinized to ensure that they match foods consumed locally, e.g., for fortification, cooking practices, color of fruit and vegetables, etc. Adapting data from another country can be challenging and there will always be uncertainty around borrowed data, thus its use should be limited.

FCTs/FCDBs should include as few missing values as possible for nutrients of interest. If values are missing, the user should estimate or borrow the missing data—this task demands a higher level of expertise. If this is not done and missing values are treated as zero, nutrient intakes will be underestimated.

In recent years, documentation at value and food levels, also called meta data, has allowed users to appreciate the origin and quality of compositional data in FCTs/FCDBs. This documentation is key for quality assessment and every published FCD and FCT/FCDB should take great care to adequately document their data, including the source of data.

### What is the global availability of FCTs/FCDBs?

Country-specific or regional FCT/FCDB should be developed, due to the different factors that may affect the composition of foods (e.g., different food varieties/breeds, soil composition, food fortification and cooking practices). Published FCT/FCDB vary considerably in terms of data quality, documentation, food and nutrient coverage, analytical methods used and accessibility. Using FCD from another country to estimate nutrient intakes may lead to wrong conclusions when evaluating micronutrient adequacy.

Published FCTs/FCDBs can be found at the INFOODS website (<http://www.fao.org/infoods/infoods/tables-and-databases/en/>). For more than 190 existing countries in 2021, 105 FCT/FCDB were available (Fig. 1), of which only 25 were published or updated less than five years ago, and only 27 were available online in user-friendly format (e.g., Excel or Access). Others were available online, but only as PDF, as food-by-food search, or as printed versions, which limits their usability, especially for dietary assessment. Although many FCT/FCDB have been published, most of the newer FCT/FCDB have been updated only in Europe and Africa (Fig. 1). A successful example is the Indian Food Composition Table published in 2017, with solely analytical data for about 200 food components in over 500 raw foods collected using a national and appropriate sampling plan (Longvah et al., 2017). FCTs/FCDBs must be regularly updated to reflect changes both in the food supply and components of interest due to advances in the nutrition science.

Few countries have a fully funded and staffed national food composition program, which regularly publishes updated FCT/FCDB with new analytical data, new foods and/or components. In most developing countries and many developed countries, political and institutional support is lacking and thus FCT/FCDB are often produced within projects or as a private initiative, i.e., not within an institutional framework. This is one of the reasons why many FCT/FCDB are outdated, cover only few foods or nutrients and are not produced according to the international standards of INFOODS. Hence many countries rely on data from high-income countries, such as the Food Data Central published by the United States Department of (<https://fdc.nal.usda.gov>).

### Selecting high-quality food composition data and databases

To assist users in selecting the most adequate FCT/FCDB, experts have developed the FAO/INFOODS Evaluation Framework to Assess the Quality of Food Composition Tables and Databases (FCT/FCDB)—(Evaluation Framework) (Charrondiere et al., 2021). This is done in two steps: a screening with eight questions and, if passed, a full evaluation from user or compiler perspective with up to 190 questions in seven categories: Documentation in the FCT/FCDB to inform users, food coverage, food identification, component and value coverage and component expression, quality of data—analysis—the compilation process and checking; public access of FCT/FCDB, and year of publication and frequency of updates.

**Fig. 1** Food composition tables and databases (FCT/FCDB) listed in the INFOODS inventory in March 2021 by region and according to the number of years since last update. Values in parentheses correspond to the total number of FCT/FCDB available in the region.

## How to assure that food composition data, FCT and FCDB are generated, compiled and used correctly

Publishing and using high-quality FCTs/FCDBs are of great importance to ensure the accuracy of nutrient intake estimations, as previously discussed. However, incorrect use of even a high-quality FCT/FCDB can lead to poor results and wrong conclusions. The appropriateness of FCD use requires trained professionals on the basic knowledge to generate, compile, evaluate and use FCTs/FCDBs.

Three pillars are needed to ensure that high-quality food composition data are correctly generated, compiled, disseminated and used:

1. International standards, guidelines and tools on the generation and compilation of food composition data must be developed and used, e.g., by INFOODS
2. National and/or regional food composition programs must exist, which update FCT/FCDB regularly, and
3. Professionals must be trained in all aspects related to food composition.

If guidelines and programs exist, but professionals do not know how to use them, they are of little interest. Therefore, there is a great need for training professionals and students in the different aspects of food composition. Despite being the most effective means to spread food composition knowledge and recognition, food composition is still rarely included in the formal training of nutritionists and other professionals. Increasingly, there are international courses, and distance and e-learning tools.

The basic food composition knowledge that any professional using, generating and compiling FCD should have (e.g., nutritionist, dietitian, health professional giving dietary advice, chemist), are included in the FAO/INFOODS e-Learning Course on Food Composition Data (FAO, 2013). This e-learning course takes about 14 h to complete, is available in English and French and can be downloaded free-of-charge (or used online) from FAO e-learning platform (<https://elearning.fao.org/course/view.php?id=191>). The course explains the importance of appropriate food and component descriptions, units, denominators, biodiversity, recipe calculation and compilation methods, and data quality, and relates all these issues to their influence on the resulting nutrient values. It also describes briefly the impact good or bad FCD can have on programs, policies, laws and regulations. This e-learning course was designed to be used in universities, even in undergraduate courses.

Those who wish to acquire more knowledge on food composition may also explore the FAO/INFOODS Food Composition Study Guide (volume 1 and 2), available in English, Spanish and French and downloadable free-of-charge from the INFOODS website (<http://www.fao.org/infoods/infoods/training/en/>). It takes about 2 weeks to complete, as it is more comprehensive and asks learners to complete questions and exercises.

Additionally, there are classroom based Food Composition Courses, such as the International Postgraduate Courses on the Production and Use of Food Composition Data in Nutrition, offered in Wageningen, Netherlands, or there are regional courses (see <http://www.fao.org/infoods/infoods/training/en/> - past and upcoming courses). In addition, FAO/INFOODS have organized many one-day training courses around nutrition conferences and held webinars (<http://www.fao.org/infoods/infoods/webinars/en/>).

Also, there are websites with important information such as the INFOODS website (<http://www.fao.org/infoods/infoods/en/>) with guidelines, training material, tools and inventories of FCT/FCDB and much more. Other websites include Compilers' Toolbox™ (<http://toolbox.foodcomp.info/>), Food Composition Explained website (<https://www.foodcomponline.info/>) or the EuroFIR website (<https://www.eurofir.org/>).

Those who wish to become a real food composition expert, however, must work with food composition data and follow international guidelines such as the ones from INFOODS, ideally under the initial supervision of a food composition expert. Experience and expert knowledge come with time.

For dietary assessment, food matching is key for the quality of nutrient intake assessment. Therefore, users should choose quality FCT/FCDB and match correctly reported foods to the foods in the FCT/FCDB, as outlined in the FAO/INFOODS Guidelines for Food Matching (Stadlmayr et al., 2012). In general, first check if the FCT includes foods and components of interest, and then check food description and components according to Table 5. The guidelines also include a quality scheme for food matching which could be used to estimate the quality of nutrient intake estimations.

## Conclusions and way forward

Great progress has been made in the availability and quality of FCD, and food composition standards. However, more analytical data are badly needed, especially on vitamins, and more people should have knowledge on food composition to assure that FCD are generated, managed and used correctly. Therefore, food composition should be recognized as science, and be taught in nutrition or dietetics programs, among others. In this case, future decision makers could be more willing to invest in food composition programs including chemical analysis, compilation and dissemination of FCD. With better compositional data, many policies and programs could be better designed and targeted.

**Table 5** Food matching criteria from the FAO/INFOODS Guidelines for Food Matching.

<b>Food description</b>	
Food name and descriptors	Food description should be complete and unambiguous, including taxonomic/scientific name and forms of preparation when appropriate.
Water and fat content (and additional components of interest)	Water and fat (for some foods) should always be checked against the food description to assess whether the values correspond to the food of interest.
<b>Food components</b>	
Mode of expression	Important for components that can be expressed in different forms (e.g., total and available carbohydrate). Some components may have the same common name but different definitions (e.g., vitamin A defined as retinol equivalents or retinol activity equivalents).
Definition	
Conversion factors	For some components not only mode of expression and definition are required, but also the conversion factors applied (e.g., nitrogen conversion factors to calculate protein values).
Analytical methods	Analytical methods may result in significantly different values (e.g., dietary fiber analyzed by AOAC-Prosky and crude fiber method).
Units and denominator	Units are used to quantify the amount of a component (e.g., g, mg, µg, kcal) while the denominator defines in how much of a food or beverage the component is found. Normally, in a FCT/FCDB present data “per 100 g edible portion on fresh weight basis,” but care should be taken, especially for liquids.

### Key points

- Understand that the biological impact of food fortification is related to the nature, quality, and quantity of the incorporated micronutrients and not to the fortified foods; however, population coverage depends on the fortification vehicle.
- Describe the use of the Estimated Average Requirement (EAR), instead of the Recommended Nutrient Intake (RNI), as the reference values for determine the need and the success of micronutrient programs for populations, and the use of the Tolerable Upper Intake Level (UL) to ensure safety and prevent excessive micronutrient intakes.
- Explain that adequate intake matters, but that bioavailability (efficient absorption) and bioconversion (transformation into the metabolically active forms) of the micronutrients to ensure their bioefficacy, i.e., their biological impact is also important.
- Illustrate that programmatic viability of a food fortification program is associated with participation of formal and centralized food industries, the presence of low cost, practical, and efficient industry quality control/assurance systems and governmental inspection actions, complemented with periodical epidemiological surveillance to demonstrate population coverage and benefit.
- Promote the recognition that more than one fortified food or more than one micronutrient intervention may be needed to correct dietary micronutrient gaps but, at the same time, their design should be coordinated to prevent excessive intake of micronutrients.
- Clarify that the distinction between mass-, targeted-, and market-driven fortification is related to the objectives and conditions of the program, not to the type of fortification vehicles, and that home-fortification is not a food fortification program.

## Glossary

**Codex Alimentarius** Inter-country organization of the United Nations system, led by FAO and WHO, with the purpose of proposing general principles, standard models, practices, and guidelines, aimed to protect the health of consumers and ensure fair trade associated with foods. The Codex recommendations are recognized by the World Trade Organization as international reference criteria in those matters

**Estimated Average Requirement (EAR)** The average daily nutrient intake level estimated to meet the needs of half of the healthy individuals in a particular physiological stage-, gender-, and age-specific population group. It is used as the reference intake value for population diets

**Fortificants** The chemical forms that are the sources of micronutrients for food fortification

**Home Fortification** Term used to identify micronutrient supplements in the form of a powder that are added into foods before consumption. It is not food fortification as the micronutrient vehicle is a supplement

**Micronutrients** These are vitamins and minerals that are required by humans in very small amounts; most of them cannot be synthesized by the human body and therefore they should be obtained from the diet.

**Premixes** Blends of fortificants with antioxidants, anticaking, excipient, and other substances to provide the adequate physical and chemical properties that are required to produce homogeneous and reasonably stable fortified products

**Recommended Nutrient Intake (RNI)** The daily average nutrient intake that meets the nutrient requirements of almost all apparently healthy individuals in a particular physiological stage-, gender-, and age-specific population group. The RNIs are set as the EAR plus two standard deviations (i.e., for covering 97.5% of the population). In some countries, the term Recommended Daily Allowance is used instead of RNI. It is the used reference value for diets aimed to individuals; and it is also used as reference for expressing the nutrient content of foods in the nutrition panels of the food labels

**Tolerable Upper Intake Level (UL)** The highest average daily nutrient intake level unlikely to pose a risk of adverse health effects to almost all (97.5%) apparently healthy individuals in a particular physiological stage-, gender-, and age-specific population group. It is used as the safe reference value of intake for diets of both individuals and populations

## Introduction

Food fortification is a strategy to increase the content of vitamins and minerals (micronutrients) in the diet by adding them to commonly edible products, mainly staple foods (cereal flours, oil, rice, and dairy products) and condiments (salt, sugar, bouillon cubes), when processed by the food industry. Biological impact is related to the correction of micronutrient gaps. Several fortification vehicles can be alternatives for the same micronutrient, and their selection depends on the industrial structure and dietary habits of each country. Although fortifying foods by small and underdeveloped factories may be feasible and even efficacious, the viability and sustainability of fortification programs depends on the involvement of formal and centralized food factories to take advantage of economy of scale, efficient governmental supervision, and population coverage. This article describes factors that influence food fortification program viability and effectiveness; reviews the biological, technical, economic, and programmatic factors that limit the quantities of micronutrients that can be added to fortified foods; and justifies the need for considering several micronutrient interventions - used in a coordinated manner—to reduce dietary inadequacies of at-risk populations.

## What is food fortification?

The Codex Alimentarius defines food fortification or enrichment as the addition of micronutrients to foods, whether or not they are normally contained in the food, for the purposes of preventing or correcting a demonstrated micronutrient deficiency. The Codex also notes that the quantity of micronutrients to add should be sufficient to correct or prevent deficiency when the food is consumed in normal amounts by the population at risk, but not likely to result in excessive intakes by individuals with high intake of the fortified food (Codex Alimentarius, 2015). These recommendations are applicable to single foods.

The WHO/FAO proposed a more appropriate definition in the Guidelines on Food Fortification with Micronutrients, which focuses on the diet rather than on single foods. A single food may contribute toward improving the nutritional quality of the diet but may not necessarily be sufficient as the only solution to prevent a micronutrient inadequacy (i.e., insufficient intake to satisfy the nutrient requirements) (Allen et al., 2006). This is the concept adopted in this article.

In food technology, fortification and enrichment have different meanings: fortification is reserved for the addition of micronutrients to a food that does not contain those nutrients naturally, whereas enrichment is applicable when the natural contents of some micronutrients normally present in the food are intentionally increased. Thus, addition of iodine to salt is an example of fortification whereas addition of iron to cereal flours is an example of enrichment. Two other related terms are frequently used: restoration, when micronutrients are added to recover the original micronutrient contents in a food that has partially or totally lost them during processing, for example, adding vitamins A and D to defatted milk to reproduce the content of those vitamins in whole milk; and nutritional equivalence or standardization, when the content of micronutrients of a manufactured food is modified to imitate

the micronutrient content of a natural food that is intended to be replaced, as, for example, adding vitamin A and D to margarine to achieve their natural micronutrient contents in butter (Richardson, 1990).

The chemical sources of micronutrients used in food fortification are called fortificants. Thus, for example, ferrous sulfate, ferrous fumarate, and NaFeEDTA are fortificants used to increase the content of iron in foods (Hurrell, 2021). Fortificants are generally added to foods as part of premixes, which also contain substances to increase the stability and the technical and sensorial properties of the fortificants.

### How does food fortification work?

Many articles in the scientific literature note that consumption of fortified foods has positive health outcomes (Keats et al., 2019; Field et al., 2020; Pachon, 2021), but rarely emphasize that those outcomes are associated with the quality and quantity of the micronutrients that are added to the foods rather than to only the consumption of the fortified foods. For example, vitamin A can be added to several food vehicles such as oil, sugar, cereal flour, milk, and even bouillon cubes, but the biological impact does not depend on the fortification vehicle but to the amount of vitamin A that is being delivered to the consumer, which is independent to the type of fortified food (Dary and Mora, 2002). The purpose of using a food vehicle is to reach a large number of individuals in vulnerable populations in an efficient and low-cost manner. Food fortification takes advantage of the manufacturing structure of the food industry and the already existent delivery system of their products. In other words, fortified foods aim to cover as many individuals as possible, but the biological impact depends on the proportion of individuals who meet their nutritional needs through the additional intake of micronutrients supplied by the fortified foods. The magnitude of impact depends on the extent to which the nutritional gap is corrected. Therefore, the benefit of fortified foods varies from population to population, as the same fortification formula does not necessarily replicate results from one community to another because the amount of fortified foods consumed and the magnitude of the nutrient intake gap may differ. The goal is that most individuals of the population reach the Estimated Average Requirement (EAR) of intake, combining diets and fortified foods (Allen et al., 2020). It is important to point out that, although the nutritional panel of food labels are expressed as percentage of Recommended Nutrient Intakes (RNI, which in some countries is similar to the Recommended Dietary Allowance, RDA), for population programs, the parameter of reference is the EAR. The RNI or RDA values are applied to diets for individuals and not for populations (Institute of Medicine, 1998).

On the other hand, sufficient intakes of micronutrients do not necessarily lead to noticeable biological impacts if the diet and/or metabolic condition of the individuals are unfavorable. The bioefficacy (i.e., the metabolic function of a nutrient) of the added micronutrients depends on three factors: intake, bioavailability (i.e., transference of the micronutrient from the intestinal track to the interior of the body), and bioconversion (i.e., transformation of the micronutrient to its metabolically active form). For example, bioavailability of synthetic  $\beta$ -carotene may vary, depending on the content of fat in the meal where the fortified food is consumed, because fat is needed for its absorption. Moreover, in individuals with zinc deficiency, the bioconversion of  $\beta$ -carotene to vitamin A may be impaired (Van Lieshout et al., 2003). Another example is folic acid (a precursor of the vitamin folate or B<sub>9</sub>, which is oxidized and stable) that is easily added to foods and highly bioavailable but does not act alone but in coordination with vitamins B<sub>2</sub>, B<sub>6</sub>, and B<sub>12</sub> (Selhub, 2008).

In summary, food fortification increases the population supply of micronutrients in the diet by using products manufactured by the food industry, but biological impact depends on the extent to which nutritional gaps are corrected. Nevertheless, the programmatic viability of food fortification is related to the involvement of large and centralized food industries, which is a characteristic that originated the terms Large-Scale Food Fortification (LSFF) or Industrial Food Fortification. Although small industries can fortify foods and those foods can have biological impact, the cost-efficiency (i.e., the relative absolute cost of increasing the supply of micronutrients) and the cost-effectivity (i.e., the relative beneficial cost to attain a biological impact) are unfavorable. Neither the saving of production at large scale nor practical tracing and inspection of the products are possible, and therefore fortification under this condition is unscalable and unsustainable. Food fortification is an opportunistic strategy that takes advantage of existent formal industries and their efficient distribution networks.

### Which factors limit the amounts of micronutrients in fortified foods?

Although the micronutrient content in the fortified food is not the only condition to attain biological impact, it continues being an important element for this objective. Micronutrient content can be adjusted to the consumption pattern of the fortification vehicle; lower food intakes require larger micronutrient content to supply the same quantity of micronutrients. However, it is important to realize that the incorporation of micronutrients to foods may be limited because of safety, technological compatibility, or cost constraints.

### Safety

Both the Codex Alimentarius (2015) and the WHO/FAO (Allen et al., 2006) recommend that fortification should be designed to ensure that almost all individuals in the population do not have excessive micronutrient intake. The total micronutrient intake for most individuals should not exceed the tolerable upper intake level (UL) (Allen et al., 2020). Young children and adult males have

the lowest and the highest UL values, respectively, and those coincide with smaller and larger intakes of staples and condiments, which are the most common fortification vehicles used in large-scale food fortification. Therefore, in practical terms, the highest micronutrient content in these fortification vehicles should not cause that some of the adult or adolescent males to reach the UL values of intake. However, for packaged foods with fixed serving sizes regardless of the population group (e.g., breakfast cereals and granola bars), the micronutrient content should be checked against the UL values for young children. It is important to point out that the calculation of total intake should be carried out for the overall supply, i.e., the combined amount provided by the diet plus all the fortified foods or any other micronutrient supplying intervention.

### Technological compatibility

In general, fortificants should not change the stability, color, odor, or flavor of the food vehicle. Negative interactions between fortificants and vehicles impede the adoption of high micronutrient content. For example, vitamin B<sub>2</sub> and  $\beta$ -carotene, when added to food matrices that are white (refined flours and rice, e.g.), cause yellowish-orange colors. Folic acid and vitamin B<sub>12</sub> may also change color of the matrix. Some iron salts with good water solubility and bioavailability, such as ferrous sulfate and ferrous bisglycinate, favor rancidity, whereas others such as NaFeEDTA may produce discoloration. Technological incompatibility reduces the impact of iron fortification, because fortificants with higher bioavailability cannot be added in high amounts. In this case, the selection of the fortificant rests on a decision that combines estimation of bioavailability and the highest possible fortification content. For example, for maize flour, it is possible to use 40 mg iron/kg from ferrous fumarate, but only 15 mg iron/kg from NaFeEDTA. If one assumes that the bioavailabilities are 5% and 15%, respectively, any of these two iron fortificants would have a similar biological impact, and the compound with the lowest cost would be preferred (Dary, 2007). Another example is the iron fortification of bouillon cubes with ferric pyrophosphate, which has low bioavailability, compared to water-soluble iron compounds; however, the latter cannot be used because it causes rancidity to the bouillon cube (Gonzalez de Mejia et al., 2015).

Fortificants in the form of encapsulates have been developed for oily vitamins (A and D, e.g.), those required in very small amounts (B<sub>12</sub>) or that are highly reactive (iron). In this form, micronutrients can be incorporated into dry foods. Moreover, micronutrients in encapsulate forms are more stable and negative interactions between the fortificant and food matrix are minimized.

### Cost

The cost of adding fortificants to foods depends on the price of the premix and the selected fortification contents. To design programs congruent with usual production and trade practices, the increment in price due to fortification should not be too high, because it might distort the market and so promote in compliance and unfair competition. Most Large-Scale Food Fortification programs are based on staples and condiments, and the increment in price should be lower than 3%. Although this small increment in the price seems low, some governments do not allow it, because the fortification vehicles are basic components of the family food basket and, therefore, the price might be politically sensitive.

Fortificants with high cost can only be added in certain conditions. Table 1 illustrates why the addition of iodine to salt is much easier than the addition of vitamin A or iron. For example, supplying 100% of the EAR to an adult male consuming 10 g d<sup>-1</sup> of salt, fortification cost per metric ton (100 kg) of salt for iodine, vitamin A, and iron are US \$1.27, US \$42.90, and US \$90.00, respectively. These costs represent 0.42%, 14.3%, and 30.0% of the retail salt price, respectively (assuming US \$0.30/kg). Consequently, the quantity of vitamin A and iron to salt must be low for a program to be feasible, and the additional contribution of these micronutrients by fortified salt would be proportionally lower or negligible. Therefore, addition of these two micronutrients to salt may not be programmatically viable or biologically effective.

**Table 1** Conditions for fortification of salt with different micronutrients.

Nutrient	Fortificant	EAR <sup>a</sup> of adult males (mg)	Nutrient content <sup>b</sup> (mg/kg)	US\$/metric ton <sup>c</sup>	% Price <sup>d</sup>	Dilution factor <sup>e</sup>
Iodine	Potassium iodate	0.100	10	1.27	0.42	1:60,000
Vitamin A	Dry 250,000 IU vitamin A	0.429	42.9	42.90	14.3	1:1750
Iron	Micronized ferric pyrophosphate	30.0	3000	90.00	30.0	1:85

<sup>a</sup>Estimated average requirement (EAR), and assuming a diet with low iron bioavailability.

<sup>b</sup>Estimated for supplying 100% of the EAR of adult males with a salt intake of 10 g d<sup>-1</sup>, and without losses of the micronutrients.

<sup>c</sup>Based on estimated global prices of the fortificants.

<sup>d</sup>Assuming that the salt price is US \$0.30/kg.

<sup>e</sup>Considers that the fortificants are not 100% micronutrient. In this case, iodine in potassium iodate is 59%; vitamin A in a dry beadlet form is 7.5%; and iron in micronized ferric pyrophosphate is 25%.

## Which other technical factors are important in food fortification?

### Physical segregation

Dry food matrices may also suffer segregation (separation) of the fortificant particle from food particles, due to differences in sizes and densities. This mainly affects food matrices with large particle sizes, such as sugar and some types of salt. To avoid segregation, the particle size of the fortificant and the food matrix should be similar, or the fortificant should be adhered to the surface of the food particles. For example, in the case of sugar fortified with vitamin A, the vitamin-containing beadlet is “glued” to the surface of the sugar crystal by means of a layer of vegetable oil. However, during storage and transportation the friction among sugar crystals may separate some of the vitamin A beadlets and reduce the content of vitamin A (Mora et al., 2000). Fig. 1 illustrates how the vitamin A beadlets adhere to the surface of the sugar crystals.

### Dilution factor

The amount of fortificant required to reach the target micronutrient content in a given food is rarely examined when food fortification programs are being considered. Table 1 shows dilution factors in salt for iodine, vitamin A, and iron at fortification contents required to provide 100% of the EAR; these are 1:60,000, 1:1750, and 1:85 (dilution factors are reduced further when the fortificants are incorporated into premixes), respectively. This dilution explains why iodine can be added as a liquid spray, while vitamin A and iron must be incorporated into dry forms. It also explains how the low dilution factor for iron requires large amounts of the fortificant and, therefore, large amounts of premix to be transported, managed and stored. Further, special devices for addition and mixing are required. Other products derived from salt, such as bouillon cubes, face the same type of limitations for fortification with iron if biologically important quantities of this mineral are desired.

### The special case of rice fortification

In developing countries, milled rice is cleaned and washed before consumption and, therefore, the methodology of adding the premix as a powder over the polished rice -as it is the practice in some industrialized countries-is not possible, because the micronutrients are going to be washed out before consumption. Therefore, rice fortification requires the incorporation of the micronutrients either through artificial fortified kernels (where micronutrients are embedded inside the kernel) or micronutrient-coated grains. In both cases, these products are manufactured by highly specialized industries. Furthermore, the dilution factor is between 1:200 and 1:100 which in the case of rice may be compatible as many rice mills mix several types of rice grains, offering different qualities of commercial rice presentations. However, the cost of the enriched kernels may be restrictive, as more than half the cost is associated with the process rather than the fortificant (for other staples, 90% or more of the total cost is due to the fortificant). The cost of rice fortification is between \$10 and \$20 per metric ton, which represents 10–20% of the rice price (assuming \$1/kg) (Alavi et al., 2008). The special manufacturing requirements and cost limit of scaling-up rice fortification, make it viable for only a few countries or social program.

### Types of food fortification

Three main types of food fortification were identified by the WHO/FAO (Allen et al., 2006) based on application and scope: mass-, targeted-, and market-driven. The same food can support any of the three types of fortification. For example, rice could be

**Fig. 1** Microphotography of vitamin A beadlets (fortificant) attached to sugar crystals (food matrix) by means of a thin layer of vegetable oil. Reproduced with permission from DSM.

mass-fortified if the country decides that all rice distributed to the population should be fortified, as in Costa Rica (Martorell et al., 2015). Fortified rice may also be used for targeted fortification if it is produced and distributed through specific social programs (Rai et al., 2019), such as in humanitarian food aid programs supported by USAID or the World Food Program. Finally, rice could also be used for market-driven fortification, as in China, where industries launched fortified rice aimed at high-income groups (Alavi et al., 2008).

### **Mass-fortification**

Mass-fortification is defined as that aimed to the general population using an already widely consumed product, without requiring changes in consumer behavior. In mass-fortification, patterns of consumption of the fortified food are determined and vary considerably among countries, regions, age groups, and socio-economic strata. This variation in food intakes limits the quantity of micronutrients that can be added because of the need to avoid excessive intakes by individuals with high intake of the fortification vehicles. Mass-fortification uses staples and condiments, which are products extensively and widely consumed. Voluntary fortification of these products is difficult because the consumer usually does not select the product by brand, and because these foods are ingredients of other processed foods and therefore “hidden” to the consumer. Moreover, small differences in price may distort the market for staples and condiments or be politically sensitive. Therefore, this type of fortification is usually mandatory and instigated by governments, and the standards are usually made compulsory through specific regulations.

Mass-fortification requires strong governmental enforcement, both for ensuring compliance of the standards as well as for creating a leveled playing-field among producers. Food industry is hesitant to adopt fortification if they do not see that the market is protected or that governmental enforcement is not guaranteed.

It is important to note that mass-fortification should not increase the intake of the food vehicles, as high consumption of most (salt, sugar, oil, refined cereal flours, polished rice) are discouraged with the purpose of preventing non-communicable diseases. Therefore, promotional campaigns on mass-fortification are not needed, because the consumers should keep their usual dietary habits. The strategy is to use fortified foods as practical delivering vehicles of micronutrients, but not to raise their intake. In this sense, mass-fortification may not have an economic incentive for the involved industries, but it is more in the area of reputational prestige and social responsibility toward the societies that they serve.

### **Targeted-fortification**

Targeted fortification describes the strategy designed for specific population groups, such as infants and young children (complementary foods), school-feeding and public health or social programs, which are implemented for benefiting special vulnerable groups. Fortified foods are generally given in specific serving sizes and, because other fortified products are rarely available, the micronutrient content is high to meet daily nutrient requirements using a few products. Furthermore, because the products are frequently subsidized, higher micronutrient content is feasible, because the cost or retaining the characteristics of the unfortified foods are not too restrictive. Fortification standards of targeted-fortification are different from those of mass-fortification, although the same food vehicle may be used, as the conditions and the intended target population for the two types of food fortification differ.

### **Market-driven fortification**

Market-driven fortification occurs when the food industry decides to introduce additional perceived value to their product to attract consumers toward a food with enhanced nutritional value. These products are usually packaged, labeled, and branded. An increasing number of countries are enacting standards that apply to these products, including nutritional claims and advertising, with the purpose of preventing unnecessary high micronutrient exposure, or to protect the consumer against misleading advertising of products that may not be healthy. The Codex Alimentarius encourages competent national or regional authorities to establish specific provisions for the addition of nutrients in food standards according to the national or regional nutritional context, including population dietary habits and specific nutritional guidelines. Thus far, few countries have introduced standards for market-driven fortification, including minimum and/or maximum contents within which essential nutrients should be present, or specifications of foods that should not have added vitamins or minerals, based on their nutrient profile. Although market-driven fortification is applicable voluntarily, governments have the responsibility of enacting standards and regulations.

### **Home fortification or fortification at the point of consumption**

The terms home fortification or fortification at the point of consumption have been used to describe use of micronutrient supplements in the form of powders that are mixed with foods just before consumption (WHO, 2011). The fact that the product is mixed with foods before being consumed does not represent an example of food fortification. Indeed, this is clear example of micronutrient supplementation, because the vehicle that is used for carrying the micronutrients is a supplement and not a fortified food.

## What else is needed to implement a fortification program?

The usefulness and success of any food fortification program requires that it is programmatically controllable and that its dietary contribution is assessed periodically. This implies the existence of practical, efficient, and reliable mechanisms for compliance and enforcement, and the introduction of dietary monitoring systems to document the epidemiological significance of the programs.

## Compliance and enforcement

Compliance and enforcement are based on the usual practices of food control, which have two components: internal checking by the industry and external confirmation by governmental authorities (Rowe, 2020). Internal checking refers to quality assurance (actions during production that are needed for complying with standards and technical specifications) and quality control (chemical and physical analyses of samples of the industry-manufactured products to check compliance with the standard and specifications, including fortification) by the food industry.

External confirmation (also known as regulatory monitoring) includes auditing (review of the industry quality assurance procedures and their documentation) and inspection (confirmation that the product complies with standards and technical specification through sampling at the production places, distribution centers and retail outlets, and importation sites) by governmental authorities responsible for public food safety.

The most important components are quality assurance and auditing, as they establish good manufacturing practices along the chain of production with the purpose of implementing timely correcting actions (Guamuch et al., 2007a).

Quality control and inspection demonstrate that the final product complies with the criteria of presentation; labeling and packaging; toxicological and microbiological safety; expected technical properties and, in the case of fortification, the specified micronutrient content. Fortification is only one element measured in these systems. Quality control and inspection require testing a few samples of foods per day, week, or month, as compliance and enforcement mostly depend on operational quality assurance and auditing actions. Fig. 2 illustrates quality control data for fortified wheat flour by formal industry testing of two daily composite samples (i.e., combination of single samples taken systematically during the day) per week.

The Central American technical standard (RTCA 67.01.15:06) specifies a minimum content of 55 mg iron/kg. Historically, standards for micronutrient content usually specify “minimum” values. However, this has created problems, because the micronutrients low concentration with variation around the mean depending on several factors: the nature of the food (liquid or dry), quantity of the fortificant (high or low), quantity of the food used for the analysis (large or small), mixing performance (good or inefficient), variation of the analytical method (small or large), and others. Fig. 3 illustrates the hypothetical example of using single or composite food samples for the determination of micronutrient content. Although the mean is similar in the two cases, the proportion of samples below the “minimum” value is much larger using single samples, even in the case where the fortification process might be appropriate and acceptable. Therefore, it is preferable to specify in the standards the mean content (i.e., the target content) as the most important value to check. For promoting homogeneity, an allowable range around the mean should also be added, and the analytical conditions should be described in detail to interpret the results against those reference values. For example, in the case

**Fig. 2** Quality control data of fortified wheat flour (iron content) in the CENTIA flour mill of Guatemala, using daily composite samples (i.e., combination of several single samples taken systematically during the day). SD = Standard Deviation; CV = Coefficient of Variation;  $P_{10}$ - $P_{90}$  = Range between percentiles 10-90 for a program with 80% compliance;  $P_5$ - $P_{95}$  = Range between percentiles 5-95 for a program with 90% compliance.

**Fig. 3** Hypothetical example of the distribution of results of the iron content in fortified wheat flour analyzing single (27% below minimum reference value when the standard deviation is 25 mg iron/kg) or composite samples (11% below minimum reference value when the standard deviation is 12 mg iron/kg), when the average content is 70 mg iron/kg and the specified “minimum” content is 55 mg iron/kg.

of wheat flour fortification using the Central American technical standard, around ten percent of results may be below the “minimum” value of 55 mg iron/kg, when the average iron content is 70 mg iron/kg, if composite samples are analyzed. However, in single samples, around 27% of samples may be found with values below 55 mg iron/kg. In both cases, the fortification process is fine (Fig. 3).

The specification of “minimum” values instead of average contents in the standards of fortified foods has also caused that, in many countries the micronutrient contents are much lower than expected. Some industries have interpreted the “minimum” values as the target value and, therefore, they add lower amounts of the fortificant.

If the value of compliance is a “minimum” value, large amounts of fortificants are needed in those foods with a large micronutrient content variation (Fig. 4). If the criterion of the “minimum” is enforced, it will increase the cost and negative sensorial reactions in fortified foods, due to high micronutrient content. Further, there is risk that these products may supply excessive quantities of micronutrients to the population.

If the coefficient of variation of the micronutrient content is larger than 30%, based on the analysis of single samples, it would be necessary to prepare composite samples to reduce the variation in the results. If this is not done, the values of the allowable range that responds to the reality of the process will be too large to be useful. Table 2 shows the situation for iodized salt in Mexico. The allowable ranges, either using 80% (i.e., percentiles 10–90) or 90% compliance (i.e., percentiles 5–95), would increase from refined (“vacuum-crystallized”) to fine (washed) to coarse types of salt, although all three types of salt are providing sufficient iodine to the population. Therefore, using the same standard for the three types of salt would be inappropriate. In this case, the use of composite samples reduces the variation of the results but is insufficient for “correcting” the situation for the coarse salt samples, whose results may even produce negative values (contents lower than 5 mg iodine/kg) despite that iodization is taking place. Using composite

**Fig. 4** Hypothetical example of the distribution of results of the iron content in fortified wheat flour if a “minimum” content of 55 mg iron/kg is enforced under two different scenarios of variation. For a compliance that less than 10% samples are below the required “minimum,” if single samples (high variation, standard deviation = 25 mg iron/kg) are used, the average content should be 87 mg iron/kg. On the contrary, if composite samples (low variation, standard deviation = 12 mg iron/kg) are used, the average content should be 70 mg iron/kg.

**Table 2** Iodine content in three different types of salt in Mexico.<sup>a</sup>

samples has the additional advantage of requiring a lower number of analytical tests; in this example one-fifth of the total number as using single samples.

## Dietary monitoring

Finally, a food fortification program is not complete if it lacks periodic evaluation of its performance and effectiveness at the consumer level (A2Z-Project, 2008). This means estimating the contribution of consumption of fortified foods to reduce the micronutrient inadequacies in different strata of the population (Engle-Stone et al., 2014; Friesen et al., 2020; Williams et al., 2021). For this purpose, micronutrient intakes should be estimated in the absence and presence of fortification programs. Three types of data are needed: (a) the basal micronutrient intakes from the usual diet, for estimating the magnitude and extension of the micronutrient inadequacies; (b) the customary intake values of the fortification vehicles; and (c) the average of the additional content of micronutrients supplied through the fortified foods. The multiplication of the last two values permits estimating the additional micronutrient intakes associated to the food fortification programs (Table 3). Food intakes can be obtained through food intake

<sup>a</sup>It was estimated that the current contents of vitamin A in cooking oil, sugar, and wheat flour are 10 mg/kg, 7.0 mg/kg, and 0.8 mg/kg, respectively.

<sup>b</sup>Possible situation if compliance of these fortification programs improves. The corresponding contents of vitamin A would be 21 mg/kg, 10.5 mg/kg, and 1.8 mg/kg, for oil, sugar, and wheat flour, respectively.

Courtesy of Tang et al. (2021).

surveys, or approximating them using secondary analysis of food acquisition data collected in household economic surveys, which are identified under the generic name of “household consumption and expenditure surveys” (Fiedler et al., 2013). Information on the micronutrient content in the fortification vehicles is obtained by analyzing samples of fortified foods collected at local levels (households or local retail stores) and determining if they are fortified or not using qualitative tests and, importantly, measuring the average micronutrient content in composite samples per cluster or subregion, using quantitative tests (Guamuch et al., 2007b).

Table 4 shows that the combination of oil and sugar fortification is needed to provide sufficient vitamin A to certain populations, such as Malawi, as the inadequacy of this vitamin fails to be corrected for all population groups even with these two fortified foods. As expected, the dietary impact of food fortification programs is better in urban than in rural areas. Currently, in Malawi, the role of fortified wheat flour is negligible, as the intake of products made with wheat flour is very low in most population strata of the country. Maize flour, although an important staple in the country, was not included in the analysis because it is processed by hundreds of small mills and, therefore, is not suitable for large scale food fortification.

Often, the performance of food fortification programs has been defined as the percent of compliance with national fortification standards at the household level. This is an erroneous practice as fortification standards are not applicable to the home level because some losses of the micronutrient are expected (Table 5). Further, measuring the micronutrient contents in single samples (generally without following the recommendations of the analytical tests) unreliable results are produced. At the consumer level, it is important to estimate the average additional supply of micronutrients through the fortified foods and not the percent of samples that comply with standards. Table 4 shows that the fortification programs can have epidemiological impact even though the fortified foods do not have the micronutrient contents specified in the standards.

The final proof of impact of food fortification programs is improvement in biomarkers associated with micronutrient status. These assessments are not specific to food fortification programs and are preferable to be done in combination with the evaluation of other nutritional and health interventions, through well designed and executed nutritional surveillance programs (Williams et al., 2021).

**Table 5** Prediction of vitamin A contents at households based on the added contents at factories and the estimated stability of the nutrient to homes—example of Malawi.

Food	Added content (mg/kg)	Stability from factory to homes (%)	Predicted micronutrient content at homes (mg/kg)
Vegetable oil	30.0	70	21.0
Sugar	15.0	70	10.5
Wheat flour	2.0	90	1.8
Maize flour	0.5	80	0.4

## Conclusions

Food fortification, especially large-scale food fortification, may be an effective and low-cost intervention to reduce micronutrient inadequacies, therefore contributing to prevent their deficiencies, if appropriately designed and implemented. The design of the programs depends on the selection of fortification vehicles that are routinely consumed by the vulnerable populations and manufactured by formal and centralized food industries. As micronutrient content may be limited because of safety, technological or costs constraints, fortification vehicles should be consumed in reasonable amounts by the target population, and micronutrient content set as low as possible to fill dietary nutrient gaps. As most fortification vehicles are foods whose consumption should be reduced to prevent non-communicable diseases, fortification should not be used for promoting the consumption of those foods. Correct implementation of food fortification programs requires the introduction of systems to check processing (quality assurance by the industry and auditing by the government), complemented with practical, simple, and low-cost measures of compliance (quality control by the industry and inspection by the government). These should be based on the use of qualitative and quantitative methods, the latter applied to composite samples following detailed procedures and instructions for interpreting results. Finally, these programs must include an epidemiological surveillance component to periodically assess population coverage and dietary contributions which, in turn, will help for scaling-up, sustainability and recognition of food fortification as an important intervention in public health nutrition.

### Key points

- To present various aspects of interest in relation to contamination by metallic elements in foodstuffs.
- To highlight the importance of the mechanism of toxic action of certain metallic elements and the consequences of interaction with target organs.

- To know the toxicity on humans of the main heavy metals and metalloids of interest in Food Toxicology, especially in chronic intoxication.
- To know that the International Agency for Research on Cancer (IARC) has classified certain metals and metalloids (Cd, Cr, Ni and As) as carcinogenic to humans.

## Glossary

Acceptable Daily Intake (ADI)  
Arsenic  
BMD (Benchmark Dose)  
Cadmium

Provisional Tolerable Weekly Intake (PTWI)  
Tin

## Introduction

Food toxicology is the branch of toxicology that specifically deals with toxicity (acute and long-term) problems arising from the presence of toxic substances in food. The great tragedies of toxic origin over the last 100 years have been linked to food contamination. In fact, food contamination by toxic agents is one of the problems of greatest concern to public health authorities. Environmental pollution represents one of the current major problems in food contamination. Pollution of air, soil, inland and marine waters is mainly a consequence of human activity (industrial, agricultural, domestic) which, indirectly, allows the incorporation of pollutants into plants and animals. The food products coming from these polluted organisms can cause harmful effects to the health of the consumers. The main xenobiotics from environmental pollution include metals and metalloids such as lead, mercury, arsenic, cadmium, tin and copper.

## General aspects

The release of heavy metals from emissions, toxic discharges, etc., is one of the main consequences of industrial pollution. Although the concentration in the environment is usually not very high, the enormous power of accumulation and environmental persistence, together with the high toxicity of these compounds, determines the possibility of generating important toxicological problems. Therefore, their study in food toxicology is essential.

Environmental contamination by metals is very diverse and comes mainly from industrial emissions, agricultural effluents, fungicides and biocides, etc. As a result of the wide variety of anthropogenic activities, the concentration of these pollutants in ecosystems has increased dramatically in recent decades. Due to the intrinsic toxicity of metals, their presence in the environment constitutes a potential threat to terrestrial and aquatic biota, negatively affecting the different species of biotic communities, including the human species (Gómez et al., 2007).

A key aspect in the toxicity of metal ions is the dose. In some cases, they act as essential constituents of living organisms, and their deficiency may lead to health problems. For example, a decrease in fluoride promotes dental cariogenic processes. Also, when selenium is deficient, the enzymatic defense systems against oxidative stress are less efficient. This sometimes determines their use as dietary supplements. However, some of them (fluorine, copper, zinc, selenium, etc.) are also capable of causing alterations when they are present in excess. In fact, there is a narrow margin between what would be a toxic dose and nutritional requirements. On the other hand, other elements (e.g., arsenic, lead, mercury or cadmium) are typically toxic as they have not been attributed an essential role in the organism so far. In this regard, dietary habits can significantly influence exposure to any food contaminant, including heavy metals (Gil et al., 2017).

Another interesting aspect is the chemical form. The metallic (elemental) form is usually non-toxic, with a few exceptions (i.e., mercury vapor), whereas the ionic forms (organic and inorganic salts) are quite toxic depending on the metal. Due to the variation in toxicity of the different metal forms, the determination of the total metal concentration (i.e., all ionic forms) is not always useful. Therefore, speciation analyses are important as they are able to separate and detect each of the metal forms (Gil et al., 2017).

Moreover, it is possible to establish a number of general characteristics in relation to the toxic effects of heavy metals and metalloids. These include the following (Pla et al., 2019):

- They tend to accumulate in the body, with a high affinity for -SH (thiol or sulfhydryl) groups of enzymes (e.g., arsenic blocks the pyruvate dehydrogenase complex). This selective binding by chemical affinity may mean that even at relatively low levels of exposure, they accumulate in the body to produce the delayed toxic effect.
- Their toxicity increases with the degree of oxidation.
- Numerous factors can modify the toxicity of metals. These include possible pathological alterations affecting the kidney (essential in the excretion of metals), increased or decreased permeability of the intestinal mucosa, interaction with other nutrients in the diet (e.g., calcium competes with lead; vitamin D promotes intestinal absorption of lead, etc.), fasting situations, age, among others.

Due to their cumulative properties and toxicity, heavy metal concentrations could reach levels that are potentially harmful to human health. Cadmium (Cd), mercury (Hg), lead (Pb) and arsenic (As) are non-essential toxic elements of particular concern because of their toxicity even at low concentrations (Hsu et al., 2006; Rao et al., 2011).

On the other hand, the level of metal accumulation in plants is influenced by numerous physicochemical properties of the soil (sediment characteristics, pH, dispersion range and presence or absence of other elements), which are determinants in the bioavailability of these xenobiotics (Sarma et al., 2011; Hernández and Gil, 2016). Furthermore, although plants readily assimilate metals through the roots, they can also do so through the leaves (Łozak et al., 2002). Cooper et al. (2007) found that certain Chinese medicinal preparations were highly contaminated with As, Pb and Hg, which theoretically would imply a serious risk to consumers. However, the risk assessment of the exposure to metals in food should take into account not only the level of the metal but also its bioavailability in the body.

The International Agency for Research on Cancer (IARC) has classified certain metals and metalloids (As, Cd, Cr, and Ni) as carcinogenic to humans due to their ability to induce DNA damage. Thus, it is important to analyze their presence in food in order to avoid excessive human impregnation. There is growing concern about the health risks of the exposure to metallic and metalloid elements, especially arsenic, because of its carcinogenic and neurotoxic potential, and its possible effects on the developing brain of children (Sarma et al., 2011; Hernández and Gil, 2016).

In 2020, the US Food Drug Administration (US FDA) released Closer to Zero, the agency's action plan for reducing toxic elements (metals) in the foods eaten by babies and young children (Woodcock and Mayne, 2021).

## Lead

### Dietary exposure

Lead is a ubiquitous metal and its use in kitchen utensils dates back to Roman times. The Romans treated these utensils (usually of copper) with alloys containing lead. It was also used in the preservation of wines. Lead poisoning was even described in the United States as a result of drinking whisky distilled in automobile radiators that contained lead.

Probably one of the main problems with lead is that it is very easily dissolved by weak acids (carbonic), organic acids (citric, acetic, tartaric, etc.) and fatty acids released from rancidity processes.

Numerous sources of exposure, which until recently caused food contamination problems, have now been eliminated. The main sources (Gil et al., 2017; Villanueva and Gil, 2018a) include (Table 1):

- Canning tins, especially where pickled foods or fruit juices were stored, which had a lead-containing solder, which could solubilize on contact with acetic acid. At present, the cans have an internal coating, usually chrome, or a special lacquering, and the soldering has been eliminated.
- Earthenware and ceramic utensils that are colored and/or vitrified with lead glazes (based on lead sulfide).
- Leaded glass vessels.
- Water pipes, which were formerly made of lead. They have now been replaced by Polychloride vinyl (PVC), which is an inert material. Thus, hard water, coming from granitic soils, could drag lead from the pipes.
- Tetraethyl lead has been used until recently as an antiknock agent in "leaded" gasoline. This has been responsible for the pollution caused by deposition of lead on leaves and fruits around motorways and busy roads. As a result of the harmful consequences of environmental lead emissions, the US Environmental Protection Agency (US EPA) banned this fuel in 1996. Another consequence of the ban on the use of leaded gasoline was the drastic decrease in lead levels in general and in foods in particular, especially vegetables and, to a lesser extent, cereals, tubers and fruits (Falcó et al., 2006).

**Table 1** Heavy metal and metalloid dietary exposure and toxicity.

Heavy metal	Dietary exposure	Toxicity
Lead	Canned food, leaded glass containers or ceramic food utensils, water, wine treated with pesticides. Migration is higher in the case of foods in contact with weak acids	Anemia (blockage of the hemoglobin synthesis pathway), neurocognitive impairment, intellectual deficit, encephalopathy, irritability
Mercury	Seafood products (biotic transformations to methylmercury-e.g., tuna fish-), food treated with organomercury fungicides, nuts (walnuts, almonds), some fresh fruits (raspberries)	Organic: cerebellar ataxia, paresthesias in hands and mouth, dysarthria, personality disorders, mental confusion, neurodevelopmental impairment, teratogenic effects. Inorganic: renal alterations (tubular necrosis and renal failure) and local irritant action on gastrointestinal tract (acute gastroenteritis and colitis)
Cadmium	Food contaminated with residues derived from pigment, battery industries or phosphate fertilizers, offal (liver, kidneys, lung), crabs and bivalves (oysters and scallops), vegetables (spinach, lettuce, soybeans, cereal -rice- and peanuts)	Renal dysfunction (tubular interstitial nephritis with hypercalciuria and proteinuria), osteomalacia, carcinogenic (prostate, testicular and lung)
Nickel	Vegetables (including mushrooms, spices and condiments, legumes, spinach, lettuce, nuts and oilseeds), baking powder and cocoa powder. Migration is higher in the case of foods in contact with weak acids	Carcinogenic in humans. Oral exposure does not usually cause dermatological reactions
Tin	Canned foods, cereal grains, dairy, meat and vegetables. To interfere with the metabolism of certain trace elements.	There is no evidence that cause cancer in humans
Copper	Seafood products (oysters), sheep, fruits, cereals, nuts and green vegetables, wine treated with fungicides	Irritant action on gastrointestinal tract (nausea, epigastric burning and diarrhea) and hepatotoxicity (hepatomegaly and jaundice)
Metalloid	Dietary exposure	Toxicity
Arsenic	Seafood products (crustaceans and shellfish), rice, food treated with pesticides (arsenate)	Carcinogenic in humans (skin), sensorimotor polyneuropathy and dermatological alterations (palmoplantar hyperkeratosis, mees bands on the nails)

- Wine, especially rosé and white wine, with a more acidity. The origin is multiple: insecticides treated with lead arsenate or from the leaded foil that covers the corks of bottles; when the cork dries out and retracts in bottles that have been stored horizontally for a certain period of time, the alcohol oxidizes to acetic acid, which can solubilize the foil, forming lead acetate.

### Permissible intakes

The daily intake of lead is around 20–25 µg/g and the maximum contribution through the diet comes in general from cereals and in particular from bread (Falcó et al., 2006).

The average lead in food is estimated to be 0.05–0.2 µg/g and in water 10–20 µg/L. FAO/WHO expert committee recommended that the weekly intake per person (provisional tolerable weekly intake, PTWI) of lead should not exceed 25 µg/kg body weight (1500 µg/person weighting 60 kg). Although EPA established an action level of 0.015 mg/L (15 ppb or µg/L) for Pb, more recently EPA has set the maximum contaminant level goal for lead in drinking water at zero because lead can be harmful even at low exposure levels (Gil et al., 2017).

With regard to lead, which may be released from certain ceramic utensils, the International Organization for Standardization has established maximum limits of 1.7 mg/dm<sup>2</sup> for flat wares and 2.5–5.0 mg/L in solution for the concave ones.

The limits in foodstuffs are summarize in Regulation (EU) No 420/2011 of April 29, 2011, which amends points 3.1.6, 3.1.9, 3.1.10 and 3.1.11 of Regulation (EC) No 1881/2006.

### Toxicokinetics

Absorption of lead from the digestive tract is highly variable and relatively low (10–20%). Pregnant women and children (who are more susceptible to the toxic effects of lead) may absorb a higher amount and this depends on the nutritional status (levels of calcium, phosphate or iron can influence their uptake). Once absorbed, it is distributed in blood bound to erythrocytes (>95%), most likely due to its high affinity for delta-amino levulinic acid dehydratase, leaving a small fraction in plasma. It accumulates in the epiphysis of long bones (e.g., femur, tibia and humerus), being eliminated mainly through urine (75%), to a lesser extent through feces and also through nails and hair.

## Toxicity

Lead in food is mainly responsible for chronic intoxications, given its cumulative character. It follows the metabolism of calcium, hence it can be stored in the form of deposits, especially in bone tissue, in epiphyseal areas, and can be mobilized in certain situations of metabolic calcium turnover.

A limit concentration without biological effect is established at 35  $\mu\text{g}/100\text{ mL}$  in blood. However, in children, due to a higher permeability of the blood-brain barrier, it has been shown that with much lower levels (even below 10  $\mu\text{g}/100\text{ mL}$ ), neurocognitive alterations together with intellectual deficit may appear (Table 1). Classically, four main effects can be distinguished (Villanueva and Gil, 2018a):

(a) Hematological effects. There are two types: metabolic and morphological.

Metabolic effects are due to the inhibition of various enzymes involved in the biosynthesis of the heme group (see Fig. 1):

- Delta-aminolevulinic acid dehydratase (catalyzes the conversion of delta-aminolevulinic acid to porphobilinogen). It is the most specific and selective, and can be used as a biomarker of response or effect to lead. Under normal conditions it should be higher than 100 U/ $10^6$  erythrocytes (Gil and Hernández, 2009).
- Coproporphyrinogen oxidase (catalyzes the passage from coproporphyrinogen III to protoporphyrinogen III).
- Heme synthetase or ferrochelatase (leads to the formation of the heme group, by incorporating a  $\text{Fe}^{2+}$  atom into the tetrapyrrole nucleus of the protoporphyrin IX or zinc-protoporphyrin).

**Fig. 1** Heme group synthesis in bone marrow erythroblasts and enzymatic interference (inhibition) by lead.

The morphological effects result in the appearance of red blood cells with basophilic granulations (consisting of non-heme iron, ribosomes and RNA).

The most important hematological consequence is a significant decrease in hemoglobin and anemia (an earthy skin tone).

- (b) Effects on the central nervous system. The occurrence of encephalopathy is possible, especially in children (Pb can cross the placental barrier and interfere with placental transport systems, thereby increasing prenatal exposure to these toxic compounds), at levels of 45–50 µg/100 mL in whole blood and above. It is characterized by headaches, irritability, memory loss, etc. The most important consequences are epilepsy and hydrocephalus. Reduced cognitive development and learning problems have been described at relatively low doses.
- (c) Effects on the peripheral nervous system. The most important alterations are revealed in the electromyogram. Motor conduction slowing, fibrillations, decrease in the number of motor units involved in the maximal contraction, etc. may appear. Sensory disturbances may also be observed. In severe cases, there is a neuritis consisting of a radial paralysis affecting the extension of the fingers excepting the supinator longus, which means that the middle and ring finger cannot extend.
- (d) Other effects. At present, it is very difficult to develop chronic end-stage saturnism with glomerular involvement and gout. During the saturnism phase, the so-called saturnine colic is accompanied by intense and diffuse pain, vomiting, diarrhea that progresses to persistent constipation and significant general involvement. However, such clinical syndrome, which was relatively common in the workplace, would be an exception in food toxicology, since exposure levels are relatively low. Lead has also been described as having the capacity to cause chromosomal alterations, especially at blood levels above 65 µg/100 mL. Pb exposure has also been associated with renal tumors and increased blood pressure, and cardiovascular disease probably due to an alteration in natriuretic peptide (Goyer and Clarkson, 2001; Garcia-Rico et al., 2007).

## Mercury

### Dietary exposure

Mercury has probably caused the greatest food-borne problems. Several poisonings have occurred throughout history, most notably in the Minamata Bay (1953) in Japan, due to the consumption of fish contaminated with methylmercury. Also, there was a massive poisoning in Iraq (1972) due to the consumption of bread made from wheat treated with organomercury fungicides. Mercury contamination has also been described in poultry and eggs due to contamination of the fishmeal used in their feed (Villanueva and Gil, 2018b).

The most important sources of food poisoning are the treatment of seeds with organomercurial fungicides and industrial discharges into inland or marine waters (Table 1). In general, discharges are in inorganic form; however, fish (and particularly tuna, sharks, swordfish, etc.) are capable of methylating it (biotic transformations) thanks to the micro-organisms present in their gills or those in the marine plankton (Gil and Gil, 2015). As a result of this process, it is obtained mainly monomethylmercury and dimethylmercury (10 and 1500 µg/kg have been found in some fish). On the other hand, it should not be forgotten that the organic forms are much more toxic to humans. Therefore, the main source of contamination of foodstuffs (>90%) is organic mercury and, commonly derives from fishery products (Olmedo et al., 2013).

Plant contamination through roots is usually minimal. In general, foods of vegetal origin are not contaminated. However, significant contributions have also been described in nuts (walnuts, almonds, etc.) and in some fresh fruits (raspberries, etc.). Some mushroom species can have considerable levels of mercury.

### Permissible intakes

The FAO/WHO Expert Committee on Food Additives sets a provisional tolerable weekly intake level (PTWI) of 0.3 mg of total mercury per person, of which, as a maximum, no more than 0.2 mg should be present in the form of methylmercury. These amounts are equivalent to 0.005 and 0.0033 mg respectively per kilogram of body weight (300 and 198 µg/person weighting 60 kg, respectively). When the total mercury intake through food exceeds 0.3 mg per week, the concentration of methylmercury compounds should also be investigated (Gil et al., 2017).

Mercury in hair can be used as a biomarker of chronic exposure due to the metal's affinity for keratin-rich structures.

### Toxicokinetics

Organic mercury compounds are very well absorbed by the digestive tract (95%), but inorganic and metallic mercury (7%) are not. Organic forms and metallic mercury are distributed to the central nervous system (it cross the blood-brain barrier) thanks to their high liposolubility. They are selectively accumulate in the hippocampus, cerebellar gray matter and calcarine cortex. On the contrary, inorganic mercury, which is not liposoluble, is fixed to the kidney (Villanueva and Gil, 2018b).

### Toxicity

Intoxication by organic mercury compounds is characterized by a progressive neurological and encephalic syndrome. Clinical syndrome is essentially cerebellar (methylmercury is distributed in the Purkinje and Golgi cells of the cerebellum as well as in three

different layers of cerebral cortical cells) with paresthesia in the hands and around the mouth, cerebellar ataxia, dysarthria, personality disorders and mental confusion (**Table 1**). Cortical signs also appear, leading to a progressive loss of visual field and hearing acuity. Finally, it should not be overlooked the teratogenic power of organic mercury, since it is capable of crossing the placental barrier, as it was shown in the Minamata poisoning. Therefore, swordfish and tuna are fishery products that should be avoided during pregnancy, to minimize the risk of high mercury intake. In fact, alterations observed following in utero exposure to organic mercury compounds during the Minamata and Iraq poisonings included increased percentage of spontaneous abortions, low weight at birth, brain and cerebellum malformations, abnormal neuronal migration pattern and neurodevelopmental impairment.

In the later stages of chronic poisoning, there is a possibility of renal damage.

On the other hand, poisoning by inorganic compounds is characterized by renal tubular necrosis with tubular obstruction and preglomerular vasoconstriction, leading to renal failure. It is usually accompanied by acute gastroenteritis, stomatitis and ulcerative hemorrhagic colitis as a consequence of the local irritant action of these compounds (Goyer and Clarkson, 2001; Garcia-Rico et al., 2007; Gil, 2018).

## Cadmium

### Dietary exposure

The presence of cadmium in the environment is due to anthropogenic pollution resulting from its industrial uses. In industry, this element is used as a pigment in the manufacture of paints, in foundries, in battery and semiconductor factories, as a waste product of the electrolysis process leading to the cadmium plating of metals, as a covering of other metals, in various fertilizers and in stabilizing additives for plastics. Another possible source of contamination comes from the use of colored pottery; some glazes, especially yellow glazes, can release cadmium when in contact with acid foods (Gil et al., 2017).

One of the most important characteristics of cadmium is its easy transfer from soil to plants, in which it differs markedly from lead. This fact determines that plants which have been fertilized with phosphate contain significant amounts of cadmium, as it is found as an impurity in these fertilizers. As a consequence, this makes exposure to Cd through the food-chain contamination a public health concern.

With regard to food of animal origin, it does not usually contain very high levels of cadmium, with the exception of offal (liver, kidneys, lung, etc.) (**Table 1**). Crabs tend to have the highest concentrations, and bivalves (oysters and scallops) have the capacity to bioaccumulate this element thanks to their filtration power. Seafood, such as mussels and oysters, can be a major source of cadmium in the diet, containing between 100 and 1000 µg/kg. Cadmium accumulates in certain vegetables (e.g., spinach, Romaine lettuce, soybeans, cereal crops and peanuts) due to the use of fertilizers and irrigation water containing cadmium. Fruits contain approximately 1–50 µg/kg and cereals 10–150 µg/kg. Drinks contain relatively low levels, as well as drinking water (usually less than 4 µg/L) (Satarug et al., 2017).

### Permissible intakes

The Joint FAO/WHO Expert Committee established 7 µg/kg body weight per week (420 µg/person weighing 60 kg) as provisional tolerable weekly intake (PTWI). At the present moment, tolerable intake is 25 mg per kg body weight per month (0.83 mg/kg body weight per day or 58 mg/day for a 70 kg person) (Satarug et al., 2017). The maximum concentration for water proposed from US FDA is 5 µg/L. Regulation No 488/2014 of May 12, 2014 amends Regulation (EC) No 1881/2006 of subsection 3.2 of Regulation (EC) No 1881/2006 and includes the maximum permissible levels (expressed as mg/kg fresh weight) in many food-stuffs, both vegetal and animal.

### Toxicokinetics

Oral cadmium absorption is high and can be increased by some trace elements such as zinc, iron or calcium. It is transported by blood cells and the main transport protein in plasma to the kidneys is the metallothionein, a low molecular weight protein cysteine-rich with numerous thiol binding sites. Metallothionein is induced by cadmium exposure and can be filtered through the kidney glomerular membrane (when its binding capacity is exceeded, renal toxicity occurs) (Gil, 2018).

Cadmium is distributed to various organs and tissues, mainly (more than 70%) to liver, muscles and kidneys, the latter being the target organs. Excretion is through the urine and at a very low rate, which justifies its extensive accumulation in the organism (the half-life in the kidney cortex and liver can be as long as 20–25 years).

### Toxicity

As indicated above, the most important target organ is the kidney, which justifies that most of the manifestations that characterize cadmium poisoning are a consequence of renal damage. In chronic poisoning, there is a significant renal dysfunction (**Table 1**) consisting of tubular interstitial nephritis with distal progression and without glomerular impairment; this leads to a “cadmic

proteinuria" with the appearance in the urine of mainly low molecular weight proteins ( $\beta_2$ -microglobulin, retinol binding protein, etc.). In the long term hypercalciuria sets in, leading to bone alteration with osteomalacia of renal origin, associated with severe bone pain and pathological fractures. These clinical aspects were evidenced in "Itai Itai disease" as a result of consuming rice contaminated with cadmium in the Kakehashi River Basin (Ishikawa, Japan) (Gil, 2018).

The Agency for Research on Cancer (IARC) has determined that cadmium and cadmium compounds are carcinogenic in humans. The EPA determined that cadmium is probably carcinogenic in humans (Group B1) and is capable of inducing prostate, testicular and lung cancers (Agency for Toxic Substances and Disease Registry, ATSDR).

## Nickel

### Dietary exposure

Nickel is widely distributed in nature and is present in water, soil, plants and animals. It is used in alloys because of certain properties such as heat and corrosion resistance as well as ductility. In fact, it is commonly used in the metallurgical and electroplating industry and also as a catalyst in the chemical industry. The main source of nickel exposure for the general population is food and water. Plants (vegetables and vegetal products, including spices and condiments, legumes, spinach, lettuce, nuts and oilseeds, etc.) are the main sources of nickel exposure. The concentration of this metal in these products depends to a large extent on the nickel content of the soil and also varies according to climate and season (Table 1). Baking powder and cocoa powder may also contain an excess nickel (Klein and Costa, 2007; Mania et al., 2019).

Nickel can also be released from materials made of nickel in contact with foods (migration is higher in the case of acidic foods or foods with citric or acetic acid) (Gil and Gisbert-Calabuig, 2018).

### Permissible intakes

The recommended dietary allowances for nickel have not been established but, estimated maximum guideline set by US FDA for Ni is 70–80  $\mu\text{g/g}$ . The European Food Safety Authority (EFSA) estimated the tolerable daily intake of nickel from any food source at 2.8  $\mu\text{g/kg}$  body weight, which is 196  $\mu\text{g}$  for an adult and 56  $\mu\text{g}$  for a child. It also determined the Benchmark Dose Lower Confidence Limit (BMDL<sub>10</sub>) associated with dermatitis at 1.1  $\mu\text{g/kg}$  body weight. There are currently no maximum levels in EU legislation for Ni in food nor in the Codex Alimentarius. For natural mineral water a limit of 0.02 mg/L has been established in the Codex (Gil et al., 2017).

### Toxicokinetics

Nickel present in food is poorly absorbed (less than 5–10%) through the gastrointestinal tract probably due to the competition with various food components (phosphates, phytates, fibers, etc.) that would reduce such absorption. However, absorption is higher through drinking water (30–40%). Once absorbed, it is distributed in the blood and stored mainly in the kidneys, and also in the lung and brain. Finally, nickel is primarily excreted through urine (Klein and Costa, 2007).

### Toxicity

Nickel compounds are classified as Group 1 carcinogen by the IARC, meaning they are carcinogenic to humans. Metallic Nickel as Group 2B, is possibly carcinogenic to humans. EFSA considered that dietary exposure to Ni is unlikely to cause cancer in humans and that only non-cancer health effects from oral exposure to Ni may occur, such as gastrointestinal, hematological, neurological and immunological effects. Oral exposure to nickel does not cause dermatological reactions (eczema) in individuals without previous contact with the metal (Table 1) (Gil and Gisbert-Calabuig, 2018).

## Tin

### Dietary exposure

This element is found in very small amounts in vegetal and animal foodstuffs. The main sources of tin are canned foods, cereal grains, dairy, meat and vegetables (Table 1). Until recently, the main route of dietary exposure was canned food (tin cans). However, their internal lacquering has significantly reduced this route of contamination. Fortunately, tin usually has a very low toxicity, partly due to its minimal intestinal absorption (Gil et al., 2017). Like the other metals, it is a thiol-binding toxicant, affecting many enzymatic activities. However, it is important to note its ability to interfere with the metabolism of certain trace elements (Zn, Fe, Mg, Cu and Se). It has also been shown to interfere with calcium, reducing its bone fixation. Fish and fishery products (especially shellfish) are considered as the main source of organotin compounds (OTC). The main species are likely to be tri-substituted compounds (tributyltin TBT and triphenyltin TPT), which have been used extensively as biocides in wood preservatives, in antifouling paints for boats and as pesticides (ATSDR). Nevertheless, because these compounds are persistent in the environment they tend to accumulate through the food chain (Guérin et al., 2007).

### Permissible intakes

The FAO/WHO Expert Committee of food additives suggests weekly maximum intake of 14 mg/kg of body weight (120 mg/day for an adult) (Gil et al., 2017).

### Toxicokinetics

Inorganic tin compounds are usually insoluble, poorly absorbed at the gastrointestinal tract (<5%) and show low tissue accumulation. Tin is widely distributed, especially in the liver and spleen, and most of it is excreted in the feces, with slow elimination through the urine.

### Toxicity

There is no evidence that tin or tin compounds cause cancer in humans. Studies of inorganic tin compounds in animals have also been negative. Several reports of food poisoning from tin contamination in canned food indicated gastrointestinal symptoms (diarrhea, abdominal pain). Organic tin can cause severe irritation of skin and can lead to systemic toxicity (renal and hepatic damage) (Ostrakhovitch and Cherian, 2007).

## Copper

### Dietary exposure

Sources of contamination arise from its use in the electrical and electronic industries, in the manufacture of pesticides (fungicides) used against vineyard pests (in particular copper sulfate), as well as in alloys with other metals (mainly zinc and nickel) (Table 1).

Oysters are the seafood that capture and accumulate the most copper. In general, fish is more susceptible of accumulating copper. Among the terrestrial animals, sheep have the highest levels. Fruits, cereals, nuts and green vegetables are important sources of copper.

### Permissible intakes

Taking into account the dietary requirement for copper, which is estimated to be around 0.05 mg/kg body weight (approximately 3 mg for an adult), the FAO/WHO Committee set a provisional value for the maximum daily intake of copper of 0.5 mg/kg body weight (Gil et al., 2017).

### Toxicokinetics

Copper present in food is well absorbed (50–75%) in the gastrointestinal tract. It is distributed in blood bound to albumin and is also incorporated into ceruloplasmin, with the highest concentrations of copper found in bone, muscle, liver and brain. The liver is an essential organ in copper metabolism, and not only acts as a storage organ but it is also essential in the regulation of biliary excretion. The majority of copper is eliminated through biliary excretion (>95%) and a small percentage through urine (<5%).

### Toxicity

The main acute toxic effects are related to the ingestion of food or drinking water heavily contaminated with copper. This metal has an irritant effect on the mucosa of the digestive tract and it mainly causes nausea, vomiting, epigastric burning and diarrhea (Table 1). Other toxic effects observed in cases of fungicide (copper sulfate) poisoning were hepatotoxicity (with typical symptoms of hepatomegaly, jaundice and alteration of the centrilobular area), and hemolysis with possible renal tubular pathology (Ellingsen et al., 2007).

## Arsenic

### Dietary exposure

The risk of food contamination by arsenic was illustrated in the early 20th century in England as a result of the consumption of beer contaminated with arsenic, which acted as an impurity in the sulfuric acid used in the manufacture of glucose (by hydrolysis of starch). Arsenic levels in the environment are usually relatively low and are present in the geological composition, mining areas, etc. ... (US FDA). Arsenic occurs naturally in the soil and in certain minerals (arsenopyrites). Arsenic can therefore pass to the air, water and soils and can even be incorporated into rainwater and leach through the soil. Moreover, arsenic is widely distributed

in nature due to the use of arsenical compounds as pesticides (rodenticides) and xyloprotectants (especially sodium arsenate, arsenic anhydride and arsenious anhydride). Of all the chemical forms, those with trivalent arsenic, and more specifically arsenious anhydride, are the most toxic compounds.

Seafood is the main contributor of this metalloid in the human diet, especially if they are in contact with areas where arsenical waste is dumped. In certain marine animals, especially crustaceans and shellfish ([Table 1](#)), arsenic tends to concentrate as arsenobetaine. It is also concentrated in algae as arsenophospholipids. Fish contains between 2 and 80 µg/g, oysters 3–10 µg/g and mussels 10–120 µg/g. Several research studies have shown that dimethylarsinic acid (DMA) and monomethylarsonic acid (MMA), two forms of organic arsenic found in certain foods. The FDA is monitoring emerging research on possible health risks from these forms of organic arsenic and will continue to monitor both inorganic and organic forms of arsenic in foods, as needed.

The arsenic compounds present in marine sources are methylated to organic forms, which are less toxic than inorganic ones. Hence, analytical speciation is very important because inorganic arsenic comes mostly from occupational exposure, whereas the organic forms are usually incorporated into the body from a seafood-rich diet. If only total arsenic levels are determined, we will not know what percentage is inorganic arsenic and what percentage is organic ([Fowler et al., 2007](#); [Gil et al., 2017](#)).

### Permissible intakes

Based on available data, the Joint FAO/WHO Committee estimated as a provisional maximum daily intake for inorganic arsenic 0.0015 mg/kg body weight, with no data assessed for organic arsenicals in food. In any case, the total daily intake of arsenic by humans not subject to industrial exposure is usually less than 0.3 mg/day. FAO/WHO expert committee recommended that the weekly intake per person (provisional tolerable weekly intake, PTWI) of inorganic arsenic should not exceed 15 µg/kg body weight (900 µg/person).

The US EPA has established a limit of 0.01 part per million (ppm) or 10 µg/L for arsenic in drinking water (ATSDR y US FDA).

Regulation (EU) No. 2015/1006 of June 25, 2015, has found it necessary to fix the maximum level of inorganic arsenic in rice and rice-based products. A scientific opinion has established that large consumers of rice in Europe, such as certain ethnic groups and children under the age of 3 years, were most exposed to inorganic arsenic from food. The estimated exposure in children would be two to three times higher than adults. The US FDA issued guidelines for industry not to exceed inorganic arsenic levels of 100 ppb in infant rice cereals. The FDA has also assessed inorganic arsenic levels in apple juice and found it to be generally low, with total arsenic levels below 10 µg/L (limit established for arsenic in drinking water).

### Toxicokinetics

More than 90% of inorganic arsenic (trivalent or pentavalent forms) is absorbed from the gastrointestinal tract. Organic arsenic compounds are also well absorbed across the gastrointestinal tract. The degree of particle fragmentation as well as the pH influences the digestive absorption of arsenic trioxide. Two processes are involved in the biotransformation of inorganic arsenic compounds: redox reactions (As III and V) and methylation reactions which convert arsenite to monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA). Arsenobetaine, cacodylic acid and arsanilic acid are apparently not biotransformed. The major route of excretion of inorganic arsenic is the urine.

### Toxicity

Among the chronic toxic effects due to arsenic there is the possibility of carcinogenesis ([Table 1](#)). Both the US EPA and the International Agency for Research on Cancer (IARC) have determined that inorganic arsenic is carcinogenic in humans and may increase the risk of skin cancer as well as liver, bladder and lung cancers. It is also capable of causing painful sensorimotor polyneuropathy and certain dermatological alterations (palmoplantar hyperkeratosis, Mees bands on the nails, among others). Inorganic arsenic exposure intra utero (arsenic passes through the placenta) and in children is associated with impaired intellectual development. In fact, certain levels of arsenic in children's urine have been associated with impaired attention and cognitive functions, providing clear evidence that postnatal arsenic exposure impairs neurological function in children, even at levels that could theoretically be considered safe ([Rodríguez-Barranco et al., 2016](#)).

### Conclusion

Therefore, as a conclusion, we must emphasize that metals represent one of the main contaminants in food as a consequence of human activity (industrial, agricultural, domestic). Metals can cause harmful effects to the health of the consumer including cancer. It will therefore be essential to establish permissible limits for these xenobiotics in foodstuffs as well as an adequate toxic risk assessment to the consumer.

## Glossary

**Anaerobic** Without oxygen

**Antigens** Markers on the surface of microbes such as bacteria that allow antibodies to recognize them

**Cholinergic nerves** Nerve cells that employ *acetylcholine* as their *neurotransmitter*

**Farinaceous** Consisting or made of starch

**Hazard analysis critical control point system** A management system in which food safety is addressed through the analysis and control of biological, chemical, and physical hazards from raw material production, procurement, and handling, to manufacturing, distribution, and consumption of finished product

**Hemolytic uremic syndrome (HUS)** Formation of clots in small blood vessels of kidneys which can lead to renal failure

**Meningitis** A serious inflammation of the thin membranous covering of the brain and spinal cord

**Multilocus sequencing typing (MLST)** A molecular technique for DNA sequence of different bacteria

**Oviduct** A passage through which ova leave the maternal body or pass to an organ communicating with the exterior of the body

**Polymerase chain reaction (PCR)** A rapid technique to synthesize large quantities of a given DNA segment

**Septicemia** Systemic disease associated with the presence of pathogenic microbes or their toxins in the blood

**Serotype** A group of closely related microorganisms distinguished by a common characteristic set of antigens

**Temperature danger zone** Temperatures between 4.4 °C (40 °F) and 60 °C (140 °F) where bacteria can grow rapidly

## Introduction

The burden of *gastroenteritis* (GE) in the world, in terms of both morbidity and mortality, is extensive. The more advanced *foodborne disease* surveillance systems become, the more food-associated GE illnesses they uncover.

Not all GE is directly caused by contaminated food. Some GE is caused by poor hygiene resulting in direct or indirect transmission of infectious microbes without a food vehicle. Nevertheless, contaminated food is a major vehicle of infectious GE throughout the world. The general definition of *foodborne illness* (FI) is acute GE caused by consumption of food contaminated with *foodborne pathogens* or their preformed toxin. *Typhoid fever* and *brucellosis* are not usually considered FI, whereas *botulism* is, even though it causes paralysis and not GE, as is *listeriosis*, which principally causes *septicemia* and meningitis.

*Norovirus* is the most commonly known cause of FI, followed by bacterial FI. Many types of bacterial FI, such as *salmonellosis* and enterohemorrhagic *Escherichia coli* (*E. coli*) O157:H7 infections, are more common in the summer than winter months (CDC, 2021a,b,c,d; WHO, 2021a).

Bacteria produce their effects on the intestinal tract either by direct invasion of the *mucosa* or by production of toxins. Some of the toxins are produced in food outside the intestinal tract; others are formed or released in the intestine. Some invasive bacteria also produce toxins in the intestine. In the developing world, diarrhea, along with *acute respiratory tract infection*, are the leading causes of childhood death. In the more developed world, GE caused by infectious microbes is a significant cause of illness and time lost from work. Death does occur, especially among highly susceptible populations with weak immune response. This article provides an overview of key bacterial causes of FI.

Objectives: Overview of FI.

- Bacterial toxins related FI
  - Staphylococcal food poisoning
  - *Bacillus cereus* food poisoning
  - *Clostridium botulinum*

- *Clostridium perfringens*
- *Vibrio cholerae*
- Invasive bacterial FI
  - *Salmonella*
  - *Campylobacter*
  - *Escherichia coli*
- Other bacterial FI
  - *Shigella* species
  - *Listeria monocytogenes*
  - *Yersinia enterocolitica*
  - *Vibrio parahaemolyticus*
  - *Vibrio vulnificus*
  - Brucellosis
  - *Streptococcal pharyngitis*
- Prevention of bacterial food poisoning
- Conclusion/Summary/Outlook

## Bacterial toxins

There are three main forms of *bacterial toxins* that cause FI: (1) *enterotoxin*, which produces excess fluid secretion into the gut (e.g., cholera and staphylococcal toxins); (2) *cytotoxin*, which causes inflammation and mucosal damage (e.g., *Shigella* and enterohemorrhagic *E. coli*); and (3) *neurotoxin*, which affects the nervous system (e.g., botulinum toxin).

Some *E. coli* strains invade and produce toxins, and are addressed under Invasive Bacteria. *Red kidney bean* toxin, scombrototoxin and other *fish toxins*, and *heavy metal poisoning* are addressed elsewhere in this encyclopedia.

## Staphylococcal food poisoning

### Background

Staphylococcal food poisoning (SFP) is one of the causes of bacterial FI commonly attributed to food handlers. Humans frequently carry *Staphylococcus aureus* either in an infected site or asymptotically. Infected sites include wounds and abscesses, which may be the source of large numbers of *staphylococci*. Asymptomatic sites include the throat, nostrils, fingernails, or hair. Several staphylococcal species (coagulase-negative and coagulase positive) produce highly heat stable enterotoxins. Some coagulase-negative *S. aureus* strains may also produce toxins, but rarely. Because the organism is also carried by many animals, outbreaks attributable to inadequate food handling, which often involves temperature abuse of a pre-contaminated food, can also occur (FDA, 2017; Park and Seo, 2019).

### Survival and growth

Staphylococci are killed by normal cooking temperatures. Any staphylococci that survive because of inadequate heating or, more frequently, by post-cooking contamination from a food handler will, if it is an enterotoxigenic strain and given the right conditions of warmth, moisture, pH, and time, produce toxin. Growth of staphylococci and production of toxins are greatest at 35 °C, but growth can occur between 7 and 47.8 °C (FDA, 2017). This toxin is heat stable, unless exposed to high temperature for a long period (i.e., autoclave at 121 °C at 15 PSI for 60 min). The toxin is also resistant to *gamma irradiation*.

Many foods have been associated with SFP. *S. aureus* can grow in foods with high salt or sugar content, and salted meat products such as ham have been a common vehicle of SFP, as have desserts, especially those containing cream. Other foods implicated in SFP include *high-protein foods*, salads, canned mushrooms, cream, cheese, *salami*, and eggs. *S. aureus* can also contaminate milk by mastitic cows infected with *S. aureus*.

### Characteristic sequence of events

For example, a whole leg of ham (or other foods) is prepared for consumption and cooked. It is then sliced warm (or handled) by a person with no skin lesions but who is a nasal-carrier of *S. aureus*. The slices are stacked on a deep tray. The tray is covered and left to cool for several hours before being refrigerated. Staphylococci from the nose of the food handler are conveyed to the warm ham slices. Because of the large surface area, the large bulk of covered overlapping slices of meat require several hours to cool, during which staphylococci grow and produce toxin. Refrigerating, freezing, or reheating the meat will not destroy the toxin. Holding cooked food, subsequently contaminated with *S. aureus* by a food handler, at ambient temperature for several hours is the major contributing factor to outbreaks of SFP.

### Clinical features

*Staphylococcal toxin* is an enterotoxin and a receptor in the gut appears to be necessary. There may also be a neurotoxic effect that acts on the vomiting center in the brain. With SFP, onset of symptoms is often dramatic. Vomiting is the most prominent symptom, generally occurring within 6 h, but may range from 30 min to 8 h, after eating. Nausea, *abdominal cramps*, and diarrhea are also common. Generally, as with most toxins, the higher the toxin concentration (or the greater the amount ingested), the shorter the *incubation period* and the more severe the symptoms. Individual susceptibility is also a determining factor in severity. The illness usually completes its course within a day or two, but deaths have occurred, sometimes as a result of acute hypotension (another well-known but rare effect of the toxin) (Park and Seo, 2019).

### Diagnosis

Many people carry staphylococci asymptotically in their throat or nostrils. Hence, to identify a food handler as the source of an SFP outbreak, it is important to confirm that the type of *S. aureus* causing an outbreak of FI is the same in the carrier and in those affected; merely showing that a food handler carries staphylococci is insufficient. The organism can be grown from, or enterotoxin can be detected in, implicated foods. Generally, *S. aureus* must grow to populations of  $>10^5$  colony-forming units per gram to produce sufficient amounts of enterotoxin to produce the illness (FDA, 2017; Park and Seo, 2019). *S. aureus* can also be isolated from vomit or stool of patients and from the hands, nose, abscess, or an infected wound of the food handler. *Phage typing* of strains, with detection and typing of enterotoxin, can also be performed. Enterotoxins A–K (but not F) are recognized, although A is the most common. With the advent of *polymerase chain reaction* (PCR) based (molecular biological detection technology), enterotoxin types other than A are being associated with illness more frequently, because they are reliable, with conclusive results. As with all FI, the absence of laboratory-supporting evidence does not necessarily mean that the diagnosis is wrong or the implicated food innocent (FDA, 2017; Park and Seo, 2019).

### *Bacillus cereus*

#### Background

*Bacillus cereus* is widely distributed in the environment and can occur in food. It is found in rice and other *natural foods*, such as herbs and spices, cream, and dry foods.

#### Survival and growth

Unlike *S. aureus*, *B. cereus* is a spore-forming bacterium that can survive prolonged boiling. It causes two fairly distinct types of food poisoning, *emetic* and *diarrheic*. The diarrheal toxin is heat labile and, like *Clostridium perfringens* food poisoning, this toxin is released in the gut. Foods commonly associated with diarrheagenic *B. cereus* FI are “proteinaceous” and, like *C. perfringens* FI, associated with meats, stews, desserts, and sauces. The emetic type is “farinaceous,” associated mainly with cooked rice, and produces an illness similar to SFP. Different *serotypes* of *B. cereus* cause these two different forms of FI, and the toxins are also different. Some strains can grow at refrigeration temperature in milk and other foods (FDA, 2017; Lindbäck and Granum, 2019). Prevalence of emetic or diarrheal attributed illness varied among different regions of the world (Lindbäck and Granum, 2019).

#### Clinical features and characteristic sequence of events

The emetic type of *B. cereus* FI is caused by preformed toxin (cereulide) in foods, usually rice (or starchy foods) that have cooled slowly. This typically happens when a large amount of rice is not properly cooled (i.e., left in a temperature danger zone for many hours, often overnight). The center of the mass will remain warm for a long enough period for the *spores* to germinate and form toxins. The toxin is heat stable and will not be inactivated by quick frying rice, as typically done in a restaurant. The incubation period is usually short (1–6 h), and the symptoms, predominantly vomiting, tend to be milder than those of SFP, which it otherwise resembles.

The diarrheal form of *B. cereus* FI is similar to that caused by *C. perfringens*. The toxin, unlike the emetic type, is an enterotoxin released in the intestine and is heat labile. The predominant symptoms are watery diarrhea and abdominal cramps. The incubation period, is also longer (6–15 h), and persists for approximately 24 h. A wide variety of foods, including meat, vegetables, and *dairy products*, have been associated with this type of *B. cereus* FI (Lindbäck and Granum, 2019).

#### Diagnosis

The mere presence of *B. cereus* in a food is insufficient evidence to confirm the food as the vehicle of FI because *B. cereus* is a normal contaminant of many natural foods. The diagnosis is confirmed by finding *B. cereus* in high concentration [ $10^6$ – $10^8$  g<sup>-1</sup>, minimum  $10^5$ ] in cooked rice, or other foods for the diarrheic type, and obtaining it from the stool or vomit of those who are ill. Alternatively, the same serotype of *B. cereus* should be present in the implicated food and patient specimens. Detection of the emetic toxin in the food may also be sufficient.

## Clostridium botulinum

### Background

*Clostridium botulinum* is an anaerobic spore-forming bacterium widely distributed in soil and mud. Botulinum toxin is the most lethal substance known to man, with an LD<sub>50</sub> of 1–2 ng kg<sup>-1</sup> body weight. For comparison, *tetanus toxin* from *Clostridium tetani* and *ricin* from the *castor bean* (the next most toxic substances) have LD<sub>50</sub> values of 0.0001 and 0.02 µg kg<sup>-1</sup>, respectively. The seven toxin types, A–G, affect the nervous systems of *vertebrate* animals, birds, and man. Birds in *aquatic environments* are especially susceptible to mass die-offs caused by *botulism*. Invertebrates are not susceptible but can harbor the bacteria and toxins in their bodies. Botulinum toxin types A, B, and E most frequently affect humans. Type E is typically acquired from fish. Type C is the primary toxin causing botulism in birds, although types D and E are also important (Johnson, 2019; FDA, 2017).

### Survival and growth

*C. botulinum* is an *anaerobe*, hence special conditions (no oxygen) must be present for it to produce toxin. Although the organism is widespread in the environment, botulism in humans is uncommon. First, the spores must be present, which, depending on the type of food, occurs because they are widely distributed in soil and aquatic environments. Second, the spores must survive cooking, which often occurs because they can survive heating at 100 °C for 2 h. Third, they must germinate and grow in *anaerobic conditions*. Although accidents have occurred, and occasionally still occur, especially with home *canned-vegetables*, *fermented fish products*, and, occasionally, with preserved meat (the term botulism is derived from *botulus*, the Latin term for sausage) and preserved rotting or fermenting food, botulism is rare among humans. Commercial canning, except for the occasional process deviation, destroys spores by the heating processes used. The vegetative forms of *C. botulinum* are as susceptible to heat as most other vegetative bacteria, and the toxin can be destroyed by boiling for 5 min. The pH of food is also important: the lower the pH, the less resistant the spores are to heat, and a low pH (<4.6) prevents *vegetative cells* from growing and producing toxin. Hence, bottled *vegetables pickled in vinegar* tend to be safe. High concentrations of salt also affect the viability and toxin-forming properties of *C. botulinum* (Johnson, 2019; FDA, 2017).

### Clinical features

The incubation period of botulism is 18–36 h (range, 4 h–8 days). The toxin destroys *cholinergic nerves* in the *motor end plates* (MEPs) of cells. These are the junctions of the nerves within muscle, preventing the release of *acetylcholine* from the cholinergic nerves in the MEP and paralyzing the muscle. Once this has happened, *antitoxin*, which is used to treat patients with botulism, is ineffective. The combination of nausea, vomiting, or diarrhea followed by symmetrical descending paralysis of cranial and *autonomic nerves* is almost diagnostic. The characteristic *neurological symptoms* are blurred vision, dry mouth, difficulty in swallowing, *dysarthria*, *diplopia*, and descending paralysis. Recovery occurs when new MEPs form. The fatality rate was once high but, with respirators, patients are often kept alive artificially until new nerve terminals have formed new MEPs, which may take several months (Johnson, 2019; FDA, 2017).

### Infant botulism

Serious illness has occurred in babies (usually younger than 6 months of age) who ingested enough *C. botulinum* spores to cause colonization in the intestine, subsequently forming toxins. The initial symptom is typically constipation, leading to poor appetite, irritability, neck paralysis, and generalized weakness. Honey is a primary vehicle of infant botulism (CDC, 2021b; FDA, 2017).

### Diagnosis

The diagnosis is made by demonstration of *botulinum toxin* in food, stool, or serum by mouse bioassay. Clinical symptoms alone can be used for diagnosing botulism, but it can be difficult to distinguish it from other disease. Growing the organism from food is suggestive but not diagnostic, whereas fecal isolates are uncommon, except in affected individuals (Johnson, 2019; FDA, 2017; CDC, 2021b,d).

## Clostridium perfringens

### Background

Food poisoning caused by *C. perfringens* is also toxin mediated. It is similar to the diarrheal form of *B. cereus* FI in that toxin is formed in the intestine after *ingestion* of the bacteria. Like other *clostridia*, it is anaerobic (but can grow in the presence of low concentration of oxygen), Gram-positive, and sporeforming. There are five types (old classification: A through–E according to the enterotoxin formed; type A is the one that causes FI. Some strains, but not generally those that cause FI, can cause *gas gangrene* (*Pig-bel* form or *enteritis necroticans*) (FDA, 2017), which is uncommon in the US. Updated classification include two additional toxin types (F and G) (García et al., 2019). *Clostridium perfringens* is primarily found in soil and is transmitted to animals and man by ingestion of vegetables and other plants. It is commonly found in the intestine of man and animals. When animals are eviscerated, the organism contaminates the inside of the *carcass*. Flies can transmit the organism to food.

*Clostridium perfringens* FI is frequently reported in countries such as the UK and the US (second most common FI as reported by the CDC); however, it is rarely fatal, except for those who are debilitated or immunocompromized (García et al., 2019; FDA, 2017).

### Survival and growth

*Clostridium perfringens* does not typically multiply on the surface of raw meat. It grows optimally at warm temperatures of approximately 43 °C (range, 10–54 °C) and where there is little to no oxygen in the interior of a cooked dish. The cooking process can remove oxygen and thereby facilitate germination and subsequent growth of the organism. Vegetative cells are not resistant to heat, but spores of the FI strains of *C. perfringens* can survive boiling conditions. If cooling is slow, vegetative cells form and can grow rapidly. After ingestion, toxin is formed from multiplying cells in the intestine, although both toxin and vegetative cells appear to be necessary to produce symptoms.

### Clinical features and characteristic sequence of events

As an example, a *casserole* is prepared containing, among other ingredients, meat pieces. It is cooked for 1 or 2 h until ready. However, it may not be consumed immediately and, because of its bulk and the lack of refrigeration facilities, is left unrefrigerated overnight in a warm kitchen. It is warmed the next day before serving. Symptoms of diarrhea with intense abdominal pain typically begin 6–24 h after exposure. The illness may last for up to 24 h, and there are no *sequelae*, except in those who are already debilitated, in which less severe symptoms can last for 1–2 weeks.

### Diagnosis

The organism can be cultured from the stools of affected people and should be compared by molecular subtyping and for toxin production with isolates from food. Enterotoxin detection in stools is important confirmatory evidence. The organism must be detected in high numbers ( $>10^5$  g<sup>-1</sup>) in food to be significant (García et al., 2019; FDA, 2017).

## Vibrio cholerae

### Background

The first *Cholera pandemic* originated in India (Ganges delta) and spread to Asia in 1817–1823. The second pandemic reached Europe in 1826–1837 and, subsequent to this, there were five additional pandemics. *Vibrio cholerae* serogroups O1 and O139 are responsible for epidemics and pandemic cholera outbreaks. It began inexplicably in 1961 with a mild strain, the El Tor biotype, which had been endemic in Indonesia since 1937. *Vibrio cholerae* O139 is a relatively new strain that emerged in the Indian subcontinent in 1992 (Ceccarelli et al., 2019). More recently, cholera has become endemic in areas of South America, and other continents (WHO, 2021b). In 2010, after an earthquake in Haiti, without sanitary water for bathing and drinking, a large cholera outbreak killed more than 7000 people (CDC, 2021c).

Cholera was responsible for the introduction of sanitation and the development of “public health.” Although not a common cause of FI or GE in developed countries, the *vibrios*, especially *V. cholerae*, still cause large, mainly waterborne outbreaks in the developing world (WHO, 2021b). Rare cases in the US are often associated with international travel. It is the only *gastrointestinal infection* that is internationally notifiable. Because large numbers of organisms are required for infection, person-to-person transmission is uncommon (Ceccarelli et al., 2019; CDC, 2021c; WHO, 2021b; FDA, 2017).

### Survival and growth

The bacteria are aquatic and prefer briny waters. They can be found in many warm plankton-rich coastal waters, including the Mediterranean, Gulf of Mexico, and those of Southeast Asia and South America. Bivalved *mollusks* concentrate them, and other fish and shellfish can also be contaminated. Inadequate cooking and unrefrigerated storage will allow *V. cholerae* to survive and grow to sufficient cell numbers to cause FI. *Vibrios* are generally associated with moist, slightly salty foods. The El Tor strain is more likely to produce *asymptomatic infections*, persist longer in the environment, multiply more rapidly in food, and produce less immunity than the classical type. The organism causes illness by producing an enterotoxin in the intestine (Ceccarelli et al., 2019; FDA, 2017).

### Clinical features

Cholera, in its most severe form, is characterized by an acute outpouring of watery diarrhea (rice water stools) and vomiting resulting in death within 24 h by acute loss of fluid and electrolytes. However, the clinical syndrome can also be mild. *V. cholerae* is not invasive, and if the loss of fluid and salts can be counterbalanced by infusion of equal amounts of fluid supplemented by electrolytes, the patient will survive. Patients with an absence of acid in the stomach, and those with *blood group O*, are especially prone to severe symptoms. The incubation period is typically 1–3 days (range, 12 h–5 days) (Ceccarelli et al., 2019; FDA, 2017).

### Characteristic sequence of events

Seafood or water contaminated with human sewage is, by far, the most common vehicle of infection. *Vibrios* can grow prolifically in cooked rice and other grains contaminated by food handlers, and salad vegetables can be contaminated by water.

### Diagnosis

*V. cholerae* is usually isolated from the stool using special media. It can also be distinguished by *light microscopy*, and specific antisera will halt motility of the organisms. *Agglutination tests* with antiserum will distinguish O1 from O139 and other serovars. The bacterium can also be isolated from the environment using enrichment media. Toxin production or the presence of the toxin gene can, and should, also be demonstrated (Ceccarelli et al., 2019; FDA, 2017).

## Invasive bacteria

### Salmonella infections

#### Background

Salmonellae are among the most commonly known causes of bacterial FI in developed (and possibly less well-developed) countries of the world (Lewis et al., 2019). *Salmonellae* cause two types of FI: Gastroenteritis, and Typhoidal fever. Annually in the US, it is estimated that *Salmonella* bacteria cause about 1.3 million infection, 26,500 hospitalizations and 420 deaths, and majority of those are non-typhoidal type (CDC, 2021a,b,d; FDA, 2017; Lewis et al., 2019; WHO, 2021a).

There are more than 2500 serotypes of *Salmonella*. They are typed according to their somatic [O] or flagellar [H phases 1 and 2] antigens according to the Kauffman–White scheme, and are sometimes named after a geographical location. Further typing or molecular subtyping, such as by *pulsed-field gel electrophoresis* (PFGE), can be done to distinguish strains of the more common serotypes. All serotypes are considered pathogenic for humans, although most have not been detected in infected humans. Salmonellae are gram-negative *bacilli* that do not form *spores*, but can survive for remarkably long periods (months or years) in *dried foods* such as *nonfat dried milk* (FDA, 2017; Lewis et al., 2019).

Salmonellae are frequently carried in the intestinal tract and excreted in the feces of a variety of animals, hence environmental contamination often occurs through contact with manure. *Salmonella*-contaminated protein-based feeds processed in bulk for livestock and poultry have caused widespread infection in animals and, subsequently, in humans. In the UK, for example, fishmeal imported from Peru and fed to poultry caused a large outbreak of *Salmonella* Agona infection in humans that lasted for many years, through the late 1960s and early 1970s. Since then, there have been outbreaks of *S. Hadar* infection in turkeys. More recently infections in poultry and hens' eggs by *S. Enteritidis* of various *phage types* have caused *salmonellosis* outbreaks in many countries. In eggs, transmission of *S. Enteritidis* is mainly “vertical” (i.e., through *oviducts* to the interior of eggs laid by infected hens). Before this, salmonellae largely gained entry to the interior of eggs through the shell. If egg shells were removed in bulk, contamination of just one or two shells would be enough to contaminate the entire batch of eggs and then salmonellae would grow under favorable temperature conditions (FDA, 2017; Lewis et al., 2019).

Other important sources of *Salmonella* contamination include sewage, manure, polluted water, and direct fecal contamination of foodstuffs. Hence, many fresh, unprocessed foods are bought already contaminated. Examples include raw meat and poultry, unpasteurized milk and eggs, legume and vegetable sprouts, and fresh produce. Many multistate outbreaks of salmonellosis in the United States and around the world have been traced to multiple produce items, and the list of implicated foods expanded to include nuts and other low moisture foods (i.e., peanut butter, tahini, and coconut). Cross-contamination in a kitchen or restaurant from raw meat or poultry has also been responsible for numerous outbreaks. Direct contamination of a food by a food handler can also occur. Although cases of human carriers with prolonged fecal shedding of *Salmonella* spp. occur, they are infrequent (FDA, 2017; Lewis et al., 2019).

#### Survival and growth

Although salmonellae do not form spores, and are fairly easily destroyed by heat (71 °C in a moist food), they can survive for a remarkably long period of time (years) in a dry environment. An outbreak of *S. Virchow* and *S. Saintpaul* infection associated with green *lentils* (mung beans) imported from Queensland occurred in several countries of Europe. The lentils were used to produce *bean sprouts*, which were grown overnight in a warm waterbath. Drying of salmonellae makes them more resistant to heat. The presence of moisture is important when using heat to kill salmonellae.

Salmonellae grow best at 37 °C, with the danger zone at 30–45 °C. Generally, growth does not occur below 7 °C and above 46 °C. Antibiotic-resistant strains are becoming an increasing concern, especially those strains that multiply are resistant to antibiotics used for human therapy (FDA, 2017; Lewis et al., 2019).

The infective dose of salmonellae in humans can be quite low, e.g., 1 cell g<sup>-1</sup>, depending on a variety of factors, including the strain of *Salmonella*, type of food vehicle, and immune status of the person. Fatty foods such as chocolate, cheese, *salami*, peanut butter, and *mayonnaise* generally can confer illness with much smaller doses, and patients with *immunosuppression*, low acid levels in their stomach (achlorhydria), as well as the elderly and debilitated may also be particularly vulnerable. Salmonellae can be transmitted nosocomially, especially in geriatric or *psychogeriatric* wards of hospitals, and in such outbreaks food may not be the source (FDA, 2017; Lewis et al., 2019).

#### Characteristic sequence of events

Examples of scenarios of outbreaks of salmonellosis are the following.

A chicken dish is undercooked and then left in a warm environment for many hours before consumption. Alternatively, the chicken may be thoroughly cooked but is then placed in an unwashed container or on a plate with juices from the uncooked chicken, or cut with a knife that was used for raw chicken, and then held at room temperature for a few hours. The contaminated utensil may also be used on another food such as lettuce, thus contaminating it with salmonellae.

#### Clinical features

The *incubation period* of salmonellosis is generally 12–36 h, but can range from 6 to 72 h. Clinical features of salmonellosis can range from mild to severe. *Enteric fever* (typhoid) is usually caused by *S. Typhi* or *S. Paratyphi A*. Salmonellae can cause severe diarrhea with fever and abdominal pain. Additional, less common symptoms include chills, headache, vomiting, and nausea. Symptoms

usually resolve within 4–7 days. Some *Salmonella* spp. such as *S. Cholerae-suis*, may cause multiple abscesses, and people with *sickle cell disease* may develop bone abscesses caused by a variety of *Salmonella* spp. *Septicemia* (blood poisoning), meningitis, *Reiter's Syndrome*, and some localized infections are also occasional complications of salmonellosis. Patients with AIDS and other *immunosuppressive* conditions are particularly vulnerable to severe complications, which can lead to death (CDC, 2021a; FDA, 2017; Lewis et al., 2019).

### **Salmonellae and hens' eggs**

In the late 1980s, *S. Enteritidis* rapidly became the most common cause of human salmonellosis in the United Kingdom. Previously, *S. Typhimurium* had been the most frequently reported *Salmonella* species associated with human illnesses. Between 1984 and 1987, the number of human *S. Enteritidis* infections increased by approximately 50% per year. In 1988, the number more than doubled and, by 1993, it was virtually 10 times that diagnosed in 1984. By 1993, *S. Enteritidis* accounted for approximately five times the number of *S. Typhimurium* infections. Most of this was due to consumption of undercooked contaminated eggs, although some cases were also attributed to chicken. Many European countries and the USA experienced similar trends (CDC, 2021a; FDA, 2017; Lewis et al., 2019).

### **Diagnosis**

The diagnosis of a salmonellosis is usually made by isolating salmonellae from stool or food and serologically identified. Some salmonellae, such as *S. Typhimurium* and *S. Enteritidis*, are so common that further differentiation is necessary for epidemiologic purposes. Further characterization of the *Salmonella* serovar can be determined by molecular subtyping (PFGE) or phage typing (FDA, 2017; Lewis et al., 2019).

## **Campylobacter infections**

### **Background**

*Campylobacter jejuni* was determined to be a cause of human GE in the mid-1970s, and is now recognized as the most common bacterial cause of GE and FI in many developed countries. In less developed countries, asymptomatic *Campylobacter* infection is more common (Habib et al., 2019; FDA, 2017). *Campylobacter jejuni* is the most common species causing diarrhea, but *C. coli* is also common in some areas.

*Campylobacter* spp. are carried in the intestinal tract of many animals and birds, including cattle and horses, household pets, and chickens. Rates of contamination of chicken *carcasses* vary from >75% in the United Kingdom to <30% in Sweden and Norway. Some of these differences may be due to the isolation or detection method used. The estimated annual incidence of human *Campylobacter enteritis* in the USA is ca. 1.5 million cases (CDC, 2021a; FDA, 2017; Habib et al., 2019).

### **Survival and growth**

The reason for the late recognition of campylobacters as causes of human GE is the fastidious growth conditions required to culture and isolate them. They grow best in an O<sub>2</sub> concentration of 5% (but not well, if at all, anaerobically or in the presence of 21% O<sub>2</sub>) in a special medium and at a temperature of 42 °C. They are sensitive to heat, being destroyed readily by cooking, and do not survive for long (probably a few hours only) when dried on the surfaces of foods or kitchen utensils. They, nevertheless are highly successful in causing infection, probably because of their ubiquity in food-producing animals and birds and the relatively small dose needed for infection (possibly no more than a few thousand organisms may be enough) (FDA, 2017).

### **Characteristic sequence of events and clinical features**

Although campylobacters undoubtedly cause FI, the vehicle of infection in most instances is unknown. It is probable that many cases are caused by direct contact with animals, birds, the environment in which fecal contamination occurs (both domestic and outside), meat carcasses, and possibly other people. Foodborne outbreaks have been traced to untreated water and unpasteurized milk, and also milk from bottles whose tops have been pecked by birds. Undercooked poultry is a major risk factor, and meat prepared at barbecues, which includes pork, *veal*, and beef, as well as chicken, has also been implicated as a vehicle of infection. Eating grapes was determined in one study to be a risk factor, and salads and fresh vegetables have also been implicated as vehicles, but it is possible that some of these foods were contaminated by another source or directly by a food handler.

Other risk factors include travel to foreign countries; handling and cooking of food, especially raw meat; contact with animals and pets (especially those with diarrhea); and visiting an animal farm.

The incubation period is generally 2–5 days. Symptoms are mostly associated with the lower GI tract hence vomiting is uncommon, with abdominal pain and diarrhea being the main symptoms. An accompanying fever, abdominal pain, and headache are usual, and the diarrhea can be bloody. The illness may last a few days, and the antibiotic *ciprofloxacin* is the treatment of choice for severe or prolonged illnesses.

Septicemia or other localized infections are rare complications. One of the well-known complications of *Campylobacter* infection is *Guillain-Barré syndrome*, in which a symmetrical paralysis affects the body some weeks after the infection. Recovery is usually spontaneous but may take several months. In the acute phases of the illness, *respiratory support* may be needed. Reactive arthritis is also a complication, although infrequent, of *Campylobacter* infections.

### Diagnosis

The organism can be cultured from stools, rectal swabs, and food. Special media and an atmosphere of 3–5% O<sub>2</sub> are needed for culturing *Campylobacter*. Additionally molecular subtyping assays (i.e., PFGE, MLST) can improve accuracy of the results (FDA, 2017; Habib et al., 2019).

## Escherichia coli

### Background

*Escherichia coli* are a remarkable group of bacteria causing a wide range of infections, including gastroenteritis, meningitis, septicemia, and urinary tract infections. Many strains are nonpathogenic. Those that cause GE have a wide range of pathogenic mechanisms and are divided into various fairly distinct groups: enteropathogenic (EPEC), enterohemorrhagic (EHEC), enteroinvasive (EIEC), and enterotoxigenic (ETEC) are the main ones, although some groups—diffusely adherent (DAEC) and enteroaggregative (EAEC)—have been described. EHEC strains, which include *E. coli* O157:H7, produce one or two primary *Shiga toxins* and possess specific adherence factors. However, because the O157 strains are much more common than the other EHEC strains that cause FI, EHEC strains are classified as O157 and non-O157. Shiga toxin is produced by other bacteria also, including *S. dysenteriae* type 1. Only these EHEC Shiga toxin-producing strains are considered in detail here because they are commonly foodborne (about 75% worldwide) and can cause serious illness and death.

ETEC is not identified routinely by stool culture methods commonly used. Infections with ETEC strains are common in developing countries at all ages. These strains are most commonly known to cause *travelers' diarrhea*, but can also be spread by food. This toxigenic group includes strains that produce heat-labile and heat-stable enterotoxins. Heat-labile enterotoxin is closely related to *cholera toxin* and causes profuse watery diarrhea. EPEC strains largely cause infections in neonates and infants, which tend to spread from person-to-person, and are not commonly associated with FI. EIEC and the two newer strains are rare. EIEC outbreaks related to food have been occasionally described, including one associated with French cheese exported to the United States.

In the United States, *E. coli* O157:H7 is estimated to cause 96,000 cases and 31 deaths annually, with 68% of cases being foodborne. Swimming in contaminated water can also transmit the infection. *Escherichia coli* O157:H7 was first recognized as a cause of FI in 1982. Some strains with the Shiga toxin gene produce a toxin that causes the *hemolytic uremic syndrome* (HUS). Many serovars of *E. coli* that can produce Shiga toxin have not been associated with human illness.

*Escherichia coli*, including *E. coli* O157:H7, is an asymptomatic inhabitant of the intestines of many ruminants, including cattle, sheep, and goats. Contamination can occur directly from the intestinal content to carcass to meat or via the feces of these animals to raw vegetables and other foods (CDC, 2021a; Gonzalez-Escalona et al., 2019; FDA, 2017).

### Survival and growth

*E. coli* O157:H7 can survive for days to weeks on contaminated meat and vegetables. The organism is more resistant to acid than *Salmonella*. *E. coli* O157:H7 can survive for 21 days in cider at a pH of 3.7–3.9 at 4 °C, with only approximately a 5% kill-off. It can grow successfully over several weeks in manure slurries. The infectious dose is thought to be very small (less than 100 cells), so person-to-person transmission may occur. Like most vegetative bacteria, it is destroyed by heat (71 °C in moist foods) (Gonzalez-Escalona et al., 2019; FDA, 2017).

### Characteristic sequence of events

As an example, 61 patients in a town in North Cumbria, England had diarrhea, many with blood, over 3 weeks. A total of 114 people were infected, ranging in age from 3 months to 85 years. Investigations implicated a farm supplying pasteurized milk. Nine days before the first case, a problem had occurred in the heat-exchanger plates of the pasteurization unit. No tests were undertaken after new plates were fitted, and temperature monitoring was inadequate. The unit was one that a few months before had been the subject of a food hazard warning. *Escherichia coli* O157 was isolated from 66 environmental and animal feces samples on the farm but not from the milk or the pasteurization plant.

In an outbreak in the United States, more than 700 became ill after eating inadequately heated hamburgers from a restaurant chain. More than 30 cases developed HUS and four died. The largest O157:H7 outbreak (radish sprouts) in Japan affected about 10,000 people.

Undercooked hamburgers and ground beef are a common vehicle of *E. coli* O157:H7 infection. The process of grinding beef can spread the bacteria from the surface of the meat to the inside. Other vehicles of infection include raw milk, unchlorinated water, apple juice, unwashed fruits and vegetables including alfalfa sprouts and bagged spinach, lettuce, and frozen raw cookie dough or swimming in unchlorinated pools (CDC, 2021a; Gonzalez-Escalona et al., 2019; FDA, 2017).

### Clinical features

The infectious dose for *E. coli* O157:H7 is thought to be fewer than 100 bacteria. The typical incubation period is 2–5 days (ranging from 2 to 8 days). Symptoms are mostly associated with the lower GI tract. Severe bloody diarrheal and abdominal cramps are the most common symptoms, but nonbloody diarrhea also occurs. Fever is unusual. The illness may last a few days, and may progress to HUS which is characterized by hemolytic anemia and renal failure, and occurs in approximately 5% of reported *E. coli* O157:H7 cases, most frequently in young children and the elderly (FDA, 2017; Gonzalez-Escalona et al., 2019).

### Diagnosis

The usual method of diagnosis is to isolate the bacteria from stools or food. However, because most of the *E. coli* in the intestine is part of the normal flora and nonpathogenic, it is necessary to demonstrate virulence by further tests or assigning it to a serotype, which normally requires more sophisticated techniques in specialized laboratories. Serotyping is performed on the *somatic cell wall antigens* (O antigen) and the flagellar antigen (H). On the basis of serotyping the O and H antigens and detecting known *virulence factors* or virulence genes such as toxins, the organisms can be classified as EHEC, EPEC, ETEC, etc. Molecular-based tests are increasingly being used. Toxins can be tested for using *immunoassays* or molecular tests based on gene sequences. *Serology* tests of blood from infected humans are also used, but they are not reliable indicators of recent infection (FDA, 2017; Gonzalez-Escalona et al., 2019).

### Other organisms

#### *Shigella* species

Humans and primates are the known reservoirs of *Shigella*, hence this bacterium is often spread by person-to-person, especially among kindergarten and primary school children. Shigellosis occurred in both economically developed and developing countries. Affected patients may excrete Shigellae for weeks. Many large outbreaks of *shigellosis* are associated with consumption of food contaminated by sewage-polluted water or food handlers. In 1995, an extensive *S. sonnei* outbreak associated with lettuce imported from Spain affected people in many countries in northern Europe. In another outbreak associated with shrimp consumption, infection was transmitted by a food handler who mixed the shrimp by hand with *mayonnaise* and tomato sauce. The *incubation period* is typically 1–4 days (ranging from 8 h to 7 days) and although large-volume bloody or mucoid diarrhea and high-grade fever are the usual symptoms, it is characteristically accompanied by *tenesmus*—a feeling of wanting to defecate without being able to do so (CDC, 2021a; Faherty and Lampel, 2019; FDA, 2017).

#### *Listeria monocytogenes*

*Listeriosis*, caused by the bacterium *Listeria monocytogenes*, is an unpleasant and rare infection that typically affects the more vulnerable, such as fetuses, infants, pregnant women, the elderly, and the immunocompromized. It causes *septicemia* and meningitis, which is unusual from an FI bacterium. Fatality rates for invasive disease are high, as many as one in four. *GI symptoms* may be absent or mild. Also unusual, this pathogen can grow (albeit slowly) at normal refrigeration temperatures (0–4 °C). It is also very resistant in the environment, both to cold and to heat, so that it can survive for long periods of time (months to years), especially at refrigeration temperatures. The incubation period for invasive listeriosis tends to be long (up to 3 weeks) but, for GI symptoms, very short periods of 1 day have been recorded. *Deli meats* (especially poultry-based), certain *soft cheeses*, and *patés* have been associated with large outbreaks of listeriosis. In the US, an estimated 1600 people get listeriosis each year and 260 die (CDC, 2021a; Ryser et al., 2019; FDA, 2017). Outbreaks occur sporadically worldwide (WHO, 2021a). South Africa experienced largest outbreak of listeriosis, with 1060 laboratory-confirmed cases and 216 deaths (ready-to-eat process meat products from 2017 to 2018) (Kaptchouang Tchatchouang et al., 2020).

#### *Yersinia enterocolitica*

Like *L. monocytogenes*, *Y. enterocolitica* can grow at refrigeration temperatures (4 °C) or below. It is often missed in the laboratory because it requires special media and generally grows best at 25–30 °C. Many strains are nonpathogenic, although those of *serotype* O 3, 8, or 9 are most commonly associated with illness. The bacterium is largely associated with swine, especially the oral–nasal cavities. Outbreaks have been associated with raw milk and *dairy products*, as well as undercooked meats (i.e., pork, beef, lamb, chitlins) and *tofu*. In one incident, a caregiver who handled swine intestines passed the infection on to some infants. While these infections appear worldwide, according to the current PCR detection, Africa and Western Pacific had the most, and the Americas the least, prevalence of *Y. enterocolitica*. The incubation period is typically 4–7 days, and symptoms of diarrhea often bloody, abdominal pain, and fever, may last from 1 to 3 weeks or longer. In older children and adults, severe right-sided abdominal pain may be confused with *appendicitis*. Infants and young children are most often affected. Clinical features are characteristically fever and profuse watery diarrhea, but may mimic *acute appendicitis*, resulting in an unnecessary operation. Occasionally, in vulnerable patients, septicemia may occur (FDA, 2017; Ukuku and Bari, 2019).

#### *Vibrio parahaemolyticus*

Like *V. cholerae*, *V. parahaemolyticus* is an aquatic bacterium that thrives in shallow coastal waters. Deep-sea fish do not tend to harbor the organism and usually become contaminated in fish markets. Precooked frozen shrimp may be contaminated and transmit FI if served without further cooking, as in a seafood cocktail. *Vibrio parahaemolyticus* FI is associated with raw, undercooked, or cross-contaminated seafood and is especially common in Japan and other countries in which seafood is a staple of the diet. Cross-contamination from raw to cooked seafood is a common mode of transmission. Recent data revealed that the incidence of *V. parahaemolyticus* FI has become the leading cause of seafood-related gastroenteritis in Japan, the United States and several other

parts of the world, caused by a pandemic clone. Diarrhea, abdominal pain, and nausea are the predominant symptoms. The diarrhea can be severe, with blood or mucus in the stool. Vomiting is a less common feature, but fever can occur. The incubation period ranges from 4 h to 4 days, but most cases occur between 12 and 24 h. Death is uncommon.

Diagnosis is made by culture of the bacterium from feces or food. *Vibrio parahaemolyticus* can be easily isolated from most aquatic environments, but such strains are predominantly Kanagawa negative. Only the Kanagawa-positive strains (i.e., those producing a thermostable *hemolysin* that can be confirmed in a laboratory) cause GE, and it is thought that they multiply selectively in the human intestine. The infectious dose is reportedly  $10^5$ – $10^7$  cells (Ceccarelli et al., 2019; FDA, 2017).

### **Vibrio vulnificus**

Like other vibrios, infection with this bacterium is acquired from seafood, largely from consumption of contaminated raw oysters. It can cause a fulminating septicemia by ingress through a skin lesion in the food handler and in people with *chronic liver disease*, through consumption of raw seafood. Gastroenteritis can also occur (Ceccarelli et al., 2019; FDA, 2017).

### **Brucellosis**

Although not usually considered as a FI, *brucellosis* deserves mention because it is associated with food consumption. *Brucella melitensis*, in particular, is largely foodborne, and cheese, milk, and other dairy products made from unpasteurized milk are primary vehicles. Occasionally, contaminated meats may be responsible. *Brucella abortus* is associated with cattle and bovine products, *B. melitensis* with goats, and *B. suis* with swine. Brucellosis is a serious and prolonged systemic illness, with fever, *night sweats*, headache, aches and pains, and, sometimes, profound depression. Many developed countries have eradicated *Brucella* from livestock (FDA, 2017; WHO, 2021a).

### **Streptococcal pharyngitis**

Notwithstanding the definition of FI as causing GE, streptococcal sore throat with fever has been well documented to spread via foods. Usually, a food handler has a *Streptococcus* group A infection in his or her throat, which may be asymptomatic, and transfers this to a food that is then left in a warm environment for several hours before consumption. Foods that have been implicated in illnesses include cheese, milk, eggs, and meat. The incubation period is 24–48 h. To confirm the vehicle, typing of strains is important, as is sound epidemiologic evidence, because many people carry these streptococci in their throats (FDA, 2017).

## **Prevention of bacterial foodborne illness**

With the increasing trend toward manufacturing of foods in large quantities for distribution and globalization, the potential for large outbreaks of *foodborne disease* is considerable. Outbreaks of *salmonellosis* and *E. coli* O157:H7 FI associated with cheese, *salami*, chocolate, peanut butter, beef jerky, dried infant formula, ground beef, and even raw cookie dough have all been documented. In one outbreak of *E. coli* O157:H7 infection, 34 lots of 281,000 lb of beef patties were manufactured in one plant, and 7 of 21 lots tested were contaminated. The introduction of *hazard analysis and critical control point* (HACCP) systems in food manufacturing processes has been a significant advance in the production of safer food and the prevention of FI. *Microbiological criteria* now exist including *ready-to-eat foods*. The establishment of various outbreak-identification surveillance systems (i.e., PulseNet) in the US and elsewhere is an important tool in the early detection of foodborne outbreaks and the curtailment of their effects. These various surveillance systems help link specific (“fingerprinting”) information on microbes causing FI to the source and to specific steps where problems occurred. For example, most outbreaks of FI recently detected in the USA are widespread in scope, with cases occurring in many states. The most commonly identified problems are inadequate cooking, improper temperature control (i.e., leaving *prepared food* too long at too high a temperature), allowing cross-contamination from raw to cooked food, improper cleaning and sanitation of equipment, and food from unsafe sources. Some of these foods were contaminated at the source by polluted water or sewage, others during harvesting or processing by infected food handlers and others by food handlers during preparation. It is difficult to avoid or prevent such infections in the kitchen short of cooking everything, and more stringent codes for hygiene at the growing farms and processing plants are required. In the kitchen, it is important to keep raw foods, such as beef and ready-to-eat foods, entirely separate. Salads and fruit are in the ready-to-eat category. Raw meats, especially, should be handled with separate utensils, surfaces, and cutting boards than for cooked food, unless the utensils and cutting boards are washed thoroughly in very hot water and detergent or a *dishwasher*, and then left to dry. Otherwise, many FI microbes can transfer from raw to cooked food and grow.

Cooking food, especially meat, thoroughly will kill vegetative microbes, including salmonellae, although *bacterial spores* can survive. If the cooling down period is too long—normally approximately 2 h is considered the limit before refrigeration is necessary—*C. perfringens* or *B. cereus* that have survived as spores will grow. So will salmonellae and many other FI bacteria if the food was inadequately cooked. Cooking will not normally destroy preformed toxins of *S. aureus*. Infected food handlers may also cause outbreaks of FI by contaminating food during preparation. Generally, *B. cereus* and *C. perfringens* originate in the

food. Infected food handlers whose hands have been contaminated with their feces are the usual source of *Shigella*, hepatitis A, or *norovirus* in outbreaks of FI.

Moist food should be held either hot (above approximately 60 °C) or cold (below 8 °C, preferably 4 °C). Cooling food, even freezing it, will not destroy foodborne bacterial pathogens. Undercooked chicken that has been refrigerated will still need thorough cooking before it is safe to eat. When in large amounts, frozen meat or poultry should be thawed before cooking. Large frozen turkeys may need several days in a refrigerator to thaw fully. The inside of the meat is the last to thaw and the last to cook. Grinding meat will disperse organisms through it. Hence, *hamburgers* and sausages need thorough cooking.

Drinking raw milk is hazardous: A large variety of bacterial pathogens, from *E. coli* O157:H7 to *Salmonella*, can be spread in this way. Hens' eggs have been the vehicle of many cases of salmonellosis FI (mainly *S. Enteritidis*), especially since the 1980s throughout much of Europe and the United States. The rate of contamination is typically low, such as 1 per 20,000 eggs, but the number of cases has been large because of the popularity of eggs as a food and because it is common practice to eat them less than fully cooked, not only on their own but also in other dishes such as sauces and mousse. Screening and *vaccination* of flocks in recent years have reduced the risk of contamination. Irradiation of food is effective in mitigating *foodborne pathogen* contamination, but is not popular with the public. From a food service and retail food standpoint, as >50% of reported FI outbreaks in recent years are from restaurants, food protection manager certification (i.e., ServSafe®, National Registry of Food Safety Professionals, Prometric) and food handler trainings are required in many states.

Education of food handlers may be straightforward but, especially in countries in which food handlers have low status and pay, compliance is more difficult. Education of the general public has been slow but has progressed, e.g., most people now realize the importance of thawing poultry and meat thoroughly before cooking, and the large outbreaks of salmonellosis. In the US, Partnership for Food Safety Education (PFSE) was formed among federal and state government, industry, and consumer leaders to sign a Memorandum of Understanding to develop science-based, consumer oriented message focusing on four core messages (Clean, Separate, Cook and Chill), and The FightBac! Keep Food Safe from Bacteria was released in 1998.

## Conclusion

Bacterial *foodborne illness* is one of the major global concerns (after norovirus), with millions of cases occurring in the US and globally. This article provides an overview of important causes of bacterial foodborne illness such Salmonellosis, *Campylobacter enteritis*, *Escherichia coli* (*E. coli*) O157:H7 infection, and *botulism*. The more advanced *foodborne disease* surveillance systems become, the more food-associated GE illnesses they uncover. Preventing bacterial FI in modern time requires a system approach with multidisciplinary filed of sciences, multifaceted approaches, multi-agency, and the latest sound science. Government body can improve sanitary infrastructure and enforce food safety regulation informed by surveillance GE data and good sciences. Changes in global environment, along with the changes in global population, and advances in science (i.e., detection, information technology), among other factors, will likely affect FI data and future intervention strategies.

## Key points

- Pesticides are largely used in agriculture to protect crops against the harmful effects insects, weeds, fungi and other pests.
- As chemical pesticides are biologically active substances, they can cause acute and chronic effects on humans and the environment because of their poor selectivity.
- Adverse effects of pesticides on human health depend on the magnitude of exposure and their intrinsic hazards.
- Although developed countries have banned the agricultural use of pesticides that are most toxic to humans and those that persist for a long time in soil and water, they are still used in many developing or underdeveloped countries.
- Agriculture workers who apply pesticides face the greatest health risks from exposure to these chemicals; however, the presence of pesticide residues in food and drinking water represent a consumer's risk.
- International regulatory agencies review evidence and set maximum residue limits (or tolerances) of pesticides in food and water to protect public health.

## Introduction

The Food and Agriculture Organization (FAO) defines pesticides as any substance or mixture of substances intended for preventing, destroying or controlling any pest, including vectors of human and animal disease, and unwanted species of plants or animals causing harm (FAO, 2002). "Pesticides" is, thus, a broad term that includes insecticides, herbicides, fungicides, rodenticides, and plant and insect growth regulators, among others. Commercial formulations of pesticides used in agriculture are referred to as

“plant protection products” (PPPs) and contain the following components which can potentially be harmful to humans and the environment:

- Active ingredient or active substance (i.e., the pesticide itself)
- Safeners, which are added to PPPs to eliminate or reduce their phytotoxic effects on certain plants
- Synergists which, despite having no or weak plant protection activity, enhance the activity of active substances
- Adjuvants, which are co-formulants marketed to be mixed with a PPP to enhance its effectiveness or other pesticidal properties.
- Co-formulants which, although used in PPPs or adjuvants, are not active, safeners or synergistic substances

Most pesticides are organic synthetic derivatives, a few are of mineral origin, and others are biological (also called biopesticides, which can be of plant origin or microbials). As pesticides are biologically active compounds, they must be assessed before being authorized for use, to ensure that they will not pose unacceptable risk to humans, animals or to the environment. While older pesticides had broad targets (they could harm insects, plants, birds, and mammals), the market is continually changing toward newer pesticides intended to be largely effective only against some species (e.g., neonicotinoids), with less toxicity for non-target organisms (Gaforio et al., 2019). However, full selectivity has not been achieved, as non-target species can still be affected (e.g., neonicotinoids are harmful to bees).

## Terminology

“Pesticides” is a broad term often confused with biocides and PPPs when, in fact, it encompasses both. PPPs are substances containing at least one active substance (chemical compounds or microorganisms) aimed at increasing crop yield by protecting plants and their products from harmful organisms. According to the European Food Safety Authority (EFSA), PPPs include insecticides, fungicides, herbicides, acaricides, plant growth regulators and repellents. In contrast, biocides are active substances, including microorganisms intended to destroy, counteract, neutralize, prevent the action of, or exert any other type of control over, any harmful organism to human or animal health and natural or manufactured materials. Biocides are used to control pests and vectors of communicable diseases (insects, rodents, etc.), so their purpose is not agricultural. In the European Union (EU), Regulation 528/2012 classifies biocides into four groups: disinfectants and general biocides, preservatives, pesticides and other biocides.

## Regulation

In the United States (US), pesticides are regulated under two major statutes, the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1996, and the Federal Food, Drug, and Cosmetic Act (FFDCA) of 2002. These laws were amended by the Food Quality Protection Act (FQPA) and the Pesticide Registration Improvement Act (PRIA) of 2003. FIFRA requires all pesticides sold or distributed in the US (including imported pesticides) to be registered by the Environmental Protection Agency (EPA). FFDCA requires EPA to set pesticide tolerances, i.e., maximum permissible level for pesticide residues allowed in or on human food and animal feed. Under FQPA, EPA must find that a pesticide poses a “reasonable certainty of no harm” before it can be registered for use on food or feed. Each pesticide registration must be reviewed at least once every 15 years (EPA, 2020).

The EPA is, thus, primarily responsible for regulating pesticides in the US. EPA’s mission is to protect human health and the environment. The EPA Office of Pesticide Programs (OPP) handles most of the regulatory issues pertaining to pesticides. The FIFRA gives the EPA authority to determine which pesticides can be used in the US, and how they can be used. The EPA (together with other federal and state agencies) evaluates new pesticides and proposed uses, determines if emergency situations warrant temporary approvals of certain pesticides, and periodically reviews current research related to the safety of older pesticides. They also enforce pesticide regulations and provide support to state and regional EPA programs designed to protect, certify and train pesticide applicators (NPIC, 2019).

The EU has a comprehensive regulatory system for pesticides. While active substances are approved at the EU level after an exhaustive evaluation carried out by EFSA in collaboration with Member States, PPPs are authorized by each Member State. The approval of active substances requires the assessment of potential acute, subchronic and long-term effects, as well as genotoxic, reproductive and developmental effects, and neurotoxic or immunotoxic effects, if applicable. The marketing and use of PPPs requires an authorization process that entails the conduct of a strict risk assessment, as established by Regulation (EC) No. 1107/2009. All EU Member States apply the same evaluation and authorization procedures to place PPPs on the market. Regulation 1107/2009 is intended to guarantee a high level of protection of human, animal and environmental health, as well as to safeguard the competitiveness of community agriculture. Vulnerable population groups, such as pregnant women, infants and children, are specifically protected. According to this Regulation, the industry must demonstrate that substances produced or marketed in the EU do not have harmful effects on human or animal health or unacceptable effects on the environment. Regulation 1107/2009 also applies to safeners, synergists, coformulants, and adjuvants.

On the other hand, Regulation (EC) No. 396/2005 establishes harmonized provisions throughout the EU, regarding the maximum residue limits (MRLs) of pesticides in food and feeds of plant and animal origin to guarantee a high degree of protection. MRLs should be set at the lowest possible level in accordance with good agricultural practice (GAP) to protect the most vulnerable groups such as children, embryos and fetuses. This Regulation is aimed to ensure that pesticide residues are not present at levels that

pose an unacceptable risk to humans or animals. Any pesticide lacking an established MRL will not be authorized, and all combinations of pesticides and basic food products that do not have established a MRL are assigned a default value of  $0.01 \text{ mg kg}^{-1}$ . When setting MRLs, the cumulative and synergistic effects of pesticides sharing a common toxicity mechanism must be taken into account. Member States are obliged to carry out controls to ensure that food marketed in the EU complies with the regulations on MRLs. The results of these controls are submitted to EFSA which provides an annual report on pesticide residue levels in foods of the European market.

## Classification

There are many classifications of pesticides, depending on the criteria used. Some are listed below:

1. Chemical nature of the pesticide. The most widespread method is based on the chemical composition and description of the pesticide active substance:
  - Organochlorines
  - Organophosphates
  - Carbamates (*N*-methylcarbamates, thiocarbamates and dithiocarbamates)
  - Pyrethrins and pyrethroids
  - Neonicotinoids
  - Triazoles
  - Bipyridyls
  - Chlorophenoxy acids
  - Triazines
  - Others
2. Pesticide toxicity. Since 2009, the WHO uses the Acute Toxicity Hazard Categories from the Globally Harmonized System of Classification and Labeling of Chemicals (GHS) as the starting point for pesticide classification (WHO, 2020). The GHS was introduced in 2002 with the intent to provide a globally harmonized system to address classification of chemicals, labels, and safety data sheets, and is now widely used for the classification and labeling of chemicals worldwide. Classification for acute toxicity is based on the acute oral median Lethal Dose ( $LD_{50}$ ) value for rats. Nonetheless, dermal toxicity must be considered, as under most conditions of handling pesticides, a high proportion of the total exposure is dermal (Table 1):

In addition to acute toxicity, the GHS also provides classification of chemicals according to their chronic health and environmental hazards. The Joint FAO/WHO Meeting on Pesticide Management (FAO and WHO, 2016) recommended that highly hazardous pesticides should be defined as having one or more of the characteristics depicted in Table 2:

3. According to the entry mode for target organisms, pesticides are classified based on:
  - Contact: action through contact with the body of the insect causing death by paralysis of the nerve centers or by suffocation.
  - Ingestion: action when ingested by the animal, causing death by poisoning.
  - Ingestion and contact: both types of action.
  - Systemic: once absorbed by plants, pesticides travel through the plant's vascular system and reach untreated leaves, flowers and fruits.
  - Fumigants: highly volatile pesticides that act or kill target pests by producing vapor.
4. According to target pests, pesticides are classified as insecticides (act on insects), acaricides (on mites), fungicides (on fungi), nematicides (on worms), herbicides (on "weeds"), phyto regulators (regulate plant growth through plant hormones), molluscicides (act on mollusks), rodenticides (control rodent populations), avicides (control bird populations) or bactericides (kill bacteria).
5. Mixed classification: is widely used and includes information on the specific target pest and the chemical family (Table 3).

**Table 1** Classification of pesticides according to their acute toxicity hazard categories (WHO, 2020).

		<i>LD<sub>50</sub> for the rat (mg kg body weight<sup>-1</sup>)</i>	
		<i>Oral</i>	<i>Dermal</i>
Ia	Extremely hazardous	<5	<50
Ib	Highly hazardous	5–50	50–200
II	Moderately hazardous	50–2000	200–2000
III	Slightly hazardous	≥2000	≥2000
U	Unlikely to present acute hazard	≥5000	≥5000

**Table 2** Characteristics that define highly hazardous pesticides according to the Joint FAO/WHO Meeting on Pesticide Management (FAO and WHO, 2016).

Criterion	Characteristic
Criterion 1	Pesticide formulations that meet the criteria of classes Ia or Ib of the GHS of classification and labeling of chemicals; or
Criterion 2	Pesticide active ingredients and their formulations that meet the criteria of carcinogenicity categories 1A and 1B of the GHS of classification and labeling of chemicals; or
Criterion 3	Pesticide active ingredients and their formulations that meet the criteria of mutagenicity categories 1A and 1B of the GHS of classification and labeling of chemicals; or
Criterion 4	Pesticide active ingredients and their formulations that meet the criteria of reproductive toxicity categories 1A and 1B of the GHS of classification and labeling of chemicals; or
Criterion 5	Pesticide active ingredients listed by the Stockholm Convention in its Annexes A and B, and those meeting all the criteria in paragraph 1 of Annex D of the convention; or
Criterion 6	Pesticide active ingredients and formulations listed by the Rotterdam Convention in its Annex III; or
Criterion 7	Pesticides listed under the Montreal Protocol; or
Criterion 8	Pesticide active ingredients and formulations that have shown a high incidence of severe or irreversible adverse effects on human health or the environment

## Magnitude of pesticide use worldwide

Total pesticide use worldwide has shown a rapid increase, with more than 4 million tons utilized by the year 2017. The major contributing country was China, followed by the US, Brazil and Argentina (**Fig. 1**). These figures give an idea of the magnitude of pesticides consumption which, together with the pesticides intrinsic toxicity, highlights the potential health risk of their use.

Statistics on pesticide sales are used as an indicator of pesticide consumption in agriculture. According to the US-EPA, the amount of pesticides used worldwide increased from 2.20 to 2.64 million tons between 2008 and 2012 (**Atwood and Paisley-Jones, 2017**). Approximately half of these figures (48.9%) corresponded to herbicides and growth regulators, followed by fumigants (19.1%), insecticides (18.3%) and fungicides (13.7%). In the US, agriculture is the activity in which the greatest use of these compounds is made, as around 90% of pesticides are used for the chemical control of pests that act on vegetable and food crops. The remainder is used for environmental (infectious disease vector control) or domestic purposes.

In the EU, pesticide sales remained stable over the period 2011–2018, at around 360,000 tons per year, reaching in 2019 the lowest volume of pesticides sold since the start of data collection (~333,500 tons), which represents a decrease of ~10%. The major groups of pesticides with the highest sales volumes in 2011 and 2019 were “Fungicides and bactericides” and “Herbicides, haulm destructors and moss killers”. Spain, Italy, France and Germany were the four EU countries that recorded the highest volumes sold for most major groups, and in total (**Eurostat, 2021**). When Regulation (EC) No 1107/2009 concerning the placing of plant protection products on the market entered into force, many of the more hazardous substances were removed from the market, as they had their authorization withdrawn.

## Toxicology of pesticides

### Insecticides

#### Organochlorines

Organochlorine pesticides (OCP) are organic compounds of low molecular weight, with a cyclic structure and chlorine atoms in their molecule. They have been widely used worldwide as insecticides and fungicides until the 1960s, when they were banned in most developed countries. OCP are ubiquitous environmental contaminants as they are lipophilic, chemically stable and non-biodegradable; hence, they persist in the environment for long periods, reach the food chain and end up accumulating in the fatty tissue of living organisms. Due to the high persistence and bioaccumulation potential of these chemicals, the Stockholm Convention classified most of them as environmental hazards and banned their use. OCP are structurally divided into 4 groups (**Fig. 2**): chlorinated derivatives of ethane (dichlorodiphenyltrichloroethane –DDT–, methoxychlor), chlorinated derivatives of benzene and cyclohexane (hexachlorobenzene –HCB–,  $\alpha$ -,  $\beta$ - and  $\gamma$ -hexachlorocyclohexane –HCH– isomers, the latter also known as lindane), cyclodienes (endosulfan, aldrin, dieldrin, endrin) and chlorinated camphenes (toxaphene and chlordane). None of these are currently authorized for use in agriculture in the EU.

OCP are efficiently absorbed by respiratory and digestive routes and can easily penetrate through intact skin due to their high lipophilicity (except for DDT). The biotransformation of DDT is extremely slow and consists of a reductive dehalogenation with formation of DDE (dichlorodiphenyldichloroethylene), which has a longer half-life. Therefore, the presence of DDE in the blood indicates long-term exposure, while that of DDT, recent exposure. The high lipophilicity of OCP determines that, once they enter the body, they are eliminated slowly because of their accumulation in the adipose tissue, where they can persist for a long time without

**Table 3** Classification of pesticides according to their functional class (i.e., target pests) and chemical group.

Functional class	Chemical class	Individual pesticide/chemical subgroup	Individual pesticide
Insecticides	Organochlorines	Endosulfan and other compounds banned in most countries (DDT, aldrin, dieldrin, lindane, etc.)	
	Organophosphates	Chlorpyrifos, chlorpyrifos-methyl, dimethoate, ethoprophos, fenamiphos, fostiazate, malathion, phosmet, pirimiphos-methyl	
	<i>N</i> -methylcarbamates	Methomyl, oxamyl, carbofuran	
	Pyrethrins and pyrethroids	Acrinthrins, bifenthrin, cypermethrin, deltamethrin, fluvalinate, cyhalothrin, tralomethrin	
	Neonicotinoids	Imidacloprid, acetamiprid	
	Formamidin	Amitraz, clordimeform, formetanate	
	Natural and biological pesticides	Macrocyclic lactones	Abamectin, spinosad
		Bacterial insecticides	<i>Bacillus thuringiensis</i>
		Botanical insecticides (tetranortriterpenoid)	Azadirachtin
	Growth regulators	Benzoylureas	Flufenoxuron, lufenuron, teflubenzuron
Fungicides	Others	Juvenile hormone analogs	Fenoxycarb, pyriproxyfen
		Bisacylhydrazines	Tebufenozide, methoxyfenozide
		Oxadiazine	Indoxacarb
		Phenylpyrazole	Fipronil
		Pyrazoles	Fenpyroximate, tebufenpyrad
		Pyridazinone derivative	Pyridaben
		Quinazoline	Fenazaquin
		Sulfoximines	Sulfoxaflor
		Tetronic and tetramic acid derivatives (cyclic ketonol)	Spirodiclofen, spiromesifen, spirotetramat
			Ferbam, thiram, ziram
Herbicides	Dithiocarbamates	Dimethyl-dithiocarbamates	Maneb, mancozeb, metiram, nabam, zineb
		Ethylene-bis-dithiocarbamates	Propineb
	Triazoles	Propylen-bis-dithiocarbamates	
		Fenbuconazole, fluquinconazole, flutriafol, myclobutanil, propiconazole, tebuconazole, tetraconazole, triadimenol	
	Inorganic	Copper-based compounds	Copper sulfate, cuprous oxide
		Sulfur and its compounds	
	Benzimidazoles	Thiabendazole, carbendazim, benomyl, thiophanate-methyl	
	Dicarboximide	Vinclozoline, iprodione, procimidone, clozoline	
	Halobenzonitrile	Chlorothalonil	
	Imidazole	Prochloraz	
Others	Morpholine group	Dimetomorf	
	Phthalimides	Captan, folpet, captafol	
	Chloro- nitrophenol	Pentachlorophenol, dinitro- <i>o</i> -cresol, dinoseb	
	Others	(Benzothiazol-2-ylthio)methyl thiocyanate (TCMTB), benzothiazole	
	Bipyridyl (bipyridinium)	Paraquat, diquat	
	Triazines	Atrazine, simazine, cianazine, propazine	
	Chlorophenoxy acids	2,4-Dichlorophenoxyacetic acid (2,4-D)	
		2,4,5-Trichlorophenoxyacetic acid (2,4,5-T)	
	<i>N</i> -(phosphonomethyl) glycine derivatives	Glyphosate, glufosinate	
	Urea and substituted urea (phenylureas, sulfonylureas)	Linuron, monuron, isoproturon, diuron, fluometuron	
Others	Fumigants	Methyl bromide, 1,3-dichloropropene, metam-sodium, aluminum phosphide, zinc phosphide	
	Rodenticides	Thallium sulfate, sodium fluoroacetate, coumarin anticoagulants (warfarin), stricnine	

causing apparent harmful effects. However, OCP can be mobilized by lipolysis in cases of fasting, infection, cancer, pregnancy, etc., eventually causing detrimental health effects (Costa, 2015; Jayaraj et al., 2016).

The main target organ of OCP is the nervous system. Specifically, they inhibit GABA<sub>A</sub>-gated chloride channels, where the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) binds, thus producing neuronal hyper-excitability. Furthermore, DDT, like pyrethroids, binds to voltage-gated sodium channels, keeping them in open state and leading to persistent depolarization and hyperactivity of the nervous system. On the other hand, cyclodienes inhibit calcium ion influx and Ca- and Mg-ATPase, causing

**Fig. 1** Pesticides utilized worldwide from 1990 to 2017. From Roser (2019).

**Fig. 2** Chemical structures of dichlorodiphenyltrichloroethane, DDT (A); endosulfan (B); gamma-hexachlorocyclohexane,  $\gamma$ -HCH (C); and toxaphene (D); representative compounds of the four organochlorine pesticide classes.

release of neurotransmitters (Costa, 2015; Jayaraj et al., 2016). In addition, long-term exposure to OCP may damage the liver and kidney, owing to the presence of chlorine atoms in their molecule, and they may cause skin and mucous membrane irritation. Some are carcinogenic, for example lindane has been classified by the International Agency for Research on Cancer (IARC) in group 1 (carcinogenic to humans) and DDT in group 2A (probably carcinogenic) (IARC, 2018).

An interesting property of OCP is their ability to induce liver enzymes involved in the biotransformation of xenobiotics, such as cytochromes P450 (CYPs), particularly subfamily CYP2B and CYP3A enzymes. This results in accelerated metabolism of both endogenous compounds (steroid hormones) and xenobiotics.

## Organophosphates

Organophosphate (OP) pesticides are mostly phosphoric acid esters (Fig. 3), which differ depending on the atoms or groups attached to phosphorus. Most are insecticides, while a few (fosetyl and tolclofos-methyl) are fungicides. Currently, fosphiazate,

**Fig. 3** Chemical structure of chlorpyrifos, an organophosphate insecticide.

malathion and pirimiphos-methyl are the only OP insecticides authorized for agriculture use in the EU. The authorization status of chlorpyrifos, chlorpyrifos-methyl, dimethoate, ethoprophos, fenamiphos and phosmet was shifted to non-authorized in the past few years.

OP compounds have partly replaced organochlorine insecticides, due to their low persistence in the environment where they undergo (bio)degradation. They do not accumulate in the body, as they are metabolized yielding non-toxic metabolites. Nevertheless, OPs have higher acute toxicity.

OPs easily enter the body by all routes. The skin is responsible for a high proportion of poisonings in occupational settings. Application of OPs generates aerosol droplets that can be inhaled by sprayers or by-standers which, like other respiratory irritants, can lead to reactive dysfunction of the airways. Irritation is generally restricted to the upper airways, although dyspnea (shortness of breath) and chest tightness may occasionally occur. When droplets are small enough ( $<10\ \mu\text{m}$  in aerodynamic diameter) they can reach the alveoli and be absorbed through the respiratory route, eventually leading to systemic effects.

The half-life of OPs and their degradation products is relatively short (hours or days). OPs are biotransformed in the liver by oxidation, hydrolysis and conjugation. Plasma esterases (paraoxonase-1, -PON1-) also play a prominent role, particularly in chronic exposure to low doses. The major breakdown products of OPs are dialkylphosphates (DAPs), which are non-specific metabolites common to many OPs. Urinary DAP concentrations have been used to estimate human exposure to OP pesticides (Hernández et al., 2019).

Many OP pesticides are not directly active, but need to be activated by oxidative desulfuration to oxons, which are potent acetylcholinesterase (AChE) inhibitors. These oxidations are almost always catalyzed by the CYP450-dependent monooxygenase system which can be induced by some agents, including OCP, hence the potential risk from combined use of these compounds (Hernández et al., 2013).

OPs exert their main toxicological effects through non-reversible phosphorylation of AChE, an enzyme responsible for degrading the neurotransmitter acetylcholine in the central nervous system, neuromuscular junction and autonomous nervous system. The irreversible inhibition of AChE leads to an excess of acetylcholine in cholinergic synapses, causing overstimulation of muscarinic and nicotinic receptors in postsynaptic neurons, resulting in muscarinic, nicotinic and central syndromes. The severity of poisoning depends not only on the extent of AChE inhibition, but also on the speed of inhibition (Costa, 2008; Hernández and Pla, 2007).

Clinically, exposure to OPs may produce four toxic syndromes. The first is the cholinergic syndrome, typical of acute poisoning with various degree of severity. The second is the so-called intermediate syndrome, which appears 24–96 h after the acute cholinergic crisis, consisting of weakness and even paralysis of respiratory muscles, neck flexor muscles, proximal limb muscles, and muscles innervated by cranial motor nerves. The third is known as organophosphate-induced delayed polyneuropathy (OPIDP), which appears 10–21 days after exposure to some OPs (e.g., methamidophos) and is characterized by impairment of distal parts of sensory and motor axons in peripheral nerves and ascending and descending tracts of spinal cord. Neuropathy target esterase (NTE) is thought to be the molecular target of OPIDP. The fourth clinical syndrome is considered as long-term effects that persist for several months after exposure to high doses of OPs, or after long-term low-dose exposure, leading to neurobehavioral changes (e.g., anxiety, mood swings, emotional lability, depression, fatigue, irritability, drowsiness, confusion, and lethargy). These symptoms, collectively known as chronic OP-induced neuropsychiatric disorders (COPIND), are thought to involve non-cholinesterase targets, due to the highly reactive nature of OPs (Abou-Donia, 2003).

### *N*-methylcarbamates

The term “carbamates” covers a wide family of pesticides, including derivatives of *N*-methylcarbamic, thiocarbamic and dithiocarbamic acids, which are used as insecticides, herbicides and fungicides, respectively. However, *N*-methylcarbamates are the only carbamates showing anticholinesterase effects and, thus, cause similar acute toxic effects as OPs. Examples of these chemicals include: aldicarb, carbaryl, carbofuran, methomyl (Fig. 4), oxamyl, pirimicarb and propoxur. *N*-methylcarbamates are not persistent in the environment and do not accumulate in the body.

*N*-methylcarbamates are absorbed by all routes, including the skin. They undergo liver metabolism through oxidation, hydrolysis mediated by carboxylesterases, and conjugation, yielding phenols as major metabolites that are eliminated in the urine. At sufficient doses, *N*-methylcarbamates cause similar acute toxicity as the OP insecticides, as both have the same mechanism of toxic action. However, *N*-methylcarbamates inhibit AChE in a reversible way (the carbamate–AChE binding reverts spontaneously in a few hours) such that their effects are less severe and of shorter duration. Hence, both the morbidity and mortality of *N*-methylcarbamates is limited. Another important difference is that these compounds do not easily cross the blood-brain barrier and barely enter into the brain, such that their effects on the central nervous system are limited; nonetheless, brain dysfunction may still occur in massive intoxication (Colović et al., 2013; Costa, 2008).

**Fig. 4** Chemical structure of methomyl, an *N*-methylcarbamate insecticide.

### Pyrethrins and pyrethroids

Pyrethrins are a mixture of six chemical insecticides found naturally in some chrysanthemum flowers. They do not accumulate in the body, their excretion is rapid, and they do not persist in environmental media, as they degrade rapidly. However, their cost, high biodegradability and lack of photostability limit the use of pyrethrins, which require piperonyl butoxide (with low oral toxicity) as a synergistic agent to enhance their insecticidal effectiveness. For this reason, analogous products were synthesized with structure and properties similar to pyrethrins, the so-called pyrethroids. These are esters of chrysanthemic acid with a broad activity spectrum, excellent selectivity and improved field stability. They are classified into two groups: type I pyrethroids (i.e., esters lacking the  $\alpha$ -cyano substituent: allethrin, bifenthrin, permethrin, phenothrin, tetramethrin, resmethrin, tefluthrin) and type II pyrethroids (esters containing the  $\alpha$ -cyan substituent: cyfluthrin, cyhalothrin, cypermethrin, deltamethrin (Fig. 5), phenpropathrin, fenvalerate, flucythrinate, flumethrin, fluvalinate and tralomethrin).

The acute mammalian toxicity of pyrethrins is generally low. The most common adverse effect is their great sensitizing power, related to the sesquiterpene lactones contained in the plant extract (pyrethrum). These substances cause allergic rhinitis and contact dermatitis (O'Malley, 1997). Natural pyrethrins are more toxic by skin contact than by ingestion, while synthetic pyrethroids are more potent when ingested. However, the latter are not skin sensitizers or irritants, although may cause inflammation and paresthesia after coming into contact with the skin. Pyrethroids can be absorbed by ingestion or inhalation and, to a lower extent, through intact skin, although significant neurotoxic effects have been observed in animals through this route. In the body, pyrethroids undergo rapid hydrolysis mediated by carboxylesterases, followed by oxidation of the resulting alcohol to aldehyde and acid metabolites, which are rapidly excreted from the body. This rapid metabolism leads to low mammalian toxicity. Urine concentration of 3-phenoxybenzoic acid, a common metabolite of many pyrethroids, can be used for biological monitoring of recent exposure to these chemicals (Costa, 2008, 2015).

Pyrethroids bind to voltage-gated sodium channels in nerves. Analogously to DDT, type I pyrethroids prolong channel opening only long enough to cause repetitive firing of action potential. Conversely, type II pyrethroids hold the channels open for such long periods that the membrane potential ultimately becomes depolarized and the generation of action potential is not possible (depolarization-dependent block) (Costa, 2015). Two distinct acute poisoning syndromes have been described in experimental animals: the T-syndrome, produced by type I pyrethroids and pyrethrins, featured by tremor, ataxia and sensitivity to sensory stimuli; and CS-syndrome, produced by type II pyrethroids, which is characterized by choreoathetosis and salivation. Both syndromes may also induce paralysis (WHO, 2005).

### Neonicotinoids

Neonicotinoids are a class of systemic insecticides that have become the most widely used group of insecticides globally. Currently there are 4 generations of neonicotinoids. Imidacloprid (Fig. 6), acetamiprid, thiacloprid, and nitenpyram belong to the first generation, all of which contain the chloropyridine ring and yield 6-chloronicotinic acid as a common metabolite, often used as a urinary biomarker of exposure in biomonitoring studies. The main second-generation neonicotinoid is thiamethoxam, which originates a metabolite that also exhibits insecticidal activity (clothianidin). Dinotefuran is the main third-generation neonicotinoid, and sulfoxaflor and cycloxaprid are members of the fourth generation (Simon-Delso et al., 2015).

Neonicotinoids have rapid oral absorption and are completely eliminated from the body by 48 h, so they do not accumulate. They undergo CYP450-mediated oxidation, which differs depending on animal species and each neonicotinoid. Certain metabolites are as or more toxic than the parent compound, such as *N*-denitro-imidacloprid, which has a high affinity for mammalian nicotinic acetylcholine receptors (nAChRs). The mode of action of neonicotinoid insecticides is similar to nicotine, a natural insecticide. They are agonists of postsynaptic nAChR in the nervous system, allowing for an influx of cations ( $\text{Ca}^{2+}$ ,  $\text{Na}^{+}$ , or  $\text{K}^{+}$ , depending on the nAChR subtype) through the central channel pore. Differences in the properties and structure of nAChR subunits between insects and mammals partly explain the high selectivity of neonicotinoids over insects and the relative low toxicity to vertebrates.

Fig. 5 Chemical structure of deltamethrin, a type II pyrethroid insecticide.

Fig. 6 Chemical structure of imidacloprid, a neonicotinoid insecticide.

While neonicotinoids are selective for receptor subtypes in the vertebrate brain ( $\alpha 4\beta 2$  and  $\alpha 7$ ), they have little or no effect on nAChRs of the peripheral nervous system. These insecticides were originally believed to exert low human and mammalian toxicity because of their lower chemical affinity for mammalian nAChRs and their inability to cross the mammalian blood-brain barrier. However, *in vitro* and *in vivo* studies, as well as ecotoxicological studies, indicated that these insecticides have adverse effects on mammals, even at sublethal doses, as they can affect mammalian nAChRs in a similar way to nicotine (Cimino et al., 2017; Houchat et al., 2020).

Following high dose exposure, neonicotinoids cause gastrointestinal symptoms consisting of nausea, vomiting, abdominal pain, and corrosive oral mucosa damage. Skin and eye irritation can also occur. Stimulation of nAChR in the autonomic nervous system leads to tachycardia, hypertension, diaphoresis, and mydriasis. Neurodevelopmental and reproductive effects have also been reported (Cimino et al., 2017; Selvam and Srinivasan, 2019).

## Fungicides

### Dithiocarbamates

The dithiocarbamic acid class of fungicides includes dimethyl-dithiocarbamates (DMDTC, e.g., ferbam, thiram and ziram), ethylene-bis-dithiocarbamates (EBDC, e.g., maneb, mancozeb, metiram, nabam and zineb) and propylene-bis-dithiocarbamates (propineb).

Dithiocarbamates (DTC) (Fig. 7) are organosulfur compounds that bind to various transition metals, forming more lipophilic complexes capable of entering the central nervous system. The nomenclature of DMDTC and EBDC compounds is derived from the cationic metals to which they are associated (e.g., iron to ferbam, zinc to ziram and zineb, sodium to nabam, manganese to maneb, etc.). Some DTC metabolites are highly reactive electrophilic compounds that can covalently bind to thiol groups in cysteine residues. Although their acute toxicity in experimental animals is low or moderate, some worrying adverse effects have been reported, such as teratogenesis and reproductive disorders (embryotoxicity). Prolonged or repeated exposure to these compounds can cause dermatitis or conjunctivitis and, if inhaled, bronchospasm. Although inhibition of AChE has been reported for some DTC, it is considered weak or null (Hernández and Pla, 2007; Janz, 2014).

EBDC are metabolized in mammals, and degraded in the environment, to ethylene thiourea (ETU), a mutagenic, carcinogenic, teratogenic and immunotoxic agent in animals, which has raised concerns about the human toxicity of EBDC fungicides. In addition, ETU affect thyroid function by decreasing the synthesis of thyroid hormones, leading to decreased plasma concentration of T4 and a compensatory increase in TSH. On the other hand, DTC fungicides yield a common metabolite, carbon disulfide, which is responsible for the fungicidal and disinfectant properties posed by many DTCs. This metabolite can also cause peripheral neuropathy that persists for a period of time (Lushchak et al., 2018).

Chronic exposure (4–5 years) to maneb can lead to parkinsonism, a syndrome that has been attributed to the extrapyramidal effects caused by manganese (although its blood concentration is not usually elevated), and also to oxidative stress as a result of dopamine autooxidation, generation of reactive oxygen species, reduced glutathione (GSH) and decreased activities of antioxidant enzymes (Lushchak et al., 2018).

### Triazoles

Azoles are antifungal agents widely used in agriculture, in clinical practice and in cosmetic products. They are classified into imidazole or triazole derivatives, depending on the number of nitrogen atoms in the 5-atom ring and which is responsible for the fungicidal activity (Fig. 8).

While imidazole compounds are used mostly as pharmaceuticals, triazoles can be used as drugs (fluconazole, voriconazole, itraconazole) or plant protection agents (tebuconazole, propiconazole, tetraconazole, fluquinconazole, hexaconazole, myclobutanil, triadimefon, triadimenol, etc.). The antifungal mechanism of action of azoles consists of inhibiting C14 $\alpha$ -demethylase (CYP51),

Fig. 7 General chemical structure of dithiocarbamate fungicides

Fig. 8 General chemical structure of azole fungicides: triazole (A) and imidazole (B).

an enzyme that catalyzes the transformation of lanosterol into ergosterol, a component of the fungal cell wall. These compounds can cause adverse effects in humans due to nonspecific binding to various CYP450 isoenzymes, although triazoles show less affinity for human CYP450 than for fungal. CYP19 (aromatase), the enzyme that converts androgens into estrogens in steroidogenesis, is one of the CYP450 inhibited by azoles in humans. They also inhibit other CYP450s involved in steroid biosynthesis and may interact with nuclear receptors, especially androgen and estrogen receptors with different affinities. In rats, maternal exposure to the imidazole fungicide prochloraz produces malformation of the male reproductive tract and diminishes testicular steroidogenesis, indicating antiandrogen effects (Ye et al., 2011).

Contact with triazoles may cause irritation and redness of the skin and mucous membranes. Orally, they have low toxicity. In experimental animals, myclobutanil produces toxicity in the testes, adrenal gland, kidney and thyroid. Most triazoles have hepatotoxic effects, and only some are toxic to reproduction and development (e.g., triadimefon), causing teratogenic effects such as craniofacial and axial skeletal malformations (Marrs and Ballantyne, 2004).

Exposure to triazoles, in general, causes rodent neurotoxicity. Acute exposures to triadimefon affect catecholamines in the central nervous system and induce a transient syndrome in rats consisting of hyperactivity and stereotyped behaviors (Crofton, 1996). Triadimefon and its metabolite triadimenol can inhibit dopamine reuptake in mammals by blocking the dopamine transporter (DAT). While tebuconazole may not produce neurotoxic effects in adults, it may lead to developmental neurotoxicity when the exposure occurs during development (Filipov and Lawrence, 2001).

### Benzimidazoles

The benzimidazole family of fungicides includes carbendazim, benomyl, thiabendazole and fuberidazole. Although imazalil and thiophanate-methyl are also included in this fungicide class, they lack the typical benzimidazole moiety consisting of a fusion of benzene and imidazole ring system (Fig. 9). These compounds inhibit microtubule formation by binding to free  $\beta$ -tubulin monomers. Thiabendazole is a slightly toxic compound also used to treat some helminthiases in veterinary medicine and in humans. Carbendazim is the main metabolite of benomyl and thiophanate-methyl, and produces toxic effects on the seminiferous epithelium by inhibiting polymerization of  $\beta$ -tubulin, thus interfering with microtubule formation. Carbendazim also exerts androgenic effects which are not related to the androgen receptor but to a lower expression of estrogen receptors (ER $\alpha$  and  $\beta$ ). Carbendazim specifically acts on the blood-testicular barrier, affecting germ cell migration (Durand et al., 2017; Pisani et al., 2016).

### Herbicides

#### Bipyridyl (or bipyridinium)

These are solid herbicides that contain a bipyridyl ring structure with quaternary ammonium that form salts with bromide and chloride anions very soluble in water. The most widely used are paraquat and diquat (Fig. 10), while cyperquat, diethamquat, difenzoquat, and morfamquat are little used or no longer marketed.

Paraquat is an excellent herbicide, widely used in agriculture, but withdrawn from the European market in 2007. Paraquat is poorly absorbed by any route but, given its high toxicity, it can cause severe and life-threatening poisonings with a high mortality rate. As paraquat is highly corrosive, it damages the skin and the digestive mucosa, thus improving its absorption through these routes. Accidental poisonings have occurred after drinking water from discarded paraquat bottles as well as from sustained dermal

Fig. 9 General chemical structure of benzimidazole fungicides.

Fig. 10 Chemical structure of the bipyridyl herbicides paraquat (A) and diquat (B).

exposure in agriculture settings due to leaking backpack sprayers. Once absorbed, paraquat is rapidly distributed through all well vascularized organs, and accumulates in the lungs, the main target organ, by selective uptake via the polyamine transport system abundantly expressed in the membrane of type I and type II alveolar cells, and Clara cells. In contrast, diquat does not bind to these transporters, which explains its different toxicokinetic and toxicity. Paraquat metabolism generates oxygenated free radicals responsible, in part, for mucous membrane lesions and secondary necrosis of the gastrointestinal tract, liver, kidney and adrenal glands by lipid peroxidation. Redox cycling and intracellular oxidative stress generation are, thus, the main molecular mechanisms of paraquat toxicity. After an irritant action on the mucous membranes (which causes acute gastrointestinal distress), and following a latency period of 7–14 days in which hepatorenal toxicity and myocardial damage occurs, paraquat produces pulmonary fibrosis. Epidemiological and experimental studies have considered paraquat as a risk factor for Parkinson's disease. Despite its cationic nature, paraquat is able to cross the blood-brain barrier using membrane transporters (Marrs and Ballantyne, 2004; Bronstein, 2004; Dinis-Oliveira et al., 2008).

### Chloro-S-triazines

The 2-chloro-s-triazine family of herbicides is widely used as broad-spectrum herbicides that inhibit photosynthesis in plants. They have a triazine ring and the best known are: atrazine (Fig. 11), cyanazine, propazine, simazine and terbutylazine, although the latter is the only one currently approved in the EU for agricultural use.

These compounds persist in the environment and are mobile in soil and groundwater. Groundwater contamination resulted in the cancellation of atrazine and simazine registrations in Europe. Triazine herbicides have low oral toxicity and are unlikely to pose acute hazards with normal use, although some of them are moderately irritating to the eyes, skin and respiratory tract. Atrazine and other triazines have raised concerns for human health based on limited evidence of carcinogenicity, reproductive/developmental effects, organ toxicity, immune system effects, and genotoxicity to humans. Atrazine, simazine and propazine, and their major chlorinated metabolites, have been reported to induce aromatase (CYP19), the rate-limiting enzyme in the conversion of androgens to estrogens, and to disrupt the hypothalamic–pituitary–gonadal (HPG) axis. Observed changes in progesterone and testosterone concentrations can be partially attributed to triazine-induced alterations in steroidogenic gene expression (Forgacs et al., 2013; Semren et al., 2018).

### Chlorophenoxy acids

These herbicides are structural analogs of auxin, a plant growth hormone not found in mammals, that causes uncontrolled and lethal growth in target plants. They are derived from phenoxyacetic acid and include 2,4-dichlorophenoxyacetic acid (2,4-D, Fig. 12), 4-chloromethylphenoxyacetic acid (MCPA), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), diclofop-methyl, mecoprop and dichlorprop. These herbicides can be easily transferred to surface and ground waters due to their polar nature and relatively good solubility.

Chlorophenoxy esters are absorbed from the gastrointestinal tract and excreted in urine, mostly unchanged, within 24 h. They are believed to elicit toxicity by inducing cell membrane damage and uncoupling of oxidative phosphorylation. Though these compounds generally have low mammalian toxicity, oral ingestion of overdoses causes nausea, vomiting, abdominal pain, diarrhea and myotonia. These symptoms are followed by muscle twitching, metabolic acidosis, and a hypermetabolic state with hyperthermia, tachycardia, hypertension, sweating, seizures, and coma. Cases of peripheral neuropathy have been described after exposure to significant amounts of 2,4-D via the skin for several days. 2,4-D has also been associated with adverse changes in lipid concentrations, glucose metabolism, and TSH concentration, which may predispose to heart disease and diabetes (Schreinmachers, 2010).

2,4,5-T has teratogenic properties in experimental animals, as it is inherently contaminated during its synthesis with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which is ultimately responsible for neurological and behavioral changes (neurasthenia gravis and depressive syndrome), and hepatic and cutaneous alterations (e.g., porphyria cutanea tarda and chloracne) (Bronstein, 2004).

Fig. 11 General chemical structure of Chloro-S-Triazine herbicides.

Fig. 12 Chemical structure of 2,4-dichlorophenoxyacetic acid (2,4-D), a phenoxyacetic acid derivative herbicide.

Chronic exposure to chlorophenoxy acids has been associated with non-Hodgkin's lymphoma, soft tissue sarcomas, chronic lymphocytic leukemia and bladder cancer; however the evidence is not entirely consistent (Jayakody et al., 2015).

### N-phosphonomethyl amino acids

The two compounds in this class are glyphosate (*N*-phosphonomethyl glycine) and glufosinate (*N*-phosphonomethyl homoalanine). Both are broad-spectrum, non-selective systemic herbicides marketed primarily as isopropylamine salt (glyphosate) or ammonium salt (glufosinate). Despite containing a P = O moiety in their molecule (Fig. 13), they are not organophosphate esters and do not significantly inhibit AChE.

Glyphosate exerts its herbicidal activity by inhibiting 5-enolpyruvyl-shikimate-3-phosphate synthase, a key enzyme in the shikimate pathway essential for the synthesis of aromatic amino acids in plants. However, this metabolic route is not found in mammals. The use of glyphosate spread due to the development of transgenic crops capable of tolerating this herbicide to the extent that it is the most widely used herbicide worldwide. As acute toxicity is low (oral and cutaneous LD<sub>50</sub> for the isopropylamine salt are >5000 mg/kg), high doses are necessary for intoxication to occur, and mortality is low. Glyphosate is poorly absorbed from the digestive tract, undergoes little biotransformation yielding aminomethylphosphonic acid (AMPA) as the major metabolite, and both are excreted by the feces and urine. Thereby, glyphosate does not accumulate in the body. While mild intoxication leads to transient gastrointestinal distress, moderate or severe intoxication causes upper gastrointestinal bleeding. In severe cases, hypotension, metabolic acidosis and pulmonary, renal, cardiovascular and neurological involvement are observed, with a decrease in the level of consciousness (Marrs and Ballantyne, 2004; Costa, 2008).

Commercial formulations of glyphosate contain other substances that have particular toxicities, such as isopropylamine and the non-ionic surfactant polyoxyethyleneamine (POEA, also known as polyethoxylated tallow amine, which increases the herbicidal effect by promoting the penetration of glyphosate in plants). While the first formulations caused acute and ocular toxicity (eye irritation) after occupational exposure to the concentrated formulation, the change in co-formulants reduced this risk. Studies in animals suggest that the acute toxicity of the glyphosate formulation was due to the surfactant POEA, with an oral LD<sub>50</sub> of 1200 mg kg<sup>-1</sup> in rats. In 2016 POEA was banned in all commercial glyphosate formulations in the EU and replaced by propoxy-lated quaternary ammonium surfactants, which are less toxic to aquatic ecosystems and humans (Mesnage et al., 2019).

Glyphosate does not show teratogenic, developmental or reproductive effects and chronic toxicity studies have shown negligible effects. Genotoxicity and carcinogenicity studies in animals have yielded controversial results and, according to the US-EPA and EFSA, the available evidence does not allow the conclusion that glyphosate poses carcinogenic risk, whereas IARC classified it as probably carcinogenic in humans (Group 2A) (Tarazona et al., 2017). The largest prospective cohort study of licensed pesticide applicators found no association with solid tumors or lymphoid malignancies (Andreotti et al., 2018).

### Dietary risk assessment of pesticide residues in food

The application of PPPs in agricultural crops represents a risk to consumer health due to the presence of pesticide residues in fruits and vegetables. The aim of dietary risk assessment is to determine whether the levels of pesticide residues in food commodities and drinking water pose an unacceptable risk for consumers. This assessment combines available pesticide residue data with data from food consumption surveys to estimate potential residue intake by consumers. The latter information is then compared with health-based guidance values (HBGVs) for each pesticide, which are based on referent points (also known as points of departure) derived from regulatory toxicology studies. The HBGVs used in dietary risk assessment of pesticide residues are the Acceptable Daily Intake (ADI, expressed in mg of residue per kg body weight per day) for long-term intake, and the Acute Reference Dose (ARfD, expressed in mg of residue per kg body weight), for short-term dietary intake (<24 h). Based on current scientific knowledge, when the dietary exposure to a substance is found to be lower than, or equal to, its HBGV, the risk to consumer health is low or negligible. Conversely, when the HBGV is exceeded, possible negative health outcomes cannot be excluded (EFSA et al., 2021; FAO, 2017).

In the EU, national and international monitoring programs have been implemented to determine the presence of pesticide residues in food to identify when MRL<sup>1</sup> are exceeded, and to provide representative data to assess the risk to consumer health derived from the presence of pesticide residues in food. According to the results of the last thirteen EU annual reports on pesticide residues in food (from 2007 to 2019), the proportion of cases where MRLs were exceeded remained stable, between 2.5% and 4.5%

**Fig. 13** Chemical structure of glyphosate, an *N*-phosphonomethyl amino acid herbicide.

<sup>1</sup>Highest level of a pesticide residue that is legally tolerated in or on food or feed when pesticides are applied correctly (i.e., according to Good Agricultural Practice) ([https://ec.europa.eu/food/plants/pesticides/maximum-residue-levels\\_en](https://ec.europa.eu/food/plants/pesticides/maximum-residue-levels_en)).

NR: not reported.

(Table 4). Nevertheless, if the uncertainty of the analytical determinations were accounted for, the percentage of exceedances of the MRL would be lower.

The analysis of the health-risk to European consumers is usually performed using a deterministic model that bases its calculations on conservative assumptions. A more realistic methodology, based on probabilistic modeling to exposure to multiple chemicals, has recently been developed and implemented by EFSA.

Overall, the risk assessment for the consumption of foods of animal or plant origin in the European population indicates that it is unlikely that short- and long-term exposure to pesticide residues could affect the consumers' health. This underlines the high standards of food safety in the EU.

## Conclusion

Pesticides are biologically active substances that undergo strict safety assessment before being authorized for use, to ensure that they will not pose harmful effects to human, animal or environmental health. The limited selectivity of pesticides has increased over time to maximize their specific effect against pests while reducing their impact on non-target beneficial organisms. The necessity of developing and using more selective pesticides has led to advances in their sustainable use. The most at-risk population are agricultural workers who apply pesticides, as they are directly exposed to these chemicals, whereas the population in the vicinity area during and shortly after spraying pesticides show indirect exposure. The general population is also exposed, although to a lesser extent, to significantly lower levels of pesticides through the presence of their residues in food and water. Important achievements in relation to pesticides have been the banning of those that are most toxic to humans, and those that remain for the longest time in the environment. The protection of public health by setting MRLs in food commodities and drinking water, as well as the regular monitoring of pesticide residues in food, represent other important achievements. Nonetheless, the implementation of environmental monitoring programs is also needed.

## Key points

- Outline the sources of fructose in the food supply
- Describe the production and uses of high fructose corn syrup in the food industry
- Outline the estimated intake of fructose and sugars in the Western diets
- Briefly outline the physical and chemical properties of fructose
- Describe the absorption and metabolism of fructose
- Discuss the health implications of increased fructose consumption, namely the effects on dyslipidemia and lipid accumulation, obesity, insulin resistance and type 2 diabetes, coronary heart disease risk and dental caries
- Describe inborn errors of fructose metabolism

## Glossary

**Glycosidic bond** A covalent bond that joins the hemiacetal group of a saccharide molecule and the hydroxyl group of some organic compound (e.g., an alcohol)

## Nomenclature

**mM** Millimolar, a molar concentration measurement unit.

## Introduction

The most frequently encountered naturally occurring sugars are sucrose, fructose and glucose (dextrose). Among these, fructose (also known as levulose) and glucose (also known as dextrose) are simple monosaccharides, while sucrose (also known as table sugar) is a disaccharide formed by a fructose and a glucose molecule linked together through a glycosidic bond. Fructose is the sweetest of all monosaccharides and it is naturally present alongside glucose in ripening fruits and honey. It can be used as fuel for the human body and it is a major constituent of industrial food sweeteners (Tappy and Lê, 2010; Scientific Advisory Committee on Nutrition, 2015).

Sugar consumption became increasingly popular after the 18th century, when sugar cane became abundant and extraction methods of refined sugars from sugar cane became available (Tappy and Lê, 2010). Sugar consumption increased dramatically during the 20th century and became a major component of the human diet.

## Properties and sources of fructose

Natural sources of dietary fructose are fruits, fruit juices, honey and some root vegetables. In these foods, fructose is found unbound and also as a component of sucrose (Table 1). However, the primary source of fructose in Western diets is sugars added to baked goods, candies, soft drinks, and other beverages sweetened with sucrose and high fructose corn syrup (HFCS), also known as added sugars. Both sucrose and fructose are used extensively in the food industry as additives to provide sweetness, texture, and palatability. These sugars also contribute to the appearance, preservation, and energy content of the food product.

### High fructose corn syrup (HFCS)

Until the 1960s sucrose was the sole sweetener ingested, with only small amounts of glucose and fructose consumed. Technological advances in the food industry in the 1960s made possible the extraction of starch from corn, its hydrolysis to glucose and subsequent conversion of part of glucose into fructose. Consequently, sweeteners from corn were produced, among which was HFCS. HFCS has useful physical and functional characteristics, among which are high sweetening power, flavor enhancement, long-lasting moisture preservation, long self-life maintenance and improved texture. These characteristics contributed to the gradual substitution of HFCS at the expense of sucrose as an industrial nutritive sweetener. HFCS is produced with varying fructose-to-glucose ratios. The predominant forms of HFCS used are HFCS-55, which contains 55% fructose, and HFCS-42, which contains 42% fructose. HFCS and sucrose contain comparable amounts of glucose and fructose. The difference of the two sweeteners is that in HFCS glucose and fructose exist in solution in their free form, while in sucrose the two sugars exist as a disaccharide.

**Table 1** Sugar content of selected common plant foods (g sugar per 100 g food).

Food item	Total carbohydrate	Total sugars	Free fructose	Free glucose	Sucrose	Fructose to glucose ratio	Sucrose as a % of total sugars
Apple	13.8	10.4	5.9	2.4	2.1	2	19.9
Apricot	11.1	9.2	0.9	2.4	5.9	0.7	63.5

Sweet potato	20.1	4.2	0.7	2.3	2.5	0.9	60.3
Yam	27.9	0.5	Trace	Trace	Trace	Not applicable	Trace
Sugar cane		13–18	0.2–1.0	0.2–1.0	11–16	1	100
Sugar beet		17–18	0.1–0.5	0.1–0.5	16–17	1	100

Data obtained from <https://nal.usda.gov/legacy/fnic/food-composition>, Nutritive and Nonnutritive Sweetener Resources accessed on February 9, 2022.

**Table 2** Relative sweetness of nutritive sweeteners.

Type of sweetener	Relative sweetness to sucrose <sup>a</sup>
HFCS <sup>b</sup> (42% fructose)	100
HFCS <sup>b</sup> (55% fructose)	100–110
HFCS <sup>b</sup> (90% fructose)	120–160
Lactose	40
Dextrose	70–80
Fructose	150–170
Sucrose	100

<sup>a</sup>Compared to sucrose in a 15% solution.<sup>b</sup>HFCS high fructose corn syrup.Data from [Pancoast and Junk \(1980\)](#).

HFCS is produced by hydrolyzing corn starch to glucose, using  $\alpha$ -amylase and glucoamylase. This process is followed by treatment with glucose isomerase, which isomerizes glucose to a mixture of 90% fructose and 10% glucose (HFCS-90). Subsequently, HFCS-90 is mixed with glucose syrup to produce HFCS-55 and HFCS-42. Both HFCS-55 and HFCS-42 have distinct physical and chemical properties, which enable their use in specific food manufacturing areas. HFCS-55 has high fructose content, is sweeter than sucrose and it is utilized as a sweetener in sugar-sweetened beverages. HFCS-42 is mildly sweet and does not mask natural food flavors. Therefore, it is utilized in canned and baked goods, and in dairy processed foods. Relative sweetness of various nutritive sweeteners is outlined in [Table 2](#).

### Fructose consumption

The major sources of fructose in the United States diet are HFCS and sucrose, which are used as caloric sweeteners in the food industry, followed by other foods sources, namely fruits, vegetables, honey and other syrups. Fructose consumption for the United States can be calculated from the United States Department of Agriculture (USDA) Loss-Adjusted Food Availability Database. According to this database, HFCS consumption in 1970 was close to zero and gradually increased with the increasing use of HFCS in the food industry ([usda](#)). The increase in HFCS intake was coupled with a decrease in the consumption of other nutritive sweeteners, mainly sucrose, peaked in 1999 and has been declining ever since. Overall, total sugar consumption did not change significantly from 1970 to 2020 and has remained less than 90 g per day in the United States, with HFCS consumption being approximately 26 g per day ([usda](#)).

Fructose consumption in the United States can be also calculated from survey data, using the third National Health and Examination Survey (NHANES) which provided data from single 24 h dietary recalls administered in 21,483 children and adults ([Vos et al., 2008](#)). According to this survey, the mean consumption of fructose was 55 g per day and 10% of total energy intake. It was observed that adolescents had higher fructose consumption at 73 g per day, which was 12% of total energy intake. Furthermore, this study showed that the largest source of fructose was sugar-sweetened beverages (30% of total energy intake), grains (22% of total energy intake) and fruit or fruit juice (19% of total energy intake).

A recent review of sugar consumption from nationally representative dietary surveys (24 h dietary recalls or dietary records) of developed countries suggests that total sugar consumption as a percentage of energy was the highest in infants and young children, with a mean value of 28% and gradually decreased in adults to 20% ([Newens and Walton, 2016](#)). Added sugars intakes in pre-school children were reported as higher than 10% in Australia, the United Kingdom, and the United States. In school-aged children and adolescents, mean added sugars intakes were higher than 19%, and gradually decreased during adulthood to lower than 10% of total energy intake ([Newens and Walton, 2016](#)). Therefore, it was concluded that added sugar intakes were the largest among school-aged children and adolescents.

Another review of worldwide trends in intake of dietary sugars of developed countries concluded that dietary sugar consumption had been either decreasing or stable in most of the countries studied ([Wittekind and Walton, 2014](#)). Multiple national surveys revealed that dietary sugar intake varied by subpopulation, and an increase of dietary sugar intake was observed only in a few countries and specific subpopulations.

### Physical properties

Fructose is a white solid, and it is the most water soluble of all sugars. It dissolves rapidly in small amounts of water, a characteristic applicable in candy making. The high solubility of fructose produces softer sweets than those containing other sugars. This property prevents fructose from forming ice crystals and is responsible for its hygroscopicity and humectancy. Therefore, fructose may improve the quality and texture, as well as enhance the self life of food products.

Fructose is the sweetest of all natural sugars and this is the main reason for its utilization in the food and beverage industry as a sweetener. Sweetness ratings of fructose are between 150% and 170%, compared to the standard, sucrose, rated at 100%. Heating reduces the sweetness of fructose. Fructose can be used as a flavor enhancer, since it displays synergistic sweetness enhancing effects when blended with other sweeteners and amplifies sweetness.

### Chemical properties

Fructose is a 6 carbon polyhydroxy ketone, shares the same molecular formula with glucose, but has distinct structural characteristics, which means that it is an isomer of glucose. The structure of fructose, similarly to all monosaccharides, can be presented as a 6-carbon linear molecule (open chain). Fructose also forms cyclic structures called hemiketals due to internal hydrogen bonding. When it is in solution, fructose exists in equilibrium mixture of its cyclic structures and open chain conformation. Fructose undergoes the chemical reactions of ketones.

### Fructose absorption

Dietary fructose is ingested either as a simple monosaccharide (pure fructose or HFCS) or as part of the disaccharide sucrose, which is digested at the intestinal brush border. Subsequently, it is transported by a fructose-specific hexose transporter, GLUT-5, located at the apical pole of the enterocyte and it is mainly expressed in intestinal epithelial cells. Fructose transport, contrary to glucose, does not require energy in the form of adenosine triphosphate (ATP) and does not depend on sodium. When fructose is inside the enterocyte, it is absorbed by facilitated diffusion using a basolateral transporter, GLUT-2, which also transports glucose and galactose. GLUT-2 is highly expressed in intestinal epithelial cells, hepatocytes, pancreatic  $\beta$ -cells, and kidney epithelial cells. When fructose is absorbed by the intestine, it arrives at the liver through the hepatic portal vein and then it is metabolized in hepatocytes.

However, the human body appears to have a limited capacity to absorb fructose, especially when ingested without concomitant glucose ingestion. Consumption of a large amount of fructose may result in abdominal bloating, diarrhea, and flatulence. The intestinal absorptive capacity for fructose increases when glucose is consumed along with fructose. Thus, co-ingesting glucose to roughly balance fructose, as occurs when most fruits or sucrose are consumed, largely alleviates problems of fructose malabsorption.

### Fructose metabolism

#### Hepatic fructose metabolism

Following absorption, fructose is quickly transported into hepatic cells through the GLUT-2 transporter (Tappy and Lê, 2010). Fructose is readily extracted by the liver because of the presence of an active hepatic enzyme system for metabolizing fructose, and the majority of ingested fructose is cleared in a single pass through the liver (Tappy and Lê, 2010). Thus, the concentration of fructose circulating in the blood is low after consumption of moderate amounts of fructose. Fructose enters the glycolytic pathway through conversion to intermediate compounds in the liver (Fig. 1), and as a result, fructose is not generally available for uptake by other tissues.

In the liver, fructose is phosphorylated and forms fructose-1-phosphate. This reaction requires ATP and is catalyzed by fructokinase, an enzyme with high affinity and specificity for fructose. Fructose-1-phosphate is then cleaved by hepatic aldolase (aldolase B) to form dihydroxyacetone phosphate and glyceraldehyde. Dihydroxyacetone phosphate is an intermediate metabolite in both the gluconeogenic and glycolytic pathways. Thus, a portion of the original fructose carbon structure forms glucose, and, in fact, a small increase in circulating glucose occurs after ingestion of fructose. The glyceraldehyde intermediate is phosphorylated by triokinase to form glyceraldehyde-3-phosphate, another intermediate in the glycolytic pathway. The triose phosphate compounds provide substrates for glycolysis and oxidative metabolism. Nonetheless, most fructose gets converted into glucose. With the formation of the triose phosphates, the metabolism of fructose and glucose converges.

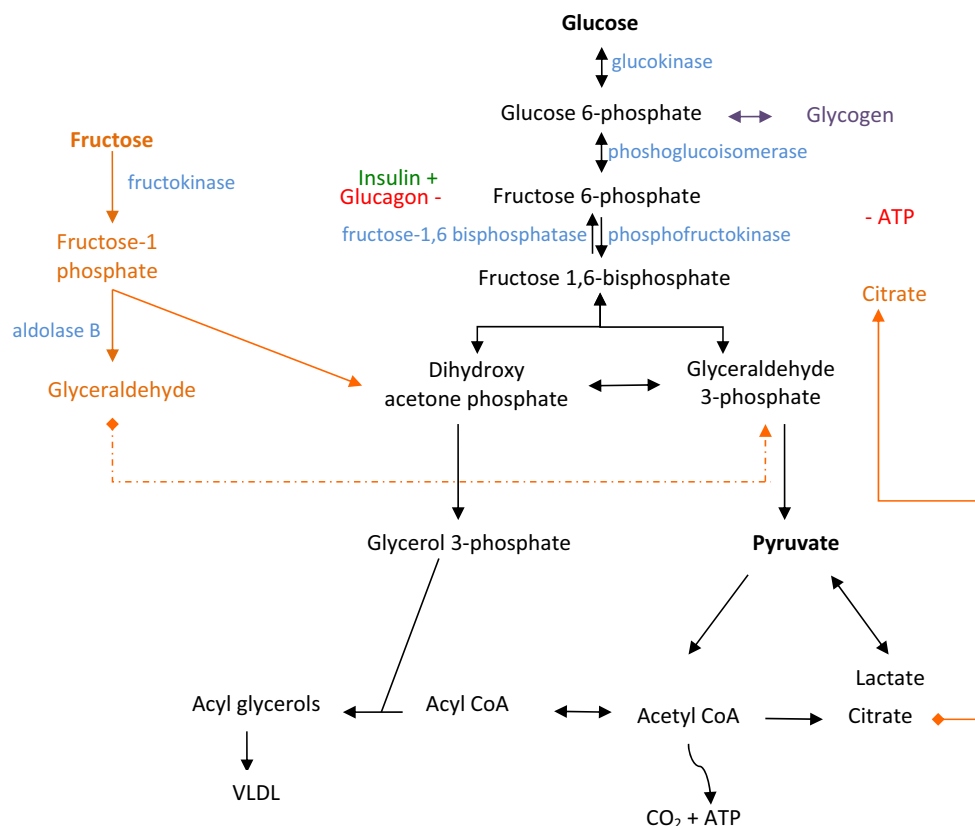

Increased fructose consumption may saturate the glycolytic pathway with intermediates, stimulating de novo lipogenesis and triacylglycerol synthesis. Dihydroxyacetone phosphate may be converted to glycerol, and acetyl CoA may enter the lipogenic pathway to form fatty acids that are then esterified to the glycerol molecule to form triacylglycerols.

The metabolic fate of ingested fructose is the following: in hepatic tissue, the largest part of fructose (~67%) is converted to glucose (Tappy and Lê, 2010). The majority (~50%) is released as plasma glucose and a small part (~17%) is stored as glycogen in the liver. A proportion of the fructose (~25%) is converted into lactate in the enterocytes and in the liver, and a minor portion of fructose is converted into fatty acids, through the process of de novo lipogenesis.

### Fructose vs. glucose metabolism

There are important differences in fructose and glucose metabolism that impact both carbohydrate and lipid metabolism. Initially, when glucose enters the glycolytic pathway, it is controlled by glucokinase, an enzyme with high affinity for glucose. The rate of glucose phosphorylation, which is catalyzed by glucokinase, changes with respect to fluctuations in glucose concentration. Glucose 6-phosphate is then converted to fructose 6-phosphate, a reaction catalyzed by the allosterically regulated enzyme

**Fig. 1** Utilization of fructose and glucose in the liver. Adapted from Elliott et al. (2002).

phosphofructokinase (PFK), which is the most important control point in the glycolytic sequence. Among the multiple effectors of PFK are ATP and citrate; these products of glucose oxidation exert an inhibitory effect on the enzyme. The allosteric inhibition of PFK effectively reduces the rate of glycolysis and decreases hepatic glucose uptake overall. Furthermore, conversion of glucose to pyruvate is controlled by insulin and energy requirements of the cell. On the contrary, fructose metabolism does not depend on insulin, and it occurs rapidly due to the lack of the inhibitory action of ATP and citrate. Consequently, there is a short-lived decrease of free phosphate and ATP in liver cells after fructose ingestion. Furthermore, large amounts of lactate are produced after ingestion of fructose molecules in comparison to equal amounts of glucose molecules.

### Extrahepatic fructose metabolism

Extrahepatic fructose metabolism does not occur under normal conditions, since extrahepatic cells do not express fructokinase for the phosphorylation of fructose (Tappy and Lê, 2010). After parenteral fructose administration, fructose concentration in the plasma raises 1–2 mM. Even high-dose fructose infusions that raise plasma fructose to 3 mM have shown to raise fructose uptake by the kidney not more than 20% of total fructose turnover (Tappy and Lê, 2010).

### Free vs bound fructose metabolism

It has been proposed that free fructose, in the form of HFCS, has different effects compared to bound fructose, in the form of sucrose. Current data from short-term studies in healthy and type 2 diabetic volunteers do not support the hypothesis that free fructose and bound fructose are metabolically different. Short-term ingestion of fructose in the form of HFCS has been shown to have similar metabolic responses (fasting plasma glucose, insulin, leptin and ghrelin concentrations) to fructose in the form of sucrose in healthy volunteers and type 2 diabetes (Tappy and Lê, 2010). Furthermore, no differences were observed between consumption of preload drinks containing sucrose, HFCS or milk on insulin, glucose, glucagon-like peptide-1 (GLP-1), ghrelin and appetite score in lean volunteers (Tappy and Lê, 2010). There is no evidence to date to support the hypothesis that free fructose in the form of HFCS is metabolically different from bound fructose in the form of sucrose.

## Health implications

As fructose is metabolized in a different manner than glucose and other monosaccharides, it has been proposed that it promotes lipid accumulation, insulin resistance, obesity and other metabolic abnormalities. Most of the accusing evidence originates from consumption of fructose in the form of sweetened beverages.

### Fructose consumption and dyslipidemia

Some studies have shown that *de novo* lipogenesis is increased after acute fructose intake (Tappy and Lê, 2010). Several randomized controlled trials have investigated the effects of short-term fructose consumption on fasting blood lipids and other measures of adiposity and lipid dysregulation at various levels of dietary intake. Some short-term studies showed increased plasma triacylglycerols after consumption of fructose sweetened beverages, in comparison to non-fructose sweetened beverages, at fructose intake 8–30% of total energy intake (Tappy and Lê, 2010). Randomized trials have reported no adverse effects of fructose vs non-fructose intake on total cholesterol, low density lipoprotein (LDL) or high density lipoprotein (HDL) at fructose intake of up to 30% total energy intake (Scientific Advisory Committee on Nutrition, 2015).

Most of these studies have used extremely high fructose intakes (25–30% of total dietary intake), which far exceed the normal quantities of fructose in the human diet. Furthermore, most studies compare pure fructose with non-fructose carbohydrate, which is different than the sucrose or HFCS consumed in the typical diet (Rippe and Angelopoulos, 2013). Dietary sources of fructose contain comparable amounts of fructose and glucose and a diet which is fructose dominant is rarely encountered.

It can be concluded that some short-term studies have reported unfavorable effects of fructose consumption on plasma triacylglycerols. Nonetheless, there is lack of concrete evidence that fructose consumption at typical population levels may contribute to lipid dysregulation. Further studies are needed to address this hypothesis.

### Fructose consumption and obesity

A large proportion of fructose in the diet originates from sugar-sweetened beverages. Foods high in sugars are highly palatable, and can create a potential risk for energy overconsumption and weight gain. Furthermore, consumption of sugar-sweetened drinks may contribute to weight gain because of the low satiety of liquid foods.

Most of the evidence on fructose-sweetened foods and beverages is derived from cohort studies. Systematic reviews of large cross-sectional studies investigating the effect of consumption of fructose-sweetened beverages and the risk of weight gain have shown conflicting results (Tappy and Lê, 2010; Rippe and Angelopoulos, 2013; Scientific Advisory Committee on Nutrition, 2015). There is a lack of experimental studies to examine the impact of individual sugars, such as glucose, fructose or sucrose on body weight.

### Fructose consumption and insulin resistance and type 2 diabetes

Historically, in the nutritional management of diabetes mellitus, the ingestion of fructose was recommended as a sweetener for patients because it causes smaller increases in blood glucose following ingestion, compared to similar amounts of glucose, sucrose, or starches. In fact, fructose, in small quantities, increases the hepatic uptake of glucose and promotes glycogen storage, probably by stimulating the activity of hepatic glucokinase. Also, in individuals with type 2 diabetes, the addition of a small amount of fructose to an oral glucose tolerance load improves the glycemic response, indicating improved glycemic control (Scientific Advisory Committee on Nutrition, 2015).

Prolonged feeding of fructose or sucrose to animals impairs insulin signaling and induces insulin resistance (Baena et al., 2016). Less is known about the effect of fructose ingestion on glucose tolerance and insulin resistance in humans, as the scientific literature contains conflicting results (Tappy and Lê, 2010; Scientific Advisory Committee on Nutrition, 2015). Studies of long-term beverage consumption using more direct measures of insulin sensitivity are clearly warranted.

### Fructose consumption and coronary heart disease risk

Prospective cohort studies have been analyzed to investigate the relationships of sugar-sweetened beverages consumption with biomarkers of coronary heart disease. Sugar-sweetened beverage consumption has been positively associated with increased risk of coronary heart disease and adverse changes in inflammatory factors (Scientific Advisory Committee on Nutrition, 2015).

Meta-analyses of prospective cohort studies have reported an increased risk of hypertension with higher intake of sugar-sweetened beverages (Malik and Hu, 2019). Further experimental studies are needed to confirm these findings and examine the impact of individual sugars, such as glucose, fructose, or sucrose on coronary heart disease.

### Fructose consumption and caries

Sucrose and fructose are considered the most cariogenic sugars. The dental plaque formed while sucrose is present has been demonstrated to have lower mineral content of calcium, inorganic phosphate, and fluoride, all of which re-mineralize enamel and dentin (Fidler Mis et al., 2017). Fructose and glucose are more cariogenic than starches because they are metabolized quickly and produce

a higher decrease in pH (Fidler Mis et al., 2017). Saliva can neutralize and repair the loss of minerals resulting from this process (Scientific Advisory Committee on Nutrition, 2015). When this loss of minerals exceeds the capacity of saliva to re-mineralize the tissues, tooth decay occurs (Scientific Advisory Committee on Nutrition, 2015). The amount of dietary sugar intake has been shown to affect caries formation, along with oral hygiene, fluoride supplementation and use. The incidence of dental caries has decreased worldwide, because of the increased use of fluoride and improvement of oral hygiene (World Health Organization, 2015).

Prospective cohort studies show that the quantity and frequency of dietary sugar and sugar-containing beverage intake play a significant role in tooth decay and are positively associated with high risk of caries development (World Health Organization, 2015; Scientific Advisory Committee on Nutrition, 2015; Fidler Mis et al., 2017). Data indicate that dental caries are less common in countries where sugar intake is below 15–20 kg per person per year (World Health Organization, 2003). This figure translates to a daily intake of 40–55 g per person and to a total energy intake of 6–10% (World Health Organization, 2003). Worldwide ecological studies and randomized controlled trials have consistently shown a relationship between high sugar consumption, mainly sucrose, and tooth demineralization and tooth decay (Scientific Advisory Committee on Nutrition, 2015; World Health Organization, 2003). When annual sugar consumption exceeds 15 kg per person per year, dental caries also increase (World Health Organization, 2003).

### Inborn errors of fructose metabolism

Several genetically based abnormalities in fructose metabolism have been described in humans. They are summarized in Table 3.

#### Essential or benign fructosuria

Essential fructosuria is an autosomal recessive disorder of fructose metabolism which occurs due to a deficiency of fructokinase, the enzyme which catalyzes the conversion of fructose to fructose 1-phosphate. Consequently, fructose cannot be contained in the liver in the form of fructose 1-phosphate and accumulates in the blood. Fructose is then partly excreted in the urine and the remaining is converted to fructose-6-phosphate in adipose tissue and muscle, a reaction catalyzed by hexokinase (McGrane, 2012). Therefore, blood fructose values decline. This disease is not harmful and does not have any symptoms.

#### Hereditary fructose intolerance or hereditary fructosuria

Fructose intolerance is an autosomal recessive disease, caused by a genetic defect of fructose 1-phosphate aldolase (aldolase B) in the liver (McGrane, 2012). The symptoms of aldolase B deficiency usually start when the infant is exposed to fructose or sucrose through their diet at the time of weaning. Fructose and sucrose consumption results in hepatic and renal accumulation of fructose 1-phosphate and subsequent toxicity. Furthermore, fructose 1-phosphate causes fructokinase inhibition and decreased fructose uptake in the liver, resulting in fructosemia (Malik and Hu, 2015). If left untreated, depletion of the cellular phosphate pool and severe organ damage can occur.

Fructose intolerance is characterized by abdominal pain, nausea, vomiting, and metabolic abnormalities, such as hypoglycemia (Malik and Hu, 2015). Early diagnosis of fructose intolerance is essential as the toxic effects of fructose can be fatal. The primary therapy is elimination of all fructose sources, intravenous glucose to alleviate hypoglycemia and supplementation with folate and vitamin C (Tran, 2017).

**Table 3** Inborn errors of fructose metabolism.

<i>Name of disease</i>	<i>Enzyme defect</i>	<i>Main clinical symptoms</i>	<i>Treatment</i>
Essential fructosuria	Fructokinase	Asymptomatic	No treatment
Hereditary fructose intolerance	Aldolase B	Abdominal pain Nausea Hypoglycemia symptoms Shock-like syndrome after fructose ingestion	Withdrawal of all sources of fructose Intravenous glucose for hypoglycemia Supplementation with folate and vitamin C Avoiding catabolic triggers
Fructose-1,6-bisphosphatase deficiency	Fructose-1,6-bisphosphatase	Life-threatening episodes of hypoglycemia  Coma triggered by a febrile episode, fasting or large amount of fructose ingestion	Frequent feeding (avoid overfeeding)  Hypoglycemia correction with oral and/or IV glucose In the absence of triggers no carbohydrate supplements needed Restriction of fructose, sucrose and sorbitol

Adapted from Tran (2017).

### Fructose-1,6-bisphosphatase (FBPase) deficiency

FBPase deficiency is an autosomal recessive disease, caused by a genetic defect of FBPase (Tran, 2017). FBPase has a critical role in the enzyme complex regulating glycolysis and gluconeogenesis. FBPase deficiency inhibits glucose production from lactate, glycerol and gluconeogenic amino acids. It is diagnosed in infants within the first weeks of life, when they become dependent on carbohydrate metabolism. When infants are fasting, normoglycemia is maintained by glycogenolysis and depends on the availability of hepatic glycogen. FBPase deficiency results in hypoglycemia and inability to synthesize glucose from gluconeogenic substrates.

Deficient individuals exhibit hypoglycemia, acidosis, ketonuria, hyperventilation, and often hypotonia and hepatomegaly. Furthermore, urinary excretion of many organic acids is altered. FBPase deficiency results in elevation of urinary glycerol, which is used in the diagnosis of this disease. It may result in life-threatening hypoglycemic episodes and coma (Tran, 2017). The treatment includes avoidance of dietary fructose, sorbitol, and prolonged fasting.

### Summary

Dietary fructose is a natural component of fruits, fruit juices, honey, and some root vegetables. Fructose is the sweetest of all natural sugars and it extensively utilized in the food and beverage industry as a nutritive sweetener in the form of sucrose or HFCS. World-wide surveys of fructose consumption have revealed either steady or declining trends in dietary intake of fructose. It is mainly metabolized in the liver, in a different manner than glucose. Although fructose in the form of sweetened beverages has been implicated in accumulation of lipids, in the development of obesity and other metabolic abnormalities, further studies are necessary to confirm this hypothesis. Fructose appears to play a role in the development of dental caries. Several genetic abnormalities of fructose metabolism have been described in humans, causing benign or serious disease.

### Key points

- To describe the chemical composition and nutritional compounds found in fruits and vegetables.
- To describe the bioactive compounds and their health effects.
- To establish the health benefits of a diet rich in fruits and vegetables.
- To present evidence on the consumption of fruits and vegetables and the risk of certain chronic diseases.

### Introduction

Daily consumption of fruits and TO PGN: check the copyright year as in nimblevegetables is essential to achieve a balanced, nutritious, and adequate diet to reach the feeling of satiety without exceeding the energy value appropriate for a correct diet. From this point of view, fruits and vegetables are essential foods for achieving “adequate nutrition” because of their relatively low caloric density, providing a wide variety of nutrients. In recent years, there has been a series of advances in nutrition on the scientific evidence showing that some food components of the diet can offer beneficial physiological effects beyond the nutritional effects traditionally considered.

According to the World Health Organization (WHO), insufficient intake of fruits and vegetables is one of the ten major risk factors contributing to mortality. It is estimated that up to 1.7 million lives could be saved each year if the global consumption of fruits and vegetables was adequate. This intake helps ensure adequate intake of vitamins, minerals, dietary fiber, and bioactive compounds, and their increased intake can help displace foods rich in saturated fat, sugars, or salt.

Fruits and vegetables have a wide variety of bioactive compounds that, even in low concentrations, have shown effects on the reduction of chronic noncommunicable diseases. Plants synthesize these substances, called phytochemicals, as a defense system against aggression by external agents, and some of them are responsible for the color, taste, and odor of these foods.

The nutritional composition of fruits and vegetables varies significantly according to type, variety, and origin, and other factors related to handling, conservation, and storage conditions. These food groups are characterized by high water, fiber, and some minerals and vitamins, and low protein and fat content. Their high capacity of hydration, low energy density, providing feeling of satiety, and hedonic character (color and attractive taste) are remarkable. They also possess small amounts of other chemical compounds such as organic acids, phenolic compounds, aromatic compounds, and pigments.

Currently, modern conservation methods, genetic improvement, the great varietal dynamism existing within crops, and the wide range of presentations available on the market (fresh, dried, canned, frozen) are facilitating, without doubt, the consumption of these foods throughout the year.

### Definition and classification of fruits

In Botany, fruits are defined as the edible parts of plants that develop from the flowers and contain seeds inside. Within this context, edible fruits of a fleshy nature that can be consumed without preparation are called fruits. Although tomato or cucumber, for example, meets the requirements of this definition, they are considered vegetables for cultural reasons ([Ruiz-López and García-Villanova Ruiz, 2017](#)).

*From a botanical point of view*, the fruits can be classified into:

1. Fleshy fruits (derived from a single flower):
  - **Drupe:** Fleshy pericarp that surrounds a seed with a woody shell.
    - Apricot, plum, peach.
    - Avocado, mango, sour cherry, cherry.
    - Aggregates (strawberry, raspberry, blackberry).
    - Rowanberries: Part of the flower is the floral receptacle (peduncle).
    - Apple, pear, quince.
  - **Berries:** Fleshy fruits with tiny seeds freely arranged in the pulp.
    - Grape, blueberry, bananas, papaya, cherimoya.
    - Date, watermelon, melon, currant, kiwi.
    - Hesperidium or citrus fruits (orange, lemon, tangerine, lime).
2. Compound fleshy fruits (derived from an inflorescence):
  - **Sorosis:** Pineapple.
  - **Syconium:** Fig.

## Nutritional components of fruits

### Energy

The fruits are characterized by low in calories, as shown in [Table 1](#), except avocado, which in many Mediterranean countries is consumed with the salad and not as dessert fruit itself, and banana, whose carbohydrate content (starch and simple sugars) provides a higher energy. The other fruits provide an energy of approximately 30 kcal/100 g of edible portion.

### Water

The mean water content is between 81% and 93%. Banana and avocado have a lower content. In general, the mean water content of the most consumed fruits is shown in [Table 1](#).

### Carbohydrates

#### Sugars

The main sugars are sucrose, glucose, and fructose. The type of predominant sugar depends on the type of fruit. Thus, the drupes (plum, apricot, cherry, peach, etc.) have mainly sucrose, except for cherries. For reducing sugars (glucose and fructose), glucose is usually in a larger proportion. Seed fruits (apples, quinces, pears) also have glucose and fructose, but in this case, the proportion of fructose is higher and continues to increase, even after harvesting.

#### Starch

It is usually found only in unripe fruit, decreasing its concentration throughout ripening. Exceptions are cherimoya and banana with 1.5% and more than 3%, respectively.

#### Fiber

It is composed of cellulose, hemicellulose, pectin, and lignin. At harvest time, it reaches values of up to 3%. Hemicelluloses contribute to the firmness of the fruits and are hydrolyzed when maturing, producing mainly pentoses, mannoses, and uronic acids. Pectins are polymeric compounds derived from galacturonic acid that highly influence the texture and consistency of fruits. The texture variations experienced by fruits during the development in the tree are closely related to the modifications that the pectins experience. Insoluble pectic substances (protopectins) are degraded by enzymatic action to soluble forms and these, in turn, to simpler compounds (galacturonic acid); the latter usually occurs in overripened fruits. Pectins are included within the so-called soluble fiber and are therefore associated with the effect of satiety, slowing glucose absorption, decrease in cholesterol absorption, and regulation of gastrointestinal motility. The total fiber content ranges from 0.3% of watermelon to 2.5% of banana.

**Table 1** Energy and major components of some fruits of habitual consumption (expressed in 100 g edible portion).

Fruit	Energy (kcal)	Water (g)	Carbohydrate <sup>a</sup>	Total sugar (g)	Fiber (g)
Apple	52	85.6	11.4	10.4	2.4
Apricot	48	86.3	9.1	9.2	2.0
Banana	89	74.9	19.8	12.2	2.6
Blueberries	57	84.2	12.1	9.9	2.4
Cantaloupe melon	34	90.2	7.3	7.8	0.8
Cherries	63	82.2	14	12.8	2.1
Grapes	69	80.5	17.2	15.5	0.9
Kiwi	58	84.0	11	8.9	3.0
Mango	60	83.5	13.4	13.6	1.6
Orange	47	86.7	9.3	9.3	2.4
Peach	42	88.3	8.6	8.3	1.5
Pear	57	83.9	12.1	9.7	3.1
Pineapple	50	86.0	11.7	9.8	1.4
Plum	46	87.2	10	9.9	1.4
Strawberries	32	91	5.7	4.9	2.0
Tangerine	53	85.2	11.5	10.6	1.8
Watermelon	30	91.4	7.1	6.2	0.4

<sup>a</sup>Carbohydrates do not include dietary fiber.

Source: U.S. Department of Agriculture, Agricultural Research Service (2019).

### Polyalcohols

Significant amounts of sorbitol, which may have a concentration-dependent laxative effect, are found in drupes—such as apples, plums, or pears. However, this polyalcohol is not found in bananas, strawberries, or pineapple, which can even be used to identify its presence in fruit preparations.

### Nitrogenous compounds

Fruits are characterized by the low content of nitrogenous compounds with values ranging from 0.1 to 1.5% and consist of free amino acids, amines, and proteins. Free amino acids are widely distributed and constitute 50% of soluble nitrogen compounds.

### Lipids

The lipid fraction of fruits comprises triglycerides, glycolipids, phospholipids, carotenoids, triterpenoids, and waxes and are found in very low concentration, with values between 0.1% and 0.5% of fresh weight. There is an exception in the avocado pulp that can reach up to 30%. The seeds of the drupes are rich in lipids (50%–37%), while those pomes have a content of 20%. In pomes, waxes covering their epidermis have also been studied because of their interest in controlling fruit transpiration and the protection they provide against the atmospheric agents and the attack of insects and parasites.

### Vitamins

Fruits supply a significant proportion of vitamins C and A (the latter, in the form of provitamin). They contain other vitamins, such as vitamin E and B-vitamins, but their contribution to the diet is small, with some exceptions (Table 2). Vitamin C is formed in plants from hexoses, and its distribution in them is uneven. For example, a gradient of the vitamin C content was found in peach from the skin, the richest part, to the fleshy portion near the stone, the poorest part. In apples, during all stages of development, the vitamin C content of the skin is three to five times higher than that of the pulp. The richest apples in this nutrient are the colored varieties and those exposed to the sun in the tree. Most of the ascorbic acid of oranges is in the peel and only a quarter in the orange juice. Strawberries ( $\approx 60$  mg/100 g), which are consumed seasonally, or kiwi ( $\approx 94$  mg/100 g), consumed throughout the year, are also notable for their contents in vitamin C. Fruits that provide vitamin C include acerola (*Malpighia emarginata*), also called cherry of the Antilles: It is an acid fruit of red color (there are other varieties of yellow and purple colors), which is characterized by containing a quantity of vitamin C of 690–4800 mg/100 g. It can be eaten fresh, although its main consumption is as juice. It is also used in the food industry for vitamin C enrichment of fruit juices. The folic acid content of fruits is low, although in oranges it is 40  $\mu$ g/100 g; it is 45–62  $\mu$ g/100 g in strawberries and raspberries; and it is 30  $\mu$ g/100 g in kiwi (Table 2). The vitamin A intake from fruits comes from carotenoids ( $\alpha$ -carotene,  $\beta$ -carotene,  $\gamma$ -carotene, and  $\beta$ -cryptoxanthin), which are the ones that can become retinol inside the organism.

**Table 2** Vitamin content of some commonly consumed fruits (100 g of edible portion).

Fruit	Thiamin mg	Riboflavin (mg)	Niacin (mg Eq)	Folate ( $\mu$ g)	Vit. C (mg)	Vit. A ( $\mu$ g RAE)	Vit E (mg)

### Minerals

Potassium is the most representative mineral element of the fruit; in some fruits, potassium can account for 50% of the ashes. Avocado, kiwi, melon, black grapes, and banana stand out as fruits with potassium content of up to 300 mg/100 g of edible portion. The low sodium content should also be highlighted, making these foods very suitable for people with hypertension. **Table 3** shows the composition in the most representative minerals.

### Definition and classification of vegetables

The definition of vegetables considers the edible parts of a plant and is usually grouped according to the consumed plant portion. This definition excludes the fruits defined above (Garcia-Villanova Ruiz, 2017).

Thus, vegetables can be classified into:

- Tubers: Sweet potato, potato
- Bulbs: Garlic, onion, leek
- Roots: Carrot, beetroot, turnip
- Fruits and inflorescence: Tomato, pepper, zucchini, pumpkin, eggplant, cucumber, artichoke
- Leaves and stems: Spinach, lettuce, chard, endive and asparagus
- Flowers: Cabbage, savoy cabbage, red cabbage, broccoli, Brussels sprouts, cauliflower.

### Nutritional components of vegetables

#### Energy

Vegetables are low energy density foods, with values less than 50 kcal/100 g, except starchy vegetables (potato, sweet potato, and cassava) and garlic (**Table 4**).

#### Water

Water is the major component of vegetables. Water content in vegetables ranges from 80% to 95%. A high percentage of vegetables show values above 90%. Starchy vegetables (sweet potato and cassava) and garlic (59%) have lower water content than other vegetables (**Table 4**).

#### Carbohydrates

They are the main macronutrient of vegetables. Carbohydrate content can be very variable, and in most vegetables the values are less than 7%, except tubers, potato, sweet potato, cassava (12–38%), and some bulbs such as garlic (33%). They are found as free sugars,

**Table 4** Energy and major components of some vegetables of habitual consumption (expressed in 100 g edible portion).

Vegetables	Energy (kcal)	Water (g)	Carbohydrate <sup>a</sup> (g)	Total sugar (g)	Fiber (g)
Artichoke	53	84.08	11.95	0.99	5.7
Asparagus	20	93.22	3.88	1.88	2.1

oligosaccharides, and polysaccharides. Starch is present in most vegetables, with values of less than 1% and stands out in starchy vegetables. It is the main polysaccharide of the tubers (potato, sweet potato, tapioca). In some countries, tubers form the basis of energy food consumed by the population. Starch is also found in garlic, pumpkin, chard, and green legumes. The most common sugars are glucose, fructose, and sucrose, and the content ranges from 0.2% to 5%. Some, such as sweet potato and garlic, have larger amounts (Table 4).

Mannitol, a polyalcohol from the hydrogenation of mannose, has been found in varieties of the Cucurbitaceae and Cruciferae families. Oligosaccharides are uncommon for rare group in foods. They are found in some types of vegetables. The galactosyl-sucrose family includes raffinose, stachyose, and verbascose, consisting of a sucrose molecule together with one, two, or three galactose molecules, respectively. They are found mainly in fresh legumes, peas, and beans. Fructans, consisting of fructooligosaccharides (FOS) (Fru<sub>n</sub>) and inulin polymer (Gal-Fru<sub>n</sub>), are found in artichoke, chicory, asparagus, onion, beet, garlic, and tomato. Raffinose, stachyose, verbascose, and fructooligosaccharides cannot be hydrolyzed by pancreatic enzymes or by those of the brush border of enterocytes, so they pass into the large intestine where they are fermented by the action of the intestinal microbiota and produce short-chain acids and gases (CO<sub>2</sub>).

Dietary fiber comprises polysaccharides, cellulose, hemicellulose, pectin, inulin, and the polymer called lignin. These compounds are not hydrolyzed by endogenous digestive enzymes. Cellulose, hemicellulose, and lignin are the main components of the cell walls, and cellulose is the most abundant. In vegetables, their values range from 0.2 to 4 g/100 g of product. Green legumes, beans (4.1 g/100 g), peas (5.7 g/100 g), artichoke (5.7 g/100 g), and cabbage (kale and Brussels sprouts) show the highest values; the rest of the vegetables have values ranging from (0.5 to 2.7 g/100 g) (Table 4). Hemicelluloses are associated with cellulose as constituents of cell walls. They can be soluble and insoluble, consisting of linear and branched polysaccharides containing hexoses and pentoses. They are characterized by their high capacity to bond with the water and serve as agents that increase the volume. The presence of acidic components in some gives them the ability to bind to cations. In the colon, hemicelluloses ferment to a higher degree than celluloses. Pectins are associated with cellulose and hemicellulose. In the immature vegetables, they are found in the form of insoluble protopectins, which ensures rigidity to the tissues, but during the maturation, they are degraded to pectins, sugars, and acids, with the consequent softening of the tissues. Some raw starch granules, such as potato granules, resist the action of  $\beta$ -amylases enzymes, probably due to the crystalline nature of starch (crystalline regions of starch are less susceptible to attack by acids and enzymes than amorphous zones). The presence of phosphate groups in potato starch also makes digestion

difficult. Cooking results in starch gelatinization and facilitates digestion, which could explain the difficulty of digesting the raw potato. Lignins are insoluble macromolecules; they are not digested or absorbed, nor are they attacked by the colon microbiota. Lignin is the most complex natural polymer due to its structure and heterogeneity. The lignification of vegetables increases the lignin content in the cell wall due to maturation, which gives these plants resistance to bacterial degradation (Garcia-Villanova Ruiz, 2017).

### Nitrogenous compounds

Vegetables are deficient in nitrogen compounds (0.6–5%), consisting of proteins, amino acids, peptides, amines, and other compounds. Vegetable proteins are of low biological value, although it is higher in potato. Most of the protein fraction is constituted of enzymes producing positive or negative effects in handling and preparing the harvested vegetables, modifying the organoleptic characteristics, such as aroma, color, taste, and texture. Oxidoreductases (such as lipoxygenases, polyphenol oxidases, and peroxidases) and hydrolases (such as glycosidases, esterases, proteases, and transferases) are responsible for many of the organoleptic changes occurring after harvesting and processing. They have protein and non-protein amino acids, including homoserine, homomethionine, and aminoadipic acid. Choline and betaine are found in cabbage; histamine and its derivatives in spinach; and serotonin, tryptamine, tyramine, and melatonin in tomato and eggplant.

### Lipids

The lipid content of vegetables is very low (0.1–1% of fresh weight). It consists of triacylglycerols, glucolipids, and phospholipids. They have saturated, monounsaturated, and polyunsaturated fatty acids.

### Vitamins

Vegetables are characterized by the supply of fat-soluble and water-soluble vitamins. The type, variety, and conditions before and after harvest, storage, and technological or culinary treatments influence the vitamin content. Some are an important source of vitamin A (in the form of its precursors, carotenoids), vitamin C, and folic acid (Table 5). They also contain other fat-soluble

**Table 5** Vitamin content of some commonly consumed vegetables (100 g of edible portion).

Vegetables	Thiamin (mg)	Riboflavin (mg)	Niacin (mg Eq)	Folate (μg)	Vit. C (mg)	Vit. A (μg RAE)	Vit E (mg)

vitamins, such as E and K, and water-soluble vitamins, such as those in group B. The vitamin content can be very variable, according to the large number of foods constituting this group. Vitamin C content can range from 2.4 to 128 mg/100 g. The vegetables with the highest content are red and green pepper and the cabbage family (kale, broccoli, brussels sprouts, red cabbage, cauliflower, cabbage). The vegetables with the highest vitamin A content are carrot, sweet potato, pumpkin, spinach, chard, lettuce, kale, and red pepper and folic acid stand out in spinach and endives.

### Minerals

Minerals account for 1–2% of fresh food. Vegetables are characterized by low sodium and high potassium content. The latter is the most representative mineral element, ranging from 150 to 560 mg/100 g (Table 6). They also contribute to the daily intake of calcium, phosphorus, magnesium, iron, and zinc. The bioavailability of iron in this food group is low, but vitamin C can help increase its absorption. The most representative anions are phosphate, chloride, and carbonate.

### Other components in fruits and vegetables

#### Organic acids

The fruits are characterized by their richness in organic acids, among which are the hydroxy acids, such as citric, malic, succinic, tartaric, and tannic acids. These compounds are responsible for the acidity in the immature fruit and decrease during ripening by transforming partly into simple sugars. The main acids in the stone fruits are malic, citric, and quinic acids. Malic acid is the one that predominates, and in some fruits, such as plum and cherry, it constitutes 90% of the acids. In grapes, tartaric acid is the majority, and in tropical fruits and berries, it is citric acid.

The content of these organic acids is lower in vegetables than in fruits. Most are in the form of salts, which makes the pH value relatively high (5.5–6.5), except in tomatoes. The free acid content is 0.2–0.4 g/100 g of the fresh product, and citric acid and malic acid contents are outstanding. Oxalic acid is found in some vegetables in high quantities (e.g., chard, spinach, and lettuce). This can lead to corrosion of tinplate containers and in the body and may contribute to the formation of urinary stones. There is controversy among researchers about the influence of oxalate in the formation of urinary stones. However, certain groups of researchers have

agreed that spinach, rhubarb, beet, nuts, cocoa, wheat bran, strawberries, peanuts, almonds, and tea cause a significant increase in urinary oxalate.

Currently, a new consumer habit is identified intake vegetables raw which are typically cooked. This may bear several risks: an increase in kidney and ureter stones by increased intake of oxalic acid; an increasing intake of oxalic acid might lead to demineralization of food and a deficiency of calcium and iron intake; an increased intake of nitrate by frequently consuming an excess of leafy greens and microbial contamination by preparing a large stock of green smoothies with insufficient cooling of this stock.

### Phenolic compounds

Fruits are very rich foods in phenolic compounds, with flavonoids being the largest group. Phenolic acids are widely distributed in fruits; they contribute to the color and flavor of many fruits. Phenolic acids are responsible for the astringency of many fruits, although they disappear with maturation in most of them. Polyphenol oxidases oxidize diphenols to quinones. The latter are the starting point of the browning reactions of the fruits, generating brown colorations when the fruit is peeled or cut. Chlorogenic acid is the key substrate for the enzymatic browning of apples and pears. Flavonoids are the largest group of polyphenolic compounds and are usually linked to sugars.

In vegetables, phenolic compounds are widely distributed, although their content compared to fruits is lower. Phenolic acids are made up of hydroxycinnamic and hydroxybenzoic acids and are generally found as esters and to a lesser extent as glycosides. Hydroxycinnamic acids are characteristic of some vegetables, such as eggplant, artichoke, potato, and chicory, with values ranging from 100 to 650 mg/100 g of fresh vegetables.

Flavonoids are the most representative group of vegetable phenolic compounds, and flavanols and flavones predominate. In some red vegetables (e.g., red cabbage and red leaf lettuce), anthocyanidins are found, and flavanones in artichokes and tomatoes.

### Aromatic compounds

The aroma is one of the most attractive organoleptic characteristics of fruits, which is due to the presence of volatile compounds. More than 500 aromatic compounds of small molecular weight, such as esters, ketones, and alcohols, are available. Only those whose concentration in the food is higher than the olfactory threshold are considered aromatic compounds. Those compounds providing the characteristic aroma of the food are called "impact compounds." In some fruits, such as lemon, pear or banana, the aroma is due to a single compound; whereas in other fruits, the aroma is due to a group of compounds with a well-characterized main compound, or to a large group of compounds difficult to characterize, such as is the case of strawberries aroma.

In some vegetables, the aroma is produced by sulfur compounds and provides less attractive odors, such as in the *Cruciferae* family (e.g., cabbage, cauliflower, and Brussels sprouts). In fresh products, the compounds are bound to sugars (glucosinolates) and are odorless, but when the tissue structure is broken by cutting, bruising, or chewing, the glucosinolates are released, and myrosinase transforms them into their hydrolysis products. The smell of those of the genus *Allium* (e.g., onion, garlic, spring onion, leek) are due to organosulfur compounds (allyl sulfur compounds): When the tissue structure is broken by cutting, bruising, or chewing, the compounds are released, and the alliinase enzyme transforms them into volatile compounds, some with penetrating odor and others with tear effect.

### Pigments

Color is one of the most attractive organoleptic characters of fruits and vegetables. It is due to the presence of pigments such as chlorophyll, carotenoids, flavonoids, and betalains.

Chlorophyll is the pigment responsible for the green color of some fruits and a variety of vegetables. It is the only pigment present in immature fruits, responsible for its green color. It has a lipophilic character; that is, as the fruit matures, a change of color occurs due to the disappearance of chlorophyll and the formation of carotenoids and flavonoids that are specific to each of them. This occurs in peaches, apricots, cherries, and strawberries, but not in some varieties of apples, pears, or plums, in which chlorophyll provides a characteristic green color that masks the presence of other pigments. In some vegetables, such as red pepper and tomato, chlorophyll disappears during maturation to allow carotenoids to show. Chlorophylls change during thermal treatments, resulting in different green tones after blanching, cooking, and sterilization.

Carotenoids are responsible for yellow, orange, purple, and red tones in fruits and vegetables. They are found in a much higher proportion in vegetables, especially  $\beta$ -carotene, with values ranging from 270  $\mu\text{g}/100\text{ g}$  in celery to 8285  $\mu\text{g}/100\text{ g}$  in carrot. The liposoluble pigments are of nutritional importance, as they are some precursors of vitamin A.

Other carotenoids, such as lutein, zeaxanthin, and lycopene, are potent antioxidants. Lycopene is not found in most fruits, except watermelon and tomato in vegetables. Lutein and zeaxanthin stand out in vegetables with values above 10,000  $\mu\text{g}/100\text{ g}$  in chards, watercress, and spinach. Fruits also have these compounds, being more abundant on the skin than on the fleshy portion. Peaches, mandarins, watermelon, and apricots are particularly rich in these compounds.

Anthocyanidins are water-soluble and dissolved in cell juice. The colors they provide range from red to blue or purple. They are the pigment of many fruits, such as strawberries, raspberries, currants, blueberries, pomegranates. These anthocyanins are found in the skin, such as plums, apples, pears, or grapes; however, they may also be in the fleshy portion, as seen in some varieties of cherries or plums. They are very unstable due to changes in pH and the action of oxygen and  $\text{SO}_2$ . The red color of red cabbage and red leaf

lettuce are also due to these compounds, while betalains are pigments responsible for the red color of beet and some types of mushrooms.

## Bioactive compounds

### Vitamin C

Vitamin C is a hydrosoluble antioxidant with high reducing power. It has the ability to scavenge a wide variety of reactive oxygen and nitrogen species in aqueous media. It is found mainly in foods of plant origin, such as ascorbic acid (reduced form) and dehydroascorbic acid (oxidized form), which is rapidly regenerated *in vivo*. Fruits and vegetables are a good source of vitamin C.

In most cell functions, ascorbate neutralizes reactive oxygen species (ROS) generated by cellular metabolism. Because of the role of ascorbate in protecting cells from oxidative stress and the involvement of ROS in neurodegenerative disorders (Alzheimer's and Parkinson's disease) or inflammatory responses (atherosclerosis), it is suggested that vitamin C could prevent heart, chronic inflammatory, and neurodegenerative diseases (Shashirekha et al., 2015).

### Vitamin E

Vitamin E (tocopherols and tocotrienols) is present in all cell membranes and plasma lipoproteins.  $\alpha$ -tocopherol is a potent lipophilic antioxidant, a suppressor of oxidative damage in biological membranes, lipoproteins, and tissues, by removing free radicals such as singlet oxygen and superoxide and hydroxyl radicals. Vitamin C regenerates oxidized vitamin E. Vitamin E protects DNA, low-density lipoproteins (LDL), and polyunsaturated fatty acids from oxidative damage (Shashirekha et al., 2015). It also plays a role in hemoglobin biosynthesis, modulation of the immune response, and stabilization of the membrane structure. Vitamin E is present in most fruits and vegetables with values between 0.1 and 2 mg/100 g.

## Sulfur compounds

### Glucosinolates (GSLs)

The GSLs are a large group of secondary metabolites of plants belonging to the genus Brassica (families Brassicaceae and Cruciferae); this genus includes vegetables such as broccoli, cauliflower, kale, brussels sprout, cress, radish, cabbage, and mustard. These vegetables represent a good source of phytochemicals, including sulfur glycosides (GSLs), phenolic compounds, and carotenoids. However, their anticarcinogenic and antioxidant potential has been attributed mainly to their high GSLs content (Mandrich and Caputo, 2020). The breakdown products of GSLs play a vital role in plant defense mechanisms against pathogens and insects.

GSLs are thioglucosides with one cyano group and one sulfate group, composed of more than 200 different types, and 30 of them are identified in Brassica crops (Quirante-Moya et al., 2020). When the tissues of these plants are processed by cutting, crushing, or chewing and other destruction of tissues, the GSLs are exposed to enzymes named myrosinases, which hydrolyze them to isothiocyanates. A likely source of isothiocyanates is the microbial degradation of GSL by the intestinal microflora. However, hydrolysis by microflora has been reported to be not very efficient, and in humans, it is very diverse and variable. These enzymes are inactivated by thermic treatment (cooking, steam cooking, microwave), and in this case, the GSL could be partially absorbed in their intact form.

The most studied compound is the sulforaphane (SFN), an isothiocyanate occurring in stored form as glucoraphanin (GRA) located in the cruciferous such as cabbage, cauliflower, and kale, and at high levels in broccoli especially in broccoli sprouts which is recognized as the best source of SFN, and GRA corresponds to 90% of the GSL content in some of its species. Sulforaphane affects oxidative stress, and antioxidant capacity, and neuroinflammation. The SFN is considered a very promising compound because it has properties that prevent, delay or reverse the development of preneoplastic lesions and improve survival rates, acting on cancer cells as a therapeutic agent. The sulforaphane may also decrease the risk of cardiovascular diseases (CVD) and help to prevent osteoporosis.

### Organosulfur compounds (OSCs)

Vegetables of the Alliaceae family are considered a rich source of a large variety of beneficial bioactive compounds, such as oligosaccharides, arginine, flavonols, and OSCs. Vegetables such as onions, garlic, shallots, leeks, scallions, and chives belong to the genus *Allium*. Allium plants are consumed worldwide as vegetables, seasonings, and spices.

The sulfur compounds are mainly obtained when these vegetables have been damaged by processed by cutting, crushing or chewing, facilitating a reaction between the enzyme alliinase and the substrate alliin (diallyl thiosulfinate) is converted into intermediate compounds (sulfenic acid, pyruvic acid, and ammonia). Two molecules of sulfenic acid condense and form allicin, intermediate compound of diallyl sulfide, diallyl disulfide, or diallyl trisulfide.

The alliin is the organosulfur compound extracted mainly from garlic (*Allium sativum* L.). Experimental studies have revealed beneficial health effects including, antioxidant, cardioprotective, antihepatotoxic, immunomodulatory, and antineoplastic effects (Rizwani and Shareef, 2011).

These intermediate products in alliaceous vegetables are considered health-promoting bioactive components. Several types of Allium products, such as pastes, oils, salts, powders, and flakes, have been used in industries and homes as food seasonings and

flavorings. These products can be prepared by different methods, including boiling, frying, baking, and drying. Commercial garlic products usually are standardized on the content of sulfur compounds.

The temperature, processing type, pH, time, and food matrix can affect the alliinase activity. Heating results in the inactivation of the alliinase enzyme, thus decreasing the amount of allicin metabolites in products. A large amount of allicin is lost during the processing of alliacious vegetables. This reduction in OSCs is linked to decreased flavor and reduced healthy effects of *Allium* products. The OSCs in *Allium* plants are thermally unstable and tend to be lost during pasteurization, sterilization, cooking, and drying (Barba et al., 2017).

Garlic organosulfur compounds decrease total cholesterol, LDL-C, and oxidized LDL due to a decrease in cholesterol biosynthesis by inhibition of hydroxymethyl-glutaryl-coenzyme A reductase (HMG-CoA reductase); they also show a moderate hypotensive effect due to their vasodilation property and are attributed inhibitory effect on platelet aggregation and decrease of fibrinolytic activity. Regular consumption of garlic significantly increases the antioxidant activity of cells, inhibiting the formation of free radicals, reinforcing the mechanism of endogenous radical uptake, and increasing antioxidant enzymes. Garlic is one of the most consumed natural supplements because it promotes a lowering of cholesterol and blood pressure, delays the progression of atherosclerosis, prevents heart disease, improves circulation, and prevents cancer.

### Carotenoids

Carotenoids have shown beneficial health effects that include improving the immune system and reducing the risk of chronic degenerative diseases such as macular degeneration, type 2 diabetes, obesity, certain types of cancer, and CVD.

Recent studies have shown a positive correlation between consuming a diet rich in fruits and vegetables with high carotenoid content and preventing mortality and morbidity related to CVD. High concentrations of lutein and  $\beta$ -cryptoxanthin have been associated with a decreased risk of myocardial infarction, and lycopene, the carotenoid with larger antioxidant capacity and higher plasma concentration, is associated with a decrease in inflammatory processes (Rodríguez-Concepcion et al., 2018).

Epidemiological studies relate the high dietary intake of fruits and vegetables rich in carotenoids to health benefits. However, supplementation of doses higher than 20 mg/day of purified or synthetic  $\beta$ -carotene may cause adverse effects, including lung cancer risk in smokers and workers exposed to asbestos and mortality from CVD.

The xanthophylls, lutein and zeaxanthin are among the carotenoids with effect on macular degeneration. These xanthophylls are found in green leafy vegetables, kale, spinach, chard, watercress, eye tissue, serum, and plasma. Their function is to protect the macula and the lens from the oxidizing action of blue light and, in addition, protect the eye from photochemical reactions due to the antioxidant capacity that both possess. Observational studies indicate that a diet high in lutein and zeaxanthin could reduce both the risk of cataracts and age-related macular degeneration.

Lycopene is the carotenoid with greater antioxidant capacity and higher plasma concentration, and it tends to accumulate in the tissues because it is lipophilic. It is found mainly in some fruits and especially in tomatoes. Epidemiological studies suggest that diets rich in fruits and vegetables such as tomato are associated with a low risk of stomach and prostate cancer. The antioxidant effect of lycopene could be the main mechanism in preventing lipid peroxidation, DNA damage and protein oxidation, processes involved in carcinogenesis, aging, and CVD.

The antioxidant and *anti*-inflammatory activity of carotenoids or their derivatives may also be relevant for obesity because obesity leads to oxidative stress and inflammation in adipose tissue, which play an essential role in the development of insulin resistance. Likewise, the mechanisms of action of lutein and zeaxanthin in relation to cognitive function may be related to their antioxidant and *anti*-inflammatory abilities, among others.

The bioavailability of carotenes depends on various factors, such as the type and amount, the food matrix, and culinary preparation. The heat treatment (cooking) improves their absorption. Dietary fat also seems to stimulate absorption because mucosal cells absorb  $\beta$ -carotene from lipid micelles, and the amount and type of fat condition the formation and type of micelles; unsaturated fats are more efficient than saturated fats. Some studies show that the bioavailability of  $\beta$ -carotene in dark green leafy vegetables is lower than that of fruits (Barba et al., 2017).

Culinary treatments have very few carotenoid losses. Treatment losses range from 5 to 10%. Vegetables have higher values of carotenoids than fruits. The high content of  $\alpha$ -carotene in pumpkin and carrot and the high levels of zeaxanthin and lutein in chard, watercress, and spinach are worth noting.

### Phytosterols

Phytosterols are found in some fruits and vegetables and have cholesterol-lowering properties reducing the risk of CVD. Phytosterols can compete with cholesterol because of their structural similarity, limiting cholesterol absorption from fat matrices in the intestinal tract.

### Phenolic compounds

Phenolic compounds are compounds from the secondary metabolism of plants and contribute to the color, flavor, and odor of plant foods. These compounds play an important role in color stability, aroma profile, and antioxidant activity.

Recently, dietary intake of phenolic compounds has been associated with a lower incidence of chronic diseases such as CVD, diabetes, cancer, and neurological diseases. Vegetables and especially fruits are sources rich in phenolic compounds.

Oxidative stress plays an essential role in carcinogenesis. The development of tumors may be due to oxidative damage, and phenolic compounds are powerful antioxidants. Several *in vitro* and *in vivo* studies have shown that flavonoids can inhibit different

stages of carcinogenesis due to their antioxidant activity and other mechanisms. Polyphenols can affect molecular events in the initiation, promotion, and progression stages of carcinogenesis, and isoflavones and lignans can affect activities related to hormone-dependent tumors. Flavonoids modulate enzymes and receptors involved in the signal transduction pathways of cell proliferation, differentiation, apoptosis, inflammation, angiogenesis, metastases, and reversal of resistance to many drugs. Apoptosis or programmed cell death is necessary to maintain a balance between cell proliferation and loss. Deregulation of this balance may lead to malignancy, while induction of apoptosis suppresses the development of cancer.

Several epidemiological studies and interventional trials suggest that polyphenols and mainly flavonoids present in fruits and vegetables are associated with a decrease in the risk of CVD. Oxidative stress can play a role in the pathogenesis of CVD, such as atherosclerosis. Polyphenols have recently been shown to have immunomodulatory and vasodilator properties, which can also help reduce the risk of CVD. Phenolic compounds may inhibit *in vitro* oxidation of LDL lipoproteins; oxidized LDL is related *in vivo* to the formation of atheromatous plaques, which may allow the development of coronary heart disease.

Anthocyanins are flavonoids responsible for the red and purple color of many fruits and some vegetables; they inhibit LDL oxidation and platelet aggregation, hence their cardioprotective effect.

Pancreatic  $\alpha$ -amylase and  $\alpha$ -glucosidase enzymes play an essential role in starch hydrolysis. *In vitro* studies have shown that phenolic compounds can act by inhibiting these enzymes, providing a strategy for postprandial management of hyperglycemia in patients with type 2 diabetes. Several *in vivo* studies have shown that phenolic compounds can reduce the blood glucose level of hyperglycemic rats. Subacute, chronic inflammation is considered an important factor in developing insulin resistance and diabetes in animals and humans. Several non-flavonoid polyphenols have been shown to reduce the production of inflammatory mediators in animal models with diabetes.

## Health effects of fruits and vegetables

### Gastrointestinal health

Constipation is a very common condition; fruits and vegetables have always been considered an adjuvant to prevent or relieve constipation. Higher dietary fiber intake and exercise are associated with a lower prevalence of this condition. Most clinical practice guidelines indicate that increased dietary fiber intake should be the first therapeutic measure in patients with chronic functional constipation (without symptoms of irritable bowel syndrome). Soluble or insoluble fiber content influences intestinal transit through different mechanisms. Constipation is associated with an increased risk of diverticulosis, colon cancer, appendicitis, and various anal conditions.

The amount of fiber from fruit (considering a daily consumption of 450 g) is estimated at 9 g. In addition, other components in the fruit can have a laxative effect, such as sorbitol or phenolic compounds. The fruit recommended due to its laxative effect is dried plum. The physiological reasons explaining the laxative effect of dried plum—which has a high fiber content (17%)—is not fully understood. Plum juice also affects intestinal motility and has small fiber content, so the substances responsible for this effect are believed to be hydrosoluble. Both dried plum and plum juice is rich in sorbitol. Studies have shown that doses of sorbitol of 0.4 g/kg weight for men and 1 g/kg weight for women have laxative effects. The average amount of sorbitol is 15% in dried plums and 6.1% in plum juice; therefore, this compound could not be solely responsible for the laxative effect. This fact suggests that there should be other compounds explaining the laxative effect of plums. In this sense, the phenolic compounds present in this fruit can also contribute to the laxative effect. Diphenyl xanthine, considered in the 1950s as one of the compounds responsible for the laxative effect of dried plums, has been discarded today, as this compound has not been isolated from any natural plant.

In recent decades, the increased consumption of kiwi has made it possible to study the effect of this fruit as a laxative. Thus, the fiber content is 3 g/100 g, and its laxative effect has been demonstrated in the elder population, provided that two pieces of fruit are consumed a day. In a 2018 review, they are indicated as a characteristic of this fruit: water retention, increases the size of the fecal bolus, softens its consistency and reduces transit time. They point to the enzyme actinidine together with soluble and insoluble fiber and polyphenols as responsible for its effect on intestinal malaise.

The fiber content of vegetables ranges from 1% to 4.3%, with values of 9.4% for artichokes. The inulin content of artichokes appears to be responsible for increasing the size of the fecal bolus, softening its consistency, and decreasing intestinal transit time. The cabbage family is the one with the highest inulin content. The ratio between soluble and insoluble fiber in vegetables is 1/1.5. The dietary fiber of wheat bran has a high insoluble fiber content.

### Cardiovascular diseases (CVD)

Coronary heart disease and infarction are the two main manifestations of CVD. The evidence accumulated so far seems to support the idea that increased intake of fruits and vegetables can reduce this type of condition.

Protective mechanisms are associated with bioactive nutrients with antioxidant, *anti*-inflammatory, and electrolytic properties, as well as functional properties such as low glycemic load and energy density. Initially, the effects were associated with the presence of antioxidant substances, folates, fiber, potassium, flavonoids, and other phytochemicals. However, currently, the evidence suggests that it is the set of these components that can interact with genetic factors influencing cardiovascular risk. Therefore, it is more interesting to look at whole foods and dietary patterns rather than at a single food component (Eman and Gordon, 2017).

According to WHO data, insufficient intake of fruits and vegetables is estimated to be responsible globally for approximately 31% of ischemic heart disease and 11% of stroke.

In this regard, the effects on blood pressure of increased consumption of fruits and vegetables, both alone and together with a restrictive diet in total fat and saturated fatty acids, were evaluated in the DASH (Dietary Approaches to Stop Hypertension) trial. Although the combined diet reduced blood pressure more effectively, the fruit and vegetable diet also reduced it (systolic blood pressure: 2.8 mm Hg; diastolic blood pressure: 1.1 mm Hg) compared to the control diet. These reductions, apparently discrete on an individual scale, would result in a significant reduction in CVD risk at the population level due to the displacement of blood pressure distribution. Furthermore, diets with a high proportion of fruits and vegetables have been shown to reduce plasma lipid levels, mainly because of dietary fiber. Soluble fiber appears to have a larger effect on lowering low-density lipoprotein (LDL-C) cholesterol levels, and total fiber levels are inversely related to CVD. Diets rich in fiber help reduce triacylglycerols and blood pressure. Dietary recommendations encouraging increasing dietary fiber intake are relevant in people at higher risk for strokes, such as smokers, overweight, and those with hypertension.

In 2014 a meta-analysis of clinical trials and observational studies found that adherence to a vegetarian diet was associated with lower blood pressure (Wang et al., 2014).

Recent studies have related the intake of folates from fruits and vegetables to the decrease in blood homocysteine levels, which are positively correlated with the development of coronary diseases through various mechanisms. However, high homocysteine levels are not a specific indicator of inadequate folate intake because they may be due to insufficient intake of other vitamins, such as B<sub>12</sub> or B<sub>6</sub>, or other factors.

Concerning the role of potassium in the etiology of these diseases, the WHO suggests that supplementation is not necessary; it is sufficient with the recommended consumption portions of fruits and vegetables, keeping in mind that these food groups also have the advantage of providing only little sodium amount and therefore are beneficial in hypertensive states too.

The high intake of fruits and vegetables determines increased antioxidant capacity in plasma shortly after intake. Therefore, these antioxidant compounds could act against the oxidative processes, which are responsible for the development of CVD. Quercetin is the most frequently isolated flavonoid in vegetables and is a powerful antioxidant capable of inhibiting LDL oxidation and exerting a hypotensive action. Sulfur compounds of the genus *Allium* have shown the most prominent effects on the cardiovascular system, so garlic sulfur compounds are commercial products of high consumption in the United States as hypotensive (Suman and Shukla, 2016).

Increased potassium intake in adults reduces blood pressure, both systolic and diastolic. The WHO recommends increasing potassium intake from food to reduce blood pressure and the risk of CVD, stroke, and coronary heart disease. Despite no significant association has been found between potassium intake and the incidence of CVD or coronary heart disease, the positive relationship between blood pressure and these diseases is a piece of indirect evidence that an increase in potassium intake may reduce their incidence due to its effect on the decrease of blood pressure.

The WHO urges adults to consume at least 3510 mg/day of potassium and reduce this amount proportionally to the energy requirements of the child. Increasing potassium concentrations decreases systolic blood pressure in children, but this variation is not significant. The potassium recommendations are complementary to the WHO guidelines on sodium intake. If the recommended amount of potassium is consumed, the approximate ratio would be one to one, which is considered beneficial to health (WHO, 2012).

In summary, strong evidence about the beneficial effect of consuming appropriate amounts of fruit and vegetables on CVD prevention is available (Hartley et al., 2013).

## Obesity

The intake of fruits and vegetables, which have a high-water content, decreases the average energy density of the diet. The caloric reduction in a diet high in fruits and vegetables could reduce the energy supply by up to 30%. Dietary fiber can slow down gastric emptying and create a feeling of satiety, especially soluble fiber, with higher water retention capacity, preventing excessive food intake.

Evidence-based nutritional recommendations for the prevention and treatment of overweight, developed by various scientific societies, conclude the following:

- Weight gain can be prevented with diets consisting of low energy-density foods.
- Strategies to enable the availability of healthy foods, such as fruits and vegetables, should be sought.
- Increasing fiber consumption from plant foods can prevent weight gain in healthy adults.
- Dietary prevention of weight gain can be modulated through diets with high fruit and vegetable consumption.
- A better control of diabetes mellitus could prevent overweight and obesity.

The European Guidelines for adult obesity management, published in 2019 (Durrer Schutz et al., 2019) specifically continues to recommend, decrease the energy density of food; increase vegetables and eat two portions of fruit per day.

## Glucose metabolism

The role of different dietary components in developing type 2 diabetes mellitus has not been clearly established. However, several studies suggest a negative correlation between a relatively high intake of fruits and vegetables and the risk of developing this condition.

The fiber contained in vegetables could slow down the rate of nutrient absorption, resulting in savings in insulin secretion and reduced blood glucose levels.

Epidemiological cohort studies show that these compounds have a protective effect, regardless of age, against type 2 diabetes. Experimental studies have shown that high fiber intake reduces blood glucose and insulin levels in people with diabetes and results in low glucose tolerance.

Experimental studies suggest that soluble forms of fiber are beneficial, whereas prospective cohort studies seem to attribute this protective effect to insoluble forms; therefore, WHO has chosen to classify the relationship as “probable” rather than “convincing.”

Foods with a low glycemic index, such as many vegetables, regardless of fiber content, are associated with a lower postprandial glucose response and an overall improvement in blood glucose control. However, a low glycemic index in itself is not a guarantee of overall health benefit because a high fat or fructose content of a food can also result in a lower glycemic index, and these foods can be of high energy density.

There is no universal dietary strategy to prevent or delay diabetes onset. Maintaining the ideal body weight and consuming a prudent diet or a Mediterranean diet pattern is considered the best strategy for preventing type 2 diabetes, especially if dietary recommendations consider individual preferences, which allows higher adherence to diet in the long term.

## Cancer

The relationship between fruit and vegetable consumption and cancer was evidenced by the Public Health Service (1988) and the National Research Council of United States of America (1989) studies in 1990. In its 2002 World Health Report, WHO estimated that low fruit and vegetable intake was the cause of 19% of gastrointestinal cancer cases. The consistency of this evidence is reinforced by the large number of studies showing a statistically significant relationship.

Fruits and vegetables are sources of fiber, vitamins and minerals, carotenoids, and other antioxidants, as well as a large number of phytochemicals, such as organosulfur compounds, flavonoids, and related compounds; that could be the mechanism explaining the effects of these foods on cancer prevention. Most of these studies conclude with the need for further study of these mechanisms.

The World Cancer Research Fund (WCRF/AICR, 1997) has published a report on nutrition and cancer based on case-control studies conducted to that date and concluded that there was “convincing” evidence that vegetables reduced the risk of mouth

**Table 7** Vegetables and fruit and the risk of cancer.

WCRF/AICR Grading		Decreases risk		Increases risk	
		Exposure	Cancer site	Exposure	Cancer site
Strong evidence	Probable	Foods containing dietary fiber	Colorectum, 2017		
		Non-starchy vegetables and fruit aggregated	Aerodigestive cancer and some other cancers (aggregated)		
Limited evidence	Limited suggestive	Non-starchy vegetables	Mouth, pharynx and larynx, 2018	Non-starchy vegetables	Colorectum, 2017
			Nasopharynx, 2017	Preserved non-starchy Vegetables	Nasopharynx, 2017
			Esophagus (adenocarcinoma and squamous cell carcinoma) 2016		
			Lung (people who smoke or used to smoke tobacco) 2017		
			Breast (estrogen receptor-negative) 2017		
		Fruit	Esophagus (squamous cell carcinoma) 2016		
			Lung (people who smoke or used to smoke tobacco) 2017		
		Citrus fruit	Stomach (cardia) 2016		
		Non-starchy Vegetables	Bladder, 2015	Fruit (low intake)	Stomach, 2016
		And fruit			Colorectum, 2017
		Foods containing carotenoids	Lung 2017		
			Breast 2017		
		Foods containing beta-carotene	Lung 2017		
		Foods containing vitamin C	Lung (people who smoke tobacco) 2017		
			Colorectum (colon) 2017		

Source: World cancer research fund international (<https://www.wcrf.org/dietandcancer/exposures/wholegrains-veg-fruit>).

and pharynx cancer, esophagus, stomach, lung, colon and rectal cancer. Based on these findings, they established the following recommendation: «eat between 400 and 800 g, or five or more portions a day, of different vegetables and fruits, throughout the year». Later, a study comparing the effects of a diet poor in fruits and vegetables with the effects of another diet with a high content of these foods showed a significant decrease in DNA damage and lipid oxidation in individuals fed with the second diet; this was attributed to the high intake of fruit and vegetables.

The latest updates on this report published by WCRF International in 2018 are shown in Table 7. In conclusion, they indicate that higher consumption of fiber-containing foods is likely to protect against colorectal cancer and generally that higher consumption of starch-free fruits and starch-free vegetables is likely to protect against aerodigestive cancer. In addition, this intake has been consistently related to a dietary pattern associated with a lower risk of cancer and other noncommunicable diseases, as well as obesity (WCRF, 2018.)

## Vision

Some fruits and vegetables have remarkable amounts of lutein and zeaxanthin, excellent fat-soluble antioxidants with an affinity for the eye system. Cataracts and macular degeneration are common vision-related aging diseases, affecting a high percentage of the population over 65 years old. Consumption of some varieties of these food groups, in particular those containing lutein and zeaxanthin, appears to reduce the risk of cataracts.

## Conclusions

Fruits and vegetables are essential foods in a daily diet because of their content in nutrients and bioactive compounds. Their low energy density and high hydration capacity provide a feeling of satiety and contribute to adequate nutrition. Recent studies have shown that fruit and vegetable consumption prevents the risk of chronic diseases such as obesity, cardiovascular disease, type II diabetes, and cancer. Therefore, the WHO recommends a daily intake of fruits and vegetables of at least 400 g.

## Key points

- The structure, chemistry, digestion and dietary sources of glucose monosaccharides, disaccharides, oligosaccharides and polysaccharides—both available (energy yielding) and unavailable (dietary fiber)—will be delineated.
- The utilization and function of these carbohydrates including starch moieties amylose and amylopectin, and dietary fibers such as resistant starches, celluloses and hemicelluloses will be discussed.
- The digestion and absorption of various glucose entities, their rate of entry into the blood stream, and potential health impacts will be described
- The glycemic index (GI) will be introduced and the issues and controversies around its use and variability will be explored.

## Glossary

**Amylase** Salivary and pancreatic enzymes that hydrolyze  $\alpha$ -glycosidic bonds of starch

**Amylose** A moiety of starch with glucose units joined linearly by  $\alpha(1 \rightarrow 4)$  glycosidic bonds, which enables them to form tight crystalline arrays

**Amylopectin** A moiety of starch with glucose units joined by  $\alpha(1 \rightarrow 4)$  glycosidic bonds but has  $\alpha(1 \rightarrow 6)$  bonds creating a more open, branched structure

**Beta-glucan** Unavailable glucose polymers from certain plants that are soluble, viscous fibers with documented health benefits

**Brush-border** Small intestinal, epithelial cells covered by finger-like microvilli, that are the key to splitting of disaccharides and glucose transfer from the intestinal lumen into the bloodstream

**Cellulose** A linear, strong, unavailable glucose polymer forming structural components of plant tissues and in the diet becomes insoluble dietary fiber and the main form of fecal bulk

**Degree of Polymerization (DP)** The number of sugar molecules in an oligosaccharide or polysaccharide.

**Dietary fiber** A carbohydrate polymer that is unavailable, meaning that it is not digested by enzymes in the upper gastrointestinal tract of humans

**Disaccharide** Two basic carbohydrate units (e.g., sucrose, lactose, maltose)

**Glycemic Index (GI)** The physiologic classification of carbohydrate-containing foods based on postprandial blood glucose responses

**GLUT carriers** One of 5 carriers of glucose that facilitate transport of sugars across cells and membranes

**Hemicelluloses** Unavailable glucose polymers are often associated with cellulose in the plant and function as dietary fiber and tend to be readily or partially fermented by colonic bacteria

**Insoluble fiber** Dietary fiber resistant to digestion and insoluble in cold and hot water. Some may be partially degraded by colonic bacteria

**Monosaccharides** A single sugar molecule (e.g., glucose, galactose, fructose)

**Oligosaccharides** Small polymers with from 3 to 20 two sugar units

**Polysaccharides** Large polymers of many sugar units such as starch or cellulose

**Resistant starch** Starches that escape digestion in the upper gastrointestinal tract. Five types have been identified

**Short-chain fatty acids (SCFA)** Metabolically active fatty acids with few carbons that are byproducts of bacterial fermentation of food components in the colon (e.g., acetic, propionic, and butyric acids)

**Sodium-linked glucose transporter (SGLT)** Carriers using active transport (ATP-requiring) to carry glucose (and galactose) across the mucosa and through the membrane

**Soluble fiber** Glucose polymer or dietary fiber resistant to digestion but soluble in cold and hot water

**Starch** Glucose polymers formed by at least 1000 glucose units joined by  $\alpha(1 \rightarrow 4)$  glycosidic bonds in the linear amylose and  $\alpha(1 \rightarrow 4)$ ,  $\alpha(1 \rightarrow 6)$  in the branched amylopectin found in grains, roots, tubers and legumes

**Viscous fiber** A type of soluble fiber which becomes viscous on contact with water

## Glucose: an introduction

Glucose is the most abundant of the simple sugars and the preferred energy source of most living cells. Plant foods are major dietary sources of sugars and available and unavailable carbohydrates. Plant chloroplasts capture energy in photons of light during photosynthesis and join carbon dioxide from air to water, usually from the roots, and form glucose and oxygen. The glucose stores energy in its bonds. Thus energy-yielding carbohydrates contain  $4 \text{ kcal g}^{-1}$ . Glucose and other sugars are found naturally in fruits, vegetables and other foods such as honey, but sugar refined from cane and sugar beets is also a significant dietary component in many diets. The primary source of blood glucose should be from starchy carbohydrate foods -grains, roots and tubers and legumes, where it is recommended that  $\sim 50\%$  of calories be derived.

While glucose in the diet is ready for absorption, digestible sugars and carbohydrates must be split to their monosaccharide form(s), usually glucose, for absorption. When absorbed glucose becomes circulating form of carbohydrate in the bloodstream. It is also a key component in plant cell walls and fibrous plant structures that provide our diets with important unavailable carbohydrates in the form of dietary fibers. This entry will look at the chemistry, structures, functions, digestion of monosaccharides, disaccharides and polysaccharide components. Further this entry will discuss their impacts of plant and starch chemistry on blood glucose response, glycemic index and other aspects of human nutrition.

## Chemistry of glucose and glucose polymers

Plant-based carbohydrate foods formed the basis of dietary patterns worldwide for millennia and usually provide more than half the energy in the human diet. This comes from foods that contain “available” carbohydrate, which means that it can be broken down to glucose or other monosaccharides for absorption in the human small intestine and for delivery in the bloodstream to provide energy throughout the body. Energy stored in bonds of available carbohydrate is released via glycolysis and other pathways as ATP and other high-energy metabolites. Glucose polymers, not split by enzymes in human upper gut, move into the large intestine to function as dietary fiber.

### Monosaccharides

Glucose and other monosaccharides in plant foods exist either free or bound. When bound to nutrients or phytochemicals, they may impact nutrient availability and stability, impart flavor or mask bitterness.

Chemically, the monosaccharide D-glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ , MW  $180.16 \text{ g mol}^{-1}$ ), from the Greek (*glukus*, sweet) or dextrose, is 2,3,4,5,6-pentahydroxyhexaldehyde. Translated, glucose is a six-carbon aldohexose. Glucose differs from other aldohexoses in positioning and conformation of hydroxyl groups on the hexose ring and from the ketohexose, fructose with its 5-member furanose ring.

Positioning of hydroxyl groups influences sugar solubility and ability to bind to the sweet taste receptor on the tongue for eliciting a sweet taste by. Glucose ranks second, after fructose, in sweetness compared and sugars and syrups (Table 1). Sweet taste is hard-wired, and its pleasurable sensation have caused humans to seek sources of sugar and sweetness, such as honey or maple sap, for preservative and sensory properties. Despite their being major sources of glucose, sweetness is not a characteristic of most starchy foods, although roasting or toasting may increase sweetness because starch dextrinizes or react with protein in the Maillard reaction. Slight sweetness is characteristic of some glucose oligosaccharides such as inulin and chicory root, which also function as dietary fiber.

**Table 1** Relative sweetness of sugars and syrups.

<i>Sugars</i>	<i>Sweetness rating</i>
Fructose	120–180 <sup>a</sup>
Sucrose—glucose bonded to fructose	100
Invert sugar—hydrolyzed sucrose to glucose + fructose	85–100
Glucose (dextrose)	70–80
Trehalose (3 glucoses)	50
Galactose	35
Corn syrups (20–42 DE <sup>b</sup> )	23–48
Maltose = glucose bonded to glucose	30–50
Lactose = glucose bonded to galactose	16–20
Maltodextrin	6–21
<b>Syrups</b>	
Date sugar/syrup -glucose, fructose, trace sucrose	120
Birch syrup—fructose, glucose, trace sucrose	110
Honey- fructose, glucose, maltose and some sucrose	110
Cane juice (sucrose, glucose, fructose)	100
High fructose corn syrup <sup>c</sup>	100–120
Palm sugar or syrup—sucrose, glucose, fructose	100

<sup>a</sup>Depends on concentration and pH.<sup>b</sup>DE = Dextrose equivalents.<sup>c</sup>Sweetness depends fructose: glucose ratio, often 55:45.

Free glucose is found often with other sugars usually fructose or sucrose in fruits, vegetables and syrups. **Table 2** gives an average content of sugars of common fruits and vegetables, but the actual amounts vary by variety, agronomic conditions, and ripeness. For example, an unripe banana is not sweet and is quite astringent, but as the banana ripens acids decrease and some starch is metabolized to release glucose, changing both the taste and texture and decreasing the amount of resistant starch in the banana.

### Glucose in disaccharides and oligosaccharides

Common **disaccharides** -sucrose, lactose, galactose, and maltoses -often contain glucose as one of the sugars. In sucrose (table sugar), glucose bonds to fructose by an  $\alpha(1 \rightarrow 2)$  link, making it a non-reducing sugar. This property differentiates it from most common saccharides, which are all reducing sugars, so they readily attach to lysine in the Maillard browning reaction. Sucrose must be split by heat or sucrase (invertase). Baking properties such as color and flavor and lysine availability by amount of Maillard reaction.

Lactose, the sugar in nearly all mammalian milks, has glucose joined to galactose by an  $\alpha(1 \rightarrow 4)$  glycosidic bond. Compared to other sugars, lactose dissolves slowly and is the least sweet of the sugars (**Table 1**). Maltose, isomaltose and trehalose have two glucose molecules, but their linkages differ,  $\alpha(1 \rightarrow 4)$ ,  $\alpha(1 \rightarrow 6)$  and  $\alpha(1 \rightarrow 1)$ , respectively. They are less sweet than many sugars. Digestion of starch and related dextrans supply the body's major source of maltose and isomaltose, but trehalose is found in honey, some plants, fungi, and fermented foods. Glucose polymers in carbohydrate foods subjected to dry heat (e.g., toasting) or moist heat, especially with acid, can be hydrolyzed to produce maltose. In addition, sprouting, malting, and fermentation of grains or other carbohydrates, as in mashers or yeast-leavened doughs, also produce maltose.

**Oligosaccharides** (Greek *oligo*, few) contain 3–20 sugar units, making their degree of polymerization (DP) 3–20. Plant oligosaccharides, function both as energy storage as chicory root inulin or structural or gummy components such as  $\beta$ -glucan in oats, barley and fungi. All oligosaccharides, including small ones such as the trimer (maltotriose) and tetramer (maltotetraose) even with  $\alpha(1 \rightarrow 4)$  glycosidic linkages, cannot be hydrolyzed by human amylases. They function as prebiotics and other fibers fermented by colonic microorganisms. Human milk is a source of animal oligosaccharides, but glucose is not the dominant sugar. Galacto-oligosaccharides contain glucose, galactose, sialic acid, fucose and N-acetylglucosamine with the precise combination varying by stage of lactation in human milk and can also be found in some plant foods. In human milk the oligosaccharides serve as probiotics that help foster a healthy microbiome and fight infection. Most jurisdictions label all oligosaccharides as dietary fiber, but a few disallow those with DPs 3–9.

**Polysaccharides** have 1000 or more sugar units and high molecular weights. In plants, many are glucose polymers that either provide stored energy, usually as starch, or materials for structural plant components (e.g., celluloses and hemicelluloses). Starch chains are formed when glucose, not needed immediately by the plant, is shuttled to amyloplasts for polymerization. Starch chains align into starch granules whose shape, size, organization, crystallinity, number, and location (e.g., roots, rhizomes, seeds, stems, tubers and corms) and amylose: amylopectin ratio are determined by plant type and variety.

**Table 2** Sugars of fruits and vegetables (g/100 g of fruit).

Fruit	Carbohydrate	Total sugar	Glucose	Fructose	Sucrose
Apple	13.8	10.4	2.3	5.9	3.1
Apricot	11.1	9.3	1.6	0.7	5.2
Avocado	8.5	0.9	0.5	0.2	0.1

Onion	7.6	5.0	2.0	2.3	0.7
Sweet potato	20.1	4.2	0.7	1.0	2.5

Data from USDA Nutrient Database, Nutritionist 5. FSA NZ Australian Food Composition.

**Starch**,  $(C_6H_{12}O_6)_n$ , is comprised of two moieties—the mostly linear amylose or the branched amylopectin (Fig. 1). While both have  $\alpha(1-4)$  bonds, amylopectin has  $\alpha(1-6)$  bonds at the branch points, approximately every 25 glucose units. Amylose (DP1000–10,000; MW  $10^5$ – $10^6$  g mol $^{-1}$ ) is smaller than amylopectin (DP  $> 10^6$ ; MW  $\sim 10^8$  g mol $^{-1}$ ).

Linear amylose chains form helical structures because hydroxyl molecules of one glucose bonds to the aldehyde portion of another glucose forming an internal hemiacetal bond causing the chain to coil. Adjacent helices hydrogen-bond together into compact, crystalline arrays, making amylose require more energy for hydration and gelatinization, absorb less water during cooking, form stronger gels, and retrograde more readily than amylopectin.

Amylopectin has areas of crystallinity, but its branched, less compact structure is far less crystalline than amylose. Amylopectin hydrates easily forming soft pastes (sols) characterized by clarity, stability, and resistance to retrogradation and gelling on aging.

**Fig. 1** Partial structures of amylose (linear) and amylopectin (branched) starches.

Further, its many branches give multiple sites for amylase attachment. All these aspects make amylase hydrolyze hydro amylopectin faster than amylose and speed glucose digestion and delivery to the bloodstream.

Starch granule structure also matters. Small granules with their larger surface area enable greater water absorption, greater aggregation, and higher glycemic responses than larger granules. Large intact granules can slow glucose release, but the resulting gelatinized starch may gel can be fragile making the gel easily penetrated by amylase and hasten glucose release into the bloodstream.

**Dextrins** and smaller maltodextrins ( $MW > 1000 \text{ g mol}^{-1}$ ) are glucose polysaccharides formed from starch, either by dry heat dextrinization or hydrolysis by enzymes or moist heat and acid. The latter process is used to produce traditional corn syrup, a mildly sweet food (Table 1). Manufacturers add glucose isomerase to corn syrup, which converts some glucose to fructose, to yield a sweetening power equivalent to sucrose (Table 1). Powdered dextrins, used as food additives, add viscosity, promote water holding, or enhance browning.

Like starch, most dextrins are digestible in the upper gut and yield  $4 \text{ kcal g}^{-1}$ . However, resistant dextrins with their  $\alpha$ -1,2 or  $\alpha$ -1,3 linkages cannot be hydrolyzed by amylases in the upper gut rendering them soluble dietary fibers.

### Glucose from carbohydrate staple foods

Glucose needs have traditionally been met by starchy staples, which can be prepared in countless ways, or their starches isolated as ingredients. Roots and tubers such as potato, yuca, and cassava or seeds of cereal and pseudocereals, and legumes are the major sources. Their starch content averages 50–80% of dry matter, except in legumes, which range from 1 to 58% dry matter with soy and peanut being very low. The actual amounts for all staples are affected by variety, cultivar, and agronomic conditions.

Most native starches are a mix of amylose and amylopectin with root starches having more amylopectin than many grains (Table 3). Some natural and hybrid grain varieties are high in amylose, which lowers their glycemic responses. Others are entirely amylopectin (sometimes called “waxy” or “glutinous” grains) and have high glycemic responses. Some pseudocereals such as amaranth have starches characterized by small granules and very little amylose and crystallinity, so they elicit high glycemic responses.

Legume starches are higher in amylose than other staples, averaging 30–50% amylose, but ranging from 14% in chickpea and 88% in peas (Table 3). Most tend to have low glycemic responses due not just to amylose content, but also to starch structures that favor creation of resistant starch (RS).

### Resistant starch

Until the 1980s, all starch was believed to be completely digested in the upper gut. However, research studies detected undigested starch in the large bowel. These starches were dubbed “resistant,” and function as dietary fibers. RSs are fermented to short-chain fatty acids (SCFA), which have beneficial effects locally in the colon but can be absorbed to impact metabolism throughout the body. Studies show substitution of RS for available starch can lower the blood glucose, improve insulin sensitivity, and reduce hunger.

**Table 3** Amylose, amylopectin, and resistant starch in staple foods.

Source	Amylose (%)	Amylopectin (%)	Resistant starch
<b>Cereal grains</b>			
Maize	28	72	1.7
Wheat	26	74	
Hi amylose maize			47.4
Barley, pearled	14–38	42–86	
Waxy maize	–	100	
White rice	20–24	76–80	1.3
<b>Legumes</b>	13–88	12–87	1.2–3.4
Navy bean	29	71	2.0
Cow pea	43	57	
Pea	88	12	2.6
<b>Root tuber/other</b>			
Cassava	17	83	
Potato	21	79	
Tapioca	17		
		83	
Buckwheat			1.8

**Table 4** Resistant starch (RS) classifications and examples.

Designation	Description	Example
RS1	Physically inaccessible starch	Whole kernel and coarsely ground seeds, grains or meals
RS2	Granular starch with the B- or C-polymorph	Starches high in amylose—basmati rice, high amylose grain varieties/cultivars, raw potato, raw banana starch
RS3	Retrograded starch	Cooked and cooled starchy foods, heat and moisture treated grains or starches
RS4	Chemically modified starches	Cross-linked starches, used as additives
RS5	Starch-lipid complex	Lipids-complexed amylose starch and longer branch chains of amylopectin

Five RS classes exist (Table 4) (Patterson et al., 2020). RS1 escapes small intestinal digestion because of large particle size, compact structure, or cellular compartments that sequester starch from amylase attack (e.g., whole-grain pumpnickel or grainy breads, bulgur wheat, or corn kernels). RS2 is high in amylose (e.g., green banana, high-amylose grains, and legumes). RS3 occurs in starchy foods that have been cooked and cooled (e.g., potato salad, fried rice, and “stale” bread) causing retrogradation. Starches higher in amylose are more likely to form RS3. RS4 is chemically cross-linking to make them resist digestion. RS5 entraps lipids within helical amylose rendering both fat and starch resistant to digestion.

Amounts of RS in foods are highly variable. Most cereals contain <3% RS, but high amylose varieties have 45–60% and green bananas contain ~75% (Table 3). In legumes RS content varies from 3% for pea and chickpea to >26% in raw beans but increases to over 50% in some processed products. For all foods the amount of RS depends on their processing, storage conditions, and accompanying ingredients. RS comprises only a small part of Western diets. For example, the daily average per capita intake in the USA is 3–8 g.

**Glycogen** is the only form of carbohydrate storage in the human body. Storage capacity is limited ~100–120 g in liver and 400 g in muscle. Glycogen’s branched structure is akin to amylopectin but contains many fewer glucose molecules (2000–60,000) and is smaller (MW ~  $10^6$  g mol<sup>-1</sup>). Glycogenolysis can generate glucose needs when none is readily available. Because glycogen stores are small, glycogen cannot be depended as way to meet long term glucose needs. During energy surfeit, signaled by an excess of phosphorylated glucose from glycolysis, insulin activates enzymes that start glycogen synthesis.

### Nondigestible glucose polysaccharides

**Cellulose** (C<sub>6</sub>H<sub>10</sub>O<sub>5</sub>)<sub>n</sub>, a linear, β-(1–4)-linked, glucose polymer (DP ~15,000), forms strong intrachain bonds that result in fibrous structures critical for plant cell walls and structures. Human enzymes cannot break β-(1–4)-links. Thus, cellulose reaches the colon, where it undergoes limited fermentation by colonic bacteria, thereby, contributing a significant amount of insoluble dietary fiber. The proportion fermented depends on the source, with vegetable cellulose degraded to a greater extent than cereal cellulose. Chemically modified celluloses (e.g., carboxy-methyl cellulose) undergo limited fermentation. The proportion of cellulose and other fibers that escape colonic bacterial fermentation contributes directly to fecal bulk and water holding (Older food composition tables report “crude fiber” derived fiber content by using strong reagents capable of destroying material that functions biologically as dietary fiber. Thus, these tables underreport the actual fiber content compared to tables using methods approved to emulate physiology).

**Hemicelluloses** got their name because they are often found with cellulose in plant structures. They are heteropolysaccharides that contain glucose, other sugars, and a variety of linkages. While some contain saccharide backbones with β(1–4)-linkages, they are unlike cellulose as they are much smaller (DP 500–3000), highly branched, amorphous structures that form weak intrachain bonds. Rather than fibrous, they are soluble and often viscous making them readily fermented by colonic microbes. Their four classes are as follows: (1) mixed linkage β-glucans, (2) xyloglucans, (3) xylans, and (4) mannans. β-glucans and xyloglucans have glucose backbones, so they will be discussed here.

**β-Glucans** are water-soluble glucose polymers found in cell walls of certain plants. Linear bacterial and algal glucans have β-(1→3) glycosidic bonds; whereas branched yeast and mushroom glucans have β-(1→3) and -(1→6), or oat and barley glucans have β-(1→4) and β-(1→3) glycosidic bonds. All are soluble in water and capable of forming viscous sols, but the viscosity is dependent on the number of β(1→3) linkages and the molecular weight. β-glucans of barley and oats have been shown to lower serum cholesterol and reduce blood glucose, and heavier and more viscous molecules show greater physiological impact. Oat β-glucan has an average MW 206–230 × 10<sup>4</sup> g mol<sup>-1</sup>. However, processes such as fine grinding, long dough fermentation, or treatments such as acid, heat, or enzymatic hydrolysis that decrease molecular weight or viscosity, lower physiological impact.

Extracted β-glucan is used to increase viscosity, cohesiveness, and dietary fiber content of various food products. Extraction from oat is easier because the glucan is concentrated in outer bran layers but barley, has β-glucan dispersed throughout the endosperm. High β-glucan cultivars of both barley and oats are being sought. Small amounts of β-glucans are found in wheat, rye, millets, yeasts, bacteria, and some mushroom and seaweed varieties. However, the health impacts are not well studied and may be limited by their presence in small amounts.

Xyloglucans are cell wall polymers that interact with cellulose microfibrils. Structurally, it is like cellulose with α-D-xylose, a 5-carbon sugar, replacing β-1,4-D-glucose in position 6. They help control plant functions such as ripening and impart pest resistance to plants. In humans they may have an immune modulating role.

Arabinoxylans are the predominant hemicellulose polysaccharide in cereals. Glucose is a minor constituent because the pentoses arabinose and xylose form their backbone. Despite low concentrations, they may have important physiological impact because the quantity of grains such as wheat eaten in many cultures.

## Digestion of glucose and its polymers

### Digestion of sugars

Most carbohydrates must be broken down to monosaccharides during digestion, but monosaccharides are ready for absorption upon ingestion. All sugars are digested quickly as they travel to the stomach where they mix with gastric acid and stomach contents. They become part of chyme, which leaves the stomach through the pylorus into the duodenum. There, monosaccharides can be absorbed quickly, especially if in liquid or little fat or protein is present.

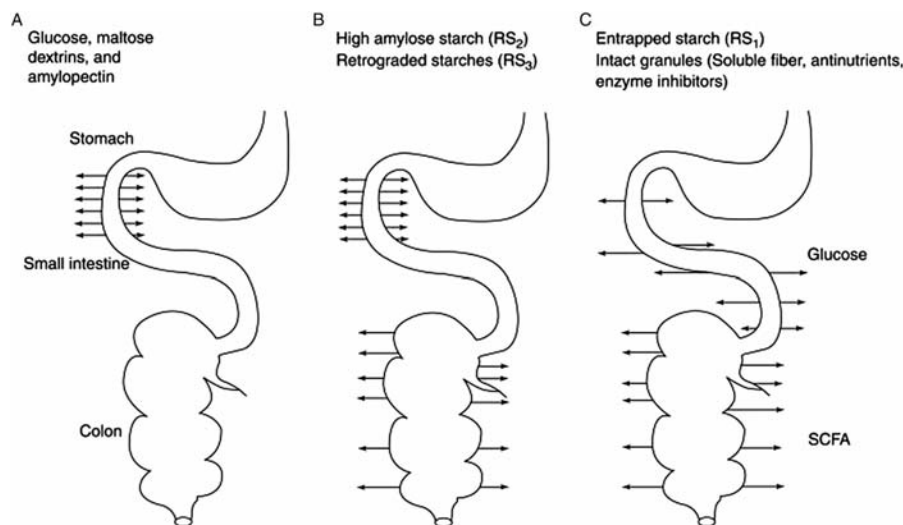

Disaccharides must be split to their respective monosaccharides by brush border enzymes—sucrase–isomaltase complex, maltase, and lactase—found in the villi of the jejunum and upper ileum prior to absorption. Several specific transporters are required to move the monosaccharides from the lumen and through the enterocytes of the intestine (Koepsell, 2020). These include sodium-linked glucose transporter (SGLT1) that carries glucose (and galactose) across the mucosa and through the membrane using active (ATP-requiring) transport. Sugars transport via facilitative diffusion involves GLUT carriers, which are sugar and tissue specific. After glucose enters the intestinal epithelium, it is carried to the basal cell side by the facilitative transporter GLUT2 for delivery to the portal vein. Once in the bloodstream glucose travels to the liver, where liver GLUT2 extracts 30–40% of the glucose to phosphorylate it in preparation for glycolysis or synthesis of glycogen. The glucose remaining in circulation is delivered to other tissues where most express GLUT1 that transfers glucose into cells for glycolysis. The largest amount of glucose goes to muscle and adipose where GLUT4 is expressed to speed glucose uptake. While neither brain nor red blood cells require insulin for efficient glucose uptake, however, insulin helps regulate oxygen and glucose metabolism and prevent hemolysis.

### Digestion of starch and related polymers

Starch must go through a series of steps to release maltoses and glucose ready to be metabolized and absorbed as described (Lovegrove et al., 2017). Salivary amylase begins starch digestion in the mouth but acts only on gelatinized starch and for the brief time while the food bolus remains pH neutral. Stomach acid stops amylases. As stomach's acid chyme moves into the duodenum, it triggers bicarbonate release and returns pH to neutral. This allows pancreatic amylase to hydrolyze starch to maltose and maltotriose. In addition to amylase, amylopectin requires  $\alpha$ -glucosidases to break down the  $\alpha$ -limit dextrin to glucose ready for absorption (Fig. 2).

Most starch digestion is completed upon leaving the jejunum; however, both rate and completeness depend on numerous factors such as the following.

- (1) Gelatinized starches are 85% hydrolyzed, but under 20% of ungelatinized may be.
- (2) Amylopectin with its multiple reducing ends for enzyme attachment and open structure is rapidly and completely digested.
- (3) Starches high in amylose with its linear chains and many fewer reducing ends for amylase attachment digest slowly. Further, the compact, crystalline structure impedes amylase penetration and enzymatic activity.

**Fig. 2** Effect of different forms of glucose on glucose absorption and short-chain fatty acid (SCFA) production and uptake from the gut.

- (4) Starches that are surrounded by seed coats, fibers or fat impair enzyme penetration and reduce both the speed and completeness of starch digestion.
- (5) Viscous soluble fibers can delay gastric emptying and act as physical barriers to intestinal absorption.
- (6) Starch–protein and starch–fat interactions both reduce digestion rate, and the fat slows gastric emptying.
- (7) Antinutrients (e.g., amylase inhibitors, lectins, tannins and phytates) and acids can inhibit starch breakdown in various ways. For example, phytate binds calcium needed by amylase, so it reduces the rate of small-intestinal starch digestion.

Food processing can change the rate of digestibility. It can increase the rate by reducing the concentration or activity of inhibitory food components or by modifying the structure of the food or the starch change its available to amylase. Examples include heating to gelatinize starch or milling crushing, flaking, or extruding crack seed kernels to increase surface area and decrease particle size. Rates of starch digestion can decrease when formulations or processes bind with or coat the starch or add or generate acid to lower the pH as in sourdoughs. Starch retrogradation generated by repeated heating and cooling, or extrusion can produce compact physical structures, as occurs during production of slow-release breakfast bars, pasta and some cereals, can decrease enzyme penetration.

### Slowly digested and resistant starch

Digestion is slowed if undigested starch reaches the ileum because it triggers the ileal brake; in the large intestine, the colonic brake. Its presence also stimulates ileal-activated glucagon-like peptide-1 (GLP-1) and peptide YY (PYY). These can suppress food intake, increase satiety, and decrease gastric emptying.

Foods that naturally contain so-called “slowly digestible starch” (SDS) are legumes or intact wholegrains or manufactured foods produced using formulations and processes usually repeated heating and cooling. Studies confirm that increasing SDS in food products slows the rate of appearance of dietary (exogenous) glucose in the bloodstream and lowers the rate of plasma glucose disappearance (Breyton et al., 2021). Thus, swings in blood glucose and insulin are blunted resulting in a steady fuel supply. SDS consumption is associated with a lower blood glucose response and beneficial changes in the microbiome and its fermentation. Such changes are factors associated with reducing disease risks related to impaired glucose tolerance.

Undigested starch in the colon can also cause marked changes in the microbiome and in fermentation products and is deemed resistant starch (Fig. 2).

Any starch not digested in the small intestine and moves into the colon becomes RS. Bacteria ferment it to hydrogen, methane and SCFAs. These provide the colon with about 10% of its energy and acidify the colonic lumen. The SCFA mix averages 60% acetate, 20% propionate, and 20% butyrate. However, the proportion depends on the size and composition of the meal, speed of transit, where in the colon fermentation is occurring and the species inhabiting the microbiome.

Different fatty acids have different roles. Butyrate specifically promotes healthy colonocytes by maintaining the mucous lining, combating inflammation, and reducing pathogenic and promoting beneficial microorganisms. Butyrate and SCFAs not utilized in the colon are absorbed and travel to the liver, where they enter the tissues with G-protein-coupled receptors. They act as cytokines to control energy metabolism by activating kinases that regulate hormone release, impact appetite, and communicate with the central nervous system (Hu et al., 2018). They also appear to mitigate negative effects of high-fat diets by inhibiting lipid synthesis and hepatic cholesterol synthesis and promoting lipolysis.

### Blood glucose response and glycemic index

Different carbohydrate foods vary dramatically in their postprandial blood sugar response, so the role of specific carbohydrate foods in health and disease is a subject of intense interest and debate. The glycemic index (GI) measure was developed to compare the rates at which different starchy foods deliver glucose to the bloodstream and raise postprandial glycemia. The GI theory suggests that choosing foods that slow blood glucose entry might aid in treating conditions with abnormal glucose tolerance and decrease the risk of diabetes and other chronic diseases.

Specifically, the GI ratio compares the 2 h blood glucose response curve for one subject ingesting 50 g of available carbohydrate from the test food with his/her own glucose response curve generated using a standard, usually 50 g of glucose. The integrated area-under-the curve (AUC) for the test food is divided by the subject's AUC for the glucose standard. The quotient is then multiplied by 100. A food's glycemic load (GL) is calculated by multiplying the grams of carbohydrate in the portion eaten multiplied by the GI (It is important to note that 50 g of available carbohydrate is rarely the same as 50 g of food and may not reflect amounts of food normally ingested. For example, USDA nutrient database shows that 28 g of beets contain 2.7 g of carbohydrate and 1.9 g of available carbohydrate, so 50 g of available carbohydrate from beets, the test amount eaten, is 0.72 kg or 5–6 medium beets).

Some argue that GI is similar to values in tables for nutrients. While similarities exist, there are important differences. First, the nutrients are determined by precise chemical analyses, but GI is a physiological measure that averages data from 10 human subjects, who have followed rigid diet and exercise protocols for 3 days prior to the test and ingest 50 g of available carbohydrate food after fasting. The blood glucose response is monitored for 2 h, and this is repeated on 3 separate occasions. The resulting AUCs are compared to each subject's own standard. Despite the strict protocols, variability within and among subjects is high (DeVries, 2008; Matthan et al., 2016). The application of data, collected on a single food after a strict protocol, to situations where foods

are eaten in combination in free-living conditions raises questions. Further, unlike other nutrients, the values in the tables are nutrient is used as touchstones for choosing or avoiding a food.

Since Jenkins et al. (1981) introduced GI, it has been used in over 10,000 scientific articles. The International Carbohydrate Quality Consortium, a group of aligned scientists, assessed the data and issued a consensus in 2013 stating the importance of postprandial glycemia in overall health and suggesting that GI is a valid and reproducible method of classifying carbohydrate foods. This group stated that low GI and GL diets were relevant for preventing and managing chronic diseases with the strongest agreement around use for diabetes to improve hemoglobin A1c (HbA1c) levels in moderately controlled type 1 and 2 diabetics (Augustin et al., 2015).

This consensus reflected findings of many epidemiological studies that showed low, compared to high, GI diets were associated with reduced risk impaired glucose tolerance and chronic diseases (Shahdadian et al., 2019; Ojo et al., 2018; Zafar et al., 2019). However, there are many studies that show high variability and mixed results (Afandi et al., 2021; Barclay et al., 2021; Gaesser et al., 2021; Vega-López et al., 2007, 2018). Reasons for variability include: (1) Imprecision with respect to assigning GI values data from food frequencies and similar instruments occurs because critical factors affecting GI are often unavailable. These include determinants of GI such as processes used, liquidity, grain structure, particle size, phytonutrients, dietary fiber, RS, and amylose: amylopectin ratios, which are important (Jones, 2013; Kanter et al., 2021). Even notes accompanying the most recent International Tables of Glycemic Index and Glycemic Load Values (2021) point out high GI variability in some food categories such as cereals (Atkinson et al., 2021).

Rice exemplifies the problem. There are >115 entries for boiled rice in the Sydney University Glycemic Index Database (Kaur et al., 2016; University of Sydney Database, 2021). Values range from very low GI (27) to extremely high (112). Knowledge of grain size, brand, variety, amount of water and cooking times, or amylose content helps, but values may still not reflect the GI of the food eaten.

(2) Epidemiological studies that compare high and low GI diets show significant confounding (Gaesser et al., 2021). Among studies the strongest evidence supporting GI is for use by diabetics. The quality of evidence for the findings for association with HbA1C is rated in meta-analyses as “moderate” and for most other endpoints is rated as “weak” or of “low certainty” (Clar et al., 2017; Reynolds et al., 2019; Jayedi et al., 2020). Eaters of diets deemed high GI and low GI often have significantly different nutrient, fiber and calorie intakes and different lifestyle characteristics. This begs the question of whether the observed health impacts are due to differences in GI or confounding factors.

Further if meal or daily diet GI is used, the calculation may introduce error. These values are calculated by multiplying grams of each carbohydrate component, (expressed as a percentage of total carbohydrate in the meal or day) by the relevant GIs and summing these. Multiplying may amplify any error, and there are questions about measures from a single food and using it in meals or daily patterns. While some defend its use, others provide data suggesting the calculations overestimate GI (Afandi et al., 2021; Balance et al., 2019; DeVries, 2008; Kim et al., 2019; Matthan et al., 2016; Meng et al., 2017a,b, 2018; Wolever and Bhaskaran, 2012).

(3) Intervention studies show less variability than epidemiological ones. A meta-analysis of 27 controlled trials showed that low GI diets provided small benefits including better hemoglobin A1C and other cardiometabolic endpoints for persons with diabetes (Chiavaroli et al., 2021). Certainty was graded ‘moderate’ for HbA1c and several secondary outcomes.

## Conclusion

Glucose, the major energy source, is supplied by foods that deliver available carbohydrates. These foods may also be important sources of unavailable carbohydrates—dietary fiber and resistant starch. To supply energy, digestive processes hydrolyze available carbohydrates to monosaccharides for absorption. Digestion begins in the mouth but takes place primarily in the small intestine. Various glucose carriers facilitate sugars movement from the villi and the gut lumen through the mucosa and into portal blood for delivery to the liver and body tissues. While sugars supply some energy, most comes from starch and related polymers with thousands glucose units. These are broken down by amylases in the upper gut. Starch exists in two forms—the rapidly digested, branched amylopectin and the slowly digested, linear amylose.  $\alpha$ -1-4 glycosidic bonds and amylopectin has  $\alpha$ -1-6 bonds glycosidic bonds. Starch that escapes digestion is deemed “resistant” and exists in five forms. These function physiologically with other non-digestible polymers and are fermented to SCFA in the colon.

The speed of glucose entry from carbohydrate foods into the bloodstream is dependent on the rate of digestion, which is impacted by many factors including gut motility, meal size and fluidity. Factors that specifically affect the rate of starch digestion include: the amylose: amylopectin ratio, fiber content, starch granule characteristics, food texture and macronutrient composition and other meal constituents, and how the food is processed, stored, and eaten. The GI was developed to compare the blood glucose excursions for available carbohydrate from various foods. Hundreds of studies link low GI diets with lower risks of various diseases. Thus, a group of scientists issued a statement suggesting GI defined carbohydrate quality. However, there is much controversy surrounding this as the findings show great variability and strength of the conclusion for most endpoints associating GI with health endpoints except HbA1c for diabetics is rated ‘as “weak” or of “low certainty”’. Sources of variability and confounding in studies comparing low and high GI diets are numerous, so the controversy continues.

Glucose, its sources, digestion, and bloodstream delivery do impact health. While GI is one measure of carbohydrate quality, the role of diets, that contain the recommended carbohydrate staples with the right mix and quantity of wholegrain, dietary fiber, fruits,

vegetables, some legumes, nuts and seeds in the recommended pattern such as DASH or MyPLATE, is important for supplying the glucose that the body needs for energy.

## Key points

- The glycemic index of foods - a marker of postprandial physiological effect.
- Fibre content does not predict the glycemic index.
- The glycemic impact of mixed meals can be predicted from the glycemic index of component carbohydrate foods.
- Diets based on low glycemic index foods improve glucose metabolism in people with diabetes and cardiovascular disease.

In the past 10 years, meta-analyses of epidemiological and experimental studies have linked the glycemic index to postprandial glucose metabolism, insulin resistance, diabetes and cardiovascular risk factors. A joint committee of the WHO and the Food and Agriculture Organization (FAO) have recommended that the physiological effects of dietary carbohydrates be classified according to their glycemic index (FAO/WHO Joint Expert Consultation, 1998). This review examines the historical and scientific background of the glycemic index.

## Background and definition

In 1939, Conn and Newburgh noted how different carbohydrate-containing foods could have the same macronutrient composition, but produce different glycemic responses. These observations were extended by Jenkins and colleagues in 1981 (Jenkins et al., 1981), resulting in systematic classification of carbohydrate foods according to postprandial glucose levels elicited by standardized carbohydrate portions. In the beginning, the “glycemic index” (GI) was introduced as a means of comparing carbohydrate “exchanges” for people with diabetes, but later broadened to have a potential role in prevention of type 2 diabetes and cardiovascular disease in the general population.

**Fig. 1** Mean blood glucose increment after equi-available carbohydrate meals. Data with permission from Jenkins, D.J., Wolever, T.M., Jenkins, A.L., 1988. Starchy foods and glycemic index. *Diabetes Care* 11: 149–159.

Glycemic indexes of thousands of foods have been published in international nutritional tables, the most recent in 2020 (Atkinson et al., 2021). Standardized methodology for glycemic index testing was published by the International Standards Organization in 2010. Specifically, the glycemic index of a food is calculated as the average postprandial glucose response after feeding a standardized available carbohydrate portion of the food (Fig. 1), relative to that of a reference food. (Table 1). The reference food (by definition, GI = 100) is usually a 50 g glucose load in solution, but a 25 g carbohydrate portion may be used for foods with lower carbohydrate content. The 2 h incremental area under the curve is summed to reflect the period of maximum fluctuation. Low GI carbohydrates have lower areas under the glucose curve, whereas high GI foods have higher areas.

Although the insulin response is not used to define GI, it can be considered a surrogate marker of the insulin demand in response to different carbohydrates. Indeed, the insulin response in individuals without diabetes to a wide range of foods (GI between 32 and 100) is highly correlated. Like glycemia, the pattern of insulin secretion caused by different carbohydrates reflects their rate of digestion and intestinal transit times. The exception to this rule is dairy products, which have a higher insulin response than predicted by their glycemic index.

It has been argued that it is the insulin response to foods and not the glycemic response that is important in the pathogenesis of insulin resistance and related metabolic disturbances and disease risk. However, high glucose levels, per se, increase the glycation of proteins and inflammatory markers such as nuclear factor-kappa B. With the advent of continuous glucose monitoring, postprandial glycemia has been linked to many cardiovascular risk markers, including body mass index (BMI), blood lipids and glycated hemoglobin (Zeevi et al., 2015).

Dietary carbohydrates stimulate insulin secretion both directly, by stimulating the pancreatic  $\beta$  cell, and indirectly, through their effect on other hormones such as GIP and GLP-1. It has been postulated that the stimulation of high GIP secretion by K cells in the upper small intestine promotes lipogenesis, fatty liver, insulin resistance, and postprandial inflammation, and reduces fat oxidation in skeletal muscle (Pfeiffer and Keyhani-Nejad, 2018).

**Table 1** The glycemic index model.

Incremental area under blood glucose response curve for the test food containing 50
corresponding areas after equi-carbohydrate portion of glucose $\times$ 100
Calculation of the GI of a mixed meal containing three separate carbohydrate-containing
foods
$GI/mixed\ meal = (GI_1)(PCF_1) + (GI_2)(PCF_2) + (GI_3)(PCF_3)$
Where
The three carbohydrate-containing foods are 1, 2, and 3
The GI for each carbohydrate-containing food is $GI_1$ , $GI_2$ , and $GI_3$
The carbohydrate content is $C_1$ , $C_2$ , and $C_3$ (g)
The total meal carbohydrate (TMC) is $[C_1 + C_2 + C_3]$ g
The proportion of carbohydrate from each food (PCF) is $PCF_1 = C_1/TMCg$ , $PCF_2 = C_2/TMCg$ , and $PCF_3 = C_3/TMCg$

## Type of dietary carbohydrate and the glycemic index

The GI of a carbohydrate food is influenced by the rate of digestion and intestinal absorption which, in turn, is influenced by the presence of other nutrients, the tertiary structure, type of starch, and susceptibility to enzymatic digestion. A recent meta-analysis showed significant reduction in postprandial glucose and insulin levels caused by starch with high amylose content, less gelatinized starch, retrograded starch and intact and large grain particle size (Cai et al., 2021).

### Chain length and composition

In the past, carbohydrates were classified as simple or complex in chemical structure, but this has no relation to their GI. Complex carbohydrates are long, polymeric chains of repeating monosaccharide units. Starches comprise repeating glucose units. Surprisingly, the GIs of different starches are determined by their susceptibility to enzymatic digestion, and not chain length. The starch in white bread and pasta have similar chain length, but bread has a higher GI, due to its tertiary structure and solubility, which creates faster digestion by increasing the access of salivary and pancreatic amylases. Short-chain carbohydrates, such as glucose and sucrose are rapidly absorbed when consumed in solution, but when part of a solid mixture such as breakfast cereals, cakes and biscuits, their digestion and absorption is often slowed. Fructose, one of the sugars in fruit and sugar sweetened beverages, is converted to glucose in the intestinal wall and preferentially oxidized in the liver (Jang et al., 2018). The GI of fructose is, therefore, low. When a mixture of sugars is consumed (e.g., glucose, fructose and sucrose in fruit), the GI is lowered proportionally. The disaccharides sucrose and lactose consist of 50% glucose and 50% fructose or galactose, respectively, and both have a lower GI than maltose, the disaccharide formed from two molecules of glucose. Maltodextrins are short chain glucose polymers that have a high GI.

### Amylose and amylopectin

The starches in cereal grains, potatoes, and other plants are composed of repeating glucose units arranged in straight (amylose) and branched-chained (amylopectin) polysaccharides. The rates of digestion and absorption and, hence, the GI of these starches is influenced by the ratio of amylose to amylopectin. The more compact structure of amylose than amylopectin results in less hydration during cooking and slower amylase digestion. Amylose-enriched starches therefore have lower GI than those enriched in amylopectin.

### Relationship of insoluble and soluble non-starch polysaccharides (NSPs) (fiber) to glycemic index

Some complex carbohydrates are not digestible by human enzymes and are commonly known as dietary fibers. They can be divided into soluble and insoluble forms. Clinical studies have shown that foods and supplements rich in viscous forms of soluble fiber, such as guar gum, pectin, and psyllium, are able to lower postprandial blood glucose and insulin levels to a meal containing rapidly digestible carbohydrate. Guar gum, a  $\beta$ -galactomannan from the Indian locust bean, is the most viscous and also reduces postprandial lipemia. Soluble fibers, such as those in pulse vegetables, whole fruits, oats, and barley, form gelatinous gels within the stomach that delay gastric emptying and enzymatic digestion, the latter by forming a physical barrier around the carbohydrate. Viscous fiber also increases the thickness of the unstirred water layer in the small intestine, thereby slowing the rate of absorption.

On the other hand, insoluble dietary fibers such as cellulose found in wheat and rice bran, have no viscosity and usually no effect on the GI. White bread and whole-meal bread, for example, both have high glycemic indices. High fiber diets and whole-grains are, therefore, not synonymous with low glycemic foods. The exception is when the bran is largely intact around the kernel forming a physical barrier to hydration of starch during cooking. Large particles of cracked wheat are digested and absorption slowly, giving products such as All-Bran a low GI. The lack of effect of insoluble fiber on glucose and insulin should not detract from important effects on laxation, bowel function and bowel pathology.

### Cell structure, food preparation, and processing

Cooking and food preparation can modify the GI. Highly gelatinized, processed convenience foods tend to have high GI. When cooking and processing disrupt the cell wall, starch granules absorb water (gelatinize), increasing the rate of amylase digestion and, therefore, the GI. The starch in bread, scones and breakfast cereals is usually fully gelatinized, while the starch in pasta, cakes and biscuits is less gelatinized, slowing digestion. Cooked pulse vegetables have low GI because their cell walls are resistant to water entry, even after canning. The largely intact cereal grains of pumpnickel rye bread, granary bread, and bulgur wheat all have low GI. However, when wheat grains are finely milled to make soft whole-meal bread, the bran is no longer a barrier to hydration and the GI rises. Cooling can lead to the formation of some starch that is resistant to human enzymes, notably in potatoes. However, the majority of the starch (>90%) is still highly gelatinized, and a cold potato salad has a high GI.

## Concerns related to the glycemic index

Over the years, scientists and health professionals have expressed concerns about the GI. These include apparent lack of reproducibility within and between individuals, the practical application to mixed meals, and inconsistent findings from clinical studies. In the intervening period, these issues have been addressed by systematic reviews and meta-analyses that have resolved much of the early controversy (Augustin et al., 2015). However, the difference between GI, glycemic load (GL) and glycemic response is often misunderstood.

### Reproducibility

#### *Within-subject variation*

The variability of the glycemic response for a given food for any individual is similar to that seen for the oral glucose tolerance test. In one study, a 25% coefficient of variation (CV) within individuals was seen when 11 healthy subjects had their glycemic response to different carbohydrates tested on eight separate occasions. In another study, the CV of the glycemic response in 22 healthy subjects given 50 g of white bread was 22%. This day-to-day variability is the rationale for testing the reference food at least twice, and preferably three times, in each subject. The average area under the curve is then used as the denominator in calculating the GI of a test food.

#### *Between-individual variation*

The variability of the glycemic response between individuals is larger than that within individuals. In other words, glucose tolerance varies. In a study that included 11 individuals without diabetes, 10 non-insulin-treated subjects with type 2 diabetes, 12 insulin-treated subjects with type 2 diabetes, and 14 subjects with type 1 diabetes; the CV between individuals within each group was 26%, 34%, 23%, and 34%, respectively. Thus, it can be seen that simple comparison of the absolute glycemic responses incorporates two sources of variability—both person-to-person and day-to-day variation. In GI testing of foods, this variability is managed by using subjects as their own control, i.e., expressing the glycemic response to any given food as a percentage of that individual's average glycemic response to a reference food, usually 50 g of glucose. By expressing the glycemic response of a test food against an equal amount of a standard carbohydrate, variations that occur with age, sex, BMI, sleep duration and ethnicity, as well as medical conditions such as diabetes, are minimized. By using the ratio and calculating the average of at least 10 subjects, the standard deviation around the mean is reduced. What remains reflects variation that is unavoidable and is also seen in diagnostic glucose tolerance testing for diabetes and carbohydrate counting.

### Reproducibility of the glycemic index

The GI of a food is a characteristic of the specific food and not a single individual. Nonetheless, it is often assumed that the GI of certain foods varies between individuals. For example, a single study reported that the GI of lentils ranged between 23 and 70 for different subjects. However, this large variability reflects day-to-day variation in glucose tolerance within individuals, rather than between individuals. When the same food is tested again and again, the mean per individual moves closer to the mean of the group, and the standard error narrows. This statistical phenomenon is known as regression to the mean. When using standardized GI testing, the standard error around the mean is approximately 10% of the mean. Even in groups of individuals with different AMY1 gene copy number (and therefore higher or lower salivary amylase activity), the GI of foods shows the same rank order. A recent inter-laboratory study reported no significant differences in mean GI values for 6 identical foods determined by the ISO method in 3 different laboratories. Although the standard error around the mean varied between laboratories, the ISO method was sufficiently precise to distinguish a low GI food from a high GI food with 97–99% probability.

### Problems arising from different methodologies used to calculate the glycemic index

Before 1998, different groups used different techniques to calculate the area under the glucose curve and to assess the postprandial glycemic response. Two reference foods, white bread and glucose solution, were also in common use, causing confusion and claims of poor reproducibility. This issue was resolved with the publication of the ISO Standard for GI methodology, that specified that when reference foods other than glucose were used, the final result should be converted to the glucose = 100 scale (International Standards Organisation, 2010). In the most recent edition of the International Tables of Glycemic Index and Glycemic load, all values are reported on the glucose scale (Atkinson et al., 2021). The GL of a food (or meal or diet) is defined as the product of its GI and the amount of carbohydrate in a serving. In the case of meals and whole diets, GL should be expressed per 1000 kJ, or otherwise adjusted for overall energy intake.

### Mixed meals and other nutrients

Carbohydrate foods are frequently taken as part of a mixed meal, and the addition of fat and protein to a high carbohydrate meal lowers the glycemic response by slowing gastric emptying and stimulating more insulin secretion. However, the relative response of

one carbohydrate food to another remains, such that lentils will always have a lower response than white bread, when part of a mixed meal.

The GI of a mixed meal can be calculated if the proportion of each of the carbohydrate-containing foods and their individual GI values are known. For example, when bread and beans are mixed in equal portions, the resulting glycemic response is midway between that of bread alone and that of beans alone. A formula for calculating the GI of mixed meals has been derived by Wolever and Jenkins ([Table 1](#)). For accuracy, this method requires all individual carbohydrate components of a mixed meal to be pre-tested. However, in practice, the GI of a mixed meal should not be tested, but rather calculated. When the average of all meals in a food record is determined in this way, it is possible to calculate the overall dietary GI and glycemic load of the person's diet. When expressed per 1000 kJ or per 2000 Kcal, it allows researchers to predict the relative glycemic impact or insulin demand of one diet versus another, but not the absolute glycemic response.

### **The second meal effect**

Dietary carbohydrates can influence the glycemic response of a second meal consumed during the postprandial period. The blood glucose response to a lunchtime meal is lower when taken after a low GI breakfast than after a high GI breakfast. Similarly, the glycemic response of a second meal taken during the postprandial period after lunch or dinner is influenced by the GI of the preceding meal ([Wolever et al., 1988](#)).

Wolever attributed the differences in the glycemic response to a second meal during the postprandial period to differences in intermediary metabolism and insulin action associated with rapidly and slowly absorbed carbohydrates. Rapidly absorbed carbohydrates produce large increases in insulin, which results in blood glucose decreasing sufficiently quickly to stimulate several counter-regulatory hormones that inhibit insulin action and glucose disposal. High GI meals are associated with significantly higher serum concentrations of glucagon, catecholamines, growth hormone, and non-esterified fatty acid (NEFA) levels in the post-absorptive period (3–5 h after consumption). The addition of guar to a meal, which slows glucose absorption and lowers the glycemic response, reduces postprandial NEFA and  $\beta$ -hydroxybutyrate and improves insulin action. In this way, chronic consumption of a low GI diet improves glucose and lipid metabolism.

### **Clinical significance of postprandial hyperglycemia**

Postprandial hyperglycemia in populations without diabetes is linked to insulin resistance, diabetes and cardiovascular disease (CVD). A glucose tolerance test containing 75 g glucose in solution is used to detect a person's ability to reestablish euglycemia after a glucose load. If glucose concentration remains above  $\geq 11.1$  mmol L<sup>-1</sup> at 120 min, this is diagnostic of diabetes; concentrations between 7.8 and 11.0 reveal a predisposition to diabetes, or pre-diabetes. The 120 min glucose concentration is also a predictor of usual response after a high GI meal. In the DECODE study, the combined 10-year mortality data from 14 studies showed that the highest versus lowest quintile for the 2 h post-load blood glucose was associated with a 2- to 3-fold increased risk of CVD mortality. Fasting glucose values were less predictive of CVD than post-load values. During a 7-year period, elderly women with isolated postprandial hyperglycemia and a 2 h value more than 11.1 mmol L<sup>-1</sup>, and fasting value less than 7.0 mmol L<sup>-1</sup> on a 75 g oral glucose tolerance test, had an approximately threefold increased risk of heart disease compared with women whose 2 h values were less than 11.1 mmol L<sup>-1</sup>.

In healthy populations, average postprandial blood glucose concentration during the preceding months is reflected in glycosylated hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>). Higher HbA<sub>1c</sub> is now used to diagnose both diabetes and pre-diabetes. Importantly, HbA<sub>1c</sub> concentration, even within the normal range, has been associated with the development over time of type 2 diabetes and cardiovascular disease ([Selvin et al., 2010](#)).

In established diabetes, postprandial glycemia appears to have a stronger relationship with microvascular and macrovascular disease than fasting blood glucose. Similarly, in gestational diabetes, adverse pregnancy outcome is more closely related to postprandial glycemia than fasting and premeal glycemic values.

### **Benefits of low glycemic index carbohydrates on diabetes control**

Diabetes control is the area in which there is most evidence of clinical efficacy. Several independent systematic reviews of global evidence have demonstrated the efficacy of low GI diets on glycemic control in management of both type 1 and type 2 diabetes. In the most recent meta-analysis ([Zafar et al., 2019](#)), 54 randomized controlled trials in adults and children with impaired glucose tolerance, type 1 or type 2 diabetes, showed that low GI diets were useful for improving glycemic control and lipid metabolism, as judged by HbA<sub>1c</sub>, fasting glucose, BMI, total cholesterol, high density lipoprotein cholesterol, triglycerides and insulin requirements. The greatest reduction in fasting blood glucose was seen in those with the longest duration. The comparison diets included carbohydrate exchange, high-fat and low-fat diets. However, many studies failed to achieve meaningful difference in GI between a low GI arm and the control arm, and only individuals with obesity showed significant reduction in body weight. Good glycemic control and favorable lipid and fibrinolytic profiles have also been reported in individuals with either type 1 or 2 diabetes who habitually consume low GI dietary carbohydrates. It remains to be shown whether these diets bestow long-term benefits on micro- or macrovascular complications.

### Benefits of low glycemic index carbohydrates on CVD risk factors

High GI foods induce postprandial hyperinsulinemia, which is a powerful predictor for metabolic risk factors and CVD in epidemiological studies. However, it has been difficult to separate the effects of high fiber and high carbohydrate intake from those of a low GI diet. The predominant concern in heart disease prevention has been saturated fat, leading to widespread adoption of low fat, high carbohydrate diets. However, recent cohort studies suggest an even greater increase in coronary heart disease progression when highly refined and rapidly absorbed carbohydrates have replaced saturated fat. In the most recent meta-analysis, 10 studies with a mean follow-up of 11 years yielded a relative risk of 1.24 per 10 point increase in GI (Livesey and Livesey, 2019). Across the global range in GI (47–82 units), the relative risk was 2.7. Similarly, 11 studies yielded a relative risk of 1.66 per 65 g increase in GL of the diet. Across the global range for GL (55–290 g day<sup>-1</sup>, the relative risk was 5.5. Based on the Bradford-Hill criteria, the findings are strong and imply causality. Some evidence suggests that the associations are more evident in females and in individuals with obesity.

### Glycemic index and the prevention of type 2 diabetes

Changes in diet and physical activity levels, both alone and in combination, reduce the progression of impaired glucose tolerance to type 2 diabetes. In a recent meta-analysis of 10 studies, the relative risk of type 2 diabetes was almost 1.3 fold higher per 10-point increase in GI (Livesey et al., 2019). The relative risk was similar per 80 g day<sup>-1</sup> increase in dietary GL. Two large US prospective population studies demonstrated a doubling of the relative risk of developing type 2 diabetes for both men and women when the habitual diet was characterized by high GI and high fat content. A similar protective effect against diabetes has been reported in populations consuming high-fiber foods and high quantities of fruit, and one would predict that these diets would also have a low GI.

### Obesity and glycemic index

Obesity contributes to the pathogenesis and morbidity of type 2 diabetes and cardiovascular disease and is associated with changes in carbohydrate and fat metabolism central to the development of insulin resistance. Although low GI diets enhance insulin sensitivity and improve metabolic cardiovascular risk factors, they are unlikely to reduce weight unless part of a lower energy diet. In the DioGenes Study (Larsen et al., 2010), a 5-arm, 26-week multi-center study in overweight adults from 8 European countries, only the low protein-high GI diet was associated with significant weight regain after weight loss. Both high protein and low GI diets were independently associated with reduced weight regain, but the difference was no longer present at 12 months. In the PREVIEW diabetes prevention study, there was no difference in diabetes incidence or weight outcomes between the high protein-low GI diet and the control moderate protein-moderate GI diet. However, a secondary longitudinal analysis of the PREVIEW data found that the highest tertiles of GI and GL were associated with greater weight regain and increase in glycated hemoglobin (HbA1c) than the lowest tertiles (Zhu et al., 2021). Hunger and satiety ratings were correlated with changes body weight. Taken together, the findings in PREVIEW imply that greater reduction in GI is needed to impact clinical outcomes than was achieved in the PREVIEW randomized controlled trial. Evidence from animal studies, in which diet can be strictly controlled, also demonstrates that the GI of the diet affects both weight and body fat outcomes (Campbell et al., 2017).

### Pregnancy and glycemic index

Throughout pregnancy, insulin resistance increases as pregnancy progresses, even in well-nourished women. As a result, many women develop hyperglycemia and gestational diabetes. Untreated hyperglycemia has serious adverse pregnancy outcomes, including macrosomia and offspring obesity. Randomized controlled trials in the West show that women with gestational diabetes assigned to a low GI diet had better pregnancy outcomes, including less need for insulin, than those consuming high GI diets (Moses et al., 2006). A meta-analysis of 5 studies showed no significant differences in risk of cesarian section, large-for-gestational age infants or small-for-gestational age infants. When the proportion of dietary carbohydrate increases above 50% in women with gestational diabetes, low GI carbohydrates improve glucose tolerance (Walsh et al., 2012).

### Proposed mechanism by which dietary carbohydrates/glycemic index influence insulin resistance

Adipocyte metabolism is central to the pathogenesis of insulin resistance, and dietary carbohydrates influence adipocyte function. The previous simplistic view that insulin resistance resulted from the downregulation of insulin receptors in response to hyperinsulinemia is being replaced by the hypothesis that high circulating NEFA concentrations both impair insulin action and reduce pancreatic  $\beta$  cell secretion. It is plausible that low GI carbohydrates reduce insulin resistance by their ability to reduce adipocyte NEFA release. There is evidence of a loss of suppression of hormone-sensitive lipase (HSL), an enzyme that breaks down triglyceride to free fatty acids and glycerol, to small physiological increases in insulin and, to a lesser extent, insulin insensitivity of lipoprotein

lipase. HSL is normally sensitive to small increases in insulin, and is totally suppressed at much lower concentrations than those required for glucose uptake. In insulin-resistant subjects, HSL is less sensitive and adipocyte NEFA release is increased. A relationship between increased adipocyte NEFA release and insulin resistance has been shown in subjects with CHD. The metabolic consequences of increased circulating NEFA are multiple, including adverse lipoprotein and coagulation changes and a lipotoxic effect on the  $\beta$  cell. Accumulation of triglycerides within the  $\beta$  cell also impairs insulin secretion.

Many of the metabolic benefits associated with low GI carbohydrates can be attributed to their ability to reduce adipocyte NEFA release. Low GI foods have been consistently shown to reduce insulin resistance, and animal studies have shown that improvements in fat and muscle insulin sensitivity are accompanied by decreases in fatty acid synthetase activity, adipocyte size, and lipid storage.

Low GI diets attenuate the insulin response for approximately 4 h postprandially. High postprandial insulin in the later stage is insufficient to affect glucose transport, but does suppress the insulin-sensitive enzyme, HSL and, thus, ensures prolonged suppression of postprandial NEFA output. The ability of low glycemic carbohydrates to do this is in stark contrast with high glycemic diets, which can cause an elevation of NEFA release postprandially by stimulating counter-regulatory hormones. Low glycemic meals taken in the evening can effectively suppress circulating NEFA concentrations and hepatic glucose output throughout the night. These metabolic effects are predicted to promote insulin sensitivity.

Our own work has shown that insulin-resistant adults with a history of, or who are at risk of, CHD improve adipocyte insulin sensitivity after consuming a low GI diet for 3 weeks. and that their circulating NEFA decline. These human studies complement animal work showing that low GI diets improve insulin sensitivity by modulating adipocyte metabolism.

## Conclusion

A low GI diet improves postprandial metabolism, reduces inflammatory markers and is associated with reduced risk of developing type 2 diabetes and cardiovascular disease. Dietary carbohydrates are absorbed and metabolized at different rates and, therefore, influence postprandial glucose, insulin, and NEFA concentrations differently. In Western society, the proportion of the day that we spend in the postprandial state is increasing as the tendency to snack throughout the day replaces the traditional three meals each day. The known detrimental consequences of high glycemic foods and snacks on postprandial metabolism should encourage us to advocate for low glycemic diets to counter the current epidemic of insulin resistance-related and inflammatory diseases. The relevance of the GI to preventable diseases of the Western world argues strongly for its greater acceptance in current nutritional guidelines.

## Conflict of interest statement

JBM is the co-author of books about the GI of foods and oversees a GI testing service at the University of Sydney. She is President of a global, not-for-profit GI-based food endorsement program, a member of the International Carbohydrate Quality Consortium and a scientific advisor to the Novo Foundation and Zoe Ltd.

### Key points

- After soybean and peanuts, pulses are the most consumed legumes
- Pulses are the main protein source in many countries
- Emerging technologies have been used besides thermal treatment to inactivate trypsin inhibitor activity of legumes
- Pulses are a great alternative for plant-based protein diets

### Introduction

*Fabaceae* or *Leguminosae* family represents the third largest group of plant life in the world. Soybean and peanuts are the legumes with highest economic relevance followed by dry bean, chickpeas and peas. Pulses are a subcategory of legumes that include the seeds that are consumed as foods. They represent an important source of protein for many countries in Africa and Latin America. Among other beneficial effects on health, they are useful for moderating blood sugar levels after meals and improving insulin sensitivity (Singh, 2017). They also play a positive role in weight reduction since their consumption induces satiety. The resistant starch and fiber act as prebiotics for the probiotic or beneficial bacteria. The content of micronutrients is also an important characteristic of legumes, and their consumption can reduce the risk of anemia. Many traditional dishes in different regions of the planet include combinations of legumes and cereals, complementing the amino acids profile. The Food and Agriculture Organization of the United Nations (FAO) promoted the nutritional and environmental benefits of the diverse crops included in this category and 2016 was proclaimed as the International Year of Pulses (IYP). Since 2019, the World Pulses Day has been celebrated on February 10th. Global market trends related to more sustainable and healthy diets have increased the consumption of pulses as ingredients for foods beyond the traditional dishes that included them boiled, stewed, germinated or fermented. Trypsin inhibitor activity has been successfully reduced with thermal treatments, but emerging technologies have been developed to improve their functionality and retain phytochemicals and nutrients with diverse beneficial effects on health.

## Classification and common food uses

Legumes belonging to the *Fabaceae* or *Leguminosae* family represent the third largest group of plant life in the world. Legumes that produce edible seeds for human and animal nutrition are named pulses. According to [FAO \(2016\)](#), the major groups are dry beans, lupines, bambara beans, broad beans, lentils, dry peas, chickpeas, dry pigeon peas, vetches, dried cowpeas, winged beans, and sword beans ([Table 1](#)).

### Dry beans

*Phaseolus* is the genera of the dry bean pulses of America and *Vigna* is found in some regions of Asia. These pulses include common beans such pinto, black, or in various colors, all belonging to the *Phaseolus vulgaris* that is one of the most widespread crops. *Vigna* includes some dry beans such as adzuki, mung, and urd beans. Dry beans are considered one of the most important edible legumes worldwide and can be found almost in every country on earth. In fact, it is a staple food in the Middle East, South America, India, and the Mediterranean.

### Lupines

Lupines include *Lupinus albus*, a native edible legume from the Mediterranean and *Lupinus mutabilis* originating in South America. They grow in Australia, Europe, Russia, and South America. Lupines have been consumed as a popular snack usually in brine or pickled, and they are also used as an additive to enrich cereal flours.

### Bambara beans

*Vigna subterranea* legumes grow exclusively in Africa and their color depends on the variety. The seeds are very similar to peanuts and they have to be cooked a long time because of their hardness. Bambara beans represent a staple food in small African communities.

**Table 1** Legumes that are considered pulses according to [FAO \(2016\)](#) classification.

Pulses	Types	Scientific name
Dry beans	Borlotti beans	<i>Phaseolus vulgaris</i> L.
	Black beans	
	Cannellini beans	
	Red kidney beans	
	Haricot beans	
	Flageolet beans	
	Pinto beans	
	Adzuki beans	
	Mung beans	
	Urd beans	
Lupines	Tepary beans	<i>Vigna angularis</i> L. <i>Vigna radiata</i> L. <i>Vigna mungo</i> L. <i>Phaseolus acutifolius</i> L. <i>Lupinus</i> L.
	Lupines	
	Bambara beans	
	Broad beans	
	Red lentils	
	Yellow lentils	
	Green or brown lentils	
	Puy lentils	
	Umbrian lentils	
	Dried green peas	
Dry peas	Bambai chickpeas	<i>Pisum sativum</i> L. <i>Cicer arietinum</i> L.
	Desi chickpeas	
	Kabuli chickpeas	
	Dry pigeon peas	
	Vetches	
	Dried cowpeas	
	Winged beans	
	Sword beans	

### Lentils

*Lens culinaris* originated from the Middle East, Asia, and North America. Lentils are one of the oldest foods and grow even in arid land and extreme temperatures. There are red, yellow, green or brown lentils that grow more in Asia and North America. Besides, there are puy and umbrian lentils.

### Dry peas

*Pisum* originates from the Mediterranean or Middle East. The leaders in peas production are Canada, Russia, and Ukraine. Unlike lentils, peas are soft and with a spherical form. Dry peas are used to make soups, flours, and snacks.

### Chickpeas

*Cicer arietium* or chickpeas originated in Turkey. They are very appreciated because of their potential use in the culinary sector, nutritional value, and storing potential. They grow around the globe and are a staple food in European, Arabic, Mexican, North American and western Asian cuisines. There are three types of chickpeas: Bambai, Desi, and Kabuli type.

### Dry pigeon peas

*Cajanus cajan* are native to India region and Africa, specifically from the Congo Republic. Now, they grow easily in some parts of the Caribbean, India, and Africa, but the greater consumers are found in Asia. Pigeon peas have become an important food source in some eastern countries.

### Vetches

*Vicia sativa* was consumed since the Neolithic Era by humans and its cultivation was standardized and documented during the Roman Empire. Now, it is used primarily for livestock fodder.

### Dried cowpeas

*Vigna unguiculata* seeds originated from West Africa. Nowadays, they grow and are consumed all over Asia, Africa, Southern Europe, and Central and South America. Besides, it is a very important ingredient in Creole and Indian curries.

### Winged beans and sword beans

Winged beans (*Psophocarpus tetragonolobus*) originating in New Guinea and sword beans (*Canavalia gladiata*) from certain tropical regions of Asia.

Pulses are mainly used for foods, but soybeans and peanuts are legumes of high economic impact. Each year, more than 342 million tons of soybeans are produced worldwide but only 6% is consumed as food, mainly in Asia (Semba et al., 2021). For peanuts, only 50% of the more than 62 Mt produced yearly are consumed as food and the other half is mainly used for oil production. Green peas and beans are also legumes but not considered pulses since they are classified as vegetables. Clover and alfalfa are also leguminous crops, but they have no economic relevance related to their consumption as food. Therefore, pulses are the most important leguminous foods, and their value has been recognized by the UN. To create a worldwide awareness of their importance for sustainable food production, the UN General Assembly proclaimed 2016 as the International Year of Pulses (IYP) and the Food and Agriculture Organization of the United Nations (FAO) promoted the nutritional and environmental benefits of the diverse crops included in this category. Since 2019, the World Pulses Day has been celebrated on February 10th.

### Nutritional value

The proximate contents, protein, fats, minerals, crude fiber and carbohydrates are given in Table 2 based on the published data of Kamboj and Nanda (2018). Legumes have high protein content, more than 20% superior quantities of protein in comparison to other plant foods and have twice the dietary protein content of cereal grains. Pulse proteins were classified into two major fractions, albumin and globulin. Globulins are the major storage proteins in pulses seeds constituting 35–72% of total protein, they have higher amounts of glutamine aspartic acid, arginine and lysine. Albumins constitute only up to 15–25% of total seed protein. The albumins have higher amounts of cystine, methionine and lysine contents as compared to globulin fractions. In general all legumes have high lysine content and are low in sulfur-containing amino acids. In the legumes methionine, cysteine and lysine are in the range of 30–90, 30–130 and 400–520 mg per g of nitrogen (N), respectively.

**Table 2** Proximate composition of legumes (as per 100 g of seeds) based on the published data of Kamboj and Nanda (2018).

Legumes	Protein (g)	Fat (g)	Minerals (g)	Crude fiber (g)	Carbohydrates (g)
Chickpea	17.1–22.5	5.2–5.6	2.5–3.0	1.0–3.9	58.1–60.9
Field bean	24.9	0.8	3.2	1.4	60.1
Moth beans	23.6	1.1	3.5	4.5	56.5
Kidney bean	22.9	1.3	3.2	4.8	60.6
Horse	22	0.5	3.2	5.3	57.2
Cowpea	24.1	1	3.2	3.8	54.5
Pigeonpea	9.8–22.3	1.0–1.7	1.0–3.5	1.5–6.2	16.9–57.6
Khesari	28.2	0.6	2.3	2.3	56.6
Lentil	25.1	0.7	2.1	0.7	59
Black gram	24	1.4	3.2	0.9	59.6
Peas	7.2–22.9	0.1–14	0.8–2.4	4.0–4.4	15.9–58.8
Green gram	24.5	1.2	3.5	0.8	59.9

Legumes contain relatively low quantities of the essential sulfur containing amino acids methionine and cysteine which are found in higher quantities in cereal. In different regions worldwide there are traditional dishes prepared with the combination of cereals and legumes. For example, in Asia and Latin America many traditional recipes have variations of rice and beans. Traditional African cuisine makes great use of a wide variety of beans, chickpeas and grains. In Mexico and Venezuela, corn tortillas and arepas are commonly accompanied with beans. In Morocco and Algeria chickpeas are paired with whole wheat couscous and chicken for a delicious exotic stew. Kochari is a typical dish made from lentils and rice in Egypt. Congee is prepared from rice as well such as millet and served with a variety of cooked pulses.

Commonly consumed legumes have carbohydrate content in the range of 15.9–60.9%. Carbohydrate comprises monosaccharides, oligosaccharides, other polysaccharides and starch. In the legume seeds, starch is the main source of accessible carbohydrate. The range of dietary fiber in legumes is from 0.7 to 6.2%. Legumes are mainly rich in resistant starch (RS) and have low glycemic index. In addition, they can help in moderating blood sugar levels after meals and improving insulin sensitivity. They also play a positive role in weight reduction since their consumption induces satiety. The resistant starch and fiber act as prebiotics for the probiotic or beneficial bacteria. Bacterial fermentation leads to the development of short-chain fatty acids, such as butyrate, which improve colon health through promoting a healthier gut microbiome and reducing colon cancer risk.

Other health promoting components of legumes are their phenolic compounds such as phenolic acids, tannins and flavonoids, which are related with the antioxidant, anti-tumoral, antiplatelet, anti-inflammatory and anti-allergic properties of different varieties of legumes. Dark colored and pigmented pulses have more phenolic content compared to light colored varieties. In addition, legumes are an important source of saponins, particularly in chickpeas, lentils, dry beans and peas. Saponins differ from phenolic compounds in their chemical structure since they are glycosylated forms of triterpenoids, mainly oleanolic acid, or steroids. In recent years, saponins have been proven to have anticarcinogenic, antimutagenic, hypoglycemic, hypocholesterolemic, hepatoprotective, immunomodulatory, neuroprotective, anticoagulant, antiinflammatory and antioxidant activities.

Legumes are normally low in fat and have no cholesterol but contain phytosterols that contribute to their cholesterol lowering effects. Additionally, they are a superior source of linoleic and -linolenic acid in the range of 21–53% and 4–22%, respectively. Chickpeas have the highest monounsaturated fatty acid content (34 g/100 g), kidney beans the highest polyunsaturated fat content (71.1 g/100 g) and butter beans have the highest saturated fat content (28.7 g/100 g). Lupines contain a higher monounsaturated fat and lower saturated fat content. Phytosterols, mono and polyunsaturated fatty acids decrease the possibility of coronary heart diseases.

As sources of micronutrients legumes are much superior to cereals because legumes have higher initial minerals. Legumes have up to 3.5% minerals, which corresponds mainly to phosphorus, calcium, magnesium and potassium (Table 3). They are an important source of other minerals such as iron and zinc, essential in human nutrition (Kamboj and Nanda, 2018). The minerals are found in the seed coat (bran) in major proportions which are discarded during processing. Most legumes, including common beans are consumed whole, resulting in conserving their mineral contents, they are an important source of iron and their consumption can reduce the risk of anemia. Dry beans and chickpeas have the highest content of essential minerals.

Legumes are a good source of B complex vitamins (thiamine, niacin, riboflavin and folic acid). Chickpea, cowpea, green gram, pigeonpea, lentil, black gram, peas and red gram contain significant amounts of free folic acid, a range of 4.6–69 µg/100 g seeds. Cowpea is an excellent source of B complex vitamins.

## Global trends of production and economic importance

According to FAOSTAT, the global production of pulses is about 88.7 million tons. Dry beans, including pigmented beans, represent about 34% of the production of the main legumes cultivated in the worldwide, followed by dry peas, chickpea, cowpea, fava bean, lentil, pigeonpea, miscellaneous beans, lupin, and Bambara bean (Fig. 1). Dry beans, often called the

**Table 3** Micronutrients contents of legumes (as per 100 g of seeds) based on the published data of Kamboj and Nanda (2018).

Legumes	Minerals (g)	Iron (mg)	Calcium (mg)	Magnesium (mg)	Potassium (mg)	Zinc (mg)	Thiamine (mg)	Riboflavin (mg)	Niacina (mg)	Folic acid (μg)
Chickpea	2.5–3.0	4.6–9.5	58–202	119–169	720–808	1.7–6.1	0.20–0.48	0.15–0.18	1.3–2.9	24–34
Field bean	3.2	2.7	60	–	–	–	0.52	0.16	1.8	–

Kidney bean	3.2	5.1	260	184	–	4.5	–	–	–	–
Horse	3.2	6.77	287	156	762	2.8	0.42	0.2	1.5	–
Cowpea	3.2	8.6	77	210	1131	4.6	0.51	0.2	1.3	69
Pigeonpea	1.0–3.5	1.1–2.7	57–73	58–90	463–1104	0.9–3.1	0.32–0.45	0.19–0.33	3	19
Khesari	2.3	6.3	90	92	644	–	0.39	0.17	2.9	–
Lentil	2.1	7.58	69	74–80	629	2.8–3.1	0.45	0.2	2.6	14.5
Black gram	3.2	3.8	154	130–154	800	1.7–6.1	0.42	0.2	2	24
Peas	0.8–2.4	1.5–7.05	20–81	34–122	79–750	2.3	0.25–0.47	0.01–0.21	0.8–3.5	4.6
Green gram	3.5	3.9	75	127	843–1150	2.8–3.0	0.47	0.21–0.27	2.1–2.4	24.5

**Fig. 1** Global production of different legumes, 2014–2019, with amounts shown in million tons (Mt) (FAOSTAT, 2020).

“meat of the poor”, provide micronutrients to more than 300 million people in the tropics and, in many areas, are the second most important source of calories following maize. In South Africa, dry beans accounted for about 80% of total caloric supply provided by pulses. Their production is key to ensuring food security in many poor regions of the world (Semba et al., 2021). In contrast, miscellaneous beans that include winged bean (*Psophocarpus tetragonolobus*), lablab (*Lablab purpureus*), jack bean (*Canavalia* spp.), guar (*Cyamopsis tetragonoloba*), velvet bean (*Mucuna pruriens*), and yam bean (*Pachyrhizus erosus*) are produced in less quantity compared to dry beans, they only represent the 5% of the production. Dry peas and chickpea represent 17% and 15% of world production of legumes for human consumption.

Pulses are diverse in their traditional food uses in Asia, Africa, and America, where they are mainly consumed in soups, spreads, meal components, snacks, and breakfast items (Table 4). As an example, boiled sword beans called “avarakai” in India are considered an essential food for pregnant women. As well, fried or boiled are the base of the meals of Mesoamerican population, they are eaten up to three times a day.

Since the common food uses of pulses include them boiled or in soups or stews, one of the most popular industrialized products is canned cooked beans. For instance, the global market of canned legumes was valued at 2.56 billion of USD in 2019 and it is expected to grow at 4.0% of annual growth rate (CAGR) from 2020 to 2027. The consumer’s demand for canned legumes has been increasing as they are a rich source of plant-based proteins (GVR, 2020).

Market trends such as the rise in awareness to increase protein consumption, vegan diets, and the relevance of ethnic food are stimulating the demand for pulses. The increase of legume consumption is also related to the growth of people looking for alternatives to animal protein, besides, the key motivations could be the plant-based food benefits, and awareness of climate change. The Planetary Health Diet highlights an increased consumption of legumes as one way to move toward sustainable and healthy diets. These trends have changed the past paradigms when the people thought that legumes were for the low-income population (“meat of the poor”) and nowadays legumes have become the main protein source even for eccentric diets.

**Table 4** Traditional dishes and their principal countries or regions.

Scientific name	Type	Common food uses	Country
<i>Phaseolus vulgaris</i> L.	Pinto beans	"Frijoles refritos" (refried beans), boiled beans, soups, in salads, stews, spreads, chilli, cowboy beans Feijoada	Mesoamerica
	Black beans		Southern of United States of America
			Brazil
			Mozambique
			Angola
			Portugal
	Red kidney beans	Boiled beans with rice	Southern of United States of America
		Minestrone	Italy
	Haricot beans	Boston baked beans	New England
			United States of America
<i>Vigna angularis</i> L.	Adzuki beans	Desserts, confections, soups	Asia
<i>Lupinus</i> L.	Lupines	Raw, pickled, in brine, mashed, cooked in soups or stews; flour used for pasta, pastry, dairy product substitutes; salty snack	Greece
		Tremocos	Jordan
		Altramuces	Egypt
		Chocho	Portugal
		Traditional dish with olives	Spain
		Traditional fermented foods such as tempe, miso, and soy sauce	Ecuador
			Italy
			Asia
<i>Vigna subterranea</i> L.	Bambara beans	Cooked in soups, stews, cassoulet	Ghana
			Zimbabwe
<i>Vicia faba</i> L.	Broad beans	Stews, salads, burrata bruschetta	South-west Asia
			Africa
			Greece
<i>Lens culinaris</i> L.	Lentils	Soups, boiled or fried, stews, sprouted grain in salads, flour (breads and cakes), food for infants	Mesoamerica
			Africa
		Gravies, snacks, sweets	India
		Dhal	India
		Koshari	Asia
<i>Pisum sativum</i> L.	Dried green peas	Dhal, soups, stews	Egypt
		Meat analogs, in vegetarian pakoras, pea flour (baked goods, pasta, and noodles, extruded snacks, breakfast cereal)	Asia
		Matzoh balls	India
		Falafel	Israel
<i>Cicer arietinum</i> L.	Chickpeas	Boiled, fried, cooked, crushed snacks, dhal, sweets, snacks, bread, hummus	Middle East
			South Asia
			Mediterranean region
			Pakistan
		Falafel	Middle East
		Fermented food (dhokla), curry, chhole	India
<i>Cajanus cajan</i> L.	Dry pigeon peas	Stew	Caribbean
<i>Vigna unguiculata</i> L.	Cowpea	Boiled, steamed, or fried; fritters or akara	Africa
			Caribbean
			Brazil
		Steamed bean pudding, moimoi	Nigeria
		In salads	Mediterranean region
		Traditional dish, "Hoppin' John"	United States of America
<i>Psophocarpus tetragonolobus</i> L.	Winged beans	Boiled or fried seeds, stews	Asia
<i>Canavalia gladiata</i> L.	Sword beans	Boiled, stews, soups	India
			Africa
			Asia

### Legume proteins/flours in emerging markets

The market of plant-based proteins has increased dramatically due to the massive investment, revenue increases, and the rise of new product development. In fact, in the first part of 2020 the international investment in plant-based proteins hit \$1.1 billion, more than double for 2019 according to FAIRR Initiative. Likewise, the global plant protein market value of \$29.4 billion in 2020 could surpass \$162 billion by 2030 according to Bloomberg Intelligence.

The global inclination of sustainable, regenerative, plant-based foods, and gluten free products are some of the drivers for the demand of these products. Besides, the growing demand for a protein-rich diet, the health and wellness trend, the focus on meat alternatives, the organic trend, and the allergies and intolerances of animal proteins constitutes the core of the demand increase of the legume protein and/or flour. The main sources of legume protein are peas, chickpeas, lentils, and lupin. The main applications are food and beverages, animal feed, supplements and others. The North America region accounted for the largest market share in the global market.

There are some formulation challenges in taste, texture, nutrition, and functionality when pea, chickpea, lentils, fava beans and other pulses were used. Different products play an important role in the market such as the native flours, precooked flours, extruded products, modified vegetable proteins, legume-based foods, plant-based meats, and others.

## Legume processing and antinutritional factors

Legume seeds enclose numerous rather minor proteins, which includes protease and amylase inhibitors, lipoxygenase, lectins and others, which are related to the nutritional or functional quality of the seed. The trypsin inhibitor activity (U/mg) of legumes varies, going from 1 for *Vigna mungo* to more than 90 for *Glycine max* (Avilés-Gaxiola et al., 2018). This has been a great concern to improve the digestibility of legume proteins and, traditionally, thermal treatments have been the alternative to inactive trypsin inhibitors like Kunitz (KTIs) and Bowman-Birk (BBTIs).

Thermal treatments such as boiling, roasting, cooking, are common ways to inactivate trypsin inhibitors but they affect functional properties of the resulting products as well as destroy certain phytochemicals. Biological processes like fermentation and germination have also been used for centuries and proven to reduce the trypsin inhibitor activity of legumes. In contrast to thermal treatments, germination and fermentation improve the phytochemical profile and the beneficial effects on health related to legume consumption. Chemical treatments, mainly using alkali, are also used to inactivate protease inhibitors in different soybean industrialization processes but remaining chemicals or side reaction products are an important disadvantage. Extrusion, ultrasound, irradiation and high hydrostatic pressure treatments are emerging technologies that have also been proved to reduce the trypsin inhibitory activity of legumes (Avilés-Gaxiola et al., 2018). With the growing demand for new vegetable proteins, emerging technologies are an excellent alternative for legume processing.

## Conclusions

Legumes are an excellent alternative to increase the protein consumption in more sustainable diets. Pulses are in a transition from being considered the “meat of the poor” thanks to their incorporation as food ingredients. Resistant starch, micronutrients and phytochemicals are legumes components that have beneficial effects beyond nutrition. Pulses commonly consumed around the globe are very diverse and this contributes with healthy diets maintaining ethnic foods and promoting innovative uses thanks to emerging technologies.

### Introduction

Lycopene, the most abundant pigment in ripe red tomatoes and in a few other fruits, is one of the major carotenoid pigments that is widely present in the diet of the human population. **Figure 1** illustrates the chemical formula of selected carotenoids that occur widely both in human diets and in the noncellular fraction of human blood in most regions of the world. Carotenoids are yellow-to-red in color, with lycopene being nearer the red end of the carotenoid series. However, unlike the other carotenes and cryptoxanthins, it does not possess a beta-ionone ring structure at either end of the molecule, and this precludes it from becoming a precursor of vitamin A in humans and animals. Nevertheless, it is readily transformed from the all-*trans* form that is characteristic of most plants and plant foods for animals and humans, to a range of mono- and di-*cis* forms within the animal's body. In addition, oxidation to epoxides and hydroxylated derivatives occurs, although the control of these oxidation pathways and the nature of their products are not yet well understood or characterized.

In plant tissues, where it is synthesized, lycopene is thought to help protect vulnerable photosynthetic tissues from light- and oxygen-catalyzed damage. Its role in humans and other animals, which can only obtain the pigment from their diet, is less well understood. Indeed it remains unproven that there is an essential role for lycopene in animal tissues. Nevertheless, considerable research effort is currently being undertaken to test hypotheses that are attempting to link human dietary and tissue lycopene levels to the risk of degenerative diseases, such as vascular diseases, cancers, etc., especially in older people. As discussed in more detail below, this research is being performed in a wide range of tissue culture and animal model systems and human epidemiological studies.

In this article, some key aspects of the chemical and physical properties, the dietary sources, biochemical status indices, and biological significance of lycopene will be described.

### Chemical and Physical Properties of Lycopene; its Food Sources and Enteric Absorption

Lycopene (molecule weight 536.9) is the most commonly encountered of that subgroup of the naturally occurring carotenoids that have a straight-chain poly-isoprenoid molecule without any terminal  $\beta$ -ionone ring structures (**Figure 1**). The chain length and number of conjugated double bonds determine the absorption spectrum, which peaks at 472 nm with a molar extinction coefficient,  $\epsilon^{1\%}$  of 3450. It is one of the most nonpolar members of the carotenoids, and in organic solution it is also one of the most easily oxidized and thus is easily destroyed, which necessitates the use of rigorous precautions against its oxidative destruction during its extraction and analysis from plants, foods, animal tissues, and body fluids. Currently, such analytical determination is usually based on high-performance liquid chromatography (HPLC), using either its characteristic light absorption property, or its natural fluorescence, or its redox character, for detection and quantitation by absorbance or fluorometric or electrochemical detection. The lycopene content of selected commonly consumed foods is listed in **Table 1**. The original information can be found in the US Department of Agriculture (USDA) ARS recent publication (2010), Nutrition Data Laboratory Home Page. It is interesting to find out that in south Asia, the fruit Gac (*Momordica cochinchinensis*) contains more lycopene, almost three-fold more, than does the tomato fruit. Another characteristic that greatly affects lycopene stability and the problems of its storage and analysis is the phenomenon of *cis-trans* isomerization. Naturally occurring lycopene in tomatoes, the major human food source of this carotenoid, is nearly 100% all-*trans* (**Figure 1**), but during the processing of food, and then during the processes of absorption and accumulation in animal tissues, there is a progressive increase in the proportion of a variety of *cis*-forms. Most of these *cis*-forms contain

**Figure 1** Structures of lycopene and certain other carotenoids found in human blood and tissues.

a single *cis*-bond (mono-*cis*-lycopene), and the 5-, 9-, 13-, and 15- mono-*cis*-lycopenes account for more than 50% of the total lycopene in human serum. Smaller quantities of di-*cis*-lycopenes are normally also present. Curiously, another food source of lycopene, red palm oil, has a much higher natural proportion of the *cis*-forms of the pigment. Isomerization is catalyzed by low pH; therefore,

stomach acid is believed to be a major factor in the conversion of the all-*trans*-lycopene ingested from tomatoes and their products to a mixture of *cis*-forms in the digestive tract. There is also evidence that further isomerization occurs between the digestive tract and the portal lymphatic lipid micelles. The *cis*-isomers differ from the all-*trans* form in their absorption and inter tissue transportation properties, and also in their functional characteristics; for instance, they are more soluble in lipophilic solvents and structures are less likely to aggregate into crystalline forms. More research data suggested that the greater bioaccessibility of *cis*-forms compared with all-*trans* form of lycopene was the reason for higher proportion of the *cis* form in tissues. A recent report showed that cholesterol membrane transporter SR-B1 was involved in lycopene intestinal absorption. However, lycopene and its various forms in association of physicochemical differences and their related biological consequences have yet to be adequately explored.

Of all the most common naturally occurring carotenoids, lycopene is by far the most efficient in reacting with and quenching singlet oxygen,  $^1\text{O}_2$ , which is a non-free-radical excited and reactive form of oxygen. This form of oxygen reacts rapidly with lycopene to yield nonexcited triplet oxygen and excited triplet lycopene. The latter then dissipates its extra energy by solvent interactions, thus regenerating nonexcited lycopene and preserving its original structure by recycling. However, another of its chemical interactions with molecular oxygen appears to result in irreversible oxidation to yield one or more cyclic epoxides, which then probably undergo ring-opening. Nevertheless, there are many unresolved questions about the nature and importance of the many degradation pathways that are believed to result in the irreversible destruction of lycopene both *in vitro* and *in vivo*.

As a food component, consumption of lycopene in tomato is well tolerated and generally safe. The possible side effect of high consumption of tomato products would be mild digestive upset. Lycopene from tomatoes is permitted as a food color.

Lycopene is an essential intermediate in the pathway for synthesis of the  $\beta$ -ionone ring-containing carotenoids such as  $\beta$ -carotene in plant tissues, and in most plant tissues it is present in only minor amounts. However, in a few, including tomato fruit, watermelon, and red grapefruit, this conversion to the  $\beta$ -ionone ring products by the enzyme lycopene cyclase is hindered, so that the intermediate carotenoid forms, lycopene, phytoene, and phytofluene, accumulate instead.

**Table 1** Lycopene (mg) content of selected foods, sorted by nutrient content collected from the USDA Nutrient Database for Standard Reference, Release 23

Food description	Lycopene content (mg per 100 g)
Tomatoes, sun-dried	45.9
Tomato products, canned, paste, without salt added	14–28.8
Sauce, pasta, spaghetti/marinara, barbecue, ready-to-serve	4.4–12.7
Catsup (Ketchup)	16.7
Sauce, salsa, ready-to-serve	10.5
Vegetable juice cocktail, canned	9.7
Tomato juice, canned, with salt added	9.0
Pasta with meatballs in tomato sauce, canned entree	7.2
Soup, minestrone, canned, reduced sodium, ready-to-serve or tomatoes, canned, stewed, prepared with equal volume water	4.1–6.4
Watermelon, raw	4.5
Tomatoes, red, ripe, canned, stewed	4.1
Spaghetti with meat sauce, frozen entree	3.2
Soup, clam chowder, manhattan, canned, prepared with equal volume water with bean, pork, beef noodle or chunky vegetable, etc.	2.9–4.3
Papayas, raw	1.8
Tomatoes, red, ripe, raw, year round average	2.6
Pizza, pepperoni, cheese, meat and vegetable topping, regular crust	1.8–2.0
Grapefruit, raw, pink and red, all areas	1.4
Fast foods, cheeseburger; single, regular patty, with condiments	1.0
Fast foods, hamburger; single, regular patty; with condiments	
Beans, baked, canned, with franks	0.4
Salad dressing, Russian dressing, Thousand Island dressing, French dressing, reduced fat, etc.	0.6–3.6

In the US, tomato products provide more than 85% of the total quantity of lycopene consumed by the human population. Mean lycopene intakes in the US are considerably greater than they are in the UK, where the mean daily intake is thought to be less than one-third that in the US, while lycopene intakes in Far Eastern countries such as China and Thailand appear to be much lower still. Wild tomatoes originated in Central America and were introduced into Europe following the opening up of the New World, and were later introduced back into North America from Europe. Because tomatoes are the major source of dietary lycopene in many human populations, some epidemiological studies have been designed on the simplistic assumption that tomato consumption can be used as a general proxy for lycopene consumption, and that any disease associations with tomato consumption can be attributed to the biological effects of lycopene. However, tomatoes also contain significant amounts of other carotenoids, vitamin C, bioflavonoids such as naringenin, and phenolic acids such as chlorogenic acid. Much of the existing epidemiological evidence for possible beneficial effects of lycopene (see the following sections.) cannot distinguish unequivocally between the biological effects of lycopene and those of the many other bioactive constituents present in tomatoes.

The bioavailability of lycopene from raw tomatoes is low, but it is greatly increased by cooking or by commercial processing such as conversion to soup, sauce, ketchup (catsup), etc., and its availability is also increased by increasing the fat content of the food.

A survey conducted by National Health and Nutrition Examination Survey (NHANES) in years 2007–2008 on “what we eat in America”, showed that the average intake of lycopene from food was 5.5 mg per day per person, see **Table 2**. More information can be obtained from the USDAs web page.

Bioavailability of synthetic lycopene in an oil capsule was reported as better than from cooked and pureed tomatoes when taken by human subjects. Interactions with other carotenoids are complex and have only partly been studied, for instance  $\beta$ -carotene in the same dish seems to increase the absorption of lycopene, but large doses of  $\beta$ -carotene given separately seem to decrease the lycopene content in serum. The strength of the correlation between dietary lycopene intake and blood (serum or plasma) lycopene concentration varies greatly among studies and clearly depends on many factors, one of which is the degree of sophistication of the food table values, since subtle differences in food sources and meal composition affect its bioavailability very considerably.

## Tissue Contents and Kinetics of Lycopene Turnover

Once absorbed, passively from lipid micelles by the enterocyte, lycopene enters the portal lymphatics and thence the liver, from which it enters the peripheral bloodstream, mainly in association with the  $\beta$ -lipoproteins, in which it is transported to the peripheral tissues. Its half-life in plasma is of the order of 12–33 days; longer than that of  $\beta$ -carotene, which is less than 12 days. Clearly, many of these factors are interdependent, and there is a need for further clarification of the key independent determinants of lycopene status, and whether plasma levels can provide an adequate picture of tissue and whole body status.

Patients with alcoholic cirrhosis of the liver have greatly reduced hepatic lycopene concentrations; indeed, hepatic lycopene seems to offer a sensitive index of hepatic health. Studies of organ concentrations (**Table 3**), suggest a gradient from circulating levels in plasma to different ones in specific tissues. The different carotenoid ratios between organs (not shown) also indicate selective transport and accumulation. However, the mechanisms involved are poorly understood. No lycopene is detectable in the retina or lens of the eye, where lutein and zeaxanthin are found; however, lycopene is present in the ciliary body.

**Table 2** Daily lycopene intake from food consumed by the US population – mean amount consumed per individual and percentages of lycopene consumed with meals and snacks by age and gender

Gender and age	Lycopene (SE) mg	Percentage of lycopene intake in meals and snacks
<b>Males</b>		
≥20 years	6.8 (0.3)	Breakfast, 7
Sample size, <i>n</i> =2662		Lunch, 31
		Dinner, 51
		Snacks, 11
<b>Females</b>		
≥20 years	4.6 (0.3)	Breakfast, 4
Sample size, <i>n</i> =2758		Lunch, 27
		Dinner, 57
		Snacks, 13
<b>Males and females</b>		
≥2 years	5.5 (0.2)	Breakfast, 5
Sample size, <i>n</i> =8529		Lunch, 30
		Dinner, 53
		Snacks, 12

Abbreviation: SE, standard error.

**Table 3** Concentrations of lycopene reported in human tissues

<i>Tissue</i>	<i>Range of mean or median (in Italics) lycopene concentrations (nmol per g weight)</i>
Adrenal	1.9–21.6
Testis	4.3–21.4
Liver	0.6–5.7
<i>Brain</i>	2.5
Lung	0.2–0.6
Kidney	0.1–0.6
Stomach, colon	0.2–0.3
Breast, cervix	0.2–0.8
<i>Skin</i>	0.4
Adipose tissue	0.2–1.3
Prostate	0.1–0.6
Plasma	0.2–1.1

*Note:* Values were gathered from 12 publications, all based on HPLC analysis.

### Functional Properties and Tissue Health

The capacity for quenching of singlet oxygen has been mentioned above; the exceptionally high rate constant,  $K=3.1 \times 10^{10} \text{ mol}^{-1} \text{ s}^{-1}$ , renders it one of the most efficient of known quenchers of this powerful oxidant. In the plant, it probably protects chlorophyll, which produces singlet oxygen as a by-product of photosynthesis. In experiments with lymphoid cells, lycopene provided better protection against singlet oxygen damage than several other carotenoids tested. In skin exposed to UV light, lycopene disappears much more rapidly than  $\beta$ -carotene. Lycopene is also able, in model systems, to inhibit the peroxidation of polyunsaturated lipids and the oxidation of DNA bases to products such as 8-hydroxydeoxyguanosine (8-OHdG). It can react directly with hydrogen peroxide and nitrogen dioxide. In addition, lycopene supplementation may modify DNA through DNA repair mechanisms.

Several studies in tissue culture have shown a reduction in the formation of oxidation damage products such as malondialdehyde, and have found less injury to cells exposed to oxidants such as carbon tetrachloride, if lycopene (or other carotenoids) is present.

Another characteristic of lycopene and other carotenoids that may be relevant to inhibition of cancer cell growth is the modulation of gap junction cell–cell communication processes. In particular, carotenoids including lycopene have been shown to enhance the efficacy of the protein, connexin43, which helps to ensure the maintenance of the differentiated state of cells and to reduce the probability of unregulated cell division, which is deficient in many tumors. They may also interact with and enhance the synthesis of binding proteins that down-regulate the receptor for the growth-promoting hormone insulin-like growth factor-1 (IGF-1). In one small clinical intervention with tomato drinks, it was reported that changes in circulating lycopene were inversely and significantly correlated with those of IGF-1.

In certain circumstances, lycopene can reduce low-density lipoprotein (LDL) -cholesterol levels, possibly by inhibiting hydroxymethylglutaryl CoA reductase (HMGCoA reductase), the rate-limiting enzyme for cholesterol synthesis (see the Section on Lycopene and Cardiovascular Disease). Lycopene was shown to have modest hypocholesterolemic properties in one small clinical trial.

Lycopene has shown significant antimigration and anti-invasion activity in association of its induction of nm23-H1 expression, a metastasis suppressor gene.

### Health, Research Models, and Epidemiological Evidence

**Table 4** summarizes the various types of evidence that have been used to test the hypothesis that lycopene may have health-promoting or protective properties in man. The ultimate proof of efficacy, which would be long-term controlled intervention studies with clinical diseases or mortality as the end points, are extremely difficult, expensive, and time-consuming to obtain, and cannot address all possible benefits in a single intervention trial.

The two disease categories that have so far received most attention for possible long-term benefits of lycopene have been the amelioration of cancers and of heart disease. Both benefits are plausible in view of the physicochemical and biological properties of lycopene outlined above, because both categories of disease are characterized by tissue damage, which is thought to be induced or exacerbated by reactive oxygen species in the environment or those generated within the body.

**Table 4** Types of evidence being sought to show that a nutrient such as lycopene may protect against oxidation-induced or other disease processes

1. Model *in vitro* systems, for example, oxygen-derived free-radical trapping in cell free chemical mixtures.
2. Tissue (cell and organ) cultures, for example, reduction of optical opacity development in cultured eye lenses; reduced growth rates or apoptosis in tumor cell cultures; and protection of key macromolecules, especially nucleic acids.
3. Animal studies demonstrating a reduction of oxidation-induced damage or disease with lycopene supplements or with lycopene-rich foods such as tomatoes or tomato products.
4. Human observation studies using intermediate biochemical markers: for example, inverse relationships between lycopene intakes or blood levels and biochemical markers, such as lipid or DNA oxidation products.
5. Studies using pathology-related intermediate markers, for example, arterial thickening or reduced arterial elasticity; precancerous polyposis, etc.
6. Relationships (without intervention) between tomato intakes or estimated lycopene intakes or lycopene contents of serum, plasma, or tissues (e.g., fat biopsies) and actual disease prevalence or incidence in human cross-sectional, case-control, or prospective epidemiological studies.
7. Intervention studies: lycopene supplements producing a reduction in biochemical markers of oxidation damage or in functional markers, or, eventually, in actual human disease incidence or progression.

### Evidence for Possible Anticancer Protection by Lycopene

Most of the indications with respect to cancer come from human studies linking tomato intake, total estimated lycopene intake, and serum or plasma lycopene concentrations to the subsequent development of cancers (Table 5). There is a small amount of evidence from experimental animal studies, for instance, rat and mouse dimethylbenzanthracene-induced mammary tumor studies have supported the hypothesis, as has a model of spontaneous mammary tumor formation in one strain of mice, but many of the animal models of tumor promotion have been criticized as being too dissimilar from the likely processes of spontaneous tumor genesis in humans.

Partly for historical reasons, there has been a particular interest in prostate cancer (Table 5). A large and early trial in the US (US Health Professionals Follow-up Study) reported an impressive difference between groups with high and low intakes of tomatoes and hence of lycopene for subsequent prostate cancer development, which was not shared with other carotenoids. Plausibility was enhanced by the fact that although human prostate lycopene concentrations are not especially high on an absolute basis (Table 3), they are higher than those of other carotenoids in this tissue. Subsequent studies have had variable outcomes. A small pilot study reported that tomato oleoresin supplements given for a short period to prostate cancer sufferers who were due for radical prostatectomy resulted in smaller tumor size and other apparent benefits, but this trial now needs to be repeated on a larger scale. Although lycopene has shown protective effects against prostate cancer and inhibits the progression in patients with benign prostate hyperplasia, there is insufficient evidence to recommend the use of lycopene supplements for cancer patients.

Several studies have provided evidence for protection of certain regions of the digestive tract against tumor occurrence or growth. Two studies, one in Iran and another in Italy, found an inverse relationship between esophageal cancer and tomato consumption. Two Italian and one Japanese studies reported evidence for protection against gastric cancer, and two studies claimed a reduction in pancreatic cancer. A case-control study on histologically confirmed pancreatic cancer cases and population-based controls in eight Canadian provinces reported that dietary intake of lycopene, provided mainly by tomatoes, was associated with 31% reduction in pancreatic cancer risk among men when comparing the highest and lowest quartiles of intake.

Results with other cancers have been mixed and inconclusive.

### Lycopene and Cardiovascular Disease

Table 6 summarizes the evidence. The European Multicentre Euramic Study reported that risk of developing myocardial infarct was inversely related to lycopene intake, after appropriate adjustment for other cardiovascular risk factors. Some Scandinavian studies

**Table 5** Summary of evidence for association of dietary intake of tomato, or serum or plasma concentrations of lycopene, with possible protection against prostate cancer

Number of studies	Locations	Total number of participants	Types of trial	Outcome conclusion
2	Greece, Canada	937	Case-control (intake of tomato or lycopene, or blood level)	Significant association
7	USA, UK, Canada, New Zealand	3824	As above	NS
3	USA	954	Prospective studies based on dietary estimates	Significant association
1	Netherlands		As above	NS
3	USA	723	Prospective studies based on serum or plasma lycopene	Inconclusive; one study found a marginal ( $p=.05$ ) benefit versus aggressive cancer

Note: Significant association= $p<.05$  and NS=no significance ( $p>.05$ ).

**Table 6** Summary of evidence for association of relatively high serum or plasma lycopene with reduced risks of cardiovascular disease (CVD)

<i>Study</i>	<i>Location</i>	<i>Sex (total participants)</i>	<i>Types of trial and outcome measures</i>	<i>Outcome conclusion</i>
Euramic	Europe, multicenter	M (1379)	C-C, MI	Significant association with protection <sup>a</sup>
ARIC	USA	M+F (462)	C-C, IMT	NS
Street	USA	M+F (369)	NC-C, MI in smokers	NS
Rotterdam	Netherlands	M+F (216)	C-C, PC	Significant association with protection
Bruneck	Italy	M+F (392)	CS+PFU, PC	NS
Linköping–Västerås	Sweden and Lithuania	M (210)	CS, mortality from heart disease	NS
Kuopio (KHID)	Finland	M (725)	PFU, acute coronary event or stroke	Significant association with protection
Kuopio (ASP)	Finland	M+F (520)	IMT	Significant protection for males; not significant for females
Physicians' Health Study	USA	M (case 499+matched free CVD,499)	C-C, CVD	NS
Women's Health Study	USA	F (case 483+matched free CVD 483)	C-C, CVD	Significant association with protection

Abbreviations: C-C, case-control study; NC-C, nested case-control study; CS, cross-sectional study; PFU, prospective follow-up study; MI, myocardial infarct; IMT, intima-media thickness estimate; PC, plaque count; NS, no significant evidence for protection.

Note: Significant association with protection is  $p < .05$ , generally after appropriate adjustment for other known CVD risk factors.

<sup>a</sup>No association with plasma  $\beta$ -carotene in this study.

have subsequently supported this claim; moreover, lycopene is capable of reducing LDL-cholesterol levels, possibly by inhibiting hydroxymethylglutaryl CoA reductase (HMGCoA reductase), the rate-limiting enzyme for cholesterol synthesis.

### Other Disease-Related Investigations

In an organ culture model, some evidence for protection of rat lenses against induction of cataractogenesis has been reported. There is good reason to believe that carotenoids in general may play a role in the protection of ocular tissues against the damaging effects of UV light and of reactive oxygen substances, whose exposure to light carries some analogy with the known functions of carotenoids in plant tissues. A possible protective role in the ciliary body and iris has been proposed, but not yet tested.

### Conclusions

Clearly lycopene possesses chemical and biological properties which make it a very attractive candidate for tissue protection and reduction of disease, especially degenerative diseases. Lycopene probably interacts more efficiently with one particular reactive oxygen species, singlet oxygen, than any other commonly occurring nutrient. It appears to share with several other carotenoids the capacity to reduce lipid peroxidation and DNA oxidative damage, and to enhance cell-cell gap junction communication and to protect normal IGF-1 function. It may reduce cholesterol formation and its tissue accumulation in some circumstances. Studies related to cancers and cardiovascular disease are ongoing and are attracting increased research interest.

## Abbreviations

AMP adenosine monophosphate  
AMPK adenosine monophosphate-activated protein kinase  
BMR basal metabolic rate  
CCK cholecystokinin  
CCK-8 octapeptide of cholecystokinin  
CoA coenzyme A  
DIT dietary induced thermogenesis  
GIP glucose dependent insulotropic polypeptide  
GLP glucagon-like peptide  
HmG-CoA reductase hydroxymethylglutaryl-coenzyme A reductase  
NPY neuropeptide-Y  
PYY peptide YY

## Introduction

Eating habits are changing. Terms such as “super-sizing,” “portion distortion,” “grazing,” and “snacking” have appeared in the contemporary vernacular as a result. Therefore, a better understanding of meal size and frequency is particularly topical, not least when considering the potential role which these eating patterns may be playing in the dramatic rise of noncommunicable diseases such as obesity, diabetes, and cardiovascular disease.

The principal consequences that variations in meal size and frequency have on the body relate to the absorption and metabolism of that meal. There are several factors in addition to meal size and frequency which influence absorption and metabolism, such as macronutrient composition, the energy density of the diet, and the physical volume of the meal. However, the particular contribution which variations in meal size and frequency have made to the dramatic change in society's eating patterns makes them worthy of special attention.

## The Effect of Meal Size on Absorption

When a meal of mixed macronutrient composition is consumed, the rate at which the carbohydrate, protein, and fat in that meal is absorbed differs. Carbohydrate in the form of glucose, and protein in the form of amino acids enter the portal vein within 30 min of meal ingestion and later appear in the general circulation. As the glucose concentration in the portal vein rises there is an increase in

the uptake of glucose into the hepatocytes. Pancreatic islet cells react to the increase in blood glucose and secrete insulin, among other hormones, into the circulation. As a result of this increase in circulating glucose and insulin there is a drop in the release of nonesterified fatty acids/free fatty acids from the adipose tissue. Fatty acid oxidation in the skeletal muscle tissue decreases and, as glucose uptake takes place, the muscle cells increase the rate at which glucose is oxidized. Glycogen synthesis in the muscle and liver cells is increased and the uptake of amino acids by muscle tissue may also occur. Up to 4 h after the ingestion of the meal, fat in the form of chylomicron-triacylglycerol enters the circulation via the lymphatic system. The action of the hormone lipoprotein lipase in the adipose tissue has by now increased, which promotes the storage of fatty acids as triacylglycerol in adipocytes. This synopsis indicates that following the ingestion of a meal, there is a marked increase in glucose oxidation with a corresponding decrease in fat utilization resulting in the storage of fat.

It is therefore fair to say that the larger a meal that is consumed, the more pronounced the responses described above will be. If a large meal is eaten, for example, the plasma glucose concentration may remain elevated for up to 4 h following ingestion. Conversely, the smaller a meal, the more subtle the effect. This indicates that meal size does indeed influence absorption. However, in order for the relationship between meal size and absorption to be fully understood, the role which absorption itself plays in determining meal size needs to be considered. The following section will therefore focus on the process of absorption and the systems which are in place to control the amount of food eaten. These systems appear not to be working optimally in many cases leading to a state of positive energy balance, which is the cause of the worldwide increase in the incidence of obesity.

### **The Regulation of Meal Size by Gut-Derived Satiety Peptides and Adiposity Signals**

The signaling systems that underlie the regulation of appetite, dietary intake, and therefore meal size are complex. These include signals from the gastrointestinal (GI) tract such as ghrelin, CCK, and GLP-1, and from adipose tissue such as leptin and adiponectin. This information is routed to the hypothalamus and brain stem where neuronal networks are activated which signal the commencement or conclusion of a meal.

Ghrelin is an orexigenic hormone whereas CCK and GLP-1 both promote satiety. Serum levels of ghrelin fall on commencement of eating whereas CCK is secreted from duodenal mucosal epithelial cells and stimulates the delivery of digestive enzymes from the pancreas, as well as bile from the gallbladder, into the small intestine. In addition, CCK is produced by neurons in the enteric nervous system and is widely distributed in the brain. Although CCK (and other GI satiety signals) acts to limit meal size, it is important to note that CCK concentration post-meal is not affected by body-fat stores, meaning that it does not take into consideration the existing energy depot of the individual when signaling the onset of satiety. Adiposity signals must therefore be considered in parallel, as they also play a part in determining the size of a meal consumed.

Until quite recently, it was thought that adipose tissue was an inert storage depot but it is now widely recognized as an active endocrine organ. Leptin and adiponectin are two adipose-derived hormones which play a role in the regulation of appetite and therefore meal size. The treatment of obese, hyperphagic, leptin-deficient individuals with exogenous leptin resulting in consumption of more appropriately sized meals has demonstrated that leptin is intimately involved in the regulation of food intake. Leptin however seems to be an overall 'caretaker' of energy intake rather than responding acutely to individual meals. When adipose mass increases, circulating leptin concentrations increase in turn suppressing appetite until which time adipose mass is lost. The mechanism by which leptin can help to reduce food intake is not fully understood although it appears to activate pathways in the brain that reduce food intake while inhibiting pathways that activate food intake.

Adiponectin is an adipokine with cardio-protective and antidiabetic properties and it is hypothesized that adiponectin regulates food intake in conjunction with leptin. When fasting, there is an increase in the adiponectin signal in the hypothalamus leading to an increase in the activity of AMP-activated protein kinase and a subsequent stimulation of food intake. The leptin signal in the hypothalamus is regulated inversely in relation to the adiponectin signal in the brain; therefore adiponectin enhances hypothalamic AMPK activity and food intake, as opposed to the action of leptin.

To conclude, the size of a meal that an individual consumes is determined by a number of physiological, behavioral, and societal factors that interact and play a critical role in the regulation of dietary intake.

### **The Effect of Meal Size on Metabolism**

Energy homeostasis, achieved by matching energy intake with energy expenditure, is partially dependent on the regulation of meal size consumed. In order for meal size to have an effect on energy metabolism, it must affect either or both components that are involved in the regulation of energy balance, namely energy intake and energy expenditure. Energy balance is the difference between energy ingested and energy expended over a given period of time. Consequently, energy storage is equal to intake minus expenditure. The following sections examine the effect of meal size on the two components of the energy balance equation.

#### **The Effect of Meal Size on Energy Intake**

Meal portion sizes have been growing steadily since the 1970s, and have been doing so in parallel with the increasing prevalence of obesity. It is known that portion and meal sizes vary depending on the food source, location of consumption, and number of people eating a meal together. Not surprisingly, the largest portions consumed in terms of energy are generally those obtained at fast food

restaurants, although the portion sizes of home-cooked meals have been growing steadily as well. Meal size may thus be contributing to the problem of obesity by leading to a daily total energy intake which is greater than the daily total energy expenditure resulting in a positive energy balance.

### The Effect of Meal Size on Energy Expenditure

Total energy expenditure can, as shown in Table 1, generally be divided into three major components: BMR, thermogenesis, and physical activity. In order for meal size to have an effect on the energy expenditure side of the energy balance equation, it must have an effect on one or more of these three components. There is no evidence to suggest that meal size has an effect on BMR, which refers to the energy expended to run the body on a day-to-day basis. Thermogenesis broadly refers to the body's production of heat, which is divided into three categories: dietary, thermoregulatory, and adaptive. It is the dietary category, commonly known as DIT, which is of greatest relevance to the current discussion of the effect of meal size on energy expenditure. It refers to the heat lost by the body as a result of the absorption and metabolism of a recently ingested meal. DIT represents approximately 10% of energy intake, and therefore the energy expended on DIT increases and decreases in relation to the size of the meal and, more importantly, the energy value of the meal consumed. The larger a meal, the more energy will be expended to absorb, transport, and metabolize the nutrients consumed in that meal. For example, in the case of a meal containing 2000 kJ of energy, approximately 200 kJ will be expended on DIT alone. It is in the physical activity component of energy expenditure that the greatest variation between individuals can be observed, as physical activity levels (and therefore the energy expended on activity) in the population are contingent on lifestyle choices such as employment and leisure time activities. The effect which meal size could have on physical activity is somewhat difficult to quantify. Meal size is perhaps more important to elite athletes whose energy expenditure is two to three times greater than untrained weight-matched athletes with up to 40% of their energy expenditure being the cost of training.

### The Effect of Meal Frequency on Absorption

Humans are eating more often than before with an average eating frequency among US adults of five eating occasions per day. The perceived health advantages of increased meal frequency (as opposed to eating larger, infrequent meals) have been interesting researchers since the 1930s. It has been suggested that frequent eating increases metabolism, reduces food cravings, improves insulin and glucose control, and reduces body weight. However, eating frequently may actually cause an increased exposure to energy-dense foods, leading to increased energy intake and weight gain as opposed to weight loss.

The benefits of a frequent eating approach were originally made apparent by the discovery that insulin requirements in diabetics could be decreased in a frequent meal regime. In a series of case reports on patients taking high insulin doses, it was demonstrated that improved glycemic control and decreased insulin requirements can be achieved when glucose is sipped at hourly intervals throughout the day. Similarly, in healthy individuals a diet composed of many small meals compared with an isoenergetic one composed of larger meals results in decreased insulin and glucose fluctuations.

Meal frequency not only affects insulin and glucose levels but also influences an individual's circulating lipids. An inverse relationship exists between meal frequency and lipid levels, suggesting that infrequent feeding leads to an increased risk of cardiovascular disease due to large fluctuations in circulating lipids. Increased meal frequency, however, is associated with several benefits such as decreased serum cholesterol levels, decreased total : high density lipoprotein cholesterol (HDL-C) ratio, decreased esterified fatty acids and decreased enzyme levels in adipose tissue associated with fatty acid storage. Paradoxically, individuals who report that they eat more frequently not only have lower total and low density lipoprotein cholesterol (LDL-C), but also have a greater intake of energy, total fat, and saturated fatty acids. Considering that some of these results were found in a free-living population, it is possible that dietary mis-reporting, a common occurrence in an overweight population, could be to blame for this inconsistency.

### Mechanisms Underlying the Metabolic Effect of Meal Frequency

The mechanisms underlying beneficial responses to frequent feeding as opposed to an infrequent meal pattern are not fully understood. Frequent feeding has been shown to elicit lower plasma glucose fluctuations than does a more infrequent eating pattern. The absolute amount of carbohydrate eaten at each episode of ingestion in a frequent feeding pattern is simply not great enough to

**Table 1** Major components of energy expenditure

<i>Component</i>	<i>Total energy expenditure (%)</i>	<i>Represents</i>
Basal metabolic rate (BMR)	60–75	Day-to-day running costs of an individual, for example, circulation
Thermogenesis	10–20	Heat produced by the body through dietary, adaptive, and thermoregulatory processes
Physical activity	100 minus (BMR+thermogenesis)	The sum of work carried out by an individual

elevate glucose to the same extent as more infrequent eating. Small elevations in plasma insulin seen with frequent feeding are most likely to have been in response to minimal fluctuations in glucose. The mechanisms responsible for the effect of an increased frequency of meal eating on lipid metabolism are not as clear cut. The lower serum cholesterol levels observed during frequent feeding may be related to lower serum insulin levels. Insulin appears to have a key role in enhancing the hepatic synthesis of cholesterol through its ability to stimulate HmG-CoA reductase, the rate limiting enzyme in hepatic cholesterologenesis. Exogenous insulin quickly increases HMG-CoA reductase activity in rats with diabetes and raises levels of the enzyme in animals without the disorder. It is possible that the reduction of serum cholesterol during a diet of habitual frequent feeding in normal healthy individuals may result from a reduction in hepatic cholesterol synthesis, secondary to the maintenance of euglycemia at lower serum insulin levels. A reduction in cholesterol synthesis would result in an increase in LDL receptors, further lowering total and LDL-cholesterol levels.

Alternatively, or in addition, the benefits associated with an increased feeding regimen may reflect unintentional or uncontrolled changes in dietary energy and fat intake that may occur when an individual's meal frequency is altered. It is not clear whether a diet of frequent eating results in any adaptational responses of enzymes or hormones which in turn may be providing additional benefit to the individual.

Much of the research in which these benefits were uncovered is difficult to interpret due to the variety of methods used, the lack of information available regarding the foods consumed and the exact nature of the dietary intervention. The majority of measurements are made on fasted blood samples, when in fact most individuals are in a postprandial state for the greater part of every 24-h period. The results of such research must be interpreted with a degree of caution for a number of reasons such as the small sample size used and the interactions with other factors which may prolong absorption time (e.g., soluble fiber, low-glycemic index foods, and the administration of alpha-glycosides).

As discussed, frequent feeding has been demonstrated to lower circulating plasma glucose, insulin, and lipids in both healthy and diabetic subjects in the short term. In addition to the lack of clarity on the mechanisms involved, further research is needed to investigate any medium- and long-term benefits of frequent feeding. It is important that, if deemed desirable in terms of metabolic control, increasing the number of periods of feeding encourages the desired dietary pattern and mix of macronutrients and micronutrients and is not offset by the failure to decrease the size of the meals.

## The Effect of Meal Frequency on Metabolism

The same maxim which was earlier applied to the study of meal size, namely that it can only influence energy metabolism if it affects energy intake and energy expenditure, is applicable to meal frequency. The following sections will focus on energy intake and energy expenditure, respectively.

### The Effect of Meal Frequency on Energy Intake

It has long been argued that the frequency of meal intake may have an effect on body weight regulation. It has been suggested that there is an inverse association between meal frequency and body weight in individuals. However, there are a number of flaws in the design of many of the research studies from which these data have been derived, and great caution is required in the interpretation of the results. Design flaws include (1) dietary under-reporting of the number of eating occasions and of energy intake, (2) reverse causality, which refers to the possibility that people abstain from eating meals when they become overweight in an attempt to lose weight or to prevent further weight gain, (3) lack of measurement of physical activity or energy expenditure, and (4) inclusion of people in a diseased state. These important confounding factors may help to resolve the contradictory results of many research trials. Erroneous conclusions have been drawn from the misinterpretation of such results because these studies are extremely vulnerable to methodological errors that may generate spurious relationships which may not actually exist. A recently published review article examined almost 200 abstracts and articles pertaining to eating frequency and body weight which ranged from one to nine eating occasions per day over intervention periods of 2–8 weeks in duration. No association between eating frequency and health was observed and the authors concluded that a number of methodological shortcomings made it difficult to fully confirm this finding. Studies of longer duration with sufficient sample size are warranted which could include the use of dietary biomarkers to validate both reported eating frequency and energy intake.

There appears to be very little direct empirical evidence in humans to suggest that frequent feeding *per se* affects appetite and energy intake. Individuals who eat frequently seem to exhibit a greater capacity to compensate for changes in the energy content of specific meals, relative to those individuals who derive most of their energy intake from fewer larger meals. Over very short periods, and under highly controlled experimental conditions, frequent feeding can decrease energy intake at a subsequent meal, which may in turn have an effect on appetite regulation. It remains to be seen however, whether the same would occur in free-living conditions. One final consideration is that of reduced eating frequency, that is less than three meals per day, and data indicate that this pattern negatively affects appetite control. It is important to note however that many of the controlled studies that were designed to investigate the effect of meal frequency on energy intake were conducted whereby meal patterns were enforced onto individuals irrespective of the habitual eating frequency of those individuals. There may also be differences in the short-term compensation of energy intake depending on an individual's habitual eating pattern.

### Mechanisms by which Meal Frequency may Influence Energy Intake

Although the evidence is inconclusive, there is a suggestion that feeding frequency may have an impact on appetite and hence affect energy intake. The control of appetite is a very complex issue which is determined by a number of factors as discussed previously. However, the question remains as to whether the frequency of feeding elicits effects on any of these factors, in turn affecting appetite and possibly body weight. It is noteworthy that rapid declines in blood glucose concentration are associated with hunger in addition to the initiation of feeding in humans.

Although difficult to measure, frequency of feeding may affect the release of appetite regulatory hormones including neuroendocrine hormones such as NPY, galanin, orexin, and melanocortins from the hypothalamus. The release of such hormones may either be stimulated or suppressed during frequent feeding, leading to either higher or lower than normal hormone levels, which may in turn have knock-on effects on energy intake and/or expenditure. When subjective appetite sensations were measured using visual analog scales, increased eating frequency tended to lead to lower peaks in perceived appetite and PYY responses compared with decreased eating frequency although this effect disappeared when investigated over a 24-h period. The release of other gut hormones such as CCK, GLP, and GIP may be altered in relation to feeding frequency. In rats, the infusion of the sulfated octapeptide of CCK (CCK-8) causes a significant reduction in meal size as previously mentioned, whereas meal frequency is increased to compensate for the small meals. However, little is known about the effects of meal pattern on CCK in animals or humans. It is possible that frequent feeding may affect CCK-release in one of two ways: (1) Frequent feeding may cause the regular release of the hormone in response to each feed, persistently alerting the brain that the individual is satiated; or (2) CCK may be released into the circulation in such small amounts in response to frequent feeding that it is not recognized by the brain and the individual continues to eat. Similar effects may occur with GLP and GIP. It is notable that the rate of gastric emptying is also unaffected by antecedent eating frequency.

### The Effect of Meal Frequency on Energy Expenditure

As detailed in Table 1, the three components of energy expenditure are BMR, thermogenesis, and physical activity. For meal frequency to have an influence on energy expenditure, it must affect one or more of these components. The first component, BMR (which represents 60–75% of energy expenditure in sedentary individuals), is not known to be influenced by meal frequency. Much the same can be said for thermogenesis, an area where extensive research has failed to demonstrate a link between feeding frequency and DIT. It is reasonable and logical to expect that any difference between frequent and infrequent meal-eating patterns would be seen most clearly during the postprandial period when food has just been eaten, where the rate of ingestion of nutrients may alter EE and fuel storage.

Although much research has been carried out on the effects of meal frequency on total energy expenditure, little of it has isolated the physical activity component *per se*. The one area where greater attention has been paid to the relationship between meal frequency and physical activity is that of the performance of elite athletes, as the manipulation of the meal pattern can potentially be used as a tool to achieve optimal performance. Because carbohydrate requirements of elite athletes are high and endogenous glycogen reserves are limited, athletes undertaking prolonged strenuous exercise seek to maximize carbohydrate availability at all times.

Irrespective of the above, the key determinant of feeding frequency's overall effect on energy balance is whether it has an impact on 24-h energy expenditure, where energy intake is fixed in content and composition, and where physical activity is kept constant. Although many of these studies have demonstrated differences in carbohydrate, fat, and protein oxidation rates in response to a gorging versus a nibbling eating pattern, each study has reached the same conclusion, namely that no relationship exists between frequency of feeding and overall 24-h energy expenditure. The majority of these studies used either direct or indirect calorimetry or doubly labeled water in their measurements, each of which are highly reliable energy expenditure measurement techniques.

In conclusion, the contemporary terminology referring to the tendency to increase the amount of food eaten at a meal and the greater frequency at which food is eaten which has appeared in our vocabulary recently demonstrates the importance of a clear understanding of the consequences of meal size and frequency on health. We know that satiety peptides and adiposity hormones attempt to control the size of a meal eaten, and that increased meal frequency, within the constraints of energy balance, has been found to have beneficial effects attenuating circulating substrates. However, in order to elucidate the influence that meal size and frequency has on absorption and metabolism, and to clarify whether this increase in the volume of food eaten at a meal and the greater frequency at which food is eaten have a direct effect on health, further research within the free-living population is required.

## Glossary

**Glycerides** Glycerol with fatty acids attached.

**Lipids** Fats, glycerides, fatty acids, cholesterol, sterols.

**Muscle foods** Meat and meat products.

## Introduction

Animal source foods are major contributors to the nutrients in the food supply in many countries. Of these foods, animal muscle (or meat) foods and products are excellent examples of nutrient-dense, naturally nutrient-rich foods, which provide a relatively large amount of many nutrients per the amount of calories provided in a typical serving. For the purposes of this review, discussion will be limited to the muscle foods: beef, pork, lamb, veal, poultry, and some of the processed products made from these muscle species. Fish/seafood will be covered in a separate article. Milk and dairy products, eggs, and major nonmuscle animal source foods, will also be covered separately.

For meat and meat products there are extensive and comprehensive nutrient databases available for reference for particular products of interest. Thus, this review will provide a sampling of the data available for representative meats and meat products.

One of the best and most comprehensive listings of the nutrient values of all meat, poultry, and other meat products is the extensive nutrient database developed and maintained by the United States Department of Agriculture. In this database complete nutrient profiles are listed for more than 700 beef, 200 pork, 195 lamb, 85 veal, 140 poultry, and 130 turkey products. This database can be accessed and searched on-line from the link/website: <http://www.ars.usda.gov/ba/bhnrc/ndl> and continues to be updated as new data become available for various food products. The most recent version of this database is USDA National Nutrient Database for Standard Reference, Release 23, published 2010.

For another extensive listing of the nutrient values of many meat and meat products, including some by brand name, the reader is referred to Bowes & Church's Food Values of Portions Commonly Used, 19th edn. This reference, although not as extensive in terms of products listed, does provide data directly on common serving sizes and on some additional nutrient and nutrient-related components of meat products (e.g., omega-3 and *trans* fatty acids, glutathione, vitamin D activity, and other vitamin-like compounds).

## Nutritional Value

The nutritional value of foods, including meat and meat products, can be defined in a number of different ways, from simply listing the quantities of various nutrients contained in the foods, to considering biological factors that affect the utilization of these nutrients by the body. Some foods may contain nutrients in forms that the body cannot readily utilize. Thus, nutrient bioavailability, or availability becomes important. Other articles and sections of this book will discuss some of these bioavailability issues and subsequent metabolism of food and nutrient sources.

The nutritional value of meat and meat products is related to the quantity and utilization of nutrients and the potential for these products to either enhance or restrict nutrient utilization by the body. There are five major classes of nutrients: proteins, lipids, carbohydrates, vitamins, and minerals.

The nutrient content of meat (muscle foods) is fairly similar among the various mammals, birds, and fish. However, differences in the levels of the various nutrients may result from differences in the carcass composition among species and within species due to differences in the ratio of fat to muscle in the edible portion. As fat percentage increases, nutrient concentration of the muscle portion decreases. Also, to a certain extent, the fat profile/composition and other nutrient content levels may be modified/affected by the animal's diet and genetic makeup.

In general, cooking or heat processing has only minimal effects on the nutritional value of muscle foods. In most cases, cooking usually decreases moisture content and concentrates other nutrients, including fat content, especially in lower fat products. This is due to moisture loss. However, in some intensely heated meat products fat content may also be reduced significantly with negligible loss of other nutrients.

## Classes of Nutrients and Meat Products

### Protein

Proteins comprise the structural unit of all muscle cells and connective tissues. As such, meat and meat products (muscle foods) are major protein sources. Further, muscle foods, as a group, are excellent sources of high-quality protein that supplies all the essential amino acids in desirable proportions for human consumption. Amino acids are the building blocks of protein and those provided by meat match or exceed the profile required by humans.

The protein content of most muscle foods, on a wet basis, is between 15% and 35%. This figure will change due to the moisture and lipid content of the specific product. On a raw weight basis as purchased at the store, the protein content is generally less than 20%. However, people do not eat muscle foods raw and visible fat in red meat products and skin in poultry products is usually trimmed away. Therefore muscle foods, as consumed, have a much higher protein content, in the range of 30%.

### Lipids

The lipid component of meat and meat products includes a diverse group of substances such as glycerides (glycerol with fatty acids attached), phospholipids, and sterols. The basic component of most meat lipids is the fatty acids, which can be saturated, mono-unsaturated, or polyunsaturated.

The relative amount of lipid in muscle foods is probably the most variable aspect of the nutritional profile. Within the lipid components, the relative amount of the different forms of fatty acids present is another variable among meat products. Despite the common reference to animal fats (and especially meat and meat products) as 'saturated', less than half of all the fatty acids of meats are saturated. The largest proportions of fatty acids in meats are monounsaturated, followed by saturated and then polyunsaturated fatty acids. Among meat products, poultry has a higher proportion of polyunsaturated fatty acids and slightly less saturated fatty acids.

The fat in meat products provides much of the flavor associated with these foods and also contributes to the palatability and overall acceptability by consumers. In addition, the fats in meat and meat products also contain several essential fatty acids (linoleic and linolenic acids) and the fat-soluble vitamins A, D, E, and K.

### Carbohydrates

Meat and meat products are not significant sources of dietary carbohydrates. Almost all dietary carbohydrates come from plant sources. The only naturally occurring carbohydrate in muscle foods is glycogen. In some processed meat products, such as those that are 'sugar-cured', there may be additional sucrose or glucose added.

### Vitamins

Meat and meat products are especially good sources of most of the water-soluble vitamins. In general, meat is the major dietary source of vitamin B<sub>12</sub> and is an excellent source of many of the other B-vitamins, such as pyridoxine (B<sub>6</sub>), biotin, niacin, pantothenic acid, riboflavin, and thiamin. For vitamin B<sub>12</sub>, red meat products such as beef and lamb are especially good sources. Pork products

are one of the very best sources of thiamin. Although present in muscle foods, the fat-soluble vitamins are less abundant than in plant foods. Vitamins E and K are present, but at lower levels.

Vitamin D activity may be present in some meat products, but at low levels. This is reflected in the latest update to the USDA Nutrient database (<http://www.ars.usda.gov/ba/bhnrc/ndl>), where vitamin D activity is listed for some beef, pork, lamb, veal, chicken/turkey, and processed meat products; however, such data is not consistently available. In recent years there has been production research with beef, pork, and lamb to determine if added vitamin D<sub>3</sub> or its metabolites, fed to the animal for a brief period of time before slaughter, can result in improved meat tenderness. Although the results are inconsistent, and commercial application is premature, there is some indication that tenderness may be improved with relatively low levels of vitamin D supplementation, but these seem to leave very little residual vitamin D<sub>3</sub> or its metabolites in the muscle. Research in Denmark found that the more biologically active 25-OH D is present at low levels in meat; however there is as yet no consensus on the conversion factor for 25-OH D to calculate vitamin D activity. Also, there is currently very little data on the vitamin D and 25-OH D levels in many meat products. This represents a potential future area of research regarding the nutrient composition of meat. Meat products are a very good source of choline, second only to whole eggs. In recent years a database for the choline content of common foods has been updated and expanded, <http://www.ars.usda.gov/Services/docs.htm?docid=6232>.

## Minerals

Meat and meat products are good to excellent sources of most minerals. Among the macrominerals, calcium is not high in muscle foods although phosphorus and potassium are prominent. In natural meat products, sodium is present, but not a significant contributor to the diet. However, processed meat products may contain significantly higher levels of sodium (added as part of curing, preserving, or flavor-enhancing ingredients). Some of the microminerals (trace elements) are especially abundant in meat and meat products. Iron is of the greatest significance from meat sources because it is present in the heme form, which is more bioavailable than the nonheme form. Of meat products, beef is an especially rich source of iron in this bioavailable form.

Muscle tissue is an especially rich source of minerals such as phosphorus, potassium, magnesium, iron, copper, zinc, and selenium. For instance, pork, poultry, and beef are especially good sources of selenium.

## Bioavailability of Nutrients and Efficiency for Child Development

Muscle foods have been shown to contain “intrinsic” factors that improve the bioavailability of a variety of nutrients. Moreover, the bioavailability of these nutrients from muscle foods is high; often exceeding the availability of the same nutrients in foods derived from plants. Heme iron is one example. Zinc and copper have been shown to be more available from meat sources than from plant sources. Several of the B-vitamins may also be more bioavailable from meat sources than from plant sources.

Another interesting aspect of meat products is the ability to promote the bioavailability of nutrients in nonmuscle foods when the two are eaten together. This has been referred to as the ‘meat factor’. Perhaps the best example of this is the positive effect of meat in the diet on nonheme iron sources, also in the diet.

The efficacy of meat in the diet for its benefits for child growth and development and micronutrient status continues to be demonstrated. Studies with school children in Kenya have shown that animal-source foods, including meat, improve dietary quality, micronutrient status, growth, and cognitive function. In the US, studies with breastfed infants have shown that feeding meat as an early complementary food is feasible and associated with improved zinc status. On a larger scale, a multi-site, multi-national study is underway to further determine the impact of a daily intake of 1/2 oz of meat in 6–18-month-old infants on linear growth, zinc and iron status, brain growth and neurocognitive development, and infectious disease morbidity. This is being done in populations traditionally dependent on nonmicronutrient fortified plant foods for complementary feeding.

## Nutrient Density of Meat and Meat Products

The nutrient density of meat is high. Muscle foods have high levels of essential nutrients per unit of weight and per amount of calories provided. Meat and meat products (muscle foods) provide significant amounts of essential nutrients at levels/concentrations higher than from most other foods relative to the calorie content also provided. The United States Food and Drug Administration (US FDA) food labeling guidelines allow a food to be designated a ‘good’ source of a nutrient if it contributes 10% or more of the Daily Value (DV), and an ‘excellent’ source, if it contributes 20% or more of the DV, for that nutrient, per 3 oz serving. Most meat products are good or excellent sources of many nutrients. It is generally recognized that in diets that lack muscle foods, greater care is required in diet/menu selection to ensure that adequate levels of essential nutrients are present and bioavailable.

## Meat Sources and Nutritional Values

### Beef

Beef is an excellent source of high-quality protein, along with significant contributions of many B-vitamins and minerals. In macro-nutrient terms, the lean to fat ratio of the particular beef product influences the calorie and nutrient composition. In general, as the

fat content decreases the concentration of other nutrients (especially protein, B-vitamins, and minerals) in beef tend to increase. Most beef products available to the consumer are much leaner than they were 20 or 30 years ago. This is a result of changes due to feeding and genetics to produce leaner animals, and also due to closer trim levels on the products that consumers see in the meat case. Whereas in the past, beef cuts with 1/4" of fat trim were common, now the same products have only 1/8" fat trim, or in some cases even 0" fat trim. In the case of ground beef products, 10 or 20 years ago, 17% fat ground beef was considered as 'extra lean'. Now ground beef is commonly available at fat levels as low as 5% or 10%. Other common fat levels for ground beef are 15%, 20%, and 25%; however, a large proportion of current ground beef sales are now in the 5–15% fat level range.

The fat content of beef contains a varied fatty acid profile, with the largest proportion being contributed by monounsaturated fat, followed by saturated fat and polyunsaturated fatty acids. In addition, being a ruminant product, beef is an excellent source of the naturally occurring fatty acid, conjugated linoleic acid (CLA), which has been demonstrated to provide anticarcinogenic properties among other health benefits.

**Table 1** provides the energy, protein, and lipid profile of beef along with other meat sources. For a comparison of the mineral composition of beef products versus that of other common meat sources, see **Table 2**. For a comparison of the vitamin composition of beef products versus that of other common meat sources, see **Table 3**.

## Pork

Pork, like beef, is an excellent source of high-quality protein and contributes significant amounts of many B-vitamins and minerals. As for other muscle foods, pork's nutrient composition is greatly affected by its fat and water content. As fat percentage decreases, the concentration of other nutrients increases. In addition, as pork is cooked, and moisture is removed, the concentration of nutrients also increases. Pork is an excellent source of minerals, such as selenium, iron, zinc, phosphorus, and potassium. Compared to other muscle foods, the contribution of pork to selenium in the food supply is especially significant.

In terms of the B-vitamins, pork is an excellent source. Pork is an especially good source of thiamin (vitamin B<sub>1</sub>), being the single best source of this vitamin among commonly eaten foods. The fat profile of pork can be influenced by feeding regimes such that it is more, or less, saturated or firm. However, overall the fatty acid profile of pork is largely monounsaturated, followed by saturated and then polyunsaturated fatty acids.

Table 1 provides the energy, protein, and lipid profile of pork along with other meat sources. For a comparison of the mineral composition of pork products versus that of other common meat sources, see Table 2. For a comparison of the vitamin composition of pork products versus that of other common meat sources, see Table 3.

## Lamb

Although representing a smaller portion of overall muscle food consumption, lamb still provides a nutrient profile with significant benefits for the human diet. As a source of high-quality protein, lamb is also a good source of many minerals and B-vitamins. Vitamin B<sub>12</sub> is especially abundant in lamb. It is also a good source of the minerals iron and zinc.

In addition, as a ruminant, lamb is another naturally occurring dietary source of CL, A a unique fatty acid with anticarcinogenic and other health benefits (from animal model studies).

**Table 1** provides the energy, protein, and lipid profile of lamb along with other meat sources. For a comparison of the mineral composition of lamb products versus that of other common meat sources, see **Table 2**. For a comparison of the vitamin composition of lamb products versus that of other common meat sources, see **Table 3**.

## Veal

Although representing a smaller proportion of overall meat consumption, veal still provides a nutrient profile that is very beneficial. As with all meat sources, veal provides high-quality protein in a product that may be slightly leaner (in terms of fat) than other red meat sources. Compared to other meat sources, veal would have a lower iron content.

**Table 1** provides the energy, protein, and lipid profile of veal along with other meat sources. For a comparison of the mineral composition of veal products versus that of other common meat sources, see **Table 2**. For a comparison of the vitamin composition of veal products versus that of other common meat sources, see **Table 3**.

## Poultry

The nutrient composition of poultry (chicken and turkey) is similar to that of red meat animals (beef, pork, lamb, veal) with a few exceptions. Poultry is lower in iron content, and thus heme iron, than beef. Turkey is slightly higher in several minerals (Ca, Fe, P, K, Zn, and Cu) than chicken. As in red meats, there are significant amounts of several B-vitamins (e.g., niacin, B<sub>6</sub>, pantothenic acid) compared to other meat sources, and these are not significantly reduced during cooking.

The fat content of poultry is predominantly monounsaturated fat, followed by saturated fat and polyunsaturated fat. Poultry fat, like pork fat, is somewhat more unsaturated than beef fat. Poultry is significantly higher in polyunsaturated fat compared to beef, pork, lamb, and veal.

**Table 1** provides the energy, protein, and lipid profile of chicken and turkey along with other meat sources. For a comparison of the mineral composition of chicken and turkey products versus that of other common meat sources, see **Table 2**, and of the vitamin composition of chicken and turkey products versus that of other common meat sources, see **Table 3**.

## Processed Meats

Processed meats represent a diverse array of products that have undergone additional treatment from the fresh meat form to the point of consumption. Some of these processing/treatments might include curing with other ingredients added, addition of salt or other flavor or preservative mixtures, etc. Also, these products often represent combined meat sources.

**Table 1** provides the energy, protein, and lipid profile of several processed meat products along with other meat sources. For a comparison of the mineral composition of these processed products versus that of other common meat sources, see **Table 2**, and for the vitamin composition of these processed products versus that of other common meat sources, see **Table 3**.

## Summary

Muscle foods (meat and meat products) provide significant amounts of essential nutrients at levels/concentrations higher than from most other foods relative to the calories provided. Most of all the essential nutrients are present in muscle foods at some level. Furthermore, muscle foods provide nutrients in a form that enhances the bioavailability of nutrients from both the meat itself and from other dietary sources. It is generally recognized that in diets that lack muscle foods, greater care is required in diet/menu selection to ensure that adequate levels of essential nutrients are present and bioavailable.

## Key points

- The Mediterranean diet is more than a food pattern. It is a lifestyle of the population living in the countries bordering the Mediterranean Sea.
- Historically it is a diet resulting from the culture of numerous civilizations that inhabited this geographical area.
- It is a food pattern in which food of vegetable origin and moderate consumption of fermented dairy and fish predominate in addition to low or occasional consumption of meat.
- MD is a healthy dietary pattern due to the presence of a large number of bioactive compounds (antioxidants, anti-inflammatory, etc.) in the food included. These bioactive compounds have a positive impact on the prevention of chronic noncommunicable diseases (cardiovascular, cancer, type 2 diabetes, obesity)
- MD is a sustainable food pattern that respects biodiversity and the environment.

## Introduction

It is important to analyze and define the two terms that we will use in this article. “Diet” and “Mediterranean”. Although we all agree that the Mediterranean Diet (MD) in the last century, in which the term was coined, was identified more by its nutritional and health aspects, subsequently, factors related to the culture and heritage of the peoples surrounding the Mediterranean Sea have been included. It is now considered a sustainable food pattern, as we will see below. The term diet is defined as: “food and drink regularly provided or consumed” or “habitual nourishing,” other meanings related to medical and health aspects are also included: “the kind and amount of food prescribed for a person or animal for a special reason” or “a regimen of eating and drinking sparingly so as to reduce one’s weight” (<https://www.merriam-webster.com>). However, etymologically, the word Diet comes from the Latin “dieta” which in turn comes from the Greek “diaita” (δίαιτα), “way of living,” “life regime,” “type of life,” we now know it as a life-style (CIHEAM, 2012).

The UNESCO, in its declaration of the MD as an Intangible Heritage of Humanity, includes the following: “... *The Mediterranean diet involves a set of skills, knowledge, rituals, symbols, and traditions concerning crops, harvesting, fishing, animal husbandry, conservation, processing, cooking, and particularly the sharing and consumption of food. Eating together is the foundation of the cultural identity and continuity of communities throughout the Mediterranean basin. It is a moment of social exchange and communication, affirmation, and renewal of family, group, or community identity. The Mediterranean diet emphasizes values of hospitality, neighborliness, intercultural dialogue and creativity, and a way of life guided by respect for diversity. It plays a vital role in cultural spaces, festivals, and celebrations, bringing together people of all ages, conditions and social classes ...*” (UNESCO, 2010).

Taking into account the above, we will include in this article all aspects of the MD such as its history and development, the foods constituting the MD, the food consumption pattern of the population, as we can know the adherence to MD, what are the health effects of this type of food and what is its scientific basis and what are the characteristics that make it a sustainable diet.

## Origin and historical development of Mediterranean food

The type of food of the peoples bordering the Mediterranean Sea (etymologically, “sea in the center of the earth”) since the beginnings of civilization in the eastern Mediterranean is considered the origin of the MD in its broadest sense. The strategic position of the Mediterranean Sea, situated between three continents, Europe, Africa, and Asia, the peoples that inhabit its shores, and the different cultures that sailed it constitute the seed of this style of feeding. In addition, from the 16th century, America entered this Mediterranean crucible through food that arrived from that continent.

Although we speak of an MD, it would be more appropriate to talk about Mediterranean diets because if we take a tour of the history of Mediterranean food, we will see that these patterns are not homogeneous throughout the Mediterranean geographical territory. Different cultures, traditions, and religious feelings exist in this area that model food patterns from diverse landscapes and sensitivities. Throughout history, various peoples and civilizations, such as Egyptians, Phoenicians, and Carthaginians, Mesopotamians, Greeks, Romans, Arabic (Islamic), Ottomans, etc., have contributed to this pattern of Mediterranean food and Mediterranean cuisine. If we travel through the Mediterranean, we can find a mixture of cultures in different regions, such as the presence of the Roman Empire in the Middle East, Israel and Lebanon, remnants of prehistoric cultures in Sardinia, Greek cities in Sicily, Arab presence in Spain or Ottoman Islam in Yugoslavia. This crossbreeding of cultures explains the richness of food and cuisine in what we call MD (CIHEAM, 2012).

The so-called Mediterranean triad (vine, olive, and wheat) already appears in Hosea’s writings in the Bible, in the Old Testament: *“She did not acknowledge that it was I who gave her the wheat, the new wine, and the fresh oil; who gave her the silver and the gold which they used for Baal”* (Hosea 2:8). These three foods are present throughout the Mediterranean, especially the olive tree, as its area of cultivation coincides with the Mediterranean basin from the Middle East (Israel, Lebanon) to Spain, from northern Italy to Tunisia or Egypt. Wheat appeared as a crop in the Neolithic with ancestral varieties and is started to be processed to facilitate its consumption in the Palestinian area and later in Mesopotamia and Egypt. It thereafter constitutes the leading food in Greek and Roman culture. The origins of the olive tree are located in Asia Minor, Crete, and Cyprus, and its cultivation spread throughout the Mediterranean thanks to Phoenicians, Greeks, and Romans. Vine and its product (wine) were already cultivated and consumed in Egypt, also appeared in Greek celebrations. Concerning beer, there is also evidence of its consumption in Egyptian civilization.

From this traditional triad as the backbone of this Mediterranean pattern, other foods have formed its structure that we will analyze later. Nuts are a fundamental part of the MD, consumed since prehistoric times (almonds and pistachios) and have continued to be consumed by different Mediterranean civilizations. Other characteristic and widely consumed foods in the Mediterranean area are the fruits and vegetables that have flooded the Mediterranean cuisine, such as artichokes, eggplants, asparagus, figs. We must not forget legumes (lentils, chickpeas): Also, the inclusion in the Mediterranean pattern of the foods that arrived from America in the 16th century and that today are characteristic of the food and cuisine of the Mediterranean basin; potatoes to a lesser extent, and especially tomatoes and peppers: The latter two, in conjunction with onions, are the base of the essential “sofrito” (sauteed or braized in cooking oil) in the Mediterranean cuisine.

It is important to mention the role of herbs and spices in feeding in the Mediterranean peoples. Garlic, saffron, aniseed, rosemary, sesame, myrrh, dill, coriander, thyme, etc., are some of the most representative and incorporated in the early moments of Mediterranean history. Herbs and spices have always been used generously in Mediterranean cuisine, and the Greeks also used them for medicinal purposes (CIHEAM, 2012).

## Origin of the term Mediterranean diet and recognition of the Mediterranean diet as an Intangible Cultural Heritage of Humanity by UNESCO

The term MD began to be used in the middle of the 20th century, referring to the food pattern of some areas of the Mediterranean basin such as Crete and other Mediterranean islands, southern Italy and Spain. Ancel Keys, an American physiologist from the University of Minnesota, described it for the first time during the development of The Seven Countries Study (SCS), a project that sought to understand socio-cultural influences, including dietary patterns, on the prevalence of cardiovascular disease in the population. SCS was the first study to systematically compare the rates of cardiovascular disease in different countries with very different cultures. This ecological study established correlations between lifestyles in these countries and cardiovascular risk factors and between cardiovascular risk factors and disease over time. The countries chosen were the United States, Finland, Holland, Italy, Greece, Yugoslavia, and Japan (Toshima et al., 1995).

The study results showed significant differences between countries in the incidence of cardiovascular diseases, including ischemic coronary disease, especially between the United States or Finland, with high rates of this type of disease, and Greece and Italy, which together with Japan, had a significantly lower incidence.

Comparing the diet of countries with a low and high incidence of cardiovascular diseases, for example, Greece, and particularly the island of Crete, a Mediterranean country, and Finland, a northern European country, respectively, they found significant differences in the consumption of some food groups. In Crete, the population consumed more fruit than Finnish (462–464 g/person/day vs. 34–40 g/person/day), more vegetables (191 g/person/day vs. 104–108 g/person/day) and legumes (1–8 g/person/day vs. 30 g/person/day). Another important difference was the higher milk consumption in the Nordic country (1090–11,192 g/person/day) than in Crete (70 g/person/day), where more fermented dairy products such as cheese or yogurt were consumed. The consumption of sugary products followed the same pattern (Crete: 13–20 g/person/day vs. Finland: 91–101 g/person/day). Perhaps the most

striking finding is that the consumption of edible fat (added and for cooking) in both countries was similar (75–95 g/person/day in Crete vs. 72–96 g/person/day in Finland).

In the middle of the 20th century, dietary fat began to be related to blood cholesterol levels, which are associated with the development of cardiovascular diseases. In this case, the dietary fat consumption was quantitatively similar between a Mediterranean country and a Nordic country. However, there was a large difference between them from a qualitative point of view because the added fat and cooking fat in Finland was mostly of dairy origin. In contrast, the fat used in the Mediterranean country was extra-virgin olive oil, extracted from the olive, the fruit of the olive tree, by using only physical means. The differences between the two types of fat lie in their fatty acid profile. While milk fat is rich in saturated fatty acids, extra virgin olive oil is rich in mono-unsaturated fatty acids, specifically, oleic acid (C18:1 *n*-9). According to the Keys studies, there was a relationship between dietary saturated fatty acid consumption and higher blood cholesterol levels (Keys et al., 1965).

The terms Mediterranean diet and Mediterranean lifestyle did not appear in a scientific journal but in a cookbook published by Ancel Keys and his wife Margaret entitled “How to Eat Well and Stay Well the Mediterranean way” (Keys and Keys, 1975) in which they collected the recipes and customs of their neighbors during the period they lived in Italy, in the Cilento region where this Mediterranean pattern was maintained. In this book, the Keys (a husband-and-wife team) gathered the main characteristics of MD, its frugality, seasonality, local biodiversity, and foods common in its diet, as we detail below.

Unfortunately, in the last two decades of the last century and the first decades of the present century, Mediterranean food habits have been lost, especially in the younger population due to globalization and Western lifestyles, the loss of culinary culture, and working hours. Distancing from MD has led the population of the Mediterranean countries to an increase in body weight, involving a high prevalence of overweight and obesity with the highest prevalence (above 40%) observed in countries of the Mediterranean area, such as Cyprus, Greece, Malta, Italy and Spain (WHO, 2021). In addition, it has led to a higher prevalence of cardiovascular diseases than those described in the 1960s in these Mediterranean countries (particularly Greece and Italy). These changes have been the result of industrialization processes, migration to urban areas from rural areas, sedentary behaviors at work and in leisure (TV, computers, smartphones, etc.) and reduced physical activity, increased availability of cheap and processed foods in supermarkets and grocery stores with high total and saturated fat content, salt, and added sugars, thus increasing energy intake and lower consumption of vegetable proteins and fats. These fats have been replaced by animal fats, providing less fiber and micronutrients (minerals and vitamins) because of their low nutritional density (Russo et al., 2021).

The current situation in adherence to the Mediterranean food pattern, and more globally, the Mediterranean lifestyle, is not very encouraging. In this context, the UNESCO, thinking more in the aspects most related to the culture and heritage of the MD than just about the nutritional and health benefits and the typical foods and dishes of Mediterranean cuisine, initiated an inscription to declare the MD as an Intangible Cultural Heritage of Humanity. This process began in 2004 as a civil society initiative driven by the Mediterranean Diet Foundation with the endorsement of the Ministry of Agriculture, Fisheries and Food of Spain, the trustee of this foundation that acted as a link between the civil society initiative and the institutions. At this first moment, Italy was involved, and subsequently Greece and Morocco. The confirmation of the DM as Intangible Heritage of Humanity took place in November 2010. In 2012, it was recognized by FAO as one of the most sustainable diets on the planet. Other Mediterranean countries such as Portugal, Croatia, and Cyprus joined this UNESCO declaration in 2013, and it is open to the future incorporation of other Mediterranean countries (Preedy and Watson, 2020; Russo et al., 2021).

Today, several initiatives have been proposed to ensure the future of MD in Mediterranean countries, including new technologies that make Mediterranean food, recipes, and menus more affordable than processed foods. Additionally, to initiate campaigns that bring together young scientists and allow synergistic projects on the characteristics of MD and its dissemination. A third aspect is a commitment of nutritionists, public health experts, and the food industry to promote traditional MD. Finally, it is important to mention that the MD is sustainable when communicating its positive aspects (Russo et al., 2021).

## Structure and characteristics of the Mediterranean diet

The MD is based on a food pattern that has been graphically represented in the MD pyramid (Serra-Majem et al., 2020) (Fig. 1). It has the following characteristics:

- (1) It is a diet rich in plant products, including the following food groups:
  - a. Cereals, mainly whole grain wheat and its derivatives (bread, pasta, couscous, etc.), are the predominant cereal in the Mediterranean basin. Although oats, barley, and rice are also consumed, they are unprocessed or poorly processed. Wheat and other cereals are consumed in very different culinary forms and prepared together with different foods from other groups in the traditional Mediterranean dishes.
  - b. Seasonal and locally grown fruits and vegetables in salads, gazpachos, vegetable stews, fruit salads, etc. Garlic, olives, onions, herbs, and spices (oregano, thyme, basil, rosemary, etc.).
  - c. Legumes (lentils, chickpeas, beans, etc.). They are the base of stews and salads.
  - d. Nuts (almonds, nuts, hazelnuts, chestnuts, etc.).
- (2) Moderate-high consumption of white and oily fish and seafood, especially in the coastal areas of the Mediterranean basin.
- (3) Milk and dairy consumption are moderate, with fermented derivatives such as cheese and yogurt always predominant.

Fig. 1 Mediterranean diet pyramid. Reproduced from Serra-Majem et al. (2020).

- (4) Consumption of meat and products of animal origin is occasional (low), with white meat (poultry, rabbit) predominating compared to red and processed meat (beef, lamb, pork, cold cuts/meats).
- (5) Consumption of added simple sugars is also limited (pastries, candies, sugary drinks).
- (6) Virgin olive oil is the predominant added fat used as a dressing for green salads and cooking (sofrito, stews, soups).

A fundamental aspect, as it appears in the pyramid of the MD (Fig. 1), is correct hydration by consuming adequate amounts of liquids, especially water and non-caloric infusions (tea, coffee, chamomile tea, pennyroyal mint, etc.), avoiding other liquids with high energy value because of added sugars.

Although not included in the pyramid, this food pattern is accompanied by other features that are also part of its overall structure, such as maintaining biodiversity by supporting the production of traditional and environmentally friendly local varieties and seasonality in their consumption. The use of traditional culinary techniques is also included in this food pattern and reduces the consumption of industrially processed foods. This makes MD a varied diet with a considerable wealth of recipes and dishes that present variations in each of the geographical regions surrounding the Mediterranean Sea.

Within the MD, it is also envisaged the consumption by adults of fermented low-alcohol beverages (wine, especially red wine, and beer), always with moderation and accompanying meals, always respecting social beliefs and religious precepts. We should not forget the hedonic aspect of food, the palatability of food associated with the response of each individual to the orosensory properties (taste, smell, flavor, texture) of food. MD is highly palatable.

In the social aspect, we must mention commensality and conviviality, eating together, sharing the table with others and enjoying during this period, consider food as a moment of social and cultural relationships. This must be complemented by avoiding sedentarism, performing regular physical activity, and adequate rest (8 h of sleep and a nap).

An important characteristic of MD is frugality, moderate in the quantitative aspect so that the caloric consumption is low and always adequate to the physical activity performed. Furthermore, the predominance of plant foods helps lowering energy consumption by having a low caloric density. All this is compatible with the maintenance of adequate body weight. This food profile of MD gives it particular nutritional characteristics due to the nutrient content and other components of the food consumed.

In general, MD is a balanced diet providing protein mainly of plant origin (legumes, whole grain cereals) (15–20% of total caloric intake), complex carbohydrates (35–40% of total caloric intake), and primarily unsaturated fat (35–45% of total caloric intake).

The high consumption of vegetables and fruits, nuts, legumes, and whole-grain cereals involves a high intake of dietary fiber and complex carbohydrates, implying a low glycemic index. Additionally, this high consumption of foods of plant origin provides a large number of micronutrients, minerals, and vitamins besides other food compounds with antioxidant and anti-inflammatory activity

such as polyphenols and other phytochemicals (allicin, isothiocyanates, etc.) with preventive properties against chronic noncommunicable diseases (cardiovascular diseases, cancer, diabetes, etc.) as discussed below.

Regarding the fatty profile of the MD, consumption of virgin olive oil as a predominant added fat involves a high intake of monounsaturated fatty acids (oleic acid; more than 50% of total fat). Moreover, fish consumption, especially oily fish, provides very long-chain polyunsaturated fatty acids of the omega 3 series such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Nuts also provide monounsaturated fatty acids (oleic acid) and omega 3 polyunsaturated fatty acids ( $\alpha$ -linolenic acid). In contrast, the low consumption of red meat and moderate consumption of fermented dairy products decreases the intake of saturated fatty acids and “trans” fatty acids, which are provided especially by low-consumption of processed foods in the Mediterranean food pattern. The low consumption of processed foods also reduces the intake of salt and added sugars.

### **Adherence to the Mediterranean diet**

In order to know the adherence to the MD, it is necessary to have tools to inform us about the adherence of the population to this food pattern. This adherence can help us relate this type of diet to its health properties.

Several indexes and scores have been developed to establish adherence to MD, taking into account the frequency of consumption of certain food groups characteristic of MD and the intake of certain nutrients that identify MD. Thus, we have the Mediterranean Diet Score (MDS) and the modified MDS in which the adherence to the MD is classified according to the fact that the consumption of legumes, cereals, fruits, nuts, and vegetables is above the median (score 1) and the consumption of meat and derivatives, milk and dairy products and alcohol is below the median (score 1); otherwise, the value assigned to the MDS is “0”. The intake of monounsaturated fatty acids is also included (score 1 if above the median and score “0” if below the median); this indicates the consumption of virgin olive oil. The difference between MDS and the modified MDS is the inclusion of fish in the latter and the ratio between the intake of monounsaturated and saturated fatty acids rather than monounsaturated fatty acids. Consumption scores are specified for alcohol according to sex.

Subsequently, new indexes have been developed, such as the Mediterranean Diet Quality Index (Med-DQI), which includes the consumption of some food groups (meat, olive oil, fish, vegetables, and fruits) and nutrients such as saturated fatty acids and cholesterol, setting consumption intervals in g/day or percentages of total dietary energy ([Table 1](#)). The Mediterranean Diet Adherence Screener (MEDAS) is an index developed within the PREDIMED study that assesses the number of servings consumed daily from different food groups and some typical recipes from Mediterranean cuisine.

A Mediterranean lifestyle index (MEDLIFE) has also been developed, which not only assesses adherence to the Mediterranean food pattern through the consumption of different food groups but also considers aspects related to dietary habits, physical activity and rest, and social aspects ([Table 1](#)).

A MD adherence questionnaire has also been developed specifically for children and adolescents, the KIDMED, which assesses the responses to questions about the consumption and acceptance of different foods and food groups and scores them positively or negatively (See [Table 1](#) for details) ([Gil et al., 2015](#)).

### **The Mediterranean diet as a healthy food pattern**

The results of the Seven Countries Study provided scientific evidence on the role of MD in the prevention of cardiovascular diseases. Numerous epidemiological studies and clinical trials have shown that adherence to a traditional Mediterranean food pattern is associated with the prevention of different chronic noncommunicable diseases (cancer, type 2 diabetes, metabolic syndrome) and is also associated with a lower incidence of obesity. It has also been stated that adherence to MD is inversely related to some neurodegenerative diseases related to the aging process, such as Alzheimer’s disease and vascular dementia, delaying its appearance. Other healthy properties of the MD have been published in recent years, such as its anti-inflammatory activity, stimulation of immune function, beneficial for mood disorders, such as depression. In general, adherence to the Mediterranean food pattern is consistent with lower mortality from any cause and cardiovascular diseases and is related to a better quality of life ([Preedy and Watson, 2020](#)).

The leading cause of death globally is cardiovascular disease (ischemic coronary disease and stroke). The PREDIMED project ([Estruch et al., 2018](#)) was conducted in a cohort of more than 7000 adult individuals with high cardiovascular risk divided into three groups: (1) MD + extra virgin olive oil; (2) MD + nuts; and (3) control group with a low-fat diet. At the end of approximately 5 years of follow-up and analyzing the occurrence of cardiovascular events, including death from these causes, the study concluded that the incidence of these events was lower in those adhering to the MD, supplemented with extra virgin olive oil or with nuts, compared to those who had consumed a low-fat diet. This lower incidence was observed for ischemic coronary disease, stroke, death from cardiovascular causes, and total mortality in the group supplemented with extra virgin olive oil especially. Today, the PREDIMED study is continued in the PREDIMEDplus, which sets objectives related to Mediterranean lifestyles with an intensive intervention that includes a Mediterranean hypocaloric diet, the performance of regular physical activity, and behavioral intervention. The results to be monitored are cardiovascular events and the decrease in body weight and its maintenance over time.

Studies regarding the relationship between cancer and the degree of adherence to MD show a lower risk of death for higher adherence to MD. The risk is low for different types of cancer, including colorectal, head and neck, respiratory, gastric, liver, and bladder ([Morze et al., 2021](#)).

**Table 1** Scores and indexes of adherence to the Mediterranean diet.

<i>Index</i>	<i>Components</i>	<i>Criteria</i>	<i>Scoring</i>
Mediterranean diet score (MDS)	Monounsaturated: saturated fatty acid ratio	<Median	0
		>Median	1
	Legumes	<Median	0
		>Median	1
	Cereals	<Median	0
		>Median	1

	White meat	2 servings/week	1
	Fish/seafood	≥2 servings/week	1
	Potatoes	≤3 servings/week	1
	Low-fat dairy products	2 servings/week	1
	Nuts and olives	1–2 servings/d	1
	Herbs, spices and garnish	≥1 servings/d	1
	Fruits	3–6 servings/d	1
	Vegetables	≥2 servings/d	1
	Olive oil	≥3 servings/d	1
	Cereals	3–6 servings/d	1
Block 2: mediterranean dietary habits	Water or infusions	6–8 servings/d or ≥3 servings/week	1
	Wine	1–2 servings/d	1
	Limit salt in meals	Yes	1
	Preference for whole grain products	Yes/fiber >25 g/d	1
	Snacks	≤2 servings/week	1
	Limits nibbling between meals	Yes	1
	Limits sugar in beverages (including sugar-sweetened beverages)	Yes	1
Block 3: physical activity, rest, social habits and conviviality	Physical activity (>150 min/week or 30 min/d)	Yes	1
	Siesta/nap	Yes	1
	Hours of sleep	6–8 h/d	1
	Watching television	<1 h/d	1
	Socializing with friends	≥2 h/weekend	1
	Collective sports	≥2 h/week	1

Modified from Gil et al. (2015).

The prevalence of type 2 diabetes in the world is increasing. Studies associating the adherence to a Mediterranean food pattern and the risk of developing type 2 diabetes show an inverse relationship. This lower risk of disease can be related to the different components of the MD, especially the anti-inflammatory and antioxidant bioactive compounds in fruits, vegetables, virgin olive oil, and other foods typical of MD. It is important to note that it is necessary to consider the role of MD and type 2 diabetes within the so-called healthy Mediterranean lifestyle mentioned above (Martin-Pelaez et al., 2020).

Another critical aspect of the MD-health relationship is the role of MD in aging and all associated pathological disorders that are among the leading causes of mortality in today's world. We have already mentioned some diseases such as cardiovascular disease, cancer, or type 2 diabetes. Neurodegenerative diseases such as Alzheimer's disease and other senile dementias also appear in this aging process. Recent systematic reviews have shown that adherence to the MD positively affects different cognitive aspects of the aging (elderly) population. In addition, it also has benefits in mood disorders such as depression). Regarding Alzheimer's disease, the MD may reduce different markers of the disease, such as the deposition of the beta-amyloid peptide and the relationship

between this peptide, the tau protein, and brain atrophy; this would lead to slowing and improving neurodegeneration and associated cognitive impairment (Limongi et al., 2020).

Some studies have been published that relate the MD pattern to the coronavirus disease 2019 (COVID-19). This relationship is established through the positive effects on risk conditions for this viral infection, such as cardiovascular diseases, obesity, and type 2 diabetes, that is related to the severity of the disease. Other authors postulate that adherence to MD may be related to the immune system, inflammation, and thrombus formation (Suardi et al., 2021).

There are numerous systematic review and meta-analysis studies on the positive effects of the MD, the Mediterranean food pattern, and the prevention of many chronic diseases (Dinu et al., 2018). All these findings can be explained based on different mechanisms involved and related to the dietary pattern of MD and the anti-inflammatory, antioxidant, antithrombotic, antineoplastic, immunomodulatory, or lipid-lowering properties of the bioactive compounds of the MD (EPA, DHA, phytosterols, dietary fiber, polyphenols, etc.). All of them have a positive role in lipid metabolism, oxidative stress, inflammation, endothelial function, peripheral tissue insulin resistance, hemostasis (platelet aggregation and coagulation), and less established processes such as autophagia, intestinal microbiome, cellular telomerase activity or nutrigenomic and epigenomic aspects (Schröder et al., 2020).

All of these studies performed to understand the relationship of the MD pattern to health prevention and maintenance have led to the inclusion of MD in Food Guidelines of many countries, including the USA since 2010, as a healthy dietary pattern along with others such as the vegetarian diet or the DASH diet (USDA, 2020).

### The Mediterranean diet as a sustainable food pattern

FAO in its 2010 International Scientific Symposium on Sustainable Diets and Biodiversity. Directions and solutions for policy, research, and action define: *"Sustainable Diets are those diets with low environmental impacts which contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair and affordable; nutritionally adequate, safe and healthy; while optimizing natural and human resources"* (FAO, 2012).

One of the sections in this publication is dedicated to MD as an example of a sustainable diet. Among the arguments mentioned are its immense diversity, which guarantees its nutritional quality, as discussed above, and the maintenance of biodiversity with a commitment to local population development. The Mediterranean gastronomy has an extraordinary richness that makes the resulting dish with the same ingredients have its own personality in the different regions of the Mediterranean basin to contribute to the diversity of its landscapes. The role of cultures and traditions in the Mediterranean basin concerning eating habits (conviviality, commensality) is also an asset in its sustainable character. As a consequence of the above, the Mediterranean food system respects nature and practices the seasonality of the usually consumed products. Finally, its healthy character also makes it sustainable (Truzzi et al., 2020).

Another study states that the indicators that can evaluate MD as a sustainable food pattern can be framed in four areas: nutrition and health, environmental (carbon and water footprint and biodiversity, etc.), economic through the accessibility and development of local economies and the cultural and social area, especially the consumption of traditional products with designation of origin and protected geographical indication (Dernini et al., 2017).

### The future of the Mediterranean diet

As mentioned above, the current situation of adherence to the MD in the Mediterranean countries is not at its best, especially among the youngest population. Food globalization, the pace of life, lack of time for cooking, convenience in access to ready-to-eat processed foods, and high palatability have led to a progressive abandonment of this food pattern. This has led to a negative change in the prevalence of food-related noncommunicable diseases and an increase in overweight and obesity in the Mediterranean population, particularly in the countries of the Northern shore.

This scenario raises what the future of this Mediterranean pattern, of the MD, maybe. Some authors suggest implementing strategies that act on the price and affordability of these Mediterranean foods by using new culinary and industrial technologies that provide easier access to traditional Mediterranean foods. It is also important to continue researching in this field to understand better the positive effects of the MD on both individual and planet health. Another aspect to consider is how to disseminate the MD to other non-Mediterranean parts of the world. In this sense, MD should not be exported but should try to reproduce in each of the territories by using the philosophy of this pattern, not only food but cultural and related to heritage. Use local food and the traditional way of preparing it, maintain native varieties, and therefore biodiversity, consider food a collective and social event within the family and social environment (Russo et al., 2021).

### Summary page

In conclusion, MD is a food pattern that includes aspects related to the lifestyle of the population. These aspects are related to agricultural practices that allow for environmentally-friendly cultivation and maintenance of local species and biodiversity, traditional

culinary practices, and commensality and conviviality at the table. The MD is a healthy food pattern that includes foods typical of Mediterranean landscapes, with a high content in foods of plant origin (whole grain cereals, vegetables, fruits and nuts, and legumes), providing large amounts of micronutrients and other food compounds with high biological activity. Moreover, consumption of animal foods is low, especially red and processed meats, although it includes moderate consumption of fish and fermented dairy products. A backbone characteristic of the MD is extra virgin olive oil as added fat for dressing and cooking. It is an unsaturated fat with many bioactive compounds beneficial for health that, moreover, it provides high palatability to Mediterranean cuisine with worldwide fame. The maintenance of the Mediterranean lifestyle pattern, the MD, in its broadest sense, today compromised, is a commitment undertaken by the countries surrounding this sea after its recognition as the intangible heritage of humanity by the UNESCO. This will affect the health of Mediterranean populations and the sustainability of the planet.

## Key points

- To review current micronutrient supplementation recommendations
- To discuss key challenges and recommendations for successful program implementation
- To identify research gaps and opportunities

## Abbreviations

**Hb** Hemoglobin  
**IU** International units  
**LBW** Low birth weight  
**RDA** Recommended daily allowance  
**WHO** World Health Organization

## Introduction

Globally almost over half of preschool-aged children and two-thirds of women are affected by deficiency of one or more micronutrient that put them at an increased risk of poor growth, morbidity, intellectual impairment, and mortality (Keats et al., 2021; Stevens et al., 2022b; Victora et al., 2021). High rates of anemia remain as a persistent global health problem, impacting over 269 million children and 571 women of reproductive age and 32 million pregnant women (Stevens et al., 2022a). Iron deficiency is one of the most prevalent micronutrient deficiencies globally and is considered the leading cause of nutritional anemia, although these estimates may vary widely by setting (Stevens et al., 2022a).

In comparison to children, less is known globally about the burden of maternal micronutrient deficiencies especially in Sub-Saharan Africa (Victora et al., 2021). However, it is well established that high nutrient demands place pregnant and lactating women at elevated risk of deficiency. Unfortunately, there is little or no data for most countries for school-age children, adolescents, adult men, and older adults (Victora et al., 2021).

Since the mid-1980s, micronutrient supplementation has been a public health strategy in many low and middle-income countries (LMIC) to prevent and control micronutrient deficiencies for infants and young children, pregnant women, and in some contexts, non-pregnant women of reproductive age. The following discussion will provide an overview of the purpose of

micronutrient supplementation, its role in the prevention and control of micronutrient deficiencies. We will briefly examine the evidence for supplementation with individual nutrients including vitamin A, iron, iodine, zinc, calcium, vitamin D, and with multiple micronutrients, and various nutrient preparations (tablets, powders, lipid-based nutrition supplements) with respect to efficacy, recommended dose, and frequency of administration, safety, and program effectiveness. Program effectiveness at scale remains a challenge in many settings and the majority of this article is dedicated to the review of key challenges and recommendations for successful program implementation.

## **The purpose of micronutrient supplementation**

Supplementation may serve one of two objectives: (1) to provide physiological amounts (i.e., a portion of or up to daily recommended doses) of nutrients that otherwise are lacking the diets of the targeted population group as a preventive approach; or (2) to provide therapeutic doses of nutrients in response to diagnosed medical conditions (e.g., treatment of severe anemia) or to achieve proven nutrition/health outcome in specific contexts (e.g., reduced mortality in populations with high prevalence of vitamin A deficiency among children).

Generally, micronutrient supplementation is intended as a short-term means of rapidly preventing and controlling nutrient deficiencies in high-risk individuals and populations until adequate and evidence that food supplies meet those needs. However, in some population sub-groups with high micronutrient needs, supplementation may be required through the duration of that life stage (e.g., pregnancy, infancy).

## **Cost of micronutrient supplements**

The 2008 Copenhagen Consensus a group of world-renowned economists, ranked micronutrient supplements (specifically high-dose vitamin A, and therapeutic zinc supplements for children with diarrhea) as among the top international development priorities. The criteria included the cost:benefit ratio, as well as feasibility and sustainability of the interventions. While promising, data to inform such analyses remain scarce. The cost of supplementation programs will depend on the scope and scale of the program, existing delivery mechanisms, the supplement product, among other considerations. Few studies have quantified the cost of supplementation programs, partly as result of their difficulty to estimate ([Fiedler and Puett, 2015](#)). More importantly, the cost and cost-benefit of supplementation programs should be estimated in light of other alternatives to provide the needed nutrients to the targeted populations. We found only one such approach using optimization modeling to determine the best combination of interventions, including supplementation among others to meet nutrient needs in the short and longer term ([Vosti et al., 2015](#)).

## **Summary of micronutrient supplementation recommendations**

There is an enormous body of evidence in the published literature on the impact of a variety of types and formulations of supplements on diverse outcomes in various population groups. To inform programs such evidence should be rigorously reviewed and consolidated to formulate guidelines that can then be adapted to context. A summary of the current World Health Organization and Lancet recommendations for micronutrient supplementation is provided in [Table 1](#) for vitamin A, iron, iodine, zinc, calcium, vitamin D, multiple micronutrient tablets, multiple micronutrient powders and lipid-based nutrition supplements. These recommendations vary by target group and setting depending on the country level prevalence in some circumstances.

As noted above, WHO recommendations are intended as global guidance on efficacious actions to address specific deficiency or health outcomes. It requires adaptation to context to translate this guidance into effective programs. There are several challenges to doing so. The WHO guideline development process relies on systematic reviews and meta-analyses of randomized controlled trials in the published literature. Recommendations can be made therefore, only within the bounds of the evidence that has been studied. This inevitably leads to some gaps in evidence, such as impact in specific subgroups, under varying levels of compliance, or other contextual considerations, in the extent to which such information may not have been included or data cannot be extracted to that level in the original trials. There has been a concerted efforts in the guideline development process to address this by bringing other evidence to bear (e.g., through the values and preferences, and additional considerations) ([Pena-Rosas et al., 2012](#)).

## **Supplementation program cycle**

Well-designed programs ([Fig. 1](#)) should be informed by evidence of the existence of micronutrient deficiency in the population, gaps in existing approaches to address them, and other evidence that will ensure that there is potential to benefit. Ideally, such evidence would include the magnitude and distribution of deficiency, including data disaggregated by sub-groups in the population most at risk of deficiency. Program design should similarly be informed by evidence of gaps in existing micronutrient and complementary programs and resources available for procurement and delivery of supplements and all related activities. The choice of supplements should also be guided by acceptance and potential for high compliance among the target population.

**Table 1** Summary of micronutrient supplementation recommendations.

Micronutrient	Summary of benefit	Target group	Dosage	Frequency & duration	Strength of evidence	WHO level of recommendation/Details	Special considerations
Vitamin A	Prevention of night blindness; lowered severity and mortality risk of infections; lowered risk of diarrhea and severe measles	Infants and children aged 6–59 months	6–11 months: 100,000 IU 12–59 months: 200,000 IU	6–11 mo: Once 12–59 mo: Every 4–6 months	Strong	Context-specific	Only recommended where the prevalence of night-blindness is 1% or more in children of 24–59 months, or the prevalence of vitamin A deficiency is 20% or higher in infants and children aged 6–59 months
	Prevention night blindness	Pregnant women	Daily: 10,000 IU Weekly: 25,000 IU	Daily or once weekly	Weak	Context-specific	Only recommended where vitamin A deficiency is a severe public health problem
Iron	Lowered risk of anemia, iron deficiency and iron deficiency anemia. Intermittent regimens specifically may lead to fewer side-effects than the daily regimen, increase adherence, and increase hemoglobin concentrations	Infants and children aged 6–23 months	10–12.5 mg of elemental iron	Daily for three consecutive months in a year	Strong	Context-specific	Only recommended where the prevalence of anemia in infants and young children under 2 years of age is 40% or more
Children aged 2–12 years		24–59 months: 30 mg of elemental iron 5–12 years: 30–60 mg of elemental iron	Daily for three consecutive months in a year	Strong	Only recommended the prevalence of anemia in children over 2 years of age is 40% or more	Only recommended where the prevalence of anemia in children over 2 years of age is 20% or more	
		24–59 months: 25 mg of elemental iron 5–12 years: 45 mg of elemental iron	Once weekly	Moderate			
Menstruating non-pregnant girls		30–60 mg of elemental iron	Daily for three consecutive months in a year	Strong	Only recommended where the prevalence of anemia in non-pregnant women is 40% or higher		
		60 mg of elemental iron	Once weekly	Moderate	Only recommended where the prevalence of anemia in non-pregnant women is 20% or higher		

(Continued)

**Table 1** Summary of micronutrient supplementation recommendations.—cont'd

<i>Micronutrient</i>	<i>Summary of benefit</i>	<i>Target group</i>	<i>Dosage</i>	<i>Frequency &amp; duration</i>	<i>Strength of evidence</i>	<i>WHO level of recommendation/Details</i>	<i>Special considerations</i>
Lowered risk of maternal anemia, puerperal sepsis, low birth weight, and preterm birth	Pregnant women	30–60 mg of elemental iron	Daily	Strong	Recommended Details: Should be a component of a combined Iron and Folic Acid supplement	If daily iron is not acceptable due to side-effects, and in populations with an anemia prevalence among pregnant women of less than 20%	
		120 mg of elemental iron	Once weekly	Moderate	Context-specific Details: Should be a component of a combined Iron and Folic Acid supplement		
Lowered risk of iron deficiency and anemia, as well as improved hemoglobin concentrations	Non-pregnant women (aged 15–59 years)	30–60 mg of elemental iron	Daily for three consecutive months in a year	Moderate	Context-specific Details: For weekly supplementation, 3 months of supplementation should be followed by 3 months of no supplementation, after which the provision of supplements should restart	Only recommended where the prevalence of anemia in non-pregnant women is 40% or higher	
		60 mg of elemental iron	Once weekly	Moderate		Only recommended where the prevalence of anemia in non-pregnant women is 20% or higher	
Iodine	Healthy brain development in the fetus and young child	Infants and children aged 6–23 months	Daily: 90 mcg Annual Iodized Oil: 200 mg	Daily or yearly (dependent on administration method)	Moderate	Context-specific	Only recommended where 20% or fewer households have access to iodized salt and complementary food fortified with iodine is not available
		Pregnant women	Daily: 250 mcg Annual Iodized Oil: 400 mg		Moderate		
		Non-pregnant women (aged 15–59 years)	Daily: 150 mcg Annual Iodized Oil: 400 mg		Moderate		

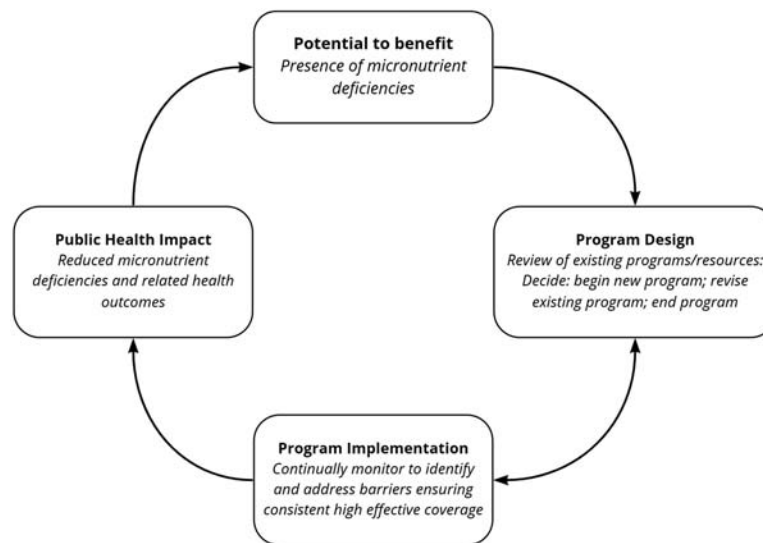

Zinc	Preventative: Lowered risk of diarrhea, lowered risk of upper respiratory tract infection, Increase of mean height	Children aged 6–59 months	Dosage to be determined through further research	Frequency and duration to be determined through further research	Moderate	N/A There are no WHO guidelines or recommendations provided	
	Therapeutic: Shortened duration of diarrhea, persistent diarrhea, and vomiting		20 mg	Daily for 10–14 days	Strong	Recommended Details: Only recommends zinc supplementation for treatment of children who already have diarrhea	Supplementation should be combined with increased fluids and continued feeding
	–	Pregnant women	–	–	Weak	Context-specific Details: Does not recommend zinc supplementation as part of routine antenatal care	Only recommended in the context of rigorous research
Calcium	Lower risk of pre-eclampsia, eclampsia, preterm births, and maternal mortality due to pre-eclampsia and eclampsia	Pregnant women	1.5–2.0 g elemental calcium	Daily	Moderate	Context-specific Details: To be administered orally	Only recommended in populations with low dietary calcium intake
Vitamin D	Oral vitamin D supplementation is not recommended for all pregnant women to improve maternal and perinatal outcomes.	Pregnant women	–	–	–	Not recommended Details: Not recommended generally, sunlight is the most important source of Vitamin D	When vitamin D deficiency is suspected, supplements of the current recommended nutrient intake of 200 IU may be given daily
Multiple Micronutrient Supplementation	May reduce risk of anemia, low birthweight, preterm birth, small for gestational age (SGA)	Pregnant women	Supplements that include – 60 mg of elemental iron		–	Context-specific Details: Does not recommend in high-income countries or to populations not at risk of micronutrient deficiencies.	Only recommended in populations where anemia is a severe public health problem in the context of rigorous research Lancet classifies MMS as strong evidence for implementation.

**Table 1** Summary of micronutrient supplementation recommendations.—cont'd

<i>Micronutrient</i>	<i>Summary of benefit</i>	<i>Target group</i>	<i>Dosage</i>	<i>Frequency &amp; duration</i>	<i>Strength of evidence</i>	<i>WHO level of recommendation/Details</i>	<i>Special considerations</i>
Multiple Micronutrient Powders (MMP)	Reduces anemia, iron-deficiency anemia, iron-deficiency, and diarrhea. Includes logistical advantages over supplements (e.g. sachets easy to transport and store) and biological advantages (e.g. reduced severity and frequency of side-effects, a more “physiological” provision of nutrients with food)	Infants and children aged 6–23 months  Children aged 2–12 years	1 Sachet <i>Sachet Composition: Iron:</i> 10–12.5 mg of elemental iron for children 6mo to 4 years, 12.5–30 mg of elemental iron for children aged 5–12 years <i>Vitamin A:</i> 6000 IU <i>Zinc:</i> 5 mg of elemental zinc with or without other micronutrients to achieve 100% of the RNI	90 sachets/doses over a 6-month period	Moderate	Context-specific Details: To be used as point-of-use fortification of foods, must be iron-containing MMPs	Only recommended in settings in which the prevalence of anemia in children under 2 years of age is 20% or more  Only recommended in settings in which the prevalence of anemia in children aged 2–12 years of age is 20% or more
Lipid-based Nutrient Supplement (LNS)	Reduces risk of severe and moderate stunting, moderate wasting, and moderate underweight  Preconception period: May reduce risk of small for gestational age (SGA) and stunting at birth  Antenatal period: No benefits when compared to MMN, when compared to IFA there is a slight reduction in risk of SGA	Children aged 2–12 years  Pregnant and lactating women	Per <i>The Lancet</i> Recommendation: Small Quantity: <120 kcal (Medium and Large Quantity are not a part of <i>The Lancet</i> recommendation)	Daily, duration to be determined through further research	Strong  Weak	N/A Details: There are no WHO guidelines or recommendations provided	N/A

Summary of recommendations is adapted from the following references: [Keats et al, 2021](#); [WHO, 2016](#); [WHO, 2019](#); [WHO 2020a](#); [WHO 2020b](#); [WHO 2021](#).

**Fig. 1** Program cycle illustrating key considerations and data needs to enhance potential for impact.

Effective program implementation must consider all programmatic components from supplement specifications and procurement, to supply chain and stocks management, effective behavior change communication, among many other considerations. To ensure potential bottlenecks and barriers to implementation can be identified and resolved, a detailed impact pathway should be developed and used to identify the types of timely data needed and points for review and continual improvement. A schematic illustration of the use of such data to identify bottlenecks is shown in [Fig. 2](#). The continual improvement of programs should be an iterative process reviewing data that may inform the need for modifications to design and/or implementation that maximize its potential for public health impact. For example, research to inform changes in supplements distributed as part of a social protection programs in Mexico provide a good example of program modifications to address design and implementation challenges ([Neufeld et al., 2019](#)). Evidence from context should also be used to identify the specific circumstances under which supplementation programs should be discontinued. Some progress has been made to identify such considerations, including biological potential for impact change (i.e., reduced prevalence of deficiency) notably for vitamin A supplementation programs ([De Pee et al., 2011](#)).

### Key challenges and success factors for program implementation

Despite evidence of efficacy, rigorous guidelines and political support for supplementation programs, successful implementation and impact remains elusive in many regions across the globe ([Global Nutrition Report, 2021](#); [Victora et al., 2021](#)). For many

**Fig. 2** Stylized example of health service coverage cascade for iron and folic acid (IFA) supplementation during pregnancy. Adapted from [Marsh et al. \(2020\)](#).

supplementations programs the evidence is clear on what to do but we are failing on how to effectively implement programs. There is growing recognition of the role of implementation research, guided by clear frameworks to improve understanding of the gaps and challenges to inform continual program improvement (Tumilowicz et al., 2015). There are several factors that impact the implementation of supplementation programs (Gomes et al., 2021). We consider here three essential considerations: (1) high coverage among intended groups; (2) continual supply of supplement and (3) effective behavior change.

Ensuring high coverage among intended groups is a key challenge across programs. Often programs suffer from inadequate targeting or coverage where deficient individuals are missed or reached irregularly. Inability to sustain high coverage over long periods of time as financial, political, or other health priorities change is an additional challenge for supplementation programs. For example, among low- and lower-middle-income countries the median coverage rates in 2020 were very low for childhood iron supplementation (12%), childhood zinc supplementation (15%) and for iron and folic acid supplementation in pregnancy (32%) (Global Nutrition Report, 2020). There are also large disparities by country and socioeconomic status. Marsh et al., argue that simply looking at intervention coverage does not account for intervention quality and may actually overestimate the health benefit, reiterating the need to measure effective coverage (Marsh et al., 2020). Effective coverage is defined as the extent and quality of coverage that results in the expected positive health outcome. It can be best assessed using a care cascade starting with the proportion of a population in need of the service, and mapping coverage rates through several steps that are needed to reach effective coverage. Fig. 2 demonstrates such a cascade for iron and folic acid supplementation during pregnancy. It highlights several key steps for effective coverage to be realized, including contact with a potential delivery platform (health facility or community health worker), adequate training and quality of care from health workers, product supply where and when needed, and consumption of the supplement as per recommendations. As described in the Bihar, India case study there is often a stark contrast between the population in need (over 60% anemia among pregnant women) and receipt and consumption of recommended IFA during pregnancy. While 80% of pregnant women reported registering their pregnancies (International Institute for Population Sciences (IIPS), 2016) and attended at least one antenatal care visit, only 10% of women reported adhering to IFA guidance and consuming the supplement for at least 100 days during their pregnancy (Wendt et al., 2018).

The coverage cascade is helpful as it combines typical intervention coverage with data on continual supply and effective behavior change communication required to impact health outcomes. Issues with supplement supply are well documented across the literature (Larson et al., 2012) and a common constraint to program impact. Unfortunately, less has been published on experiences that identify and apply innovative solutions to address these challenges. Effective behavior change is likewise a challenge and often overlooked and underinvested in. For example, individuals may receive the supplement but be provided limited information on how or why to take them and what side effects may be expected, resulting in poor compliance (Fite et al., 2021). Tailored communication approaches with messages that address key barriers or common misperceptions, and are delivered through channels that targeted individuals access and trust are needed to motivate supplement use.

### Case studies

To illustrate these considerations in practice, we present three case-studies including lessons learned from IFA supplementation among women in Bihar, India (Box 1), oral zinc supplementation among children in Bangladesh (Box 2), and Vitamin A supplementation in children in Nicaragua (Box 3). The common lessons learned from the three case-studies are summarized in Table 2. For example, the zinc supplementation program in Bangladesh showed that scaling-up required a shift in communication methodology. Although mass media campaigns to promote awareness were largely successful, there was little impact of the individual behavior change communication component. This emphasizes the importance of formative research to understand the local context and what might motivate the population and to use these findings in communication design. Experience from India and Nigeria demonstrate the importance of a continual supply of supplements. Not only was implementation negatively affected by the lack of a functional management systems and documentation of delivery, stock, and usage, but inconsistent and unreliable supply fostered

#### Box 1

##### Case Study 1: Distribution of antenatal iron and folic acid (IFA) supplements to pregnant women using existing health care channels in Bihar State, India

India has one of the highest prevalence of anemia, particularly the state of Bihar where over 60% of pregnant women are anemic (International Institute for Population Sciences (IIPS), 2016). In 2016, however, only 10% of pregnant women received the recommended dose of 100 IFA tablets through antenatal care services (Wendt et al., 2018). CARE-India in collaboration with Emory University launched a mixed-methods study to carefully examine the gaps and challenges that need to be addressed to improve effective coverage, i.e., the provision and consumption of IFA supplements daily by pregnant women for at least 100 days during pregnancy (Wendt et al., 2018). This case study assessed the availability of IFA supplements at various levels in 8 selected districts in Bihar combined with key interviews with various stakeholders including field level workers and community members to evaluate awareness of the program and processes related to procurement and distribution. The lack of compliance was attributed to a high rate of reported side-effects. Lack of demand and awareness of the importance of consuming supplements during pregnancy and supply issues were also identified. Specific programmatic adaptations were suggested to address these (Table 4). Several of these issues (e.g., health sub-center infrastructure; access to early and quality antenatal care) reflect broader health systems investment and quality assurance issues with implications well beyond supplementation.

**Box 2****Case Study 2: Oral zinc supplementation for treatment of diarrhea in Bangladesh**

In 2004, the World Health Organization WHO/and UNICEF revised their clinical management of childhood diarrhea guidelines to include provision of zinc supplementation based on evidence from several large randomized clinical trials that demonstrated reductions in disease duration and severity as well as the risk of a repeat episode following the receipt of 10–20 mg of zinc daily for at least two weeks (WHO/UNICEF, 2004). The recommendation was to provide oral zinc supplements that would be consumed daily for 10–14 days along with standard treatment of diarrhea in young children (under age 5 y) that included oral rehydration salts (ORS).

The Scaling up of Zinc for Young Children (SUZY) project that was established in 2003 in Bangladesh is one of the few well documented case-study that describes the various steps and challenges in the national scale-up of oral zinc supplementation to young children with diarrhea (Larson et al., 2012). Key factors that distinguish this case include: (1) the formation of a partnership with public, private, non-governmental organizations and multinational sector agencies; (2) formative and implementation research that informed product development, acceptability, awareness building and preparation of mass media messages and (3) continuous monitoring and evaluation of coverage, utilization and potential unintended consequences (i.e., reduced ORS use). The project involved the scaling up of a dispersible, 20-mg zinc sulfate tablet, referred to as “Baby Zinc” (Larson et al., 2012). The tablet is placed in a spoon, or a small cup, and water is added which leads it to disperse into a sweet, vanilla flavor that masks the taste of zinc. The treatment is packaged in a 10-tablet blister pack, and caretakers are instructed to give one tablet per day for 10 days. Studies of acceptability were promising but formative research that included caretakers of children with diarrhea, health care providers, drug vendors and medical representatives who sold drugs revealed disparities in care favoring urban settings and wealthier households (Larson et al., 2009). Nevertheless, the mass media promotion campaigns that included TV were successful in increasing awareness dramatically from less than 10% in all communities prelaunch to 90%, 74%, 66% and 50% in urban non-slum, municipal, urban slum, and rural sites by 10 months (Larson et al., 2009). However, after ~2 years, utilization was low and only 25%, 20%, 20% and 10% in the same sites, respectively. Many children also did not receive the correct ten-day course with ~50% receiving seven or fewer tablets (Larson et al., 2009, 2012). The implementation research identified several factors that may have contributed to these results (Larson et al., 2009, 2012). For example, drug vendors commonly sell medications to cover only a few days with the expectation that caregivers will purchase additional or alternative medications if child remains sick. Caregivers had limited experience continuing medications once their child appears to be cured, resulting in failure to complete the recommend ten-day course. While the project succeeded in high early awareness with mass media campaign a critical challenge was the transition from awareness to practice. There was a need to strengthen interpersonal communication and address potential barriers to use related to household level decision making for behavior change. These findings clearly showed the gaps and challenges to move from increasing awareness to actual program coverage and fidelity.

**Box 3****Case Study 3: Vitamin A supplementation using an integrated approach to anemia reduction in women and children in Nicaragua**

In the early 1990s, anemia among women and children in Nicaragua was identified as a problem of public health significance. The estimated prevalence of anemia at that time was about 28.5% and 33.6% in children ages 1–4 and non-pregnant women of reproductive age, respectively (Mora, 2007). While the identified causes of anemia in these populations were varied and include iron, thiamine, riboflavin, and folate deficiencies, reducing Vitamin A deficiency (VAD) was chosen to be the goal of the ensuing programmatic interventions address the issue of inadequate vitamin A intake (Mora, 2007). The program was a part of the National Micronutrient Plan created by the Ministry of Health (MOH) in Nicaragua and included a variety of multisector interventions (Mora, 2007). Vitamin A supplements were distributed for children younger than 5 years of age and post-partum women. Additionally, sugar fortification with Vitamin A was made mandatory, as sugar is regularly consumed by nearly all Nicaraguan families. Vitamin A supplements were distributed at biannual National Health Rallies (NHRs) that were largely successful, due to high community mobilization from media engagement, district-level MOH staff, the church, community groups, and NGOs. Additionally, the MOH implemented an Integrated System for Surveillance of Nutritional Interventions, an information system that monitors implementation to inform decision-making in nutrition programs (Mora, 2007). In 2000, the results of a national micronutrient survey revealed a striking reduction in VAD (Mora, 2007). In children under 5 years old, VAD prevalence was 31.3% in 1993 and dropped to 8.8%. In women, VAD was found not to be a problem of public health significance. The success of the program can be in part attributed to a series of concrete steps taken by the MOH: high-level advocacy; in-depth formative research surrounding the causes of VAD, current policies and programs in place, and resources available; and the creation of a taskforce charged with coordinating program development and implementation (Mora, 2007).

distrust among the target population. All three case studies emphasize obtaining high coverage as a key component of successful implementation. They show that this can be achieved in part by multi-intervention approaches that incorporate local ownership of the program and activities. Formative research concerning constraints and acceptability of activities, and a well-developed monitoring and evaluation plan are also referenced in all three cases as essential implementation actions.

**Research gaps and future directions**

There remain critical gaps in knowledge to improve the targeting, coverage and impact of supplementation programs globally (Table 3). First, better reporting from supplementation efficacy and effectiveness trials could lead to better formulation of recommendations with concrete suggestions for adaptation to context. For example, data are lacking to guide when programs can shift from daily to weekly IFA supplementation during pregnancy, or when population-based supplementation programs can be stopped

**Table 2** Lessons learned from program implementation case studies.

<i>Criteria</i>	<i>Lessons learned</i>
Effective behavior change	<ul style="list-style-type: none"> <li>• Mass media can be useful for drawing attention to supplementation programs, but clear messages through effective channels are needed to go beyond awareness to directly influence practices and lead to lasting behavior change</li> <li>• Formative research should always be carried out to design behavior change campaigns (messages and means of delivery) that respond to the local situation</li> </ul>
Continual supply	<ul style="list-style-type: none"> <li>• A functional management logistic system is critical to maintain continued availability of supplements and buffer stocks at delivery posts</li> <li>• Effective management and documentation is needed at lower administrative levels (village, sub-district) to more accurately track existing inventories and needs</li> <li>• Effective international cooperation and coordination facilitates the establishment and maintenance of a reliable supply chain when supplements are not manufactured in-country</li> </ul>
High coverage	<ul style="list-style-type: none"> <li>• The most effective programs simultaneously address effective behavior change, continual supply and high coverage</li> <li>• Building capacity for local production and dispersion of supplements is pivotal, as local program ownership facilitates policy decisions and program sustainability</li> <li>• Creating constraint frameworks is extremely useful, constraints can be initially identified via a pilot program or other methods</li> <li>• Effective monitoring is essential and should be designed at the beginning of a program, drawing on an explicit mapping of the program implementation process (the impact pathway) to identify and prioritize data that will identify bottlenecks and solutions to address them</li> <li>• Process and impact evaluation should be included wherever feasible to generate objective evidence of program delivery and effectiveness, which together with monitoring data should be used to adapt programs as needed</li> </ul>

**Table 3** Key implementation research priorities to enhance supplementation program delivery.

- Up-to-date evidence of the prevalence of micronutrient deficiencies disaggregated to potentially high-risk population subgroups is lacking in several regions of the world for most population groups. Data are particularly scarce for among pregnant women, children >5 years of age, adolescents, and older adults
- Program coverage data is lacking and requires improvements to monitor the equity in which supplementation programs are delivered. Robust coverage data should be collected to understand the coverage cascade and factors that are limiting it
- Innovations in implementation science are needed in how to best deliver supplementation programs to maximize coverage among target population and achieve impact at scale
- Further development of simple costing and cost optimization tools that can be applied to inform decisions related to program continued relevance and need for revision or cessation

given decrease in the burden of deficiency or the existence of other effective actions. Trials should always report baseline nutrient status of participants, along with detailed description of other population characteristics. In addition, trials are recommended to include details of supplement content, and the coverage cascade identifying key points that inform progress toward effective coverage. Second, up-to-date evidence of the prevalence of micronutrient deficiency is woefully lacking for most populations groups across most countries in the world (Brown et al., 2021). Similarly, program coverage data is lacking and requires improvements to monitor the equity in which supplementation programs are delivered. Finally, innovations in implementation science are needed in how to best deliver supplementation programs to maximize coverage among target population and achieve impact at scale.

## Summary

Global guidance for the potential of many different types of supplementation exist, and programs are implemented in many countries globally, including many with high burden of micronutrient deficiency. Such guidelines have been informed by ample evidence of efficacy of supplements, but rigorous implementation research to inform the design, implementation and continual improvement of such programs is lacking. Further research and investment on effective strategies to achieve high coverage among intended groups, continual supply of supplement and effective behavior is required to reach impact at scale.

**Table 4** Identified bottlenecks of Bihar's iron and folic acid (IFA) supply chain and proposed actions.

Stage	Identified bottleneck/issue	Proposed action
Demand	Lack of appropriate IFA need forecasting	<ul style="list-style-type: none"> <li>Standardized demand forecasting based on accurate estimates of district needs and previous consumption</li> <li>Computerization and clear documentation of inventory, stock requests, and expiry dates</li> <li>Estimates to include lactating women population; IFA distribution and counseling standard</li> </ul>
Supply acquisition & utilization	Late supplier deliveries resulting in inconsistent supply	<ul style="list-style-type: none"> <li>Implement centralized supply system whose policy is to deduct payment upon late delivery, damaged stock, etc.</li> </ul>
	Perceived or actual inability to procure IFA when needed through local purchasing	<ul style="list-style-type: none"> <li>Set aside and explore use of untied funds to purchase IFA locally in times of shortage or emergency</li> </ul>
	Lack of buffer stock use at all levels	<ul style="list-style-type: none"> <li>Implementation, monitoring, and evaluation of existing buffer stock requirements</li> <li>Ensure adequate storage facilities so stock can be stored safely</li> </ul>
	No safe disposal plan for expired medicines and pushing of expiring drugs to patients and frontline workers	<ul style="list-style-type: none"> <li>Transparent plan to prevent expired medicines through appropriate purchasing practices and safe disposal of expired medicines</li> </ul>
Storage	Inconsistent training on IFA counseling/distribution across FLW types	<ul style="list-style-type: none"> <li>IFA counseling/distribution training for all frontline workers who work with pregnant women</li> <li>Training for all frontline workers together at health sub-center level to improve coordination and communication</li> </ul>
	Storeroom transiency and disorder	<ul style="list-style-type: none"> <li>Construct, purchase, or long-term rental of adequate storerooms, including resources for racks, labels, and shelves in resource development proposals</li> <li>Training for storekeepers including storeroom order and inventory protocols</li> </ul>

### Key points

- To know the overall composition of milk from different species
- To know the main proteins, lipid components and carbohydrates of milk
- To know the main mineral elements and vitamins of milk
- To know the overall composition of fluid milks and dairy products
- To understand the role of milk and dairy products in disease prevention and health promotion

## Introduction

Milk is the secretion of female mammals to nourish newborns in their first months of life. Due to its high nutrient density, milk also has a recognized nutritional role in the diet of adolescents and adults. From a nutritional point of view, there are several important aspects of milk consumption that can be highlighted: (1) In milk there is a good balance between the main components, fats, proteins, and carbohydrates, which are present in comparable proportions. (2) It provides high levels of nutrients in relation to caloric content. This is especially interesting for people following a weight control diet. (3) Taking into account the consumption figures for dairy products as a whole, it can be concluded that they provide more than one-fifth of the recommended daily allowance (RDA) of protein, zinc, riboflavin (vitamin B2), and vitamin A, as well as smaller proportions of the recommended amounts of many other vitamins (B12 and D). On the other hand, its calcium content stands out, close to 60% of the RDA. In addition, recent studies consider that milk is the most important source of natural bioactive components and that its effects on health are the result of the interaction of all nutrients and go beyond the simple sum of individual effects (Thorning et al., 2017).

At the physicochemical level, milk is a balanced mixture of proteins, fat, carbohydrates, salts, and other minor components dispersed in water as emulsions, colloidal suspensions, and true solutions. In the dissolved state, lactose, water-soluble vitamins, and salts are found, totally or partially ionized, and constitute a stable phase. The micellar complex, a calcium phosphate associated with caseins, is a macromolecular aggregate of varied shape and structure, which has a net negative charge, ensuring stability by electrostatic repulsion. In the whey fraction, specific whey proteins, serum proteins, and low proportions of soluble caseins are also found. The fat globules are surrounded by a membrane of lipoprotein nature, which keeps the fat in an emulsion state.

Although the composition of milk can vary due to the animal (breed, lactation stage) or other factors (climate, diet, type of milking, etc.), variations are limited by certain physical properties such as osmotic pressure, since milk is isotonic with blood; in both fluids, the sum of molar concentrations of solutes is approximately 0.3. The main contributors are lactose and sodium, potassium, and chloride ions. Another limitation on the composition of milk is the solubility of calcium phosphate and citrate, as well as the melting point of fat, which should not be higher than body temperature (37–40 °C). Of the milk components, fat is the one with the greatest variability due to genetic factors, with notable differences not only between different breeds but also between individuals of the same breed. However, the composition of milk fat varies mainly with cattle feeding and less markedly because of other factors (Table 1).

## Milk composition

### Proteins

Cow's milk contains between 3 and 3.5% proteins, distributed in fractions whose importance varies according to dairy technology and nutrition: caseins, soluble proteins or whey proteins, and non-protein nitrogenous substances (Table 2). The colloidal dispersion in milk is very stable even at extreme temperatures and concentrations. In general, the dispersion recovers after drying or concentration, a circumstance of great technological importance. Milk proteins are differentiated by the size of their molecules, with molecular masses from 12,000 to 380,000 Da. They occur in two different phases: the caseins, an unstable micellar phase formed by suspended micelles that diffuse light and give the milk an opaque white appearance. The other phase is soluble, formed by different hydrophilic protein polymers named whey proteins.

Caseins are the major proteins in milk (75%–85%). They are a group of phosphorous proteins, which are present in the form of an organic complex, the micelle, of  $\alpha_s$ ,  $\beta$  y  $\kappa$ -caseins, bound by colloidal calcium phosphate and to a lesser degree, citrates and magnesium. The micelle is hydrated (65% water) and its size varies from 30 to 300 nm. The most phosphorylated caseins ( $\alpha_s$ ,  $\alpha_s$ , and  $\beta$ ), are unstable in the presence of Ca, and are located in the interior of the micelle; toward the exterior is located most of the  $\kappa$ -casein, hydrophilic, stable in the presence of Ca. If the integrity of the casein is lost, the milk coagulates. A fraction of caseins, mostly  $\beta$ -casein, is soluble (1% at 20 °C), a fraction that increases when milk is kept refrigerated (10% at 5 °C), which can affect cheese yield. At pH 4.6 the micelles have zero overall charge, aggregate, and coagulate, separating from the aqueous phase. At this pH, whey proteins remain in solution. Whey proteins represent 19% of total proteins and during thermal processes; they denature and lose their solubility approximately to isoelectric point, although the degree of denaturation depends on the intensity of

**Table 1** Average composition of basic nutrients in milk from different species.

Species	Fat (g)	Protein (g)	Lactose (g)	Total solids (g)	Ash (g)	Energy (kcal)
Cow	3.7	3.2	4.7	12.8	0.7	69
Sheep	7.9	5.7	4.8	19.3	0.9	105
Goat	4.0	3.5	4.3	13.0	0.9	70
Buffalo	7.6	3.8	4.0	17.2	0.8	102
Human	3.8	1.4	7.0	12.6	0.3	68

Values are expressed per 100 g.

**Table 2** Average values of cow's milk protein content.

Component	g/kg	%
<b>Total protein</b>	33.0	100.0
<b>Total caseins</b>	26.0	79.5
$\alpha$ S1-casein	10.0	30.6
$\alpha$ S2-casein	2.6	8.0
$\beta$ -casein	9.3	28.4
$\gamma$ -casein	0.8	2.4
k-casein	3.3	10.1
<b>Total whey proteins</b>	6.3	19.3
$\alpha$ -Lactalbumin	1.2	3.7
$\beta$ -lactoglobulina	3.2	9.8
Seroalbumin	0.4	1.2
Immunoglobulins	0.7	2.1
<b>Membrane proteins</b>	0.4	1.2
Others	0.8	2.4

heating and other conditions such as acidification. Whey proteins include  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, immunoglobulins, proteoses-peptones, and other non-specific minority components such as lactoferrin and lysozyme, with bacteriostatic properties.  $\alpha$ -lactoglobulin is the quantitatively most important whey protein in cow's milk. At normal milk pH, it exists as a dimer and due to the cysteine radicals that it contains, it can create disulfide bridges, which stabilize dimerization. The binding of casein and  $\beta$ -lactoglobulin that takes place in heated milk also results from an S–S bridge between the two molecules.  $\alpha$ -Lactalbumin stands out from the biological point of view since it participates in the synthesis of lactose. Non-protein nitrogen (NNP) varies from 3% to 7% of total nitrogen, and in sheep's milk, it represents 5% of total nitrogen.

Milk also contains a certain number of enzymes that are important from the technological point of view in cheese making and ripening, such as lipases that give rise to hydrolytic rancidity, proteases that hydrolyze casein, etc. On the other hand, the heat lability of certain enzymes provides the basis for analytical tests that determine whether milk has been subjected to heat treatment; in this sense, the analysis of alkaline phosphatase deactivation is used as a marker of adequate pasteurization. Therefore, the major milk proteins, caseins, and whey proteins contain all the essential amino acids required to meet our nutritional needs and they present high digestibility and biological value, so they are defined as high-quality proteins. Because of their high lysine content, milk proteins can complement proteins from other foods, such as cereals. Moreover, gastrointestinal digestion of milk proteins generates bioactive peptides that are reported to have numerous beneficial effects on health or on reducing the risk of disease. These peptides are also ending products of enzymatic hydrolysis of the milk proteins that are liberated during fermentation and ripening of fermented milks and cheeses. Apart from the positive data on milk proteins based on amino acid composition, milk has minor proteins with documented specific functions, such as lactoferrin (0.2 g/L) and lysozyme whose confer protection against microbial infections. Milk also contains immunoglobulins (0.7 g/L) that modulate aspects of immunity. Other minor milk proteins are bioactive molecules of great interest especially in infancy and adolescence, with the same content and molecularly identical to those present in human milk, which have been described as growth factors and modulators. On the other hand, the protein fraction includes in its structure two-thirds of the calcium and half of the phosphorus in milk, as well as practically all of the iron, manganese, and zinc, which facilitates their bioavailability. Besides, milk whey proteins alone or together with bioactive peptides, amino acids produced after digestion or combined action with other milk constituents, such as calcium, have been shown to contribute to the regulation of body weight, by providing satiety signals that affect the regulation of food intake in preference to proteins from other sources. Faster digestion of peptides and increased thermogenesis have also been reported.

## Lipids

They are among the most important constituents of milk in terms of economic and nutritive aspects and because of the physical and organoleptic characteristics that they impart to dairy products. They are present in the form of globules (MFG) with a hydrophobic nucleus that consists mainly of triacylglycerols (TAG) surrounded by a membrane (MFGM) composed mostly of phospholipids (PL) and glycoproteins. These polar lipid compounds are indispensable elements that form part of cell membranes and transport liposoluble vitamins (A, D, E, and K). In the composition of milk lipids, together with the major TAG components, there are also simple lipids (diacylglycerols, monoacylglycerols, and waxes), complex lipids (mostly PL), cholesterol, cholesterol esters, antioxidants (especially tocopherols), and squalene (Table 3).

Milk fat is very complex, with about 400 different fatty acids (FA) which have from 4 to 26 carbon atoms, although only just under 30 are present in a proportion greater than 0.1% and the rest are only present as traces. About 60%–70% of all the FA are saturated (SFA), 20%–25% are monounsaturated (MUFA) mainly oleic acid (*cis*-9 C18:1), and 1%–4% of *trans* fatty acids (TFA) and 3%–5% are polyunsaturated (PUFA), which include essential FA such as linoleic acid (LA, *cis*-9 *cis*-12C18:2, or 18:2 n-6) and  $\alpha$ -linolenic acid (ALA, *cis*-9 *cis*-12 *cis*-15C18:3 or 18:3 n-3), with concentrations of 1%–3% and 0.3%–1%, respectively, which have a recognized beneficial effect for cardiovascular health (Fontecha and Juárez, 2017).

**Table 3** Range composition of lipid classes in cow's milk fat.

Component	%
Triacylglycerols	97–98
Diacylglycerols	0.4–0.6
Monoacylglycerols	0.02–0.03
Free fatty acids	0.03–0.1
Phospholipids	0.3–0.8
Cholesterol	0.25–0.35
Hydrocarbons	Traces
Cholesterol esters	Traces

Milk fat differs from other animal fats because of the exclusive presence in it of short-chain fatty acids (SCFA), as butyric acid (C4:0) and caproic acid (C6:0), and medium-chain FA, namely caprylic acid (C8:0) and capric acid (C10:0), which have been shown not to have an effect on increasing the levels of cholesterol in the blood. These SCFA make up 8%–12% of the total in cow's milk, while in sheep and goat milk the levels of the C6 to C10 acids are two to three times higher than in cow's milk (Park et al., 2007) (Table 4). In addition, milk fat has 1–4% of naturally occurring TFA. The major isomer of naturally occurring TFA is *trans*-11C18:1, a physiological precursor of conjugated linoleic acid (CLA), for which a multitude of health benefits have been described. As previously stated, whole milk has a high content of SFA and therefore there have been recommendations advising against indiscriminate consumption of it. Nevertheless, new research has been conducted in recent years which has shown the nonexistence of an association between intake of balanced dairy foods (containing all components) and cardiovascular risk in healthy individuals (Fontecha and Juárez, 2017).

## Carbohydrates

Lactose is the only sugar found in milk in significant quantities. They constitute the largest fraction of the dry milk powder, and the most labile to microbial action, being transformed into lactic acid and other products responsible for the sour taste of fermented milk. Lactose is a disaccharide of glucose and galactose, found in aqueous solution as two anomers named  $\alpha$  and  $\beta$ -lactose. The crystallization of lactose is of great practical importance in the manufacture of various dairy products: condensed milk, powdered milk, whey powder, ice cream, etc., and the relative insolubility of lactose is of special significance in obtaining concentrated milk. An improving effect of lactose on the absorption of calcium and other mineral elements from milk has been reported. However,

**Table 4** Average composition of the main fatty acids of milk from different species.

Fatty acids	Fatty acids	Species (%)		
		Cow	Sheep	Goat
Butyric	C4:0	3.1	3.5	2.2

Conjugated linoleic	CLA	1.0	0.7	0.7
$\alpha$ -Linolenic	<i>cis</i> -9 <i>cis</i> -12 <i>cis</i> -15 C18:3	0.6	0.6	0.4

lactose does not cross the intestinal membranes and in lactase deficient people, it is utilized by the microorganisms present in the intestine producing a series of intestinal disorders known as lactose intolerance. Individuals with difficulties to tolerate milk can consume fermented products such as cheese -since after the first days of ripening it has very low lactose content- or even yogurt. Yogurt has lower lactose levels than milk, but it has also been demonstrated that yogurt lactose is better digested.

### Mineral elements

The most abundant mineral elements in milk are Ca, P, K, Na, Cl, and Mg whilst Zn, Fe, Cu, and Mn are the trace element more remarkable. Representative values for the average mineral content of milk from different species are presented in Table 5. The levels of Ca, P, Mg, Zn, Fe, and Cu are higher in sheep than in cows milk, while the opposite appears to be the case for K and Na.

Cows milk contains about 1% salts. Sheep milk has around 0.9% as compared to 0.7% in cow's or goat's milk (De la Fuente and Juárez M. 2015). Of the major constituents, Ca and P are especially important, both in the nutritional aspect and for their role in the physical state and stability of the caseins. These two elements are distributed in the soluble and colloidal phases of milk as follows Ca: 1/3 soluble and 2/3 micellar; P: 1/2 soluble and 1/2 micellar. The calcium/phosphorus ratio is optimal for absorption. Mg is an important element since it intervenes as Ca in the stability of the micelle and has also been related to blood pressure regulation through their effects on cardiovascular diseases (CVDs). Approximately 1/3 of the Mg is micellar and the rest is in solution. Citric acid raises the level of soluble Ca in milk, in the form of calcium citrate. Concerning the elements K, Na and Cl, together with lactose, they contribute to the osmotic pressure of milk. About 95% of Mn and Zn, and 50%–75% of Fe and Cu respectively, are distributed in the colloidal phase of milk. Soluble proteins have affinity only for Fe, which bind from 18% to 33%. Lactose, ascorbate, citrate, phosphopeptides, and lactoferrin may have a significant impact on the absorption of mineral elements. Furthermore, milk does not contain substances such as phytates which could inhibit the absorption of minerals. Therefore, the bioavailability of minerals for dairy products is very high.

### Vitamins

Milk is an important source of water-soluble vitamins for the child and adult, which come partly from forage, but are mostly synthesized by rumen bacteria and their quantity shows little variation. The recommended intake of group B vitamins (B1, B2, and B12),

**Table 5** Average composition per 100 g of mineral and vitamin content of milk from different species.

<i>Minerals</i>	<i>Species</i>		
	<i>Cow</i>	<i>Sheep</i>	<i>Goat</i>
Ca (mg)	122.00	193.00	134.00
Mg (mg)	12.00	18.00	16.00

Folic acid (μg)	5.00	5.00	1.00

and an important percentage of A, is covered with the consumption of one liter of milk. As for fat-soluble vitamins, the vitamin A content depends on the diet, vitamin D on solar radiation, and E and K are in trace form; as they are associated with fat, are concentrated in fat-rich products (Table 5).

## Drinking milk

According to the U.S. Department of Agriculture (USDA) drinking or fluid milks are products pasteurized (or heat treated), homogenized and packaged. They shall be clean, sound, wholesome, and free from foreign material such as, but not limited to, dirt, insect parts, hair, wood, glass, or metal, and comply with State, local laws, regulations, or requirements. The USDA has authorized the use of the following fluid milks:

*Whole milk:* Not less than 3.25% total milkfat.

*Reduced fat milk:* At least 25% less total fat.

*Lowfat milk:* Maximum of 3 g or less total fat in 240 mL (1 cup or 8 fluid ounces).

*Nonfat/skim/fat free milk:* Less than 0.5 g of total fat in 240 mL (1 cup or 8 fluid ounces).

The European Union (EU) Regulation defines the following sales descriptions, which must be used for drinking milk, which is intended for delivery to the consumer:

- *Whole milk* such as heat-treated milk that, with respect to fat content, meets one of the following requirements: i) standardized whole milk with a fat content of at least 3.50%. However, EU member states may provide for an additional category of whole milk with a fat content of 4% or above. ii) non-standardized whole milk as milk with a fat content that has not been altered since the milking stage either by the addition or removal of milk fats or by mixture with milk whose natural fat content has been altered. However, the fat content may not be less than 3.50%.
- *Semi-skimmed milk* such as heat-treated milk whose fat content has been reduced to at least 1.50% and at most 1.80%
- *Skimmed-milk* such as heat-treated milk whose fat content has been reduced to not more than 0.50%.

Heat-treated milk not complying with the fat requirements for the above products, i.e., whole milk/semi-skimmed milk/skimmed milk can be considered drinking milk provided that the fat content is clearly indicated with one decimal and easily readable on the packaging in the form of "X% fat". The legislation states that this milk must not be described as whole milk, semi-skimmed milk or skimmed milk.

The average composition of the main nutrients in drinking milk, as well as its energy intake, can be modified by its fat content as shown in Table 6.

## Dairy products

The US FDA defines milk products as "Food products made exclusively or principally from the lacteal secretion obtained from one or more healthy milk-producing animals, e.g., cows, goats, sheep, and water buffalo, including, but not limited to, the following: lowfat milk, skim milk, cream, half and half, dry milk, nonfat dry milk, dry cream, condensed or concentrated milk products, cultured or acidified milk or milk products, kefir, eggnog, yogurt, butter, cheese (where not specifically exempted by regulation), whey, condensed or dry whey or whey products, ice cream, ice milk, other frozen dairy desserts and products obtained by modifying the chemical or physical characteristics of milk, cream, or whey by using enzymes, solvents, heat, pressure, cooling, vacuum, genetic engineering, fractionation, or other similar processes, and any such product made by the addition or subtraction of milkfat or the addition of safe and suitable optional ingredients for the protein, vitamin, or mineral fortification of the product"

The different processed dairy products have wide ranges of composition so that they can cover both different consumption habits and very different uses of nutritional interest. Apart from cream and butter, which are products enriched in milk fat with low levels of other nutrients, other milk products are marketed with different fat contents and with different levels of minerals and vitamins (enriched milk), concentrated milk, especially fermented milks (yogurts) that maintain all the nutrients in milk. Different types of cheese include concentrated fat, part or all of the milk proteins (depending on the manufacturing process), and important proportions of the minerals calcium and phosphorus.

**Table 6** Average composition (%) of basic nutrients in milk by its fat content.

Milk type	Fat (%)	Protein (%)	Lactose (%)	Ca (mg)	Vit. A (μg)	Energy (kcal)
Whole	>3.5	3.2	4.7	124	46	63
Semi-skimmed	1.5–1.8	3.5	4.8	125	18.9	46
Skimmed	<0.5	3.9	4.9	121	0.1	35

## Fermented milks

They belong to the group of probiotic foods, i.e. those that contain live microorganisms that, when ingested in sufficient quantity, can exert beneficial effects on health by favoring the balance and maintenance of the intestinal microbiota. The bacterial groups most commonly used as probiotics are lactobacilli and bifidobacteria.

Yogurt is, in its different presentations, the best-known fermented milk. It is made from pasteurized milk and milk fractions inoculated with a mixture of microorganisms, *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus*, which are responsible for the metabolic transformations of carbohydrates, proteins, and lipids, leading to the development of its characteristic flavor, aroma, and texture.

During lactic fermentation, the microorganisms hydrolyze lactose, using the enzyme lactase ( $\beta$ -galactosidase), into glucose and galactose. Glucose is mainly transformed to lactic acid - with a consequent decrease in pH, which hinders the development of undesirable microorganisms - and to small amounts of compounds that contribute to flavor and bioactivity. On the other hand, the proteolytic enzymes of the microorganisms act on the casein giving rise to polypeptides and peptides, and although hydrolysis is slow and in low proportion, the same amino acid composition is maintained as in milk. Besides, during fermentation and as a consequence of the decrease in pH, minerals such as calcium and phosphorus pass to the soluble form, and caseins precipitate in the form of a fine coagulum, which facilitates their proteolysis and consequently favors their absorption and digestibility.

Regarding the vitamins present in yogurt, although they can be metabolized by lactic acid bacteria, during the period of exponential growth they are also synthesized by the bacteria. The levels of fat-soluble vitamins depend on the fat content, and those of thiamine, riboflavin, vitamin B6, pantothenic and folic acid may be comparable or slightly higher, and vitamin B12 content lower, than those present in milk.

The most recent scientific evidence allows us to conclude that the consumption of fermented milks, in addition to favoring digestion in people who are partially lactose intolerant, enhancing immunomodulation, and maintaining body composition, are associated with a lower risk of diabetes, hypertension, CVD, or loss of bone mineral density (especially when supplemented with vitamin D). A reduction in the risk of breast and bladder cancer has also been observed, and it has not been possible to conclude that there is an association between the intake of fermented dairy products and the risk of prostate cancer, colon cancer, or all-cause mortality.

## Cheese

Cheese contains in concentrated form many of the nutrients of milk, caseins, fat and fat-soluble vitamins, colloidal minerals, and some whey constituents. Some of the water-soluble vitamins (up to 90%) may be gone in the whey, but the final levels in the cheese depend on their synthesis and utilization by microorganisms. During processing and in the first stage of the ripening process, the transformation of lactose into lactic acid takes place, which favors the action of rennet, facilitates the separation of whey, prevents the development of undesirable microorganisms, and regulates proteolysis and subsequent lipolysis.

Hydrolysis of proteins into peptides and amino acids, by residual rennet and microbial proteases, is perhaps the most important stage in the ripening of many types of cheese, as it affects both flavor and texture. The nutritive value of cheese proteins is not affected by processing and the bioavailability of lysine is comparable to that of total milk if the cheese incorporates the whey proteins, which is the case when used in the production of fresh cheese by membrane processes. During the ripening process, part of the caseins are hydrolyzed to peptides and amino acids. The decarboxylation of amino acids during cheese ripening can give rise to amines, but in general, the potential health risk is negligible, except in individuals with amine metabolism difficulties.

The fatty compounds formed during ripening by the action of microbial lipases, the free fatty acids in the first stage, contribute significantly to the aroma of the cheese. The Ca and P contents of cheese -except for those of acid coagulation- are much higher than those of milk, 4–5 times in fresh or soft cheeses, 7–8 times in a semi-hard cheese, and up to 10 times in hard cheese. The transformations that take place during cheese processing and ripening do not usually affect calcium bioavailability. On the other hand, scientific evidence collected in recent publications, on the relationship of cheese consumption with different fat contents on health, shows that there is no association or even an inverse association with cardiovascular risk and all-cause mortality. Cheese has a high content of proteins of high nutritional quality and calcium and contributes with significant health benefits, within the framework of a healthy diet.

## Cream and butter

Cream has been defined as milk rich in fat (fat emulsion in skimmed milk), with low levels of protein and lactose. There are different types of cream, depending on the fat content (from 12 to 55%) and the type of heat treatment. The concentration of vitamin A increases with the fat content; e.g. in 40% cream, it is 8–12 times higher than in milk.

Butter is essentially milk fat (82% fat) with 16% water and 2% non-fat solids. It is made from cream, sweet or acidified, and can be marketed with or without salt. In its preservation, the favorable effect of vitamin E and the unfavorable effect of copper levels, the type of packaging, and storage conditions have a decisive influence on the degree of protection of butter against oxidation. The vitamin A content can be very markedly reduced by storage in light-permeable containers.

## Role of milk and dairy products in disease prevention and health promotion

The relationship between diet and health has been known since ancient times, and there is increasing scientific evidence on the relationship between diet and the prevalence of chronic noncommunicable diseases such as obesity, metabolic syndrome (MS), CVD, type 2 diabetes mellitus (DM2), osteoporosis and even some types of cancer, but also for its impact on health promotion. Among the foods available in our diet, the role of milk and dairy products stands out for the wide range of nutrients present in their composition, such as fat, proteins, carbohydrates, minerals, and vitamins - with a good balance between their majority constituents -, which play a fundamental role in the diet of children, adolescents, and adults. Recent studies, moreover, consider milk as one of the most important sources of natural bioactive components and its health-promoting effects are the result of the interaction of all nutrients, which go beyond the simple sum of individual effects, and by the effect of its matrix that increases the bioavailability of many of its nutrients and bioactive compounds.

The most recent scientific evidence allows concluding that dairy products are vital in the stages of growth and development. In addition, they are not related to all-cause mortality, enhance the maintenance of body composition, promote the reduction of certain types of fractures and loss of bone mineral density, and their consumption is associated with a lower risk of MS, DM2, and CVD, as well as an anti-inflammatory effect, favor a reduction in the risk of breast, colorectal, bladder and liver cancer and no association with other cancers, and may play a beneficial role in improving cognitive function.

### Overall mortality

Considerable controversy exists regarding the association between milk and dairy consumption and mortality risk. In the available meta-analysis, relative risk ratios (RR) ranged from 0.96 to 1.01 per 200 g per day of dairy consumption, from 0.99 to 1.01 per 200–244 g of milk, and from 0.99 to 1.03 per 10–50 g of cheese (Cavero-Redondo et al., 2019). Yogurt intake equal to or greater than 200 g per day was significantly associated with a decrease in all-cause mortality. However, high-fat milk consumption was significantly associated with a higher risk of overall mortality, increased by 15%, CVD by 9%, and cancer by 17%. However, total dairy consumption was associated with a lower CVD mortality risk of 7%. Dose-response analysis has revealed a significant non-linear association of total dairy consumption with all-cause and CVD mortality (Naghshi et al., 2022)

### Pregnancy, maternal health, and newborns

The maternal diet should enable the mother to provide the nutrient reserves necessary for adequate fetal development, as well as good health and quality of life in childhood and later adulthood. Among the food groups, dairy plays a very important role in meeting these goals due to its high nutrient density and bioavailability, as well as its widespread consumption. There is evidence regarding maternal milk intake during pregnancy being positively associated with infant birth weight and length.

Regarding maternal health and during pregnancy, the benefits of yogurt consumption have been studied. It has been observed that the consumption of this product improves metabolic, inflammatory and infectious parameters associated with pregnancy, being remarkable the decrease in preterm births. The use of yogurt is promising as a nutritional supplement in pregnancy. In addition, the consumption of a greater amount of dairy products during pregnancy has been associated with higher birth weight and length of the baby at birth and with a lower risk of having small-for-gestational-age and low birth weight babies.

### Growth and development

The relationship between milk consumption during the pediatric age and increased linear growth and bone mineralization has been extensively studied. The consumption of dairy products during that period is justified to promote growth and development because they are sources of energy, macronutrients, and micronutrients, being remarkable in their contribution of protein, calcium, phosphorus, magnesium, and several vitamins.

The consumption of dairy products increases the secretion of insulin-like growth factor type I (IGF-1) which benefits skeletal development. Specific dairy compounds, such as some peptides derived from the hydrolysis of caseins, are believed to help calcium absorption from dairy foods to be more consistent throughout the day. In developed countries, a daily intake of 500 mL is recommended for children under 9 years of age, and for adolescents, an intake greater than 600 mL per day.

Dietary supplementation with dairy has been described to significantly increase bone mineral content during childhood. However, results regarding a possible association between dairy consumption and linear growth have been inconclusive.

### Weight gain

Several studies and metaanalysis have documented that dairy is not associated with weight gain, even when their intake was increased, including low-fat milk, whole milk, and cheese. On the opposite, it was reported that dairy consumption had little effect on body mass index (BMI), and led to a reduction in fat mass, an increase in lean body mass, and a decrease in waist circumference. When comparing the type of dairy products to prevent long-term weight gain, the best was yogurt followed by cheese and then milk. On the other hand, increasing total dairy intake without energy restriction in adults does not affect body composition. In the context

of an energy-restricted diet, however, increased dairy intake results in lower fat mass and body weight but has no conclusive effects on waist circumference or lean mass (Lopez-Sobaler et al., 2020).

Effects of dairy consumption on body weight and body composition have been inconsistently observed in randomized control trials (RCTs). In a meta-analysis that included 37 RCTs, dairy consumption decreased body weight, body fat, and waist circumference, among adults with energy restriction. Nonetheless, high dairy consumption in the absence of caloric restriction might increase body weight (Geng et al., 2018).

### Osteoporosis

Having adequate peak bone mass and maintaining it as long as possible is important to prevent osteoporosis. One of the most important sources of calcium is dairy. Milk should be consumed regularly at different stages of life to try to prevent bone loss.

Dairy product consumption is related to hip fracture risk, but numerous studies have found inconsistent results. Higher levels of dairy intake, compared to lower levels, are associated with a 5% decrease for osteoporotic fractures at any location, 13% for hip fractures and 16% for vertebral fractures. Regarding bone mineral density, studies described between 1.7 and 3% lower bone mineral density in young and postmenopausal women with low milk intake in their youth and a positive correlation between milk consumption and change in bone mineral density at the radius in women over 65 years of age.

Hip fracture risk reduction has also been studied concerning yogurt consumption, which is often associated with healthy lifestyles and dietary patterns that contribute to improved bone health. Accumulating evidence from studies following numerous individuals over a long period suggests that the risk of hip fracture may be maintained among people who consume dairy and that higher milk or yogurt consumption may be associated with a lower risk of hip fracture (Cuesta-Triana et al., 2019).

### Metabolic syndrome

MS is a set of clinical and biochemical alterations that result in altered carbohydrate and lipid metabolism with negative health consequences. It is defined as the presence of three or more CV risk factors: abdominal obesity, elevated blood pressure, elevated glucose and serum TAG concentrations and decreased HDL-cholesterol levels relative to normal ranges MS is associated with two of the most prevalent diseases worldwide, DM2 and CVD.

Numerous studies have associated the consumption of dairy products with a lower risk of MS. In a systematic review (SR) and meta-analysis, it could be observed that subjects who consumed higher amounts of total dairy products had a 27% lower risk of developing MS than people classified in the lowest consumption categories. Intake of low-fat dairy products and total yogurt consumption has been associated with a decreased risk of developing over time SM of 23% and 26%, respectively. It could be observed that, for one serving of yogurt consumed per day, there was a 23% decrease in risk. In the case of low-fat yogurt, a decrease of 28% was observed, and for the whole yogurt, 19%. Total milk consumption was associated with a 21% decrease in the risk of this disease.

### Diabetes and insulin resistance

Total dairy intake has been associated with a lower risk of DM2, especially for yogurt and low-fat dairy products, the association with cheese being more moderate. In a SR and meta-analysis, the scientific evidence indicated that higher total dairy consumption is associated with a decreased incidence of DM2 (between 9% and 14%). In addition, a decrease of 17–19% was observed for low-fat dairy products, 18% specifically for low-fat milk, and 14%–26% for yogurt. (Alvarez-Bueno et al., 2019). Analyses, according to the amount of consumption, showed a decrease in the risk of DM2 of 3%–7% for total dairy products (consumption of 200–400 g per day) and for low-fat dairy products, a decrease of 9%–12% (intake of 200 g per day).

Numerous investigations suggest that dairy intake, especially low-fat dairy products, presents a beneficial effect on an indicator of insulin resistance called HOMA-IR (Homeostasis Model Assessment-Insulin Resistance), waist circumference, and body weight.

### Cardiovascular disease (CVD)

Among the dairy components with the greatest relevance in CVD, the following stand out:

#### Dairy proteins

The major dairy proteins, caseins, and whey proteins, contain all the essential amino acids and have high digestibility and biological value, and are therefore defined as high-quality proteins. Due to their high lysine content, milk proteins can complement proteins from other foods, such as cereals. In addition, during the process of gastrointestinal digestion or by enzymatic hydrolysis during fermentation and ripening of fermented milks and cheeses, "bioactive peptides" with important biological activities are generated, among which is their antihypertensive capacity, by inhibition of the angiotensin-converting enzyme (ACE), which is associated with a reduction of blood pressure (BP) and lower risk of hypertension and CVD. Therefore, milk proteins in isolation, or together with other milk components, such as mineral elements, are associated with a lower risk of hypertension. These functionalities of peptides in human health and physiology also include antimicrobial, antioxidative, antithrombotic, opioid, anti appetite,

immunomodulatory, and mineral-binding activities. The results of several clinical studies and meta-analyses have shown that milk proteins alone, or together with other milk components such as mineral elements, are associated with a lower risk of hypertension.

### **Milk fat**

As stated before, unlike other animal fats, the exclusive presence in milk fat of short- and medium-chain fatty acids (from C4 to C10), has been shown to not affect LDL-cholesterol levels in the blood. In addition, TAG from these FA in the diet are hydrolyzed during digestion and absorbed from the intestine into the circulatory system without TAG resynthesis. Hence, they are used as a fast source of energy, have a low tendency to accumulate in adipose tissue, and are therefore recommended in weight control programs, and increasing their intake increases muscle mass and reduces the percentage of body fat. The stearic acid (C18) in milk fat (10%–12%) is considered neutral from the viewpoint of human health, although it is undoubtedly effective for reducing plasma cholesterol as well as oleic acid, also present in milk fat in high concentrations, as has been mentioned. Therefore, only a third of the concentration of FAs present in milk, corresponding to the SFA C12, C14, and C16 (lauric acid, myristic acid, and palmitic acid), could be considered detrimental if consumed in excess. Recent research has shown that milk matrix components, mainly calcium, peptides, phosphorus, and fat globule membrane modify the blood lipid response to SFA intake (Thorning et al., 2017). As a result, these SFA considered hypercholesterolemic would have no impact on CV health parameters when supplied in the dairy matrix. Milk fat, and especially goat milk fat, also has methyl-branched saturated acids, the importance of which is due to their anticancer properties, reported in tumor cell cultures and maintenance of microbiota and the inhibition of growth of some tumors in animal models. C15 and C17 FAs with an odd-numbered chain of carbon atoms are considered biomarkers of consumption of dairy fat and have been used to document non-association or even a protective effect against type 2 diabetes and CVD. The presence in milk fat of naturally occurring TFA has also been described, although scientific evidence concludes that consumption of moderate amounts - less than 1% of energy - does not contribute to increased CV risks.

In the last decade, a large number of clinical studies have been conducted on the effect of dairy consumption and CVD. Dairy consumption, regardless of fat content, is not associated with an increased risk of CVD. In a SR and meta-analysis study regarding the effect of dairy consumption with CVD, it is concluded that there is no association of whole or skimmed dairy consumption, including dose-response studies, with CVD and, in addition, an inverse association with stroke was found (Fontecha et al., 2019). This study also reports that dairy consumption has a moderate effect on risk factors associated with CVD, especially blood pressure and plasma lipids, decreasing systolic and diastolic blood pressure and LDL-cholesterol (Fontecha et al., 2019). Along the same lines, according to data obtained in other studies to estimate associations between specific dairy product substitutions and risk of myocardial infarction (MI), it was concluded that intake of whole yogurt or cheese, regardless of fat content, was associated with a lower risk of developing MI. Indeed, it is clear that the health effects of saturated fats seem to depend on the food source, and whole or low-fat dairy products have no impact on or protection against CVD when consumed in moderation and as part of a varied and balanced diet. Therefore, current dietary recommendations recognize the contribution of dairy products to a healthy diet, since their consumption involves raising the levels of multiple nutrients, mineral elements, vitamins and proteins of high nutritional quality, without risk of CVD, hypertension and general mortality.

### **Minerals**

In recent years, many publications have reported scientific evidence of the benefits of consuming calcium-rich dairy products, with health claims approved by the EFSA-EU, not only in dental health and osteoporosis prevention, in weight control and body mass index (especially in obese individuals), but also protection against hypertension and cardiovascular risks. In this context, it has been reported that diets with high levels of calcium gave rise to greater fecal excretion of fat and they correlated with benefits in cardiovascular markers such as lower levels of total cholesterol and LDL-cholesterol. In addition, other elements are present in milk in very small quantities; some of them are indispensable in nutrition and their content can be increased by external factors.

## **Cancer**

### **Breast cancer**

Breast cancer is the most common cancer in women with almost 1.7 million new cases diagnosed in 2012 and is the second most common cancer overall. This represents about 12% of all new cancer cases and 25% of all cancers in women.

Regarding breast cancer, in an SR it was observed that a higher intake of milk and dairy products was associated with a lower risk of breast cancer in most studies. To better understand whether dairy consumption may influence the risk of developing this type of cancer, more research is needed on the biological mechanisms, including the relationship of different dairy products with hormones, as well as the study of other bioactive components contained in these foods.

### **Colorectal cancer**

Colorectal cancer (CRC) is the third most commonly diagnosed malignancy and the fourth leading cause of cancer-related death worldwide. In 2017, 1.8 million incident cases of colon and rectal cancer were diagnosed, and 896,000 deaths occurred. The global CRC burden is estimated to increase by 60% to over 2.2 million new cases and 1.1 million deaths by 2030.

High dairy consumption has been associated with a lower risk of developing CRC in any anatomic location. In an SR and meta-analysis with 15 cohort studies and 14 case-control studies (>22,000 cases), a significant and consistent decrease in CRC risk associated with higher dairy consumption, approximately 20%, compared with lower consumption was observed. These studies also showed a protective association between low-fat milk consumption and colon cancer, 27%. Cheese consumption was associated with a 15% lower risk of CRC and 26% lower risk of proximal colon cancer. Low-fat milk intake was associated with a lower risk of CRC. Cheese consumption was associated with CRC prevention, specifically proximal colon cancer (Barrubés et al., 2019).

In another meta-analysis of 31 prospective cohort studies, which included 24,964 and 2302 cases for CRC incidence and mortality, respectively, a 29% lower risk of death from CRC in subjects with high dairy consumption compared with those with low intakes of dairy products was found, but each type of dairy consumption did not show a significant association (Jin et al., 2020).

Moreover, numerous studies have suggested that calcium-rich foods, such as dairy, may have a more effective role than calcium in the form of supplements concerning the risk of colorectal adenomas (CA).

### Ovarian cancer

Ovarian cancer is one of the most common cancers in women, accounting for 2.5% of all malignancies. In 2018, 295,414 new cases and 184,799 deaths from ovarian cancer were reported worldwide. Of all gynecological malignancies, this cancer is the one associated with the worst prognosis.

Results on the role of dairy, calcium, and vitamin D on ovarian cancer risk remain controversial. Some evidence suggests that whole milk intake may contribute to an increased risk of ovarian cancer, whereas low-fat milk, dietary calcium and vitamin D, may reduce it. In a SR, in comparisons of higher versus lower intakes, it was observed that a high intake of whole milk was associated with an increased risk of ovarian cancer, a 35% increase. However, a decreased risk was observed at the highest intakes of low-fat milk, 16% decrease and dietary calcium and vitamin D, 29% and 20%, respectively. For every 100 g per day increase in consumption, higher risks of ovarian cancer were found for total dairy products, 3% increase and for whole milk 7% increase. However, lower risks were observed for 100 g per day increase in consumption of low-fat milk (5%), cheese (13%), dietary calcium (4%), total calcium (2%), and dietary vitamin D (8%).

### Liver cancer

Primary liver cancer is ranked as the sixth most common form of cancer worldwide and the third leading cause of cancer death, with approximately 800,000 cases in 2012. Analysis according to amounts consumed showed that the risk of liver cancer decreased by 5.4% with an increase of 40 g per day of yogurt consumption.

### Prostate cancer

According to the latest IARC report, prostate cancer is the second most common cancer in men worldwide, with more than 1.1 million new cases diagnosed in 2012 and 307,000 deaths recorded, accounting for 15% of diagnosed cancers. In more developed regions, prostate cancer is the most frequent cancer in men (759,000 cases).

The literature on the association of dairy consumption and the risk of developing prostate cancer is controversial and limited. The overall positive association between milk consumption and the risk of prostate cancer development and prostate cancer mortality has been documented in multiple epidemiological studies. However, there is limited literature on the association between types of milk, as classified by fat content (skim, low fat, and whole), and the risk of developing prostate cancer. In an SR it was observed that high consumption of total dairy products compared to low consumption accounted for a 7% increased risk of developing this cancer (400 g per day). No significant associations were found for all types of milk and cheese. Further research is needed to examine the relationship between dairy consumption and the increased risk of prostate cancer that has been observed in some studies due to numerous controversies.

### Bladder cancer

According to the International Agency for Research on Cancer (IARC), bladder cancer is the ninth most common cancer worldwide, with 430,000 new cases diagnosed in 2012 (3% of all new cancer cases).

An SR and meta-analysis observed that average total dairy intake compared to low intake was associated with a lower risk of bladder cancer (10%). Milk intake also reduced the risk by 10% and fermented dairy products by 13%. High consumption, compared to low, was significantly associated with a lower risk of this cancer: for milk, a decrease of 11% and for fermented dairy products, a decrease of 12%. However, high compared to low consumption of whole milk was significantly associated with a higher risk (21% increase). Another recently published meta-analysis has described that the intake of milk and dairy products decreases the risk of bladder cancer (Wu et al., 2020).

### Cognitive function

The activity, functioning, and maintenance of the nervous system depend substantially on the nutrients that are incorporated in the daily intake. Although the importance of breastfeeding for the cognitive development of the infant is well known, recent studies

indicate that dairy consumption also supports proper brain function during adulthood and later life. Milk components with action on brain function mechanisms include calcium, proteins, especially  $\alpha$ -lactalbumin, bioactive peptides, vitamin B12, and the phospho- and sphingolipids of the MFGM, which affect different aspects of the nervous system, such as learning and memory abilities, mood maintenance, as well as their potential activity in the prevention of age-related cognitive decline (Bermejo-Pareja et al., 2020). Thus, clinical studies have shown that dairy consumption in adults, in addition to increasing nutrient intake, also has a positive impact on the performance of cognitive functioning. Dairy proteins provide all the essential amino acids essential in the synthesis of neurotransmitters and neuromodulators that contribute to proper brain function. Alpha-lactalbumin ( $\alpha$ -La) is a good source of tryptophan and cysteine, precursors of the neurotransmitter serotonin and glutathione respectively.

Longitudinal nutritional studies included in a SR, describe that, both in the adult population and in the elderly, those individuals who consumed dairy products had a better global cognitive function which they explain as a consequence of the nutritional contribution of dairy products and especially by components such as vitamin B12, calcium and vitamin D that have been associated with neuroprotective, antioxidant and anti-inflammatory effects. The lipids in MFGM have been shown to provide important benefits to nervous system functions such as memory by reducing the risk of senile dementia and cognitive dysfunction in old age. These lipids also appear to play an important role in immune-related diseases and anti-inflammatory responses. Among the different PL, phosphatidylserine and sphingomyelin present in MFGM have been linked to positive effects on diseases such as Alzheimer's disease, depression, and stress. Clinical trials have been conducted using MFGM concentrates and the results are encouraging and would allow MFGM to be considered as a potential bioactive ingredient in functional foods. In conclusion, these studies suggest that dairy products may play a beneficial role in improving cognitive function and thus aid thought processing and mental capacity.

## Conclusions

Milk and dairy products provide practically all the essential nutrients for the different stages of life, especially during childhood and adolescence, but also in adulthood. Milk is still considered the most complete food from a nutritional point of view, providing proteins with all the essential amino acids and high bioavailability, fat with a great variety of short and medium-chain fatty acids, and carbohydrates such as lactose, as well as a great contribution of minerals and vitamins. All this in a balanced and low caloric value.

Excessive consumption of milk and dairy products is associated with several chronic diseases, mainly CVD and some cancers. However, that moderate dairy consumption has many benefits on health outcomes. Indeed, milk and dairy contribute to the maintenance of body composition, favor the reduction of some types of fractures and loss of bone mineral density, and their consumption is associated with a lower risk of MS, DM2, and CVD, as well as an anti-inflammatory effect, they favor a reduction in the risk of breast, colorectal, bladder, and liver cancer and there is no association with other cancers or all-cause mortality. Finally, they may play a beneficial role in improving cognitive function. Therefore, the most recent scientific evidence allows us to conclude that dairy products are vital in all stages of growth and development.

## Key points

- To obtain an overview of the toxicity of major mycotoxins
- To have information about the occurrence and human exposure to mycotoxins
- To understand the process of mycotoxin risk assessment
- To have information about mycotoxin regulations
- To know the mitigation processes for reducing the presence of mycotoxins

## Introduction

Mycotoxins are secondary metabolites produced by microfungi, capable of causing diseases and death in humans and animals. The chemical structures of mycotoxins vary considerably, but they are all relatively low molecular mass organic compounds (Fig. 1).

The untoward effect of fungi was known in ancient times. In the seventh and eighth centuries BC the festival “Robigalia” was established to honor the god Robigus, who had to be propitiated to protect grain and trees. It was celebrated on April 25th because that was the most likely time for crops to be attacked by plant rust diseases or mildew. In the Middle Ages, outbreaks of ergotism caused by ergot alkaloids from *Claviceps purpurea* reached epidemic proportions, mutilating and killing thousands of people in Europe. Ergotism was also known as *ignis sacer* (holy fire) or St Anthony’s fire because, at the time, it was thought that a pilgrimage to the shrine of St Anthony would bring relief from the intense burning sensation experienced. Renewed interest in mycotoxins as causing diseases resulted from the death of thousands of turkeys and ducks, named Turkey X disease in England in the early 1960s. The animals were fed diets containing peanut meal contaminated by aflatoxins (AFs), produced by the fungus *Aspergillus flavus* (Janik et al., 2020).

The use of certain molds in the production of cheese and salami and in the fermentation of beer and wine has a long history. Molds are also used in the production of drugs. The classification of mold metabolites as antibiotics or mycotoxins is based on their toxicity or beneficial effect in treating diseases.

Mycotoxin-producing molds may grow on many foods before or after harvest, during storage, especially in hot and humid environments. Most mycotoxins are chemically stable and persist after food processing. Several hundreds of mycotoxins have been

**Fig. 1** Structures of major mycotoxins.

identified, but the most common concerning human and livestock health are AFs, ochratoxin A (OTA), fumonisins (FBs), zearalenone (ZEA), patulin, (PAT) and trichothecenes T-2 and HT-2, and deoxynivalenol (DON).

Mycotoxins appear throughout the entire food chain, from field crops to raw or processed food and feed. Some unprocessed foods susceptible to mycotoxin contamination and contributing to exposure include cereals, oilseeds, fruits, vegetables, nuts, dried fruits, coffee beans, cocoa beans, and spices. As mycotoxins are not destroyed during processing, cereal-based products (bread, pasta, breakfast cereals, etc.), beverages (wine, beer, coffee, cocoa, juices, etc.) are important sources of exposure to mycotoxins, as are foods of animal origin (milk, cheese) and baby foods (Table 1).

Despite many years of research and the introduction of improved agricultural and manufacturing practices in the food chain, mycotoxin occurrence remains a global problem. Significant economic losses are associated with their impact on human health, animal welfare and productivity, and both domestic and international trade. Regulation of mycotoxins varies in the different regions of the world. At the global level, the Codex Alimentarius Commission of International Food Standards, the joint inter-governmental body of the Food and Agriculture Organization (FAO) and World Health Organization (WHO), is the main operator in standard setting. Because compliance with mycotoxin concentrations in food and feed maximum limits (MLs) allows food and feed business operators to place their commodities on the market, a large amount of analytical occurrence data is generated for this purpose.

## Toxicity

Chemical structures and characteristics of major mycotoxins are shown in Fig. 1 and Table 1. A broad range of adverse health effects have been identified for mycotoxins in animals and humans (Marin et al., 2013)

Aflatoxins are acutely and chronically toxic compounds. AFB1 is a hepatocarcinogen, one of the most potent known, and long-term chronic exposure to very small amounts of this toxin through the diet has important consequences for human health. AFB1 is a potent chromosome-damaging mutagen in a variety of plant, animal, and human cells. The carcinogenic effect of AFB1 has been studied in at least 12 different species and AFs are classified by IARC as a group 1 carcinogen. Slightly less potent as liver carcinogens than AFB1, and acting more as renal carcinogens, AFG1 and M1 appear to be toxicologically similar to AFB1, although they have not been studied extensively. Among the subacute and chronic effects of AFs are liver cancer, chronic hepatitis, jaundice, hepatomegaly

**Table 1** Main characteristic of major mycotoxins and US-EU limits.

Mycotoxin	Fungal species	Food commodity	Toxic effects	US FDA ( $\mu\text{g/kg}$ )	EU ( <sup>a</sup> $\mu\text{g/kg}$ )
Aflatoxins B1, B2, G1, G2	<i>Aspergillus flavus</i> , <i>A. parasiticus</i> , <i>A. nomius</i>	Maize, wheat, rice, peanut, sorghum, pistachio, almond, ground nuts, tree nuts, figs, cottonseed, spices	Liver cancer, chronic hepatitis, jaundice, hepatomegaly, cirrhosis	20 for total	2-12 for B1 4-15 for total
AFM1	Metabolite of AFB1	Milk, milk products	Possible carcinogen	0.5	0.05 milk 0.025 in infant formulas and infant milk
Ochratoxin A	<i>Penicillium verrucosum</i> , <i>P. nordicum</i> , <i>A. ochraceus</i> , <i>A. carbonarius</i>	Cereals, dried vine fruit, wine, beer, grapes, coffee, cocoa, cheese	Carcinogenic, nephrotoxic, teratogenic, immunotoxic, and possibly neurotoxic properties	Not set	2-10
Fumonisin B1, B2, B3	<i>Fusarium verticillioides</i> , <i>F. proliferatum</i>	Maize, maize products, sorghum, asparagus	Neurotoxic effect Possible carcinogens	2000-4000	200-4000
Deoxynivalenol	<i>F. graminearum</i> , <i>F. culmorum</i> , <i>F. cerealis</i>	Cereals, cereal products	Decrease in growth and weight gain, immunotoxicity	1000	50-200
T-2, HT-2	<i>F. langsethiae</i> , <i>F. sporotrichioides</i>	Maize, wheat, barley, oat, rye	Immunotoxicity	15	25-1000
Zearalenone	<i>F. graminearum</i> , <i>F. culmorum</i> , <i>F. equiseti</i> , <i>F. verticillioides</i>	Cereals, cereal products, maize, wheat, barley	Hyperestrogenic effects, reproductive toxicity	Not set	20-100
Patulin	<i>P. expansum</i> , <i>A. clavatus</i> , <i>P. patulum</i>	Apples, apple juice, and concentrate, pears, peaches, grapes, apricots, olives low acid fruit juices	Harms liver, kidney, intestinal tissues and immune system	50	10-50

<sup>a</sup>(EC, 2006)

and cirrhosis, caused by the frequent ingestion of small amounts present in food. AFs can also affect the immune system (Cimbalo et al., 2020).

Ochratoxin A is a powerful toxin mainly affecting the kidneys, where it can cause acute and chronic effects, depending on the dose exposure and duration, as OTA accumulates in kidney tissues. Its nephrotoxic capacity has been demonstrated in all mammalian species in which it has been evaluated. Studies on its acute toxicity show different degrees of affect, depending on the animal species exposed. Dogs and pigs are especially susceptible. OTA has been shown to be a potent teratogen in mice, rats, hamsters, and chickens but, apparently, not in pigs. Its teratogenic and reproductive effects have been demonstrated. It is also known to affect the immune system in some mammals. It is genotoxic both *in vivo* and *in vitro*, but the mechanism by which it is genotoxic has not been established. Ultimately, OTA is a mycotoxin with carcinogenic, nephrotoxic, teratogenic, immunotoxic, and possibly neurotoxic properties. OTA has a long half-life in humans.

Effects of Fumonisin have been observed for years in the form of a fatal disease in horses and related species, called equine leukoencephalomalacia. Compared with AFs based solely on the dose necessary to produce acute poisoning, fumonisins have lower toxic capacity, but FBs in corn can reach very high concentrations, even higher than 300 mg/kg. The toxicity of FBs is mainly due to their effects on the synthesis of sphingolipids in neurons. Alterations in the synthesis of these sphingolipids occur almost immediately after oral FB exposure through contaminated product. The range of effects that FBs can produce in mammals is dependent on the species. For example, affected equines start losing their appetite, then appear lethargic and develop neurotoxic effects after consumption of contaminated feed. Generally, the liver is also affected and, in severe cases, significant liver lesions with fibrosis can be seen in areas of the central lobe. Porcines induce pulmonary edema and hydrothorax. In rats, the development of hepatocellular carcinomas has been observed. Further, FB1 has shown effects on fetuses in pregnant rats, decreasing litter weight and affecting bone development. In humans, there appears to be a relationship between consumption of highly contaminated corn in some parts of the world (China and South Africa) and development of esophageal cancer, but more studies are needed for confirmation.

Acute Deoxynivalenol intoxication in pigs is characterized by the appearance of vomiting (hence the common name as vomitoxin), rejection of feed, weight loss and diarrhea. Acute poisoning can produce necrosis in various tissues, such as the gastrointestinal tract and the lymphatic system. Subchronic oral exposure to DON in experimental animals (pigs, mice, rats) can also cause rejection of food and decreases in growth. Studies also suggest that DON may have effects on the immune system. However, there is no evidence that this toxin has carcinogenic, mutagenic or teratogenic effects. Symptoms of food poisoning in humans caused by consumption of DON contaminated wheat (0.34–8.4 ppm) in India in 1987, included abdominal pain, dizziness, headache, throat irritation, nausea, vomiting, diarrhea and presence of blood in the stool.

The T-2 toxin inhibits protein, RNA and DNA synthesis, and other biochemical mechanisms that can alter the integrity of cell membranes, synthesis of immunoglobulins and, therefore, humoral immunity. The immune system is most affected by the action of these toxins, which can increase susceptibility to infection. Alterations of cell membrane functions and lipid peroxidation are

responsible for many of the acute effects of T-2 and HT-2 toxins, including the necrotic lesions seen in contact areas. Apoptosis in tissues that are renewed with a high growth rate (such as bone marrow - inhibition of hematopoiesis) and in the immune system is responsible for the systemic toxicity that follows dietary exposure. T-2 toxin is rapidly metabolized into other products, with HT-2 toxin as the main metabolite. The metabolic processes are varied (hydrolysis, hydroxylation, etc.) and the distribution and excretion of the T-2 toxin and its metabolites is rapid. There is no significant information on the toxicity of most of its metabolites. T-2 and HT-2 are toxic to all animal species and to humans. Historical cases of intoxication in humans associated with the consumption of moldy cereal stored throughout the winter are described as alimentary toxic aleukia, characterized by sepsis, hemorrhages and general pancytopenia. The significant differences in sensitivity to T-2 and HT-2 toxins between monogastric and ruminant species are attributable to the effective presystemic elimination of the toxins exerted by the microbial flora of the rumen.

The most important effects of Zearalenone are on the reproductive system. The ability of ZEA to cause hyperestrogenic effects, particularly in sows, has been known for many years. Feeding breeding sows with a diet containing 50 mg/kg of pure ZEA caused abortions and stillbirths, while 10 mg/kg reduced litter size and weight of the piglets. Trials with less contaminated diets (0.25 mg/kg or less) showed different effects on the reproductive system of the sows. The pig has been shown to be the most sensitive domestic animal to ZEA, but effects have also been reported in calves, cows, and sheep. Studies to determine the subacute and sub-chronic toxicity of ZEA on various species for exposure times greater than 14 weeks show that most effects are due to its estrogenic capacity. The estrogenic capacity and potency of ZEA has been compared to other estrogenic derivatives of plants, suggesting that ZEA is one of the most potent natural xenoestrogens. Studies to determine the genotoxic and carcinogenic capacity of ZEA show that results appear to be highly dependent on the species. Although ZEA was considered as the possible causal agent of the outbreak of precocious pubertal development in thousands of girls registered in Puerto Rico, more studies are needed to confirm or not possible genotoxic and carcinogenic effects in humans. It has also been suggested that it may increase risk of cervical cancer.

Patulin harms liver, kidney, intestinal tissues, and the immune system by increasing ROS production and oxidative stress in mitochondria, and activating the unfolded protein response in the endoplasmic reticulum. Several studies have demonstrated its cytotoxicity, embryotoxicity, chromosomal aberration, DNA damage, and micronucleus formation. Patulin acute and sub-acute toxicities have been analyzed in mice and fish. Its exposure in humans is associated with immunological, neurological and gastrointestinal effects.

## Occurrence and human exposure of mycotoxins

The presence of mycotoxins in food for both human and animal consumption is an issue of concern for health authorities. Factors that health authorities must consider include the large number of existing mycotoxins, which belong to different chemical families, and the limited knowledge regarding the interactions that occur among them and with other toxic substances present in food. Generally, mycotoxin prevalence in feed samples is higher than in food. Cereals have been the most analyzed type of food for mycotoxin detection around the world (Alshannaq and Yu, 2017).

In the last century, mycotoxin allusion was exclusively made to the large families (AFs, OTA, FBs, trichothecenes, ZEA and some of their metabolites) and in relatively high quantities while using liquid chromatography coupled to ultraviolet and fluorometric detection systems. Today, advances in extraction, purification and concentration methods, coupled with widespread use of detection systems based on tandem mass-mass spectrometry, enable detection in the ng/Kg, including the classic mycotoxins, as well as emerging ones (enniatins, beauvericin, fusaproliferin and alternaria), together with the derivatives that are present in food (glucurunoconjugated, sulfated, hydroxylated, acetylated) known as modified mycotoxins. Therefore, the spectrum of compounds classified as mycotoxins is becoming broader. Analytical reports point to occurrence percentages in crops, ranging from 50 to 90% containing at least one mycotoxin, with about half displaying multiple contamination at any detectable concentration.

Mycotoxin values have been detected in raw and ready-to-eat foods in different quantities, resulting from agricultural handling, factory treatment, preservation efforts and packaging. Values provided in reports from scientific institutes and enterprises are the product of analyses carried out at a precise moment and may vary from one region and year to another for the same crop or product. For example, AF prevalence in unprocessed food-grade cereals has been estimated at around 55%, oscillating from 15% in America to 63% in Asia, with 10% in cashew nuts to 40% in pistachio and Brazil nuts, 45% in dried figs, and 53% in coffee. Prevalence varied for OTA, depending on the type of food crop, but was approximately 70% for beer, 50% for cereals (from 20% in Europe to 42% in America), and 36% in coffee. FBs have been found in approximately 70% of maize samples worldwide. T-2 and HT-2 toxins have been globally detected in cereals, ranging from 71% to 10% in barley, 100%–4% in rice and 22%–1% in maize. DON occurrence was 50% in oats, 70% in barley, wheat and rice and 90% in maize, 60% in beer and 43% in coffee. Worldwide incidence of 46% ZEA was calculated in cereals, being the lowest in Asia (15%) and the highest in Africa (59%).

Studies to assess the presence of mycotoxins are usually based on the analysis of one mycotoxin in one type of food although, in recent years, multi-mycotoxin analyses have become widespread. Foods may simultaneously contain several mycotoxins produced by fungi of different species. Co-occurrences found varied from 2 to 8 mycotoxins in the same food. For example, co-occurrence was found in durum wheat from Italy in 70% of the samples, of which 35% contained 3 enniatins. In wheat-based foods from Spain, 10% of the samples contained DON plus HT-2 or NIV. Livestock feedstuffs showed co-occurrence in at least 85% of the samples analyzed and, of these, 22% contained 5 mycotoxins and 4% eight mycotoxins. As one of the food safety agencies' concerns is to know the total intake of a certain mycotoxin, analytical approaches are carried out on a certain set of foods consumed during 24 h by a specific subset of the population. Therefore, all these studies lead to a partial knowledge of reality.

Food undergoes various treatments, mainly thermal, before being consumed and heat generally affects mycotoxins by hydrolyzing them. Therefore, concentrations in ingested food are lower than before preparation. Another aspect that deserves attention is the bioaccessibility and bioavailability of mycotoxins in humans and animals. Foods that generate a higher fecal content, due to the presence of indigestible substances, mainly dietary fiber, have a greater capacity to retain mycotoxins and, as they do not solubilize in the intestinal lumen, they are not accessible to the intestinal barrier cells. In addition, not all mycotoxins soluble in intestinal fluids are absorbable and only a percentage reaches the bloodstream, usually less than 50% and sometimes not even 10%, due to the different compound polarities presented, even within the same chemical family.

As occurrences in food are uncertain and variable, human biological monitoring for mycotoxin exposure through biological fluids is a useful tool. The most studied mycotoxin biomarkers are: AFB1 adducts with albumin or lysine (AFB1-alb and AFB1-lys) in human plasma, AFB1-N7-guanine in urine, OTA and its metabolite OTα in urine, plasma, serum and blood and DON-glucuronides in urine. It should also be highlighted that human breast milk samples in Spain contained ZEA, HT-2 and NEO and AFM1. Importantly, in countries such as Tanzania, Mexico, Iran and Jordan, AFM1 has been detected in 100% of the samples analyzed. OTA has also been found in Chile, Turkey and Italy.

## Exposure and risk assessment of mycotoxins

Risk assessment is the process of quantifying the magnitude and exposure, or probability, of a harmful effect to individuals or populations from certain agents or activities. There are four steps: hazard identification, dose-response or hazard assessment, exposure assessment, and risk characterization. Risk assessments using these principles have been conducted on the major mycotoxins as AFs, FBs, OTA, DON, and ZEA by various regulatory agencies for the purpose of setting food safety guidelines (Table 1). Apart from the well-established risk posed by aflatoxins, many uncertainties still exist about risk assessment for other major mycotoxins, often reflecting a lack of epidemiological data. Differences exist in risk management strategies, and in the ways different governments impose regulations and technologies to reduce mycotoxins in the food-chain. Regulatory measures have little impact on remote rural and subsistence farming communities in developing countries, in contrast to developed countries, where regulations are strictly enforced to reduce and/or remove mycotoxin contamination (IARC, 2012).

### Exposure assessment

Exposure to mycotoxins depends on the level of these substances in different foods and on the intake of those foods. Large national and regional differences in the intakes of foods mean that exposure assessments are country specific. Monitoring data for food commodities of concern over several years provide data on levels. Estimates may then be refined by considering further modifications to the levels of mycotoxins in foods as consumed, including information on manufacturing and processing both by industry and at home. These may be calculated for different age or target groups.

The risk of dietary exposure to mycotoxins for consumers has been the objective of numerous recent studies. In general, two approaches are used to estimate human-mycotoxins exposure. The first and the most widely used method involves integrating mycotoxin levels in food samples with food consumption data. These results are further standardized by dividing by average human body weight (60 kg for adults) and expressed as ng/kg body weight/day (ng/kg bw/d). Dietary data are typically obtained through dietary intake surveys using 24 h recalls or food frequency questionnaires. The European Food Safety Authority (EFSA) has developed detailed guidelines for dietary data collection and processing for risk and exposure assessment purposes (EFSA, 2009). An alternative approach, considered a more accurate way of measuring human-mycotoxin exposure, is by measuring mycotoxin biomarkers in human biological fluids.

### Risk assessment

Parameters of risk characterization of major mycotoxins are shown in Table 2.

### Aflatoxins

It has not been possible to establish a toxicological reference point for Afs, making approximations that led to underestimation of the toxicological reference point and, therefore, to overestimation of risk. Therefore, both the Joint FAO/WHO Committee on Experts in Food Additives (JECFA) and EFSA have adopted the margin of exposure (MOE) approach, which is the ratio between the dose (BMD) at which no adverse effects are observed (NOAEL) divided by the actual exposure to that substance through diet. The MOE approach provides an indication of the level of health hazard on the presence of a substance in food, without quantifying the risk. Using the MOE can help risk managers define possible actions necessary to keep exposure to these substances as low as possible.

As there is no real safe level of intake of AFs, it is not appropriate to establish a tolerable daily intake, therefore, the “as low as reasonably achievable” (ALARA) principle is applied for the legal limit. EFSA selects one BMDL10 of 0.4 µg/kg body weight for AFB1. For the AFM1, use a power factor of 0.1 in relation with AFB1. For AFG1, AFB2 and AFG2, the *in vivo* data are not sufficient to derive power factors. For aflatoxins, the same power as for AFB1 has been assumed, leading to an overestimation of risk for AFTs.

**Table 2** Major mycotoxins and risk characterization. MOE, margins of exposure. TDI, tolerable daily intake. PMTDI, provisional maximum TDI.

Aflatoxins B1, B2, G1, G2	The calculated MOE is below 10,000, particularly for the younger age groups, so EFSA concludes that a concern for the health of European consumers cannot be ruled out in light of these results.
Ochratoxin A	The estimated MOE for OTA is below 10,000 across most consumer groups, suggesting a possible health concern.
Fumonisin B1, B2, B3	2 µg/kg bw/day TDI based on increased incidence of megalocytic hepatocytes found in a chronic study in mice
Zearalenone and modified forms	0.25 µg/kg bw/day TDI based on estrogenic activity in pigs
Deoxynivalenol DON, 3-Ac-DON, 15-Ac-DON and DON-3-glucoside	1 µg/kg bw/day TDI based on reduced body weight gain in mice
H2 y HT2 and modified forms	0.02 µg/kg bw/day TDI based a reduction of total leukocyte count in rats
Patulin	0.4 µg/kg bw/day PMTDI based on a long-term toxicity/ carcinogenicity study in rodent species

In risk characterization, MOEs were below 10,000, particularly for younger age groups, so EFSA concluded that there was no concern for the health of European consumers in view of these results. The MLs in food and feed has been established by Regulation (EC) No. 1831/2006, being 0.1–2 µg/kg.

Contamination of AFs in human food is strictly regulated by the US. Food and Drug Administration (FDA) and AFs in cereals and cereal-based foods should be less than 20 µg/kg. Notably, AFs are the only group of mycotoxins with FDA established advisory and action levels. Some other countries have also set maximum level or limits of AFs in various foodstuffs.

In addition to the establishment of maximum limits in legislation, there are several Codes of Hygienic Practice at the international level in the Codex Alimentarius that help to reduce the presence of aflatoxin-producing fungi in certain foods.

### Ochratoxin A

EFSA experts have estimated a margin of MOE for OTA in food, considering possible human safety problems, including genotoxic and carcinogenic. EFSA concluded that current exposure levels posed a potential risk for the health of the majority of studied consumer groups. The calculated MOEs for non-neoplastic effects were above 200 in most of the dietary surveys for average and high consumers and, therefore, of low health concern. However, in high consumers, MOEs were below 200 in infants, toddlers and other children, indicating a possible health concern for these age groups.

Based on current risk calculations from foodstuffs in American marketplaces, there is negligible risk to the US population from OTA exposure. Current OTA concentrations are not high enough to elicit toxic effects, even at high intakes of the foods that may contain OTA. Exposure to OTA in the United States is highest among individuals less than 5 years of age, because of lower body weight and relatively higher consumption of oat-based cereals, however their lifetime cancer risk is considered negligible (Kuiper-Goodman et al., 2010).

### Fumonisin

JECFA has identified kidney and liver effects as crucial effects of fumonisin mediated toxicity, and established a provisional maximum tolerable daily intake (PMTDI) of 2 µg/kg bw/day. It must be noted that the mandate from the Commission for the present assessment concerns FB1 and FB2. However, occurrence data available covered the sum of FB1, FB2 and FB3. Considering that most toxicological assessments of PMTDI are derived from data with FB1, and the structural similarities of the different fumonisin derivatives, this is considered acceptable. The calculated exposure to in European countries was lower than the PMTDI, whereas exposure in toddlers and other children was above the PMTDI in several surveys. This indicates a concern for fumonisins exposure in toddlers and other children with high intakes of fumonisins in food, without the additional exposure from modified forms of fumonisins. However, the unexpectedly high contribution from wheat-based products to the total exposure is associated with high uncertainty, due to the low number of quantified results. This uncertainty also affects exposure estimates for their modified forms.

### Deoxynivalenol

Deoxynivalenol (DON) is a mycotoxin primarily produced by *Fusarium* fungi, occurring predominantly in cereal grains. The TDI of 1 µg/kg bw/day was established for DON by JECFA and EFSA, based on reduced body weight gain in mice with exposure to the sum of DON, 3-Ac-DON, 15-Ac-DON and DON-3-glucoside. A group-acute reference dose (ARfD) of 8 µg/kg bw/eating occasion was

calculated, based on epidemiological data from mycotoxicosis. Available occurrence data suggest that acute dietary exposures to the sum of DON, 3-Ac-DON, 15-Ac-DON and DON-3-glucoside were below the group ARfD of 8 µg/kg bw/eating occasion for all age groups of humans and, therefore, not considered an acute health concern. However, estimates of chronic dietary exposure to the sum of DON, 3-Ac-DON, 15-Ac-DON and DON-3-glucoside, based on available occurrence data, were above the group TDI of 1 µg/kg bw/day for infants, toddlers and other children and, to some extent, for adolescents and adults. The limited data on dietary habits of vegetarians, with data available for only five European countries, with few subjects in four of them, did not indicate notable differences in acute and chronic dietary exposure between the vegetarians and the general population.

## T-2 and HT-2

T-2 toxin (T2) and HT-2 toxin (HT2) belong to the group of compounds known as trichothecenes, which are part of the largest group of *Fusarium* mycotoxins, comprising more than 150 compounds. In 2017, EFSA published a scientific opinion on the appropriateness of setting a group health-based guidance value (HBGV) for T-2 and HT-2 and its modified forms. In an *in vivo* acute toxicity study, emetic events in mink exposed to T-2 and HT-2 were identified as critical effects for setting an ARfD of 0.3 µg/kg bw. Another *in vivo* subchronic toxicity study with rats identified a reduction in total leukocyte count as the critical effect for setting a TDI of 0.02 µg/kg bw. In food, the highest amounts of T-2 and HT-2 have been reported in grains for human consumption, particularly in oat-containing breakfast cereals. Very high levels have been reported for specific plant extract formula dietary supplements. In humans, the mean chronic dietary exposure to the sum of T-2 and HT-2 was highest in toddlers and infants. Among processed foods, the main contributors were cereal flakes, bakery products including, for acute exposure, breads and rolls. Among elderly adults, dietary supplements made an important contribution.

## Zearalenone

The main biological activity of zearalenone (ZEA) is its oestrogenicity, i.e. the ability to act like the endogenous steroidal sex hormone 17- $\beta$ -estradiol. ZEA was evaluated by JECFA in 2000, establishing a PMTDI of 0.5 µg/kg bw. In that same year, the European Scientific Committee on Human Nutrition (SCF) established a TDI 0.2 µg/kg bw. In 2011, the European Commission requested information from the European Authority to Food Safety (EFSA) on the safety of ZEA and possible risk to consumers in the event of a possible increase in the maximum level for this mycotoxin in breakfast cereals. In the human 2011 ZEA risk assessment from EFSA, (EFSA CONTAM Panel, 2011), a TDI of 0.25 µg/kg bw/day was derived from a non-observed effect level (NOAEL) of 10 µg/kg bw for estrogenic effects in immature gilts. The highest concentrations of ZEA were found in wheat bran, corn and products derived from these grains, such as corn flour or corn flakes. EFSA established a TDI for ZEA of 0.25 µg/kg bw and has considered extending this TDI to the group of ZEA and its modified forms (metabolites in Phase I and II). Dietary exposure estimates suggest that current exposure to ZEA may be close to the TDI.

## Patulin

At the international level, JECFA established a NOEL of 43 µg/kg bw/day and a PMTDI of 0.4 µg/kg bw/day for patulin, based on a long-term toxicity/carcinogenicity study in rodent species. In 2000, these values were adopted by the EU Scientific Committee for Human Nutrition (SCF) at the EU level. Apple containing products are the major source for patulin exposure, with major intake differences according to age and living region. Young children are most at risk of patulin intoxication, because they consume more apple products than adults.

## Mycotoxin regulations

Mycotoxin presence and dispersal across markets due to trade make it impossible to ban mycotoxins completely from food. Many countries have set levels that ensure consumer protection and food safety and keep the exposure to mycotoxins as low as possible. Tolerances, guidelines, and residue levels have been set in several countries and maximum admissible levels have been established for mycotoxins that occur in several food commodities, especially those traded and consumed extensively. Current regulations encompass 13 mycotoxins, and they are increasingly based on scientific opinions of authoritative bodies as JECFA, EFSA and FDA. Although efforts have been made, mycotoxin regulation is not global and many countries still lack of appropriate guidelines, particularly in Africa and Latin America. Owing to their significant toxicological impacts on both human and animal health, the focus on mycotoxins has been a high priority by the FAO and WHO.

Food legislation must protect both the health of consumers and economic interests of food producers and traders. Therefore, it is preferable to harmonize regulations, especially in countries with trade agreements such as the North American Free Trade Agreement (NAFTA) between the US, Canada, and Mexico, the European Union or MERCOSUR between Argentina, Brazil, Uruguay, Paraguay, and Venezuela, and to adapt uniform international food safety standards regarding mycotoxins. However, current mycotoxin regulations vary significantly, and the absence of a unified and transparent approach has led to a wide range of disparities in guidelines, with several differences in maximum admissible levels set in different countries. Further, in many developing countries, especially those facing food availability issues, regulations may not be present or, if present, not enforced (Barajas-Ramirez et al., 2021).

Regulations serve as a safeguard for food markets from contaminated imported commodities. In many cases, commodities are rejected due to food safety threats. For example, according to the European Commission Rapid Alert System for Food and Feed (RASFF) annual report, mycotoxins were the primary hazard in border rejection from non-EU countries in 2019, with 440 notifications. Strict regulations may create an economic imbalance and affect exporting countries, which may face difficulties finding new markets or maintaining their usual ones. This may also lead to an abundance of foods contaminated with mycotoxins in local markets in developing countries, particularly those with hot and humid climates.

## Mycotoxin mitigation

Prevention is the main tool to reduce the presence of mycotoxins in food and feed. Therefore, the development of toxigenic fungi in agricultural crops should be avoided through the use of Good Agricultural Practices. In 2003, the Codex Alimentarius established recommendations for the prevention and/or reduction of mycotoxins, including crop rotation, use of varieties resistant to toxigenic fungi and insects, control of water supply, use of suitable fungicides and insecticides, use of collection and transport equipment that avoid damage and free of fungal contamination, and control of humidity and temperature in the silo. However, when mycotoxin values still exceed the maximum limits established for human or animal consumption, reducing procedures based on the use of physical, chemical, and biological methods have been proposed. The application of these procedures should not alter the nutritional and organoleptic qualities of the food, while not leaving residues of any kind that could represent a hazard (Agriopoulou et al., 2020).

Physical procedures include ionizing radiation such as  $\gamma$  and X rays, which have been widely used to reduce aflatoxins in seeds, due to their penetration capacity. However, a large part of society rejects the use of ionizing radiation, although it is authorized in various countries. Non-ionizing radiation such as UV rays are effective only on the surface. Thermal inactivation generates partial results against the various chemical families of mycotoxins due to its varied heat resistance.

Chemical mitigation procedures are prohibited in the European Union due to the possibility of generating artifacts of unknown toxicity, although the use of oxidants such as chlorine, ozone, hydrogen peroxide and ammonization has been proposed. More recently, the use of natural substances present in food such as isothiocyanates from *Brassicaceae*, have been shown to form higher molecular weight complexes that present less toxicity *in vitro* by joining the amino and aldehyde groups of fumonisins and zearalenones. This may be an alternative in the future, provided that research releases more data about safety.

Biological methods are based on the addition to food of microorganisms capable of stopping fungal growth or transforming mycotoxins. Lactic acid bacteria (LAB) naturally present in food and in the intestinal flora are an important bet for the future. LABs affect the development of fungi by competing for space and nutrients, and also produce metabolites with antifungal activity, such as aliphatic and phenolic organic acids (lactic, phenyl-lactic, acetic, propionic, benzoic, 4-hydroxybenzoic, ferulic, vanillic, hydroxycinnamic) as well as ethanol, hydrogen peroxide, and diacetyl, which act by altering the plasma membrane of fungi to modify the electrochemical potential and increase its permeability. LABs also produce antimicrobial peptide compounds (AMP), whose mechanism of action is linked to their amphipathic character, which results in the ability to destabilize the phospholipids of the fungal membrane. The fermentation of the lacto-albumin and caseins of milk by *Lactobacillus spp.* produce AMP, which can contain from 3 to 20 amino acids with antimicrobial activity; their degradation by the proteases of the digestive tract would limit their action on the intestinal flora when they are used as food additives. The production of mycotoxins generally begins at the end of the fungal growth phase, and the direct influence of LAB and other fungal growth inhibitors lowers the presence of mycotoxins. In addition, LABs can reduce mycotoxins by adsorption, as polysaccharides and peptidoglycans surrounding the cytoplasmic membrane. Finally, LABs can also reduce the presence of mycotoxins through hydrolysis, specifically OTA is transformed into a non-toxic metabolite,  $\alpha$ -OTA, and an amino acid, phenylalanine.

For the detoxification of feed, additives capable of adsorbing mycotoxins and preventing their intestinal absorption are being widely used. Good results are seen with aluminosilicates, such as bentonites and zeolites, diatomaceous earth and activated carbon. However, they have the disadvantage of also adsorbing vitamins and trace elements and, therefore, cannot be used in high quantities. Naturally, not all adsorbents are capable of binding all mycotoxins, the chemical structure of both determine the possibility of interacting.

## Climate change

Fungal growth in crops depends on the plant species and various environmental factors, including temperature, humidity and the presence of insects. All of these are closely related to climate and, therefore, dependent on climate change. A temperature increase of 2–3 °C may change the presence of different species and genera of fungi. *Aspergillus flavus*, a predominant fungus in tropical and subtropical areas, is spreading to temperate areas as temperatures progressively increase, including in southern Europe and the Mid-western US. This is of concern, as it is generating production of aflatoxins in cereals and nuts, especially in corn. When temperatures of up to 37–40 °C, are reached, the synthesis of aflatoxins is inhibited. In contrast, a decrease in aflatoxins in maize is predicted in the Philippines, due to increased rainfall. In northern Europe, the DON-producing *Fusarium culmorum* was predominant in wheat and is being replaced by *F. graminearum*, a DON producer more typical of southern Europe, together with other *Fusarium* species that produce T-2 and HT-2 toxins, both more toxic than DON. Insects and other vectors influence the spread of fungal infections by

altering the outer layer of grain pods and ears. High temperatures may favor insect reproduction and their activity. In some temperate zones where winters are milder and summers are hotter, winter survival and the number of annual generations will increase. The change in climatic conditions at a global level will produce a migration of plant pests and diseases in the direction of the cooler latitudes. This may lead to the substitution of some species of fungi for others and the presence of different mycotoxins. Some researchers point to the possibility that a change from toxigenic species to others that do not produce mycotoxins may occur, especially in hot countries. Although the new fungus/host plant/geographical area combinations are of great interest regarding changes in mycotoxin production, there is currently insufficient knowledge for diagnosis. Omics and other new tools will provide keys for prediction and the fight in the dissipation of mycotoxins (Daou et al., 2021).

## Conclusions

Mycotoxins are the most abundant and abiotic toxins present in food, a significant risk to the health and well-being of humans and animals, and a food safety issue with potential for important economic losses. Although efforts to prevent mycotoxin formation have been undertaken, contamination of those secondary fungal metabolites still occur. The presence of mycotoxins in food is inevitable, and the complexity of these contaminants will possibly increase due to the influence of climate change. Furthermore, our ability to detect existing complex contaminants will develop with the increase in knowledge regarding the diversity of molecules and modified forms, their co-presence, and toxicological interactions. The entire population is exposed to mycotoxins but, given the high proportion of cereals in the diet with mycotoxins, children and high consumers are of greatest concern.

The application of Good Practices of Hygiene throughout the food production chain and MLs in food management are the most effective measures in reducing exposure to mycotoxins.

It is essential for toxicologists together with other health professionals to continue working on their knowledge, risk assessment and prevention with the collaboration of regulatory bodies.

## Key points

- Nutraceuticals are products falling between nutritional and pharmaceutical product categories.
- There is no clear and comprehensive definition for nutraceuticals approved by international authorities, which is needed to regulate their safety or therapeutic efficacy.
- Nutraceuticals are generally comprised of ingredients derived from foods and herbs.
- Health benefits of nutraceuticals must be substantiated by clinical evidence, with preclinical data used to support mechanisms of action.

## Introduction

Nutrition science has evolved from the provision of basic nutrition to support of essential functions and structures of the body for health promotion and disease prevention. Nutraceuticals are products derived from both food and non-food sources that are purported to provide health benefit in support of structure or function of the body, prevention and mitigation of diseases, delay of the aging process, and promotion of wellbeing. Many nutraceuticals are appreciated for their health benefits beyond basic nutrition in different systems of the human body, such as cardiovascular, immune, musculoskeletal, and nervous systems, via an array of mechanisms of action, including hypolipidemic, immune-modulating, antioxidant, anti-inflammatory, antitoxic or ergogenic effects. Popular nutraceuticals include cranberry, *Ginkgo biloba*, ginseng, green tea, glucosamine, lutein, micronutrients, omega-3 fatty acids, probiotics, and St. John's Wort. Although the pharmacological activity of most of these substances is well established in vitro or in small mammals, establishing clinical evidence poses a challenge for nutraceutical research. In this article, the health benefits of nutraceuticals with clinical evidence supported by meta-analysis are discussed.

## Nomenclature of nutraceuticals

The term “nutraceutical” is a portmanteau of 2 words, “nutrient” and “pharmaceutical,” first conceptualized in 1989 by Stephen L. DeFelice. More recently, a redefinition of this concept was made as “the phytocomplex if they derive from a food of vegetal origin, and as the pool of the secondary metabolites if they derive from a food of animal origin, concentrated and administered in the more suitable pharmaceutical form, which are capable of providing beneficial health effects, including the prevention and/or the

treatment of a disease" (Domínguez Díaz et al., 2020). Thus, nutraceuticals fall within the border of nutritional and pharmaceutical product categories. There is confusion related to the terminology of nutraceuticals, functional foods and dietary supplements. Nutraceutical is a term often used interchangeably with the term functional foods, but they are not truly interchangeable as the former refers to nearly any purified or isolated bioactive component delivered in a supplement form, while the latter includes products containing bioactive components in food form. Additionally, unlike functional foods, nutraceuticals may have a recommended daily dose.

According to FDA regulations, most nutraceuticals are categorized as dietary supplements under the authority of the Federal Food, Drug, and Cosmetic Act, even though they are not specifically defined by law in the US, and are widely used in the marketplace (Reader, 2019). The 1994 Dietary Supplement Health and Education Act (DSHEA) in the US defined dietary supplements as "a product taken by mouth that contains a dietary ingredient intended to supplement the diet." The dietary ingredients may include vitamins, minerals, herbs, botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, or metabolites./ Importantly, dietary supplements in the US are not allowed to claim to treat, mitigate or cure diseases or conditions, but only to be marketed to support the structure or function of the body. The Food Directorate of Health Canada (Canada, 2002) defines nutraceuticals as products isolated or purified from foods that are sold in medicinal forms and demonstrated to have a physiological benefit or provide protection against chronic disease. There is no specific regulation for nutraceuticals in the US, Europe, or Japan providing a statutory definition. Thus, a clear and comprehensive definition approved by international authorities is needed to regulate their safety and health or therapeutic efficacy.

### Health benefits of nutraceuticals

A diet composing diverse healthful foods and adequate essential nutrients is crucial for health promotion and prevention. Nutraceuticals can be part of a healthy diet supporting human health by reducing risk factors of chronic disease and promoting wellbeing and quality of life, particularly in those who have moderate or high risk for disease. On some occasions, under a physician's supervision, they can be added to therapeutic regimens when prescribed medicines do not suffice for treatment goals. For example, calcium nutraceutical products can be added to hormone replacement therapy for the management of osteoporosis, and red yeast rice to statin therapy for hypercholesterolemia. A benefit of nutraceutical and pharma combinations, for example, may be a reduction of side effects that may occur at high doses of prescribed medications. The efficacy of nutraceuticals in recommended dosage must be proven in clinical studies before they can be marketed to consumers.

### Brain health

According to the US Centers for Disease Control and Prevention (CDC), a healthy brain is "one that can perform all the mental processes that are collectively known as cognition, including the ability to learn new things, intuition, judgment, language, and remembering" (CDC). Poor brain health may eventually manifest as cognitive impairment. Various nutraceuticals have been investigated in relation to cognition, with a few demonstrating promising beneficial evidence. Examples of common nutraceuticals that have been investigated for their ability to help maintain or enhance cognitive function in healthy individuals include *Bacopa monniera* (Brahmi), *Ginkgo biloba*, ginseng, vitamins, and omega-3 fatty acids. Several clinical trials on *B. monniera* in healthy adults have shown improvements in learning and intelligence (Downey et al., 2013; Morgan and Stevens, 2010), attention (Calabrese et al., 2008; Peth-Nui et al., 2012; Stough et al., 2008), memory (Barbhaiya et al., 2008; Calabrese et al., 2008; Kumar et al., 2016; Morgan and Stevens, 2010; Peth-Nui et al., 2012; Roodenrys et al., 2002), and processing speed (Calabrese et al., 2008; Stough et al., 2001). A meta-analysis of nine clinical trials involving healthy subjects and those with memory complaints suggested that *B. monniera* has the potential to improve attention speed, but not memory (Kongkeaw et al., 2014). Beneficial effects of *G. biloba* in healthy adults have been observed in several clinical trials on memory (Kaschel, 2011; Kennedy et al., 2002; Rigney et al., 1999; Silberstein et al., 2011; Steiner et al., 2016; Wesnes et al., 2000), attention (Kennedy et al., 2000; Kennedy et al., 2002), and processing speed (Cieza et al., 2003). However, a meta-analysis of 13 clinical trials showed non-significant effect sizes of *G. biloba* for memory, executive function, and attention (Laws et al., 2012). Improvements in memory and attention have been shown in healthy adults with ginseng (Kennedy et al., 2001; Reay et al., 2005; Reay et al., 2006; Scholey et al., 2010). A meta-analysis of 22 clinical trials reported no significant effect of B vitamins or antioxidant vitamins on cognitive function, and insufficient evidence to evaluate the effect of omega-3 fatty acids on cognition (Jia et al., 2008).

In addition to maintaining a healthy brain, nutraceuticals may be beneficial for brain-related diseases or disorders, but clinical data are limited. A meta-analysis of clinical trials involving Alzheimer's disease (AD) patients showed inconclusive evidence on whether ginseng was an effective treatment (Wang et al., 2016). Melatonin supplementation in AD patients has been shown to improve sleep and suppresses sundowning (a state of confusion occurring in the late afternoon and spanning into the night) in several clinical trials (Cardinali et al., 2010). Additionally, a meta-analysis of seven clinical trials reported improvement in minimal state examination (MMSE) score in mild AD patients receiving >12 weeks of melatonin treatment (Wang et al., 2017a,b).

The most commonly investigated nutraceuticals for depression are St. John's Wort, omega-3 fatty acids, and S-adenosyl-methionine. A meta-analysis of 27 clinical trials suggested that St. John's Wort had comparable efficacy and safety to selective serotonin reuptake inhibitors (the most commonly prescribed antidepressant) in patients with mild-to-moderate depression (Ng et al., 2017). A meta-analysis of 26 clinical trials showed that intake of omega-3 PUFAs with EPA  $\geq 60\%$  at a dose  $\leq 1$  g/d had beneficial effects

on depression (Liao et al., 2019). Finally, in a meta-analysis of eight clinical trials, the authors concluded that a firm conclusion on the use of S-adenosyl-methionine for treating depression in adults could not be made, due to the lack of high-quality evidence (Galizia et al., 2016).

Putative mechanisms by which nutraceuticals modulate brain function are numerous. A well-studied mechanism is amelioration of oxidative stress and inflammation in the brain. Additionally, neurodegenerative diseases such as AD and epilepsy, as well as brain injury, typically involve the accumulation of misfolded proteins, e.g., amyloid- $\beta$  peptide, resulting in a cascade of events leading to increased inflammation and oxidative stress (Makkar et al., 2020). An important consideration for exogenous antioxidants is their ability to cross the blood-brain barrier (BBB). Bacosides, believed to be the active constituents of *B. Monnieri*, can be metabolized into aglycones (jujubogenin and pseudojujubogenin) and these metabolites are likely responsible for the diminished oxidative stress in the brain, as they have good BBB penetration (Ramasamy et al., 2015). In contrast to bacosides, melatonin readily passes through the BBB and has been shown to be protective against A $\beta$ -induced lipid peroxidation, decreased inflammation in the brain, and prevention of amyloid- $\beta$  peptide generation (Rosales-Corral et al., 2003; Shukla et al., 2017). Reduction in brain inflammation has been observed following omega-3 fatty acid treatment in animal models of AD and aging (Larrieu and Laye, 2018). Additionally, omega-3 fatty acids, especially EPA, are important in limiting the degradation of BBB integrity, which is implicated in neurodegenerative diseases and aging (Barnes et al., 2021).

Certain nutraceuticals, particularly those associated with psychiatric disorders, are believed to modulate neurotransmitter production, release, and synaptic concentration. For example, St. John's Wort alleviates symptoms of depression by inhibiting monoamine (e.g., serotonin and/or noradrenaline) reuptake into nerve terminals, which is a common mechanism of action of a variety of antidepressants (Butterweck, 2003). *B. Monnieri* has been shown to decrease plasma corticosterone concentration in stressed rats and to maintain brain levels of noradrenaline, dopamine, and serotonin, which were otherwise reduced with stress (Sheikh et al., 2007).

Together, evidence exists in support of potential benefits of nutraceuticals in maintaining cognitive function in healthy adults, as well as of their potential therapeutic role for neurodegenerative diseases and mental disorders, through various putative mechanisms. However, most clinical trials present inconsistent results for nutraceuticals. Indeed, no health claims have been approved by the FDA for brain-related outcomes. However, there is a qualified health claim for phosphatidylserine and reduced risk for cognitive dysfunction, where the FDA concluded that "the science provides minimal and preliminary evidence sufficient for qualified health claims about phosphatidylserine and reduced risk of these conditions." More rigorous and robust studies on the efficacy of nutraceuticals in regulating brain health are warranted to better understand the potential of nutraceuticals in maintaining and improving brain function and reducing the risk of neurodegenerative diseases.

## Cardiometabolic health

Cardiometabolic disorders represent a cluster of interrelated cardiovascular risk factors, primarily insulin resistance, impaired glucose tolerance, dyslipidemia, hypertension, and central adiposity. Various nutraceuticals have been examined for their ability to regulate each of these risk factors, and those that are promising are described below.

### Glucose regulation

Examples of common nutraceuticals that have been investigated for their beneficial effects on glucose homeostasis include the minerals zinc and chromium, fiber, and non-nutrient nutraceuticals, garlic, ginseng, and berberine. Two meta-analyses of clinical trials involving participants with type 2 diabetes (T2D), prediabetes, obesity, polycystic ovary syndrome (PCOS), metabolic syndrome or gestational diabetes showed that zinc improved fasting glucose, Insulin, 2 h postprandial glucose, homeostatic model assessment for insulin resistance (HOMA-IR), and HbA1c (Wang et al., 2019; Pompano and Boy, 2021). Dosages of both <25 mg/d and  $\geq$ 25 mg/d have been effective in improving HOMA-IR, while lower dosages (<25 mg/d) were more beneficial for fasting blood glucose and higher dosages ( $\geq$ 25 mg/d) were better for HbA1c, a long-term marker of glucose regulation (Pompano and Boy, 2021). Chromium supplementation of >200  $\mu$ g/d decreased HbA1c among individuals with baseline HbA1c  $\geq$  8% (indicative of uncontrolled diabetes) in a meta-analysis of 25 clinical trials (Suksomboon et al., 2014). Additionally, chromium was effective in reducing fasting blood glucose (Suksomboon et al., 2014).

Adding additional fiber (4–40 g/d) to habitual diet has been shown to reduce fasting blood glucose and HbA1c in T2D patients (Post et al., 2012). In a meta-analysis of nine clinical trials with T2D patients, significant reduction in fasting blood glucose, fructosamine, and HbA1c were observed following garlic supplementation (0.05–1.5 g/d) (Wang et al., 2017a,b). Ginseng supplementation has also been reported to improve fasting glucose, postprandial insulin, and HOMA-IR, but not postprandial glucose, fasting insulin, or HbA1c in a meta-analysis of 8 clinical trials with individuals with T2D or impaired glucose tolerance (Gui et al., 2016). In another meta-analysis of four trials with T2D patients, berberine (an isoquinoline derivative alkaloid isolated from *Rhizoma Coptidis*) with a co-intervention of lifestyle modification was better than lifestyle modification alone or placebo in improving fasting blood glucose, postprandial glucose, and HbA1c (Dong et al., 2012). Two meta-analyses of clinical trials report beneficial effects of turmeric and curcumin on HbA1c and HOMA-IR in adults with cardiometabolic disorders (e.g., T2DM, metabolic syndrome) (Tabrizi et al., 2018; Altobelli et al., 2021).

This clinical evidence shows that nutraceuticals appear to have a role in the management of blood glucose, particularly in people with impaired glucose regulation.

## Lipids

Many nutraceuticals have been investigated for their lipid-lowering effects. The International Lipid Expert Panel (ILEP) reviewed several lipid-lowering nutraceuticals with the objective of providing recommendations for their optimal use to manage dyslipidemia in patients not on statin therapy, those on statin or combination therapy who have not achieved lipid goals, and patients with statin intolerance (Cicero et al., 2017). According to their review, red yeast rice extract, berberine, and omega-3 fatty acids showed evidence that treatment was beneficial, useful, and effective (Cicero et al., 2017).

Red yeast rice, obtained by the fermentation of yeast (*Monascus purpureus*) in rice, contains substances with lipid-lowering activities, including polyketides such as monacolin K, which is structurally identical to lovastatin. Two meta-analyses reported reduction in low density lipoprotein-cholesterol (LDL-C) and triglycerides (TG) as well as increases in HDL-C with red yeast rice extract supplementation in diverse populations, including myocardial infarction patients with borderline hypercholesterolemia, and patients with dyslipidemia, coronary heart disease, T2DM, hypertension, and non-alcoholic fatty liver disease (Sungthong et al., 2020). Red yeast rice-based therapy is safe and well tolerated independent of dose and duration of therapy and health condition of users (Fogacci et al., 2019). Additionally, EFSA concluded that a relationship exists between the administration of red yeast rice and the maintenance of plasma LDL-C, specifically using a dose of red yeast rice containing 10 mg of monacolin K (Efsa Panel on Dietetic Products and Nutrition and Allergies (NDA), 2011). Due to the similarity in structure between monacolin K and lovastatin, the primary cholesterol-lowering putative mechanism of action of red yeast rice is thought to be a reversible inhibitory action on 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase (the key enzyme in endogenous cholesterol synthesis) (Cicero et al., 2017).

Berberine is a quaternary benzyloquinoline alkaloid present in *Coptis* (*Coptis chinensis*, *Coptis japonica*), *Hydrastis* (*Hydrastis canadensis*), and *Berberis* (*Berberis aristata*, *Berberis vulgaris*, *Berberis croatica*). Two meta-analyses on berberine report decreases in total cholesterol (TC), TG, and LDL-C and an increase in HDL-C (Ju et al., 2018; Dong et al., 2013). Another meta-analysis comparing the effects of berberine alone or combined with statins reports that berberine was effective only in reducing TG when compared with simvastatin, and that the combination of berberine and simvastatin was more effective in decreasing TG and TC compared to simvastatin alone (Zhang et al., 2019). According to the International Lipid Expert Panel (ILEP), the use of berberine at doses ranging between 500 and 1500 mg was effective in lipid-lowering and relatively safe both in primary and secondary prevention. The effect of berberine on the reduction of TG and TC is partly related to its positive effect on insulin resistance and clearance of LDL-C, respectively (Cicero et al., 2017).

Several meta-analyses report reduction in TG following omega-3 fatty acid supplementation (Natto et al., 2019; Gao et al., 2020; Berge et al., 2014). Additionally, the lipid-lowering effects of omega-3 have been recognized by several authoritative organizations. The EFSA established a claim in 2010 indicating that the intake of at least 2 g/d of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) can maintain normal blood TG concentration (Efsa Panel on Dietetic Products and Nutrition and Allergies (NDA), 2010). The American Heart Association has also indicated that doses from 2 to 4 g/d of EPA/DHA reduce TG by 25%–30% (Miller et al., 2011). The hypolipidemic effects of omega-3 fatty acids are mediated through lowering synthesis of hepatic very-low-density lipoprotein and TG, and increasing beta-oxidation of fatty acids and the synthesis of phospholipids (Harris and Bulchandani, 2006).

## Body weight

Supplements claiming to decrease body weight feature several putative mechanisms, such as delaying or limiting nutrient absorption, inducing satiety and decreasing appetite, or increasing energy expenditure (Watanabe et al., 2020). Nutraceuticals most actively investigated for their weight loss properties include green tea, caffeine, conjugated linoleic acid, and garcinia (Payab et al., 2020; Maunder et al., 2020; Batsis et al., 2021). Although the efficacy of these nutraceuticals in reducing body weight, fat mass, or waist circumference has been reported by some clinical trials, the reductions are modest, and their clinical significance is unclear.

A Cochrane meta-analysis of six clinical trials of at least 12 weeks' duration reported non-significant changes in body weight or waist-to-hip ratio in overweight or obese adults following green tea supplementation (Jurgens et al., 2012). A more recent meta-analysis on green tea supplementation in varied populations reported reduction in body weight and BMI (Lin et al., 2020). The decrease in body weight was most evident for dosages <500 mg/d for 12 weeks. Reduction in waist circumference was found for supplementation of green tea ≥800 mg/d for <12 weeks. Another meta-analysis on green tea catechins concluded that green tea catechins with caffeine were associated with significant reduction in body weight and waist circumference, but catechins alone do not show benefits (Phung et al., 2010). Thus, it is likely that caffeine in green tea extract or its additive, or synergistic interaction with catechins contribute to weight loss. This speculation is supported by one meta-analysis reporting reduction in body weight, BMI, and fat mass following caffeine consumption (Tabrizi et al., 2019). However, the inclusion of studies with other bioactive compounds, such as ephedrine, weakened the evidence of caffeine (Tabrizi et al., 2019). A separate meta-analysis of epidemiologic studies reported that higher coffee intake was significantly associated with modestly lower BMI and waist circumference in men only (Lee et al., 2019). Additionally, higher coffee intake was associated with overall reduced central adiposity, which was not significant when analyzed by sex subgroups (Lee et al., 2019). Similarly, another meta-analysis reported that green coffee bean extract significantly reduced body weight and waist circumference (Asbaghi et al., 2020). All these data support the effectiveness of polyphenols and caffeine in body weight management.

In a meta-analysis of long-term (at least 6 months) clinical trials, conjugated linoleic acid was reported to reduce body weight and fat mass, although authors cautioned that the decreases were small and, thus, their clinical significance is unclear (Onakpoya et al., 2012). A more recent meta-analysis also concluded that conjugated linoleic acid reduced body weight and fat mass and

increased lean body mass. Additionally, subgroup analyses indicated that conjugated linoleic acid was more effective in individuals >44 y and when provided for more than 12 weeks at dosages >3.4 g/d (Namazi et al., 2019 #80). One meta-analysis reported that *Garcinia cambogia* significantly reduced body weight, percent fat mass, and waist circumference (Golzarand et al., 2020). Dose-response analysis revealed a nonlinear association between *Garcinia cambogia* dosage and change in body weight, whereby peak reductions corresponded to a dose of ~2000 mg/d (Golzarand et al., 2020).

### Blood pressure

Among foods, beetroot juice has the most convincing evidence of antihypertensive effect; among micronutrients, magnesium, potassium, and vitamin C can improve blood pressure, and among non-nutrient nutraceuticals, soy isoflavones, cocoa catechins, and melatonin have been proposed (Borghi et al., 2020; Cicero et al., 2019). However, the non-nutrient nutraceuticals reviewed were showed only limited evidence of effect (Cicero et al., 2019).

Nitric oxide is a potent vasodilator and vascular endothelium relaxant, and a reduction in its availability and/or bioactivity is linked to the development of hypertension, endothelial dysfunction, atherosclerosis, and CVD (Li and Forstermann, 2000). Beetroot juice is a concentrated source of inorganic nitrates, contributing substantially to nitric oxide availability via the nitrate-nitrite-nitric oxide pathway (Lidder and Webb, 2013). Two meta-analyses reported decreases in blood pressure (both systolic and diastolic) of normotensive/pre-hypertensive/mild hypertensive adults following beetroot juice supplementation (Bahadoran et al., 2017; Jackson et al., 2018). One of these also reported improvements in endothelial function assessed using flow-mediated dilation and reductions in arterial stiffness and platelet aggregation (Jackson et al., 2018). However, such hypotensive benefits were not observed in patients with chronic obstructive pulmonary disease (Alshafie et al., 2021). Cocoa catechins, known to regulate availability of nitric oxide, can significantly improve endothelial function and decrease systolic and diastolic blood pressure, with an optimal effect observed with 710 mg total flavanols, 95 mg (–)-epicatechin or 25 mg (+)-catechin (Sun et al., 2019; Jafarnejad et al., 2020).

Numerous mechanisms have been proposed to explain  $Mg^{2+}$ -induced BP reduction, including a calcium-channel blocking action and an increase in prostaglandin E and nitric oxide synthesis. Seven meta-analyses on oral magnesium and blood pressure/hypertension were found. Of those, one reported no effect (Jee et al., 2002), one reported lowering of diastolic BP (DBP) but not systolic BP (SBP) (Dickinson et al., 2006), four reported lowering both SBP and DBP (Zhang et al., 2016; Rosanoff and Plesset, 2013; Kass et al., 2012; Dibaba et al., 2017), and another reported population dependent effects (Rosanoff et al., 2021). Specifically, magnesium at >600 mg/d is effective to reduce BP in untreated adults with hypertension ( $\geq 140/90$  mmHg) and at 240–607 mg/d in uncontrolled, treated adults (Rosanoff et al., 2021). However, oral magnesium did not affect BP in normotensive subjects or those with controlled hypertension (Asbaghi et al., 2021; Rosanoff et al., 2021).

### Immunity and infection

Many micronutrients are well-known for their roles in the immune system (Maggini et al., 2018). Copper, iron, selenium, folate, zinc, vitamin A, vitamin B12, vitamin B6, vitamin C, and vitamin D all have approved EFSA health claims to support the normal function of the immune system based on their well-established biochemical roles and/or on deficiency symptoms involving the immune system (Efsa Panel on Dietetic Products and Nutrition and Allergies (NDA), 2016). Additionally, available clinical evidence suggests that some of these nutrients positively affect the incidence and severity of infections and immune-related medical conditions. Examples include vitamin D as prophylaxis for respiratory infection (Martineau et al., 2019; Martineau et al., 2017), as an adjuvant treatment for pneumonia (Yang et al., 2021), reducing the severity of atopic dermatitis in adults and children (Kim and Bae, 2016; Hattangdi-Haridas et al., 2019), and decreasing asthma exacerbations (Jolliffe et al., 2017) and vitamin C as a supplementary therapy along with antiviral regimens to relieve patients from the symptoms of the common cold (Ran et al., 2020). Probiotics have recently gained increasing attention for their potential immune-modulating properties, as evidenced by the results of several meta-analyses providing support for their beneficial effects on the respiratory infection (Yeh et al., 2018; Lei et al., 2017; Hao et al., 2015), gastroenteritis (Ansari et al., 2020), *Helicobacter pylori* infection (Shi et al., 2019; Lu et al., 2016), *Clostridium difficile* infection (Shen et al., 2017), and atopic dermatitis (Zuccotti et al., 2015; Li et al., 2019; Jiang et al., 2020; Amalia et al., 2020).

### Urinary health

Urinary tract infections (UTI) are prevalent worldwide, particularly in women. Clinically, UTIs are categorized as uncomplicated or complicated, with the latter defined as those associated with factors that compromise the urinary tract or host defense. The recurrence rate in the 12 months following an initial uncomplicated UTI in women ranges from 25 to 44%. The typical treatment for UTI is antibiotics but, given the rapid rise of multi-drug resistant uropathogens, many complementary and integrative approaches to managing UTI have been proposed, including nutraceuticals, such as probiotics, D-mannose, and cranberry products.

Cranberry juice is perhaps best known for the prevention and treatment of UTI. This health benefit received a US FDA qualified health claim in 2020 (FDA, 2020), “consuming one serving (8 oz.) each day of an at least 27% cranberry juice beverage or 500 mg each day of cranberry dietary supplement may help reduce the risk of recurrent UTI in healthy women.” However, cranberry-containing products, including cranberry-containing nutraceuticals, were effective in women with recurrent UTI, but not in populations with potentially complicated UTI such as those with neuropathic bladder, elderly patients, or pregnant patients (Wang et al., 2012; Fu et al., 2017). Additionally, a recent meta-analysis (Raguzzini et al., 2020) showed that cranberries were ineffective against UTI in patients with spinal cord injury, compared with controls. Although the mechanism by which constituents in cranberries

modulate UTI incidence remains to be elucidated, the anti-adhesion activities of cranberry constituents against uropathogenic *E. coli* are likely responsible for the benefit.

D-mannose is an inert monosaccharide metabolized and excreted in urine which can inhibit bacterial adhesion to the urothelium, representing a promising nonantibiotic prevention strategy for UTI. D-mannose has been used by some women in an attempt to prevent the recurrence of UTI. A meta-analysis study showed that D-mannose with dosing between 420 mg/d to 2 g three times/d could reduce the risk of UTI recurrence, compared to placebo, but the reduction was not statistically significant when compared to preventative antibiotics (Lenger et al., 2020). Additionally, D-mannose appears to be well tolerated with minimal side effects.

Probiotics are “live microorganisms that, when administered in adequate amounts, confer a health benefit on hosts.” Probiotics, such as *Lactobacillus* and *Bifidobacterium*, are beneficial microorganisms that may block pathogenic bacteria adhesion to urothelial cells and defend against infections in the urogenital tracts. The concept originated from observation of an inverse association between *E. coli* colonization in women with recurrent UTI and *Lactobacillus*, the most common bacteria genus in the human vaginal microbiota. Nevertheless, mixed data have been reported on the efficacy of probiotics in preventing recurrent UTI in adults (Vagios et al., 2020). Similarly, a meta-analysis of 10 clinical trials showed a null effect of probiotic therapy on the incidence of UTI and its recurrence in children (Hosseini et al., 2017). A significant moderate benefit was only observed when probiotics were used as adjunct therapy to antibiotics. Thus, using probiotics in the protection and prevention of UTI remains to be further researched.

Taken together, clinical evidence exists regarding the potential beneficial role of nutraceuticals in the prevention of recurrent UTI. Apparently, cranberry products are more promising than D-mannose and probiotics.

## Eye health

Advancing age is associated with increased risk for ocular diseases, such as cataract, age-related macular degeneration, and dry eye syndrome, with the first two being the leading cause of vision impairment and blindness, and the final being the most common complaint in ophthalmologic practice (McCusker et al., 2016). While treatments are available for age-related vision loss, such as surgical removal of cataracts, many causes of vision loss, such as dry age-related macular degeneration (AMD), remain poorly understood, and no treatments are currently available. The importance of nutrition in eye health has been well appreciated. In particular, results of the Age-Related Eye Disease Study (AREDS) studies demonstrating that high intake of vitamin A, vitamin C, zinc, copper, and carotenoids could reduce the progression of AMD by approximately 25% (Francisco et al., 2020). Thus, nutraceuticals may help support eye health and protect against age-related eye diseases.

AMD involves damage to the macula, an area of the retina necessary for high-acuity vision. There are two forms, dry and wet AMD. The former is the most common and results from radical-induced damage to retinal pigmented epithelial cells and accumulation of extracellular protein- and lipid-containing deposits called drusen. Thus, antioxidants may protect against cellular damage in the retina by reducing sunlight-derived free radicals. However, results of a meta-analysis of five clinical trials showed that vitamin E supplements did not affect the development of AMD compared with placebo (Evans and Lawrenson, 2017a,b). Similarly, a null effect was noted with vitamin C or beta-carotene supplementation. Nevertheless, the AREDS formula containing a battery of antioxidants, vitamin A and C, zinc, copper, and carotenoids appears to be protective against AMD progression to the late-stage (Evans and Lawrenson, 2017a,b). Additionally, a small significant protective effect on AMD progression was found in people taking zinc alone. Nutraceuticals containing lutein and zeaxanthin that are heavily marketed for AMD have shown little or no impact on the progression of AMD (Evans and Lawrenson, 2017a,b). This result conflicts with the finding that lutein supplementation (10 or 20 mg per day) was associated with an increase in macular pigment optical density (MPOD), a marker of lutein accumulation in the macula, where high MPOD suggests larger protection against blue-light induced drusen formation (Feng et al., 2019). There was no evidence that omega-3 fatty acid supplements were protective against progression to advanced AMD (Lawrenson and Evans, 2015) even though there was an inverse relationship between dietary intake of omega-3 fatty acids and risk of developing AMD or progression to advanced AMD.

A cataract is the result of opacification in eye lenses that impair vision and cause blindness. While it is most commonly corrected with surgery to restore vision, dietary antioxidants may delay and/or prevent cataracts because oxidative damage plays a major role in its etiology. A meta-analysis of 12 observational studies showed that vitamin A, C, and E,  $\beta$ -carotene, and lutein were associated with reduced risk of age-related cataracts (Jiang et al., 2019). However, a meta-analysis result of 8 clinical trials showed that vitamin E or  $\beta$ -carotene interventions were not protective compared with placebo (Jiang et al., 2019). Thus, antioxidants may be protective against cataracts but need to be substantiated in human trials.

Dry eye disease is a chronic disease marked with irritation and burning that can cause inflammatory damage to the cornea and conjunctiva and is prevalent in the elderly population. The main cause of the disease is dysfunction of the Meibomian gland due to hyperkeratinization of the ductal epithelium of the gland and reduced production of meibum, as well as tear hyperosmolarity and tear film instability. Current therapeutic strategies for managing dry eye disease include enhancing tear volume and quality by using artificial eye drops and reducing ocular inflammation. However, two-thirds of dry eye sufferers remain symptomatic despite adherence to treatment (Downie and Keller, 2015). With their anti-inflammatory effect, omega-3 fatty acids may help mitigate the symptoms of dry eye disease. A meta-analysis study with 17 clinical trials demonstrated that compared with placebo, omega-3 fatty acid supplementation decreased dry eye symptoms and increased the tear breakup time (Giannaccare et al., 2019). Another meta-analysis of 13 clinical trials showed that without eye medication, polyunsaturated fatty acids, including  $\alpha$ -linolenic, linoleic, eicosapentaenoic, or docosahexaenoic acid, improved tear breakup time, osmolarity and ocular surface disease index score, compared with the placebo (Chi et al., 2019). Thus, omega-3 fatty acid nutraceuticals may play a role in managing dry eye disease.

## Sleep

Sleep is an essential and complex biological process that needs to be satisfied to maintain many physiological functions, e.g., muscle recovery and repair, neurological development, cardiac, immune, and metabolic functions, cognition, and mood (Watson et al., 2015). Additionally, inadequate sleep (i.e., duration and/or quality) is a threat to health because of the association of insufficient sleep with obesity, metabolic, immunological, and cardiovascular health, some types of cancer, pain, and mental illness. The prevalence of sleeping problems (during the past 12 months) has been increasing in developed and developing countries worldwide. There are different medications for sleep disorders, such as antihistamines, zolpidem (Ambien), zaleplon (Sonata), benzodiazepines, doxepin, eszopiclone, and emborexant. However, their use is accompanied by adverse side effects, ranging from dizziness during awake time to gastrointestinal discomfort, neurologic side effects, and long-term dependence. Thus, nutraceuticals can be an alternative or complement with pharmacological therapies without common serious side effects.

A recent study showed that a polyphenol botanical blend supplement improved self-reported sleep quality and daytime functioning and reduced insomnia severity in individuals with subclinical sleep disturbances, but did not compromise neurocognitive functioning during daytime (Tubbs et al., 2021). The gut-brain axis, extensive two-way interaction between the gastrointestinal tract and central nervous system, informs a new direction for developing strategies for nervous system-related health conditions, such as modifying the gut microbiota for sleep. Wong et al. (2015) reported that 6 weeks of probiotic (8 strains in *Bifidobacterium*, *Lactobacillus*, and *Streptococcus* genera) supplementation in men with irritable bowel syndrome (IBS) increased salivary melatonin, a hormone involved in the regulation of circadian rhythmicity. A meta-analysis study of 14 clinical trials showed that probiotic (live microbes)/paraprobiotics (inactivated or non-viable microbes) consumption induced positive changes to perceived sleep health in people suffering from inadequate sleep but did not affect objective parameters of sleep, i.e., efficiency and latency (Irwin et al., 2020).

## Bone health

Bone comprises an organic phase (matrix) and an inorganic mineral phase, together with different cells responsible for a cycle of bone resorption and formation. The matrix consists of structural proteins, collagen, and mucopolysaccharide; hydroxyapatite containing calcium is the main mineral in the inorganic phase. Joints are comprised of synovium, cartilage, ligaments, bone, and muscles. Aging is accompanied by reduced bone thickness and density, and stiffer and less flexible joint movement. Osteoporosis is a progressive, systemic bone disease with loss of bone and its microscopic structure, resulting from dysregulation of proinflammation. Osteoarthritis, the most common form of arthritis among older people, is caused by the degradation and loss of articular cartilage due to the age-related increase in free radicals and inflammation. Thus, nutraceuticals that support bone structure and ameliorate oxidative stress and inflammation can benefit bone and joint health (Pandey et al., 2018).

Calcium supplements are commonly taken to maintain a calcium intake of at least 1000–1200 mg/d to prevent or treat osteoporosis. A meta-analysis study shows that increasing dietary calcium intake increases bone mineral density at the total hip, lumbar spine, femoral neck, and total body (Tai et al., 2015). Calcium supplements also increase bone mineral density. However, the magnitude of the increase from both types of interventions is small (<2%), which may not lead to a clinically significant reduction in risk of fracture. Vitamin D has been included in common regimens for osteoporosis management, due to its effect on calcium absorption in the small intestine and bone formation. However, the result of a meta-analysis study showed there was a small benefit of vitamin D supplementation at the femoral neck but no effect at any other body site (Reid et al., 2014). While vitamin K is known for its involvement in blood clotting, its contributions to bone formation are emerging. A meta-analysis of clinical trials showed that vitamin K decreased risk of clinical bone fracture, compared to controls, but bone mineral density was not altered (Mott et al., 2019). Thus, using nutraceuticals containing vitamin D or K to protect against osteoporosis seems unjustified at this time. However, there may be potential benefit of combining vitamin D and K on bone mineral density (Kuang et al., 2020). Soy isoflavones with estrogenic activity may modulate maintenance of the bone structure, supported by a meta-analysis showing that daily ingestion of an average 56 mg soy isoflavones moderately decreased bone resorption, but not bone formation (Taku et al., 2010). As short-chain fatty acids produced from microbes in the human gut can regulate bone loss (Zaiss et al., 2019), nutraceuticals that modulate the gut microbiota are anticipated to affect bone health. A meta-analysis of 5 clinical trials showed a significant positive association between probiotic supplementation and bone mineral density in the lumbar spine, but not in hips (Yu et al., 2021).

Osteoarthritis involves the deterioration of articular cartilage and underlying bone. Chondroitin sulfate is a major component of the extracellular matrix of many connective tissues, and glucosamine is a component of articular cartilage. Foods containing these 2 ingredients may reduce joint deterioration and related pain and disability. However, meta-analysis data show that chondroitin (1200 mg/day) or glucosamine had some effectiveness on pain reduction but no effect on cartilage volume (Knapik et al., 2019; Knapik et al., 2018). Inflammation is an underlying cause of pain and deterioration of joints. Nutraceuticals formulated with anti-inflammatory ingredients may be beneficial to arthritis. For example, omega-3 fatty acids can decrease joint pain intensity in people with rheumatoid arthritis (Goldberg and Katz, 2007). Thus, nutraceuticals containing chondroitin sulfate, glucosamine and/or omega-3 fatty acids may help pain management in people with arthritis, but may not be adequate to stop deterioration.

## Muscle health

Loss of muscle mass, power, and strength, a pathogenic condition called sarcopenia, can impair physical function and increase the risk of frailty in the elderly population. Nutritional interventions maintaining muscle quality and quantity can support quality of

life and extend health span. Amino acids, omega-3 fatty acids, creatine, and  $\beta$ -hydroxy- $\beta$ -methylbutyrate, are thought to affect muscle mass and strength (Martin-Cantero et al., 2021; Gielen et al., 2021). While protein is the primary source for muscle synthesis, a meta-analysis showed that protein supplementation alone did not benefit upper-limb, lower-limb, or handgrip strength, compared to resistance exercise training in healthy elderly adults (Labata-Lezaun et al., 2020). Nevertheless, individual amino acids can exert specific effects in muscle synthesis and function. For example, leucine is a building block and serves as a nutritional signal for protein synthesis. A meta-analysis of 16 clinical trials showed that, compared with controls, leucine supplemented in the range of 2–7.8 g/d significantly increased gain in lean body mass and body weight in older people; the effect size was even larger in those with manifested sarcopenia (Komar et al., 2015).  $\beta$ -hydroxy- $\beta$ -methylbutyrate has been shown to promote turnover of muscle protein, potentially playing a role in ameliorating skeletal muscle wasting and weakness. A meta-analysis of 15 clinical trials showed favorable effects of 3 g/d  $\beta$ -hydroxy- $\beta$ -methylbutyrate on increasing skeletal muscle mass and strength (Bear et al., 2019). Similar to  $\beta$ -hydroxy- $\beta$ -methylbutyrate, omega-3 fatty acids, particularly at  $>2$  g/d, can promote muscle mass gain (Huang et al., 2020). Creatine can modulate muscle mass via several mechanisms, including ATP production, glycogen synthesis, calcium reuptake, and protein turnover. Its supplementation ( $\geq 5$  g/d) augments increases in lean muscle mass and strength from resistance training in older adults, compared to placebo (Forbes et al., 2021). Thus, nutraceuticals can be added to an exercise regimen to protect against loss of muscle mass and strength, a condition that can lead to frailty and morbidity of older populations.

## Summary

The term “nutraceutical” is a portmanteau of 2 words, “nutrient” and “pharmaceutical,” and they can be derived from vegetal and animal origins and are capable of providing beneficial health effects, including the prevention and/or the treatment of disease. However, there is no specific regulation for nutraceuticals in the US, Europe, and Japan, providing statutory definition. Additionally, nutraceuticals are categorized as dietary supplements in the US, which are not allowed to claim to treat, mitigate or cure disease or condition. Numerous nutraceuticals have proven clinical efficacy in a wide range of health indications, such as *Bacopa monniera*, *Ginkgo biloba*, ginseng, melatonin, St. John’s Wort, and omega-3 fatty acids for brain health; garlic, berberine, turmeric, red yeast rice, omega-3 fatty acids, green tea, conjugated linoleic acid, garcinia, beetroot, cocoa catechins for the cardiometabolic system; probiotics for immunity and infection; cranberry, D-mannose, probiotics for urinary health; probiotics for sleep; calcium, vitamin D and K, chondroitin sulfate, glucosamine, and omega-3 fatty acids for bone and joints; leucine,  $\beta$ -hydroxy- $\beta$ -methylbutyrate, and creatine for muscle. Thus, nutraceuticals may be used to improve health, delay the aging process, prevent chronic disease, increase health span, or to support the structure or function of the body. However, their effectiveness and safety must be substantiated by human studies, with supporting evidence on mechanisms of action from preclinical studies.

### Key points

- To determine the nutritional composition of major types of nuts and seeds grown for human consumption.
- To update the health benefits of nuts and seeds according to the latest research.
- To learn some curiosities about nuts and seeds.

In botanical terms, the word “nut” is used to describe a wide range of seeds, mostly from trees; however, there are some exceptions. Peanuts are the seeds of a legume and other nuts grow inside of leathery fruits. Nuts include among others the almond, cashew, chestnut, Brazil nut, hazelnut, macadamia, peanut, pecan, pine nut, pistachio and walnut. Nuts and seeds come from a diverse range of different plants (vegetables, flowers, or crops grown for a variety of uses), so their nutritional composition is quite varied. Seeds, such as pumpkin seeds, sesame and sunflower, are sources of protein, unsaturated fatty acids, various micronutrients, and fiber (non-starch polysaccharides (NSP)). Nuts and seeds have a wide range of uses. In the typical Western diet or Mediterranean diet they tend to be used either as snack items or added as minor ingredient to savory and sweet dishes, but they have wider applications

in vegetarian and other plant-based diets as important sources of protein and other nutrients. Certain nuts and seeds are also made into spreads, for example peanut butter and tahini (sesame seed spread) or vegan “cheeses” (mainly made by cashew paste).

## Types of nuts and seeds

The major types of nuts and seeds grown for human consumption are shown in [Table 1](#). These are the most commonly consumed nuts and seeds by the worldwide consumers.

## Nuts

### Almonds

The almond (*Prunus amygdalis* var. *dulcis*), sometimes called the sweet almond, is one of the oldest nut crops have long been known as a source of essential nutrients. It is believed to have originated in Southeast Asia but is now grown more widely. Nowadays, the USA is the largest almond producer, followed by Spain and Australia.

Almonds are high in fiber, vitamin E, riboflavin and minerals such as calcium, iron, magnesium, phosphorus, potassium, zinc, copper and manganese ([432/2012 n.d.](#); [432/2012 n.d.](#); [1924/2006 n.d.](#)). They are mainly eaten raw, roasted and/or salted.

Almond hulls are the main almond by-product used for animal feeding and energy production, which is a good way to reduce their environmental impact. In addition, interest in these by-products has increased as they have beneficial properties (caused by their content in polyphenols and unsaturated fatty acids) which can be used for new ingredients such as food, cosmetic, and pharmaceutical industries ([Mandalari et al., 2010](#)).

### Brazil nuts

The Brazil nut (*Bertholletia excelsa*) tree grows in non-flooding areas in the Amazon rainforest in South America, being Bolivia, Peru and Brazil the main producing countries. A Brazil nut tree is one of the tallest of the Amazon Basin’s tropical rainforest, reaching up to 50 m in height and it can produce around 250 pounds or 113 kg of Brazil nut kernels. Brazil nuts are high in selenium and vitamin E (antioxidants), which contribute to the protection of cells from oxidative stress. In fact, Brazil nuts contain more selenium than any other food on the planet.

### Cashews

Cashews (*Anacardium occidentale* L.) are native to northeast Brazil but is now cultivated extensively in all tropical areas, notably in India and East Africa. The main producing countries of cashews are India, Cote d’Ivoire and Vietnam.

The cashew fruit, which contains the seed or “nut”, hangs at the end of a false fruit called cashew “apple”. The cashew nuts are usually eaten raw or roasted and they are high in vitamin K and minerals such as iron, magnesium, phosphorus, zinc, manganese and copper.

### Chestnuts

The sweet or Spanish chestnut (*Castanea sativa*) is a native tree of southern Europe. After pollination by insects, female flowers are converted into brown fruits wrapped in a green spiky case. Inside the fruit, the seeds or “nuts” can be found, which are covered with a outer coat. The shell of the nut is hard and inedible for that reason has to be cooked before being eaten, often by roasting or boiling.

**Table 1** Major types of nuts and seeds grown for human consumption.

Almonds	Pecans
Brazil nuts	Pine nuts
Cashews	Pistachios
Chestnuts	Walnuts
Coconut	Pumpkin seeds
Hazelnuts	Sesame seeds
Macadamias	Sunflower seeds
Peanuts	

### Coconut

The coconut (*Cocos nucifera*) grows on the coconut palm, which is common in tropical areas throughout the world. The coconut tree is a species of palm in the *Arecaceae* family; their native origin is unknown, as the nuts were easily dispersed between islands and continents by ocean currents and explorers.

An adult palm usually carries 30–40 paripinnate leaves in its crown and attains a height of about 15–30 m when fully mature. The white coconut “meat”, which can be eaten either fresh or desiccated, is actually part of the endosperm of the seed. Coconut contains more water in comparison with other nuts and also has more saturated fat than unsaturated fat.

Coconut “milk” is found in the unripe nut and is commonly used in some Asian dishes.

### Hazelnuts

The most widely grown hazelnut (*Corylus avellana*) is a native of Europe, although approximately 10 different species of *Corylus* grow throughout Europe, North America, and Asia. The main producing countries of hazelnuts are Turkey, Italy, Azerbaijan, Georgia, USA, Chile and Iran, being Turkey the largest producer. Hazelnuts are high in monounsaturated fat, which may help lower LDL-cholesterol levels (Orem et al., 2013). Hazelnuts are mainly eaten raw or roasted.

### Macadamia nuts

The macadamia nut (*Macadamia integrifolia*, smooth-shelled; *Macadamia tetraphylla*, rough-shelled) is a member of the *Proteaceae* family and native to eastern tropical Australia. The main producing countries of macadamia nuts are South Africa, Australia and Kenya. Macadamia nuts are high in monounsaturated fat, fiber, vitamin B1, magnesium, manganese and copper. After harvesting, the nuts are dried, roasted, and sometimes roasted and salted. Macadamias can be used as snacks or as an ingredient in confectionery products. In addition, macadamia oil is used for cooking.

### Peanuts

The peanut (*Arachis hypogaea*), sometimes referred to as the ground nut or monkey nut, originated in South America. Although referred to as a nut, it is in fact part of the legume family. Spread by European explorers, the plant reached Asia, Africa, and North America. The main producing countries nowadays are China, India, and the US. Peanuts are high in plant protein, an ideal food for vegetarian or vegan diets. The peanut itself may be eaten raw, roasted and/or salted.

### Pecans

The pecan (*Carya illinoensis*) is a member of the walnut family, and the tree is classified botanically as a hickory. The tree is a native of North America, grown wild along the Mississippi River and its tributaries. Pecans are high in thiamin, also known as vitamin B1, which contributes to the normal function of the heart. Pecans are also high in monounsaturated fat, which may help to reduce the risk factors of cardiometabolic disease, such as dyslipidemia, insulin resistance and hypertension (McKay et al., 2018). The United States and Mexico are the largest producers of pecans, accounting for 92% of world production. The nut is similar to the walnut, but with a more mild and sweet flavor. The pecan nut kernel is eaten fresh and in the US, it is used widely in confectionery and baked goods, such as in the well-known Pecan Pie.

### Pine nuts

Pine nuts or kernels are small edible seeds, which are extracted from the cones of various species of pine. The most commonly eaten variety is that from the European stone pine (*Pinus pinea*), which is native to northern Mediterranean regions. Pine nuts are high in vitamin K, which contributes to the maintenance of normal bones. They are widely used along Europe in confectionary and especially for the famous Pesto sauce.

### Pistachio nuts

The pistachio nut is the seed of the pistachio tree (*Pistacia vera* L.). Originating from West-Central Asia, it was cultivated 3000 years ago, and it has also been cultivated for many years in Mediterranean regions and in California. Nowadays, the main producing countries are the USA, Iran, Turkey, Syria and Afghanistan. The green nut kernels are mainly eaten raw, roasted, and roasted-salted. Pistachio consumption has been positively associated with some cardiometabolic risk factors in adults with well-controlled type 2 diabetes (Hadi et al., 2021).

## Walnuts

The walnut tree is one of the oldest fruit tree known for humans. The walnut (*Juglans* spp.) is the common name given to approximately 20 species of trees in this family but the most important species is *Juglans regia* – also known as the English or Persian walnut –, which is believed to have originated in Ancient Persia. The main producing countries of walnuts are USA, China, Ukraine, Iran, Chile and Turkey. Walnuts are high in polyunsaturated fat. Due to their nutritional composition, they also may help to reduce the risk of heart disease (Guasch-Ferré et al., 2021).

## Seeds

### Pumpkin seeds

The large flat and oval-shaped seeds of the members of the pumpkin family (*Cucurbita maxima*, *Cucurbita moschata*, *Cucurbita pepo* and related species) can be dried and eaten raw, used in both sweet and savory cooked dishes, or roasted. Pepitas are known by their Spanish name. They are native from South America and are mainly grown in Brazil. Pumpkin seeds are a natural source of antioxidants, vitamins and minerals.

### Sesame seeds

The sesame plant (*Sesamum indicum*) belongs to the *Pedaliaceae* family, and is native from Africa, grows in tropical, subtropical regions and southern temperate areas of the world. The seeds are small and off-white in color. They may be eaten whole or ground. These seeds are very common to be used in confectionery and baked goods. In some countries, especially in Asian countries, it is very popular to use the sesame oil in cooking. The seeds can be also ground to a paste called tahini, used in all hummus recipes.

### Sunflower seeds

The sunflower seed is the seed of the sunflower plant (*Helianthus annuus* L.) which is a member of the *Compositae* family. Native from Central North America, the sunflower seeds were cultivated by the native Indians, and were introduced to Europe in the sixteenth century. The flat seeds may be dehusked and eaten raw or dried as a snack, but the plant is mainly cultivated for the sunflower oil, which is widely used for cooking and also for margarine manufacture.

## Macronutrient content of nuts and seeds

Raw nuts may contain 50% or more water, but these nuts are usually dried or roasted for consumption and storage, so the water content of these nuts is between 2 to 7 g/100 g of product. The exceptions are fresh coconut and chestnuts, with a moisture content of 40% and 47%, respectively. The water, macronutrients, and energy content of the nuts and seeds more commonly consumed and discussed in this article are shown below, in Table 2.

**Table 2** Water, macronutrient, and energy content of selected nuts and seeds (per 100 g, kernel only or edible part).

	Water (g)	Protein (g)	Fat (g)	Carbohydrate (g)	Energy	
					kJ	kcal
Almonds (unroasted)	4.4	21.2	49.9	21.6	2424	579

<sup>a</sup>No data available.Source: U.S. Department of Agriculture, Agricultural Research Service. FoodData Central, 2019. [fdc.nal.usda.gov](https://fdc.nal.usda.gov).

## Fat

Nuts and seeds are high in fat, especially, unsaturated fats (polyunsaturated and monounsaturated fatty acids). However, the amount of fat is quite variable, ranging from approximately 76% in the macadamia nut and 72% in the pecan to approximately 44–61% in nuts such as the almond, cashew, hazelnut, and pistachio, and as low as 2% in chestnuts. The fat content of the edible seeds is around 49–51%.

The different fatty acid fractions contained in these nuts and seeds are also quite variable, as shown below, in [Table 3](#). In some nuts, such as the peanut, hazelnut, and macadamia nut, monounsaturated fatty acids predominate, whereas in the walnut and in sunflower seeds polyunsaturated fatty acids predominate. The exception is the coconut, in which saturated fatty acids constitute the major fat fraction.

## Carbohydrate

The carbohydrate content of nuts and seeds is quite variable. With the exception of the starch-rich chestnut (almost 53% carbohydrate), the carbohydrate content of most nuts is relatively low at approximately 10–27%. From the seeds, are the pumpkin seeds the ones with a lowest content of carbohydrates (10%). Whereas, Brazil nuts and pine nuts are the nuts with the lowest content of carbohydrates in comparison with the other nuts (11 and 13%, respectively).

## Protein

The protein content of nuts is quite variable, but most nuts are considered to be a good source of protein. Only the chestnut and coconut have a low content of protein (3%). For most other nuts, the protein content is high (14–25%), being an exception the macadamias and pecans with a medium content of protein (8–9%). Pumpkin, sesame, and sunflower seeds are also high in protein (17–30%).

However, all plant foods, also nuts and seeds, contain low proportions of indispensable amino acids in comparison from those needed in the human diet. The first limiting amino acids are lysine (Brazil nut, cashew nut, hazelnut, pine nut, and walnut), sulfur amino acids methionine and cysteine (almond), tryptophan (macadamia, pecan), and threonine (peanut). Thus, although the total amount of protein in nuts and seeds may be high, these foods must be complemented by other sources of plant protein, such as legumes, quinoa, tofu and/or animal protein (meat, fish, eggs, and dairy products), to ensure that the overall protein quality of the diet is adequate.

<sup>a</sup>No data available.Source: U.S. Department of Agriculture, Agricultural Research Service. FoodData Central, 2019. [fdc.nal.usda.gov](https://fdc.nal.usda.gov).

## Micronutrient content

The vitamin and mineral contents of the nuts and seeds discussed in this article are shown in [Tables 4](#) and [5](#), respectively.

In general, nuts are a good source of the vitamins B complex, including folic acid (vitamin B<sub>9</sub>) and tocopherols (vitamin E). Nuts are also high in fiber and contain minerals such as, selenium, zinc, calcium, magnesium and phosphorus. To highlight, Brazil nuts are the richest source of selenium in the planet.

Seeds contain quite large amounts of many minerals. In particular, sesame seeds are a good source of calcium. Seeds are also high in potassium, magnesium, phosphorus, iron, and in trace elements such as copper, zinc and manganese.

## Fiber content

Compositional values for the total amount of fiber, and the different fiber fractions are shown in [Table 6](#) for the nuts and seeds discussed in this article. It can be seen that nuts and seeds are good sources of fiber, similar to the amounts found in vegetables

**Table 6** Total dietary fiber, as measured by the Englyst method, and fiber fractions in selected nuts and seeds (g per 100 g, kernels only).

	Total fiber	Fiber fractions			
		Cellulose	Noncellulosic polysaccharide		Lignin
			Soluble	Insoluble	
Almonds	12.5	— <sup>a</sup>	— <sup>a</sup>	— <sup>a</sup>	— <sup>a</sup>
Brazil nuts	7.5	1.6	1.3	1.4	N
Cashews	3.3	0.6	1.6	1.0	N
Chestnuts	4.1	1.1	1.3	1.7	N
Coconut	9	0.8	1.0	5.5	N
Hazelnuts	9.7	2.2	2.5	1.8	N
Macadamia nuts	8.6	1.4	1.9	2.0	N
Peanuts	8.5	2.0	1.9	2.3	N
Pecans	9.6	1.2	1.5	2.0	N
Pine nuts	3.7	N	N	N	N
Pistachios	10.6	1.3	2.7	2.1	N
Walnuts	6.7	1.1	1.5	0.9	N
Pumpkin seeds	6	1.1	1.7	2.5	N
Sesame seeds	11.8	N	N	N	N
Sunflower seeds	8.6	1.4	1.8	2.8	N

<sup>a</sup>Estimated value.<sup>b</sup>Nutrient present in significant quantities but no reliable information available on the amount.

Source: U.S. Department of Agriculture, Agricultural Research Service. FoodData Central, 2019.

[fdc.nal.usda.gov](https://fdc.nal.usda.gov).

and fruits. Nuts and seeds contain more insoluble fiber than soluble, much of which is cellulose. Of the insoluble noncellulosic polysaccharides, arabinose predominates in most nuts, although the coconut contains large quantities of mannose. Most nuts and seeds are likely to contain quite large amounts of lignin, particularly those with a tough seed coat such as sesame seeds, although actual values are not available.

## Polyphenols and phytosterols

Natural antioxidants present in nuts are in the form of nutrient and non-nutrient antioxidants. Nutrient antioxidants, namely vitamins A, C and E, and minerals such as selenium, there are also non-nutrient antioxidants, namely phenolics and carotenoids. Several studies have also reported that phenolic compounds possess much stronger antioxidant activities than nutrient antioxidants (Alasalvar et al., 2020b). Phytochemicals are defined as non-nutritive, naturally occurring, and biologically active compounds found in plants. They mainly consist of phenolics, carotenoids, nitrogen-containing compounds and alkaloids. These antioxidants serve as the primary defense against lipid peroxidation by protecting body's cells from free radical damage. In addition, nuts are rich in phytosterols that contribute to lower LDL cholesterol levels (Alasalvar et al., 2020a).

## Toxins and contaminants

### Phytic acid

Phytic acid (*myo*-inositol hexaphosphoric acid) is found in all seeds. In addition, nuts naturally contain a high amount of phytic acid. The phytate content of the commonly eaten nuts and seeds is quite variable. In general, the oil seeds, such as sesame and sunflower, and the tree nuts (almond, walnut, hazelnut ...), have higher phytate levels than the leguminous peanut or the coconut and chestnut, which is particularly low. Phytic acid is a highly effective chelator, which forms insoluble complexes with mineral cations. Therefore, its presence in some plant foods, such as nuts and seeds, has led to concerns that it may reduce the bioavailability of various dietary minerals and trace elements, including calcium, magnesium, iron, zinc, and copper. The phytic acid present in nuts and seeds can have an inhibitory effect on mineral absorption but soaking nuts in water before eating them may reduce phytic acid levels.

It is likely that in a mixed diet of animal and plant foods, dietary phytate may be of less significance than among people consuming diets where plant foods are the basis source of nutrition (vegans). Current data suggest that the mineral status of most vegetarian or vegan adults is adequate, but because of increased requirements for growth, vegetarian children may be more

vulnerable to the reduced bioavailability of minerals and trace elements, notably zinc, which could be a consequence of the ingestion of large amounts of phytate-containing plant foods.

### Intolerances/allergies to nuts

Nuts have become part of any healthy diets, and this enhanced consumption is reflected in an increased prevalence of nut allergies. Tree nuts are common food allergen sources that induce IgE-mediated allergic reactions. An allergic reaction to nuts can cause severe health problems or lethal results (McWilliam et al., 2015).

According to recent study (Midun et al., 2021), epidemiological data have shown that the prevalence for tree nuts is between 0.05% and 4.9% and for peanuts between 0.5% and 3%. Recently, it has been demonstrated that a significant proportion of nut allergic patients are able to tolerate other nuts. But avoidance remains the key treatment of management of nut allergy. In case of the children population, researchers from the LEAP study (Learning Early About Peanut Allergy) observed that the introduction of peanuts into an infant's diet, prior to 11-months old, reduced the prevalence of peanut allergy by approximately 70–80%. In addition, they found that this tolerance to peanut remains after one year of not eating peanuts. In case of nut-allergic subjects, complete avoidance of nuts is the safest approach. On the other hand, nut intolerance is less frequent. The symptoms of a food intolerance usually occur several hours after eating the food and you need to eat a larger amount of food. In addition, symptoms are less serious than the allergy symptoms. For example, a food intolerance is never a life-threatening event, unlike an allergy case (Borres et al., 2022).

### Nuts and seeds contaminants

Nuts and seeds can be contaminated by pathogens at any stage during production, processing, storage, and distribution. Certain molds produce secondary metabolites, which are toxic to humans and animals, known as the mycotoxins. Of these mycotoxins, the aflatoxins, notably aflatoxin B<sub>1</sub>, are produced by three closely related species of mold: *Aspergillus flavus*, *Aspergillus parasiticus*, and *Aspergillus nomius*. These molds may contaminate tree nuts, but one of the most important crops to be affected is the peanut. Aflatoxins and ochratoxins, which are produced by *Aspergillus* species, have been found to contaminate nuts.

Some species of mold are able to proliferate within growing crops even before they are harvested. This relationship has been found to exist between *A. parasiticus* and peanuts. There are regulatory limits for the aflatoxin levels in foods. For example, in the UK, the sale of nuts for direct human consumption is prohibited if the aflatoxin content exceeds 4 µg kg<sup>-1</sup> or 10 µg kg<sup>-1</sup> for nuts, which are to be subjected to further processing before being sold. Nowadays, contaminants controls are very strict and have to accomplish the law of each country, in order these nuts can be sold. The numbers are low and their significance in public health terms is small.

### Nuts and their role in the diet and health

Nuts and seeds are recognized as healthy foods because of their unique nutritional composition which can make a useful contribution to the dietary intake of macronutrients (notably plant protein, and unsaturated fatty acids), micronutrients (vitamins and minerals), dietary fiber, and energy. Although nuts and seeds are not in the basis of an average Western diet, they play a key role in the Mediterranean diet or diets of Western vegetarians, especially vegans.

All nuts are good sources of dietary fiber, which may help improve the digestive health. In addition, they provide macronutrients, micronutrients, fat-soluble bioactives and phytochemicals. Because nuts are an energy-dense food containing a high amount of fat, there is a concern regarding body weight increase (Julibert et al., 2020). Contrary, due to their fat composition (high in unsaturated fatty acids), nuts may help improve cardiovascular health and prevent CVD diseases and there is enough scientific evidence that frequent nut consumption does not lead to weight gain or increase in the risk of abdominal obesity when incorporated into healthy diets (Nishi et al., 2021). A frequent nut consumption has been associated with lower rates of coronary heart disease and total cardiovascular disease (CVD) incidence and mortality (Becerra-Tomás et al., 2019). Nut intake was also related to lower rates of sudden death as well as of peripheral artery disease, atrial fibrillation, and all-cause and CVD mortality. Nuts have a lipid-lowering effect, so this explains their protective effect on CVD. In addition, nut consumption may help improve endothelial function, reduce postprandial glycaemia and insulin resistance (Becerra-Tomás et al., 2021). Recent studies have also been shown that nut intake may change gut microbiota composition and metabolism.

In summary, a large body of scientific evidence suggests that individuals who regularly consume around 30–42 g/day of nuts, disclose lower rates of highly prevalent chronic non-communicable diseases such as cardiovascular diseases, diabetes and cognitive decline. Thus far, the FDA has approved three qualified health claims on nuts in general and walnuts and macadamias in particular, whereas the EFSA has approved one authorized health claim for walnuts and endothelial function. Nuts and seeds has been included in different dietary guidelines and association reports on goals for health promotion and disease reduction for 2020 (Alasalvar et al., 2020a).

## Conclusion

Nuts and seeds are energy-dense foods, which stand out for their unique nutritional composition and health benefits. They are high in dietary fiber, plant protein, polyunsaturated and monounsaturated fatty acids, several vitamins and minerals. Due to its interesting nutrient composition, especially fat composition, nut consumption has been associated with cardiovascular disease prevention, as well as postprandial glycaemia and insulin resistance decrease, which helps reducing the risk of type 2 diabetes mellitus. There is a large body of scientific evidence, which suggests that a regular consumption of nuts (around 30 g per day) has been associated with lower rates of highly prevalent chronic non-communicable diseases such as cardiovascular diseases, diabetes and cognitive decline.

## Key points

- The chemical composition of organic foods is not significantly different from that of conventional foods for the main nutrients
- Higher levels of polyphenolic compounds in certain organic fruits and of omega-3 polyunsaturated fatty acids in organic milk from grass-fed cows do not contribute significantly to the total dietary intakes
- Pesticide residues in conventional plant products are almost always lower than the allowed maximum limit
- Organic foods also contain natural toxins and residues of allowed pesticides
- Some beneficial associations observed between the consumption of an organic diet and several pathologies are not causal relationships but are due to the better hygiene of life and the dietary behavior of “organic eaters”
- Better nutritional and health values should therefore no longer be claimed for choosing to consume organic foods
- Organic farming cannot be sustainable, especially for cereals, without the proximity of animal husbandry to provide the essential organic fertilizers.
- The lower productivity of organic agriculture require more land, at the expense of biodiversity and carbon storage, and is not sufficient to feed the future world population.

## Introduction

Organic farming, also known as biological or ecological agriculture, should follow a well-defined regulation and the mode of production must be controlled by a certification body. Its main constraints are a minimal use of off-farm inputs, the ban of synthetic chemicals including fertilizers, pesticides, drugs, the use of organic fertilizers and natural pesticides, long crop rotations, the maintenance of organic matter and microbial life in the soil, the ban of genetically modified plants. For organic husbandry, regulations concern welfare, use of organic feeds and limitation of therapeutic interventions (especially antibiotics and hormones). When necessary, derogations are granted. The conversion time from conventional to organic farming varies from 2 to 3 years. Organic farming involves obligations in relation to means of production but not to results with respect to nutritional, health, or sensory properties of the products. Foods marketed under the label “organic” must contain at least 95% ingredients from organic agriculture, with possible food additives from a restrictive list. For processed foods, only biological and physical treatments, except irradiation, are allowed.

Certified organic agriculture represents currently approximately 1.5% of agricultural land worldwide, over two-thirds are grassland-grazing areas. This average hides large variations between continents and countries: for example, 0.3% in Africa and Asia, 1% in North America, 3.3% in Europe (8% in the European Union) with a maximum of 25% in Austria. In the last case, the mountain regions with predominance of grazing livestock are more conducive to organic farming. About half of the world organic land is in Australia but 97% is extensive pasture. In contrast, in sub-Saharan Africa, farmers who have no access to chemical fertilizers and pesticides unknowingly practice a form of non-certified organic farming.

The organic market is increasing everywhere. The demand is mainly motivated by health maintenance, protection of the environment, including water resources, but also for ethical reasons. Thus, fear of “chemical” and attraction to the “natural” are the main reasons for choosing organic foods. Productivity is much lower in organic agriculture, the yields being 20–50% lower than in conventional farming, especially in the case of cereals. As costs of production are higher, selling prices are also significantly higher (30–100% more in stores). The market for organic foods ranges from 1% to 8% of food purchased, according to country, but demand is growing and most of the major consuming countries are dependent on imports.

Although motivations of consumers’ choice, whether ethical or ideological, are not discussed in this article, it is important to know whether the widespread belief of better nutritional and health quality for organic foods is supported by scientific studies.

## Scientific bases for the comparisons of food quality

The chemical composition of foods varies depending on many factors which are not all directly linked to the mode of production. These are, for crops, species and variety, ripeness at time of harvest, yield, climate, season, and for animal products, breed, age, fat content, growth rate and feed intake. It is obvious that when these conditions are comparable, it is unlikely that tissue composition is different. The clearest example is that of milk, whose lipid composition depends strongly on the consumption of grass or fresh forage, regardless of the production system, being organic or conventional.

The differences between organic and conventional products have been the matter of numerous studies and reviews. Several studies failed to demonstrate a significant change in product composition attributable to the mode of production, either because the experimental design or characterization of food were not suitable or well defined, or because statistical interpretation was missing or impossible. This resulted in a lack of useable compositional results, particularly for some vitamins.

It is significant that most reviews published by organizations or associations of organic farming drew a positive balance in favor of organic foods (Soil Association, 2000; Worthington, 2001; Organic Trade Association, 2008; Leifert and Niggli, 2009), whereas independent academic publications claimed that there was an overall lack of significant differences (Williams, 2002; Winter and Davis, 2006; Magkos et al., 2006; Williamson, 2007). The data summarized below result mainly from several reviews published before 2010 in Germany (Woëse et al., 1997), in UK by the Food Standards Agency (Dangour et al., 2009, 2010), in France in 2003 by the French Agency for Food Safety (Afssa, now Anses) with a 2010 update (Guéguen and Pascal, approximately 100 new references added), an US systematic review (Smith-Spangler et al., 2012), two Danish critical reviews (Jensen et al., 2012, 2013) and, more recently, three European comprehensive systematic reviews and meta-analyses (Baranski et al., 2014; Średnicka-Tober et al., 2016; STOA, 2016; Mie et al., 2017) and a French critical review (Guéguen, 2018).

## Essential or beneficial nutrients

### Plant products

A trend toward higher dry matter content in some organic vegetables has sometimes been reported. This difference is not systematic and depends greatly on the cultivar and stage of ripeness at harvest. No significant differences were observed for carbohydrate, protein, and total lipids of vegetables and fruits, particularly when expressed on a dry matter basis.

Organic cereals are generally poorer in protein, which raises, in the case of wheat, technological problems for bread production and requires the choice of adapted varieties. However, it seems that the balance of essential amino acids is sometimes better in organic compared to conventional wheat.

For minerals and trace elements, it can be concluded, from a large number of individual results on approximately 15 species of fruits and vegetables, that overall there is a lack of differences in levels. Occasionally, magnesium and iron contents have a trend to be somewhat higher in some organic vegetables, but no differences were observed for most minerals (calcium, potassium, sodium, copper, zinc, or selenium). Some extremely high levels of copper were found in potatoes, tomatoes, and grapes, due to repeated treatments with copper sulfate. The mineral composition of seeds is almost constant and no difference was recorded. Mineral and trace element contents of bread depend on the proportion of bran in the flour and not on the mode of production of wheat.

Too few studies have been done on vitamins A, E, and B group in vegetables and fruits, but the differences between organic and conventional products seem small. However, many studies have examined vitamin C, especially in tomatoes (Dangour et al., 2009), and a trend toward higher levels in some organic fruits and vegetables was confirmed but not systematically: for 43 individual comparisons, 19 (44%) were higher, 18 (42%) were equal, and 6 (14%) were lower (Guéguen and Pascal, 2010). This trend must be tempered by taking into account other factors that affect even more the level of vitamin C, especially the freshness of the product.

Several studies have shown the presence of larger amounts of phytomicrocomponents such as polyphenols and other phenolic compounds in organic plants. In the absence of phytopharmaceutical treatment, this increase can be explained by an increased defense reaction of the plant unprotected against attacks from insects or fungi. The production of secondary metabolites, including molecules with beneficial antioxidant properties, is then promoted. Low availability of soil nitrogen could also have the same effect. Thus, the levels of polyphenols, especially flavonoids, are sometimes 20–40% greater in organic vegetables and fruits, as mostly shown for tomato. However, this observation is not systematic because among 70 individual validated data across all products,

31 (54%) were higher in organic agriculture, 23 (40%) were equal, and three (5%) were lower (Guéguen and Pascal, 2010). In contrast, levels of carotenoids in organic fruits and vegetables are essentially lower or equal, especially for lycopene in tomatoes.

Several studies have shown that the antioxidant power of organic apples is 10–15% greater than that of conventional apples, but it remains to show that these small differences have any nutritional significance.

A systematic review (Baranski et al., 2014) on nutritional quality of conventional vs. organic foods, supported by the UK Food Standards Agency, has found significant differences only for nitrogen (protein in grains and nitrate in vegetables), being lower in organic products, and phosphorus, being lower in conventional products. However, it is important to remind that phosphorus is not a limiting factor in the human diets. Despite the use of very strict criteria for exclusion of publications, this review is currently the most comprehensive.

The data of this last meta-analysis were utilized by an international group of experts in a Science and Technology Options Assessment (STOA) report submitted in 2016 to the European Parliament (report condensed in the review of Mie et al., 2017), the conclusions of which are as follows: “In summary, collectively the published meta-analyses indicate a modestly higher content of phenolic compounds in organic crops, which is plausible. These compounds are believed to play a role in preventing several non communicable diseases in humans, although the detailed mechanisms are not generally well understood. It is important to bear in mind that in many cases the variation in the concentration of phenolic compounds is greater between different types and varieties of crops and between years, climates, soils, etc. than between production systems”.

For all the very many other constituents analyzed (dry matter, fibers, minerals, trace elements, vitamins, nitrate, etc.), the differences are not significant or have no nutritional impact. The lower protein content of organic cereals, which affects the baking value of wheat, is confirmed by all systematic reviews. A better protein (e.g., amino acid balance) quality of organic cereals, in particular slightly higher contents of threonine and leucine in wheat and more globulin and albumin in triticale have sometimes been observed. However, these differences are not always significant and have not been confirmed by all recent reviews. As for mineral and trace elements, it is well known that their contents are not very variable in the grain and do not depend on fertilization.

Here is the general conclusion of the STOA European report on organic plants: “Most aspects of crop composition, including vitamins and minerals, are not affected by the agricultural management system. If they are it is only to a limited extent. From the perspective of nutritional guidelines, which are generally concerned with macronutrients, vitamins and minerals, there is no reason to prefer organic over conventional plant foods or vice versa”.

## Animal products

The diet of organically farmed animals is not very different from that of conventional animals, particularly for pigs and poultry, which eat mainly grains and oil-seed cakes. The only difference is that most feeds (95–100%) must come from organic farms. However, the chemical composition of these feeds, mainly seeds, depends little on production mode. A supplement of minerals, trace elements, and vitamins in organic diets is allowed.

For most constituents, the composition of meat depends little on the mode of production. Only lipid composition varies according to animal's breed and age. Thus, comparisons must be made on animals of the same age because the degree of adiposity varies accordingly. For example, an “industrial” 40-day-old chicken cannot be compared to an 80-day-old organic chicken. Feed can affect fatty acid composition, especially of unsaturated fatty acids in meat, and more in pigs and poultry than in ruminants. Thus, the meat of cattle mainly fed with grass or fresh forage, preferred in organic husbandry, is richer in polyunsaturated fatty acids (PUFA) omega-3 and sometimes in conjugated linoleic acid (CLA) than the meat of cattle fed with corn silage and concentrate. It is the same for the composition of eggs. However, similar compositions are obtained for extensive grazing livestock or for hens with an outdoor run.

Several recent and validated studies have focused on the composition of milk which, for most of its constituents (protein, lactose, minerals, and trace elements), is fairly constant. Only very omega-3 PUFA levels and CLAs that depend heavily on the season and the proportion of grass in the diet (Butler et al., 2008). Similar results, even better, can be obtained by extensive livestock grazing or by incorporation of clover or flaxseed. Only two trace elements from milk, iodine and selenium, are influenced by dietary intake and their levels are increased by the use of a mineral supplement. Selenium content of feed strongly depends on soil concentration.

Modeling was done in the recent STOA report. Based on results from the meta-analysis by Średnicka-Tober et al. (2016), the increase in PUFA content of organic meat is not clearly demonstrated. Even under the high assumption of the all-organic food scenario, the maximum nutritional impact would be less than 7% of the requirement. Here are excerpts from the findings of this report on omega-3 in humans ... “On average, replacing conventional with organic dairy products while keeping the diet constant will increase the intake of omega-3 PUFA by approximately 4%. Replacing conventional meat products with organic meat products may increase the omega-3 PUFA intake by an additional 6% ... Accordingly, at this point, there is no strong evidence available that would support the existence of health benefits of a higher ruminant fatty acid content in organic compared to conventional milk ... It is therefore not possible to conclude any specific health benefit offered by a modest increase in omega-3 PUFA intake from a change from conventional to organic milk and meat.”

The desirable increase in the intake of omega-3 fatty acids in the diet is much more effective by using certain vegetable oils (flaxseed, rapeseed) or fatty fish, which simultaneously leads to a decrease in intake of saturated fatty acids.

Another conclusion of all the reviews is that organic milk is always poorer in iodine and selenium, two essential trace elements added to the mineral supplement in intensive conventional breeding.

## Undesirable components

Nitrate is abundant in vegetables but not in fruits, cereals, milk, or meat. Nitrate levels in vegetables vary according to several factors, including sunlight, rainfall, and especially nitrogen fertilization. Nitrate levels are lower in greenhouse production, and in autumn compared to spring and summer for field production. They increase when nitrogen is provided by rapidly available soluble fertilizers. Organic farming uses mostly organic fertilizers such as guano, meat or blood meals, which are rapidly assimilated by the plant and thus also lead to high levels of nitrate. Nevertheless, the published comparisons show that organic vegetables (lettuce, spinach, rucola, carrot, beet, etc.) have usually lower nitrate levels than conventional vegetables.

Nitrate does not have a good reputation because of past accidents of methemoglobinemia in infants with poor food hygiene, notably contaminated feeding bottles in which microorganisms accelerated the reduction of nitrate to nitrite. Improvement of hygiene leads to a very low risk nowadays. In adults, the formation of carcinogenic nitrosamines has long been suspected. In fact, many studies have shown that nitrate of vegetables, which represent approximately 75% of ingested nitrate, have no negative effect on health in adults and their carcinogenic effect has not been demonstrated (European Food Safety Authority, 2008). It is noteworthy that water is also a vector of nitrate in the diet but the maximum limit (usually 50 mg L<sup>-1</sup>) is not a threshold of toxicity for adults. In addition, several studies (Katan, 2009; Hord et al., 2009) emphasize the beneficial effects of nitrate, thanks to the formation of nitrogen monoxide (NO), especially in the immune protection of the mouth and stomach, in the prevention of hypertension and cardiovascular disorders.

The fear of residues of synthetic pesticides in conventional plant products is by far the main reason for the choice of organic foods by consumers. It is true that the ban of their use in organic agriculture should logically lead to the absence of residues in food. Many surveys have been conducted on these residues in the US, UK, New Zealand, Netherlands, France, and elsewhere. For example, an annual report of the European Food Safety Authority (EFSA) compiles the results of legal controls in the Member States on a large number of plant products. For 2018, no detectable traces of synthetic pesticide residues were found in 58% of samples (all origins confounded), traces were detected in 40.5% but at levels below the maximum residue level (MRL), and only 1.5% samples exceeded the MRL. These results overlap well with those of other national studies. It is noteworthy that the tests are done on raw, unwashed, unpeeled products.

MRL is the pesticide residue level in a particular food following its production according to Good Agricultural Practice (GAP). There is an MRL for each pesticide and each plant species, and values adopted have been harmonized in the UE in 2008. Taking into account food habits of consumers, the sum of residues of a given pesticide from all food respecting MRL must not from a regulatory point of view exceed its acceptable daily intake (ADI). However, when a residue of one food is found above the MRL, the result does not automatically mean the levels of residue found are a risk to people's health. What matters is the sum on all residues in the total diet. ADI itself is calculated with a safety factor of at least 100, from the highest dose without effect observed in laboratory animals.

These assessments are based on a calculation of risk, taking into account the possible cumulative effects of several molecules of the same chemical group having the same mechanism of action, and leading to a "reasonable certainty of no harm".

If synthetic pesticides raise a distinct risk to health (e.g., skin disorders and hematopoietic cancers) for the farmer highly exposed and poorly protected, this should not be amalgamated with the negligible risk to consumers who ingest doses of residues of the order of one million times lower. Based on studies published by international bodies, residues of synthetic pesticides are without any risk to the consumer and the expected marginal benefit of eating more organic products is insignificant. Thus, according to an UE study, individual chronic exposure to pesticides would be between 0 and 0.2% of the acceptable daily intake (ADI). Other studies done in the US by the FDA also show pesticide exposures below 1% of ADI, or approximately 10,000 fold lower than the highest dose having no effect on the animal. A study from the University of Oxford found no difference in overall cancer risk when comparing 180,000 women aged 50 years or over who reported never eating organic food with around 45,000 women usually or always eating organic food.

To be on the safe side, it is advisable, especially for infant feeding, to wash and peel vegetables and, if possible, fruits. It should be noted that there is a consensus on the beneficial health effects of consumption of fruits and vegetables, whereas nearly half contain detectable residues of synthetic pesticides. Arguments based on pesticide residues (and nitrate in the case of vegetables) should not, therefore, be used as a pretext for decreasing the recommended consumption of fruits and vegetables.

It is true that organic plant products do not generally contain residues of synthetic pesticides. However, surveys sometimes reveal their presence at levels below the MRL, which is due to pollution, errors, faults, or derogations. Furthermore, organic products can contain residues of natural pesticides authorized as rotenone, pyrethrins, azadirachtin from neem oil (from *Azadiracta indica*), and particularly copper often heavily used. These residues are not taken into account in official inspections, although their safety is not guaranteed. Thus, rotenone is neurotoxic and is banned in the EU since 2008, whereas azadirachtin from neem oil, permitted in some countries (e.g., by derogation in France), is an endocrine disruptor. Copper in excess poisons the soil and is not without health consequences.

Like the beneficial antioxidants, toxic secondary metabolites can be formed as a defensive response to attacks by insects or fungi in untreated plants. The effects on human health of hundreds of natural toxins acting as insecticide or fungicide have not been well studied. Some such as cruciferous glucosinolates (sometimes beneficial), glyco-alkaloids in potatoes and tomatoes and celery furanocoumarins are well known. Others have not been identified or studied, and it may be important consider their effects on health.

Similarly, lipid transport proteins in Rosaceae (most edible fruits) are defense proteins responsible for severe allergies in children and adults. Studies have shown that they are more abundant in the skin of organic apples and plums whose consumption should not be recommended for allergic patients (Barré et al., 2009).

It would be logical to find higher levels of carcinogenic mycotoxins in organic cereals not protected by antifungal pesticides. In fact, if cases of severe contamination by mycotoxins have been found in organic cereals, the difference with the conventional grains is not systematic (Murphy et al., 2006). Thus, the presence of *Fusarium* mycotoxins in wheat depends on many factors and several recent studies in various UE countries (Germany, UK, Netherlands, Italy) showed that organic wheat is sometimes the least contaminated. The main factors of variation in mycotoxin levels are the year, the climate, and the storage conditions.

The risk of pollution by heavy metals, polychlorobiphenyls (PCBs), or dioxins is not different in the two modes of production but it depends on exposure to atmospheric deposition. All outdoor productions, animal or vegetable, are most at risk. This is usually the case for organic agriculture but also often for conventional agriculture, especially for the meat of grazing animals (Dervilly-Pinel et al., 2017). Thus, milk from cows on pasture, whether organic or conventional, is less well protected than the milk from cows in barn because the consumption of grass and soil may be an important vector of various pollutants. It is the same for eggs from hens with outdoor run, often more contaminated than eggs from hens reared in cages.

For similar reasons, the risk of bacterial or viral contamination is greatest in outdoor production, from hydrotelluric sources (e.g., *Clostridium botulinum*) or contact with wildlife fauna (e.g., *Campylobacter*).

Microbial contamination of plants can be enhanced by the use of organic fertilizers compared to mineral fertilizers. Thus, the use of manure, even composted, increases the risk of contamination of fruits and vegetables by *Escherichia coli*, *Salmonella*, or *Listeria monocytogenes*. On the one hand, poultry manure from organic livestock is often contaminated with *Campylobacter*, which may be an increased risk for eggs. However, according to several studies, these are only trends and, on the other hand, it appears that the resistance of these bacteria to various antibiotics is lower in organic farming.

Cases of mastitis in dairy cows are more frequent without that with antibiotic treatment. However, milk is not sold then and a limited use of antibiotics in livestock is also authorized in organic husbandry, if required. Internal parasites in sheep are conditions prevalent in organic farming, but the new UE regulation now allows the use of antiparasite treatments without limitation.

The use of hormones is universally prohibited in organic animal husbandry, but also in conventional husbandry in the UE. Several countries (USA, Canada, Australia, South Africa, New Zealand, Mexico, Chile) authorize steroid hormones (estradiol, progesterone, testosterone, zeranol, trenbolone acetate, and melengestrol acetate) to increase meat yield in beef cattle, or a protein hormone, rBST (recombinant bovine somatotropin) to increase milk production in dairy cows (prohibited in Canada based on concerns about health effects, including mastitis in treated animals). The Food Safety authorities of these countries ensure that the possible residues found in meat and milk do not present any health issue for the consumer (e.g., early puberty in girls, risk of breast cancer or allergy, endocrine disruption have been mentioned in countries where these treatments are not allowed) if the treatments are applied according to the regulation.

## Health effects

### Clinical trials

Given the many factors that determine the nutritional and health qualities of agricultural products, it is difficult to demonstrate significant differences resulting specifically from the production system, organic or conventional.

Ten controlled clinical studies comparing organic and conventional foods were included in the systematic review supported by the UK Food Standards Agency. Most were carried out on subjects consuming conventional or organic vegetables and fruits, and the antioxidant status of blood plasma was used as a biomarker. None of these studies could demonstrate a positive effect of diet on this blood parameter but this does not suffice, however, to characterize the health status. There is no published long-term study comparing the health effects of a diet exclusively organic or conventional, using several criteria relevant to health. This lack is unfortunate, but the small differences found in the composition of foods would leave little chance of finding a significant health effect.

In several trials, none of the numerous measured health biomarkers were affected by the cultivation system, particularly for the effect of organic fruits and vegetables on blood anti-oxidant status. In fact, the antioxidant capacity of the diet depends, for about half, on the polyphenolic compounds which are mostly provided, in Europe, by tea and coffee (50%), followed by cocoa and red wine, the contribution of fruits and vegetables being less than 10%. Therefore, an eventual increase of 15–30% of the content of polyphenolics in organic fruits cannot have a detectable effect on the blood anti-oxidant status.

### Epidemiological studies

Observational epidemiological studies involving large cohorts of consumers receiving long-term organic or conventional food are scarce. This is primarily due to the fact that it is difficult to recruit participants who regularly consume a significant proportion of certified organic foods (which represent in France less than 5% of the foods) and that a fully organic diet is exceptional.

The largest prospective study was published by epidemiologists from Oxford University in 2014 (Bradbury et al., 2014). It was conducted over 9 years on more than 600,000 women older than 50 years. It showed that the consumption of organic food had no influence on the incidence of common cancers, except perhaps on non-Hodgkin lymphoma. This should, in this regard, exonerate the traces of residues of synthetic pesticides that can potentially be found in products from conventional agriculture.

A large French prospective study, NutriNet-Santé (and its BioNutriNet component), covers cohorts of 60,000 to 70,000 adult volunteers, 78% of whom are women, that are followed since 2009 and periodically respond to a questionnaire on their diet. This study first observed that the frequency of overweight, obesity and metabolic syndrome was lower in heavy organic consumers

(Kesse-Guyot et al., 2017). However, as the authors acknowledged, these are associations and not causal links. Many causes of bias and confounding factors, partially taken into account in the interpretation of the results, are involved in this study: on the one hand, the proportion of organic foods in the diet, evaluated by questionnaire, is imprecise and clearly overestimated and, on the other hand, it is well known that organic food eaters are more attentive to the balance of their diet and, more generally, to their lifestyle (tobacco, alcohol, physical exercise...).

The most publicized study (Baudry et al., 2018) concerned the association between organic food and cancer and its conclusions were translated in the medias by headlines such as “eating organic reduces cancer risk by 25%”. This study was the subject of many critical reactions because, despite the precautions objectively taken by the authors of the article, this purported beneficial effect made public opinion. The study compared the 20% of the cohort who never consumed organic with the 20% for whom more than half of the food was organic. In fact, this association has only been observed in women and it is not for all types of cancers but only for postmenopausal breast cancer and some lymphomas. According to the authors, one explanation could be the lower ingestion of synthetic pesticide residues by organic consumers. The very low contribution of pesticide residues in conventional fruits and vegetables, not quantified in the study, certainly does not support such a hypothesis, especially since, when the statistical interpretation only takes into account the consumption of plant products, the only ones that may contain pesticide residues, the observed association is no longer significant for breast cancer. The statistical interpretation of data from NutriNet-Sant  has also been severely criticized and therefore the conclusions of the studies strongly contested. In addition to the flaws in the statistical methodology, the poor evaluation of the share of organic in the diet does not allow any associations observed to be attributed to the differences between organic and conventional foods but to the behavior of the “organic eater”, more vigilant about his hygiene of life and eating more balanced diets, including less meat and more fruits and vegetables. The noted associations concern, therefore, the effect of the lifestyle and eating behavior of organic eaters and not the favorable effect of organic foods alone. These would then be possible beneficial effects on the health of a flexitarian diet (less meat and more vegetable foods). This is objectively and clearly admitted by one of the co-authors of the article: “The main lesson is that going organic without reducing the share of meat in our consumption is useless, neither for health, nor for the environment”.

### Organoleptic quality

Organoleptic characteristics of organic foods have not been the subject of many comparative studies. Those that have been published do not highlight superior sensory qualities due to the production method, as results are variable and contradictory. For fruit and vegetables, sensory properties are mainly determined by the variety, ripeness and freshness. Organic farming often uses more hardy cultivars and, if production is local, the harvest can be later. For meat, taste properties depend mainly on breed, age, and degree of fatness. The mode of production, organic or conventional, is not a criterion of taste. For milk and eggs, no reproducible difference was obtained in the literature. In line with the nutritional values and health attributes, regulation of organic agriculture does not imply any better organoleptic quality of its products, but only an obligation of means of production.

### Conclusions and prospects

Consumption of organic foods cannot have a nutritional effect in the overall diet. Even if we admit a slight superiority of organic foods for some nutrients in some foods, the difference would be insignificant in the global regime. For example, measures taken in France for “one organic meal per week in collective catering” cannot have significant influence on the quality of diet throughout the week. The health impact is also negligible because the effect of organic vegetables or fruits on blood antioxidant status could not be demonstrated, nitrate in vegetables are safe and chemical residues of conventional foods, including synthetic pesticides, are almost entirely below the allowed maximum limit and do not pose a risk to health. The few clinical or observational epidemiological studies have failed to attribute any beneficial effect to organic food on the incidence of various diseases, including cancer. Better nutritional and health values should therefore no longer be claimed for choosing to consume organic foods. The argument of preventing climate change or preserving biodiversity is also highly debatable. Indeed, the lower yields of organic farming (20–50%) lead to devoting more areas to the same production, at the expense of forests, fallows, wetlands and permanent meadows, and therefore biodiversity and carbon storage.

In most Western countries, organic foods account for less than 5% of foods consumed. Despite a strong trend of increasing demand, this share will be limited if a larger supply does not bring down the selling prices of organic foods. Significant imports from distant areas are not desirable because they are incompatible with the ecological spirit of organic agriculture. Organic production in industrialized and emerging countries will also be limited by local availability of organic fertilizers and especially by heavy yield losses (e.g., 50% for wheat in France). In developing countries, particularly in several parts of sub-Saharan Africa, food production could be increased through a wide application of the principles of organic agriculture for food crops associated with animal husbandry. However, this production will be self-consumed and may not be sufficient without recourse to a minimum of mineral fertilizers and plant protection products to reduce the very high crop losses. The increasing demand for organic foods, currently hampered by higher purchase prices, could explode if a large increase in local production or imports led to falling prices. However, this would be a vicious circle as farmers’ income could drop and then discourage their conversion. In addition, throughout the world, intensive conventional farming will be subject to environmental constraints worldwide, including the use of pesticides.

Reductions of 30–50% of the amounts used presently are already planned in some countries. Under these conditions, the difference in food quality and ecological effects perceived by consumers will decrease and will not be market-friendly with organic foods.

Organic farming cannot be sustainable, especially for cereals, without the proximity of animal husbandry, including intensive breeding, to provide the essential organic fertilizers. An objective of the European “Green Deal project” to reach 25% of land in organic farming by 2030 seems paradoxical and unrealistic, while productivity is much lower and that, according to the FAO, it would be necessary to increase food production by 50–70% to feed the future world population.

Between the two extreme forms of agriculture, intensive conventional and organic farming, there are several intermediate modes of production that provide good quality food and preserve the environment, without sacrificing the high productivity required to maintain the food sovereignty of developed countries and to ensure, or even improve, global food security.

### Glossary

**Aglycone** A non-sugar compound remaining after replacement of a sugar by a hydrogen atom.

**Conjugate** Two or more compounds bound together.

**Enzyme** A protein with contains an active site which binds to a substrate to help catalyse a reaction.

**Glucosidase** An enzyme that cleaves the bond between glucose and another compound.

**Glycoside** Organic compounds formed when a monosaccharide is bound to another compound.

### Abbreviations

CVD	Cardiovascular disease
eNOS	Endothelial nitric oxide synthase
NADPH oxidase	Nicotinamide adenine phosphate-oxidase
NF-κB	Nuclear factor kappa B
NO	Nitric oxide
NRF2	Nuclear factor (erythroid-derived 2)-like 2
SOD	Superoxide dismutase

### Introduction

There is considerable evidence to suggest that populations that consume diets rich in fruits and vegetables, whole-grain cereals, and complex carbohydrates have a reduced risk of a range of chronic diseases. This has led to the suggestion that the diversity of substances found in food, particularly plant-derived foods, may underlie the protective effects that are attributed to diets high in

fruits and vegetables. Although fruits and vegetables are rich sources of micronutrients and dietary fiber, they also contain a wide variety of secondary metabolites, which provide the plant with color, flavor, UV protection, and antimicrobial and insecticide properties. Many of these substances have been attributed a wide array of biological properties but have yet to be recognized as nutrients in the conventional sense. These potentially protective plant compounds, termed phytochemicals, are receiving increasing attention and some have been termed phytonutrients, as they have been shown to exert numerous physiological functions in mammalian systems. However phytonutrients are not currently defined as 'nutrients' as they are not essential for human/animal growth and development but may help maintain health throughout life, including the prevention of chronic disease. Many of them are ubiquitous throughout plants and as a result are present in our daily diet in varying amounts. Among the most important classes are the flavonoids, which are classified based on their chemical and structural characteristics. The present article focuses on the different classes of phytochemicals and their potential relationships to human health.

### Phytochemicals: General

Phytochemicals comprise a wide group of structurally diverse plant compounds, which are predominantly associated with the cell wall and widely dispersed throughout the plant kingdom. They are secondary metabolites in plants, characterized by having at least one aromatic ring with one or more hydroxyl groups attached. The nature and distribution of these compounds can vary depending on the plant tissue in which they are located, but they are mainly synthesized from carbohydrates via the shikimate and phenylpropanoid pathways. They range in chemical complexity from simple phenolic acids, such as caffeic acid, to complex high-molecular-weight compounds, such as the procyanidins/tannins, and they can be classified according to the number and arrangement of their carbon atoms. In plants, they are commonly found conjugated to sugars and organic acids and can be classified into two groups, flavonoids and nonflavonoids. Although there are many subclasses of bioactive phytochemicals, including flavonoids, stilbenes, lignans, phytosterols, sulfides, glucosinolates, and carotenoids (**Figure 1**), this article focuses mainly on the flavonoid subgroup, one of the most researched classes of phytochemicals to date; however, a brief introduction to the other classes is provided below:

- Stilbenes are present in a wide range of plants and one of the most studied stilbenes, *trans*-resveratrol, found in grapes and wine, is known for its effects on vascular activity and longevity.
- Lignans are phenolic compounds present in high concentrations in linseed (flaxseed) and studies suggest they have the potential to reduce the risk of cardiovascular disease (CVD) and cancer.
- Phytosterols are found in vegetable oils and are most notably known for their ability to decrease blood LDL-cholesterol levels and lower the risk of CVDs.
- Sulfides and glucosinolates are present in garlic and brassica vegetables and are most commonly investigated for their anticarcinogenic properties.
- Carotenoids are pigments (red, orange, yellow) common to many fruits and vegetables and their consumption has been linked to reduced risk of chronic degenerative diseases.

### Flavonoids

Flavonoids constitute a large class of phytochemicals that are widely distributed in the plant kingdom, are present in high concentrations in the epidermis of leaves and skin of fruits, and have important and varied roles as secondary plant metabolites. More than 8000 varieties of flavonoids have been identified, many of which are responsible for the colors of fruits and flowers. They are found in fruits, vegetables, tea, wine, dark chocolate, grains, roots, stems, leaves, and flowers and are thus regularly consumed by humans. Although it has been widely known for centuries that chemical derivatives of plant origin possess a broad spectrum of biological activities, it was first suggested that flavonoids may be important for human health in the 1930s when it was observed that a fraction from lemon juice could decrease the permeability of arteries and partially prevent symptoms in scorbutic pigs. At the time, it was suggested that these compounds should be defined as a new class of vitamins, vitamin P, and the substance responsible for these effects was identified as the flavonoid rutin. However, the data were not generally accepted and the term vitamin P was abandoned in the 1950s. There was renewed interest in flavonoids when a potentially protective role of flavonoids in relation to heart disease in humans was reported. Since then, there has been a surge of interest in the potential role of flavonoids in human health, with research suggesting antioxidant effects, hormonal actions, anti-infectious actions, anti-inflammatory and cancer-preventative effects, the ability to induce chemical defense enzymes, and actions on blood clotting and the vascular system. However, concrete clinical evidence that they positively influence human health is lacking, and potential adverse effects have also been reported for a limited number of polyphenols.

Other flavonoid groups that are thought to be less important from a nutrition perspective are the dihydroflavones, flavan-3,4-diols, coumarins, chalcones, dihydrochalcones, and auronones. The basic flavonoid skeleton can have numerous constituents; hydroxyl groups are usually present at the 3-, 5-, and 7-positions. Sugars are very common, and the majority of flavonoids exist naturally as glycosides. The presence of both sugars and hydroxyl groups increases water solubility, but other constituents, such as methyl or isopentyl groups, increase flavonoids lipophilicity. Although many thousands of different flavonoids exist, they can be classified into a few different subclasses. The main subclasses that are important from a human health perspective are the flavones, flavonols, flavan-3-ols, flavanones, anthocyanins, and isoflavones (and their polymeric forms) (**Figure 2**). Extensive

**Figure 1** Chemical structure of flavonoid, stilbene, lignan, phytosterol, sulfide, and carotenoid.

information on the different flavonoids present in commonly consumed plant-based foods including fruits, vegetables, and drinks is available; however, there is wide variability in the levels present in specific foods, in part due to seasonal changes and varietal differences.

### Flavonols

Flavonols are arguably the most widespread of the flavonoids because they are dispersed throughout the plant kingdom. The distribution and structural variations of flavonols are extensive and have been well documented. The most common flavonols are quercetin, kaempferol, myricetin, and isorhamnetin.

### Flavones

Flavones have a close structural relationship to the flavonols, but unlike flavonols they are not widely distributed in plants. Their only significant dietary occurrences are in celery, parsley, and a few other herbs, and they predominantly occur as 7-O-glycosides (e.g., luteolin and apigenin). In addition, polymethoxylated flavones have been found in citrus fruits (e.g., nobiletin and tangeretin).

**Figure 2** Structures of the major subclasses of flavonoids: flavones, flavonols, flavan-3-ols, flavanones, anthocyanins, and isoflavones.

### Flavan-3-ols (Both Monomeric and Polymeric Forms)

Flavan-3-ols, often referred to as flavanols, are the most complex class of the flavonoids because they range in size from simple monomers (catechin and its isomer epicatechin) to the oligomeric and polymeric proanthocyanidins, which are also known as condensed tannins. Proanthocyanidins can occur as polymers of up to 50 units, and when hydroxylated they can form gallocatechins or undergo esterification to form gallic acid. Red wine contains oligomeric proanthocyanidins derived mainly from the seeds of black grapes. Green tea is also a rich source of flavan-3-ols, principally epigallocatechin, epigallocatechin gallate, and epicatechin gallate. However, during fermentation of tea leaves the levels of catechins decline and thus the main components of black tea are high-molecular-weight thearubigins, whose structures are derived from flavonoids. The catechins are widespread, but the main sources in the diet come from processed plant-foods such as tea, wine, and chocolate.

### Anthocyanins

Anthocyanins are widespread in nature, predominantly in fruits, leaves, and flower tissues, in which they are responsible for the red, blue, and purple colors. They are also found in stems, seeds, and root tissue. In plants, they protect against excessive light by shading leaf mesophyll cells and scavenging radicals. Additionally, they play an important role in attracting pollinating insects. The most common anthocyanins are cyanidin, pelargonidin, delphinidin, peonidin, petunidin, and malvidin, which are present in plants as sugar conjugates.

### Flavanones

The flavanones are the first flavonoid products of the flavonoid biosynthetic pathway. They are characterized by the presence of a chiral center at C2 and the absence of the C2–C3 bond. The flavanone structure is highly reactive, and they have been reported to undergo hydroxylation, glycosylation, and O-methylation reactions. Flavanones are present in high levels in citrus fruits, with the most common glycoside known as hesperidin (hesperetin-7-*o*-rutinoside), which is present in citrus peel. Interestingly, flavanone rutinosides are tasteless, whereas the flavanone neohesperidoside conjugates (e.g., neohesperidin) from bitter orange and naringenin (naringenin-7-*o*-neohesperidoside) from grapefruit peel have an intensely bitter taste.

### Isoflavones

Isoflavones are flavonoids, but they are also called phytoestrogens because of their ability to bind to estrogen receptors and exert weak oestrogenic activity. Apart from some basic structural similarities to mammalian estrogens, the key to their estrogenic effect is their unique structural orientation and the presence of the hydroxyl groups on the A and B rings. They are classified as both estrogen

agonists and antagonists because they compete with estrogen for their receptors. They have also been demonstrated to exert a wide number of biological effects that are independent of their estrogen receptor activity.

### Current Estimates of Intake

Diets rich in plant-derived foods can provide more than 1 g of phenolic compounds per day (which includes phenolic acids, flavonoids, and their polymers), although there are major international and inter-individual differences in exposure. There are six main diet-derived flavonoid subclasses of present interest to human health; namely, flavonols, flavones, flavan-3-ols, flavanones, anthocyanins, and isoflavones, and their principal dietary sources are shown in (Table 1).

Given the differences in dietary intake, particularly for fruits and vegetables, between populations, it is not surprising that the relationships between the predominant flavonoids and their sources will vary between populations, nor is it unexpected that there will be wide inter- and intra-individual variations in intake of the individual flavonoid subclasses. It is only recently that comprehensive databases for estimating intakes of the diverse subclasses of flavonoids have become available. Previous estimates have been based on only a few subclasses and vary considerably among studies depending on which subclasses were included and which foods were considered in the assessment of intake. Two recent studies have estimated the range of intake of the different flavonoid subclasses in the USA and Spain (Table 2). In the USA, flavan-3-ols contributed the most to total flavonoid intake, although no data were available for estimating proanthocyanidin intakes in this study. In Spain, higher intakes of flavanones and anthocyanins were observed compared to the USA. The main sources of total flavonoid intake were apples, red wine, and other fruits in Spain, whereas tea and citrus fruits and juices were the main contributors in the USA. (Table 1).

### Absorption and Metabolism of Flavonoids

Many flavonoids occur as glycosides in foods, and both flavonoid structure and the type of sugar moiety determine their primary site of absorption. Some flavonoid species are absorbed in the small intestine, where the sugar moiety becomes hydrolyzed by either lactase phloridzin hydrolase, which is located at the brush border membrane or via intracellular beta-glucosidase activity. The type of glycoside present has a significant impact on the site of flavonoid absorption; glucosides are primarily absorbed from the small intestine whereas rutinoides (a disaccharide) require hydrolysis by colonic bacteria before absorption. Methylation, glucuronidation, and sulfation are also common metabolic conjugates of flavonoid metabolism. In addition, the type of flavonoid structure also

**Table 1** Principal dietary sources of flavonoids

Flavonoid	Compound	Food source
Flavonol	Quercetin, kempferol, myricetin	Onion, apple, broccoli, tea, olives, kale, cranberry, lettuce, beans (green, yellow)
Flavone	Luteolin, apigenin, tangeretin	Olives, celery, parsley, tangerines
Flavan-3-ol	Catechin, epicatechin, epigallocatechin	Tea, red wine, chocolate, apple
Flavanone	Naringenin, hesperidin	Citrus fruit
Anthocyanin	Cyanidin, delphinidin, malvidin, petunidin	Grapes, cherries, berries, blood orange juice
Isoflavone	Genistein, daidzein, glycitein	Soy and soy products

**Table 2** Estimated dietary intake of flavonoid subclasses in different countries

Flavonoid subgroup	Estimated intake (mg day <sup>-1</sup> )		
	USA	Spain	Japan
Flavonol	13	19	16
Flavone	2	3	<1
Flavan-3-ol	157	33	40
Flavanone	14	79	No data
Isoflavone	<1	<1	50
Anthocyanins	3	19	No data
Proanthocyanidins	No data	189	No data

impacts absorption as some forms of flavonoids, such as the isoflavones (glycosides), also require colonic hydrolysis of the sugar moiety before absorption. The absorption and metabolism of flavan-3-ols differs markedly depending on the chemical complexity of the species; for example, the location of absorption for monomeric species is primarily in the upper small intestine whereas absorption of higher-molecular-weight polymers requires prior bacterial metabolism in the large intestine before absorption of the metabolites. Absorption from the small intestine generally results in peak plasma concentrations within 1–3 h after ingestion, which is the case for most flavonoids, whereas absorption from the large intestine can take as long as 8–12 h before peak plasma concentrations of metabolites are observed.

Human and animal studies exploring the absorption and metabolism of flavonoids identify significant proportions of glucuronide, sulfate, and methylated metabolites in both the circulatory system and in tissues/organs such as the stomach, intestine, liver, brain, and eyes. Following absorption, flavonoids are readily metabolized in intestinal cells to form glucuronide and sulfate conjugates that appear in portal blood although additional conjugation (such as methylation) can occur in the liver. The conjugation of flavonoids in the small intestine and liver generally has a significant impact on polarity/water solubility and therefore rates of urinary excretion. Metabolism in other organs and tissues (such as the kidney) has also been reported. Flavonoids for the most part are processed in the body much the same as phenolic drugs, and their absorption and subsequent metabolism can also be affected by such factors as matrix, chemical composition, relative pH, age, gender, and host genetics.

Even though some species of flavonoids are absorbed intact (i.e., primarily nonglycosylated forms), substantial amounts of lower-molecular-weight products of flavonoid degradation (spontaneous) or microbial catabolism (via colonic micro flora) are also absorbed after initial biotransformation by the colonic microflora. The colon contains numerous microorganisms, and as a result has significant capacity for catalytic and hydrolytic reactions. These colonic bacteria produce enzymes that are capable of stripping flavonoid conjugates of their sugar moieties, thus enabling free aglycones to be absorbed. The enzymes produced by colonic bacteria can also break down the flavonoids into simpler compounds, resulting in the production of a range of derivatives. The main identified products of colonic metabolism are benzoic acids, phenylacetic acids, and phenylpropionic acids. In addition various lower-molecular-weight products of ring fission can occur where all of these above listed products may be subsequently reabsorbed from the colon and enter the systemic circulation or be eliminated in feces. These products of colonic metabolism are a very active area of current flavonoid research and some of these products may be common across many species of flavonoid and in the future may prove to be useful biomarkers of flavonoid intake. The bacterial transformation of flavonoids is also an important area for future research because these metabolic reactions may result in deactivation of bioactive compounds or activation of previously inactive compounds.

### Bioavailability of Flavonoids

Bioavailability in a nutritional context is a term used broadly to include a full range of digestive and metabolic factors that influence the amount and type of compound that reaches the systemic circulation. Bioavailability or pharmacokinetics of flavonoids is based on data from absorption, distribution, metabolism, and excretion (ADME) studies conducted both in humans and animals. Available data suggest that the most abundant flavonoid compounds may not necessarily lead to the highest concentrations of biologically active metabolites in target tissues nor be the most biologically active in relation to specific health outcomes. Some subclasses are rather well absorbed; for example, following ingestion, isoflavones, the flavan-3-ol epicatechin, and the flavanones can reach micromolar concentrations in plasma. On the other hand, even large oral doses of anthocyanins result in only nanomolar plasma concentrations. Absorption rates vary significantly, with anthocyanins reaching peak concentrations within 1–2 h following ingestion compared to 6–8 h for isoflavones (depending on food matrix, compositional effects, and site of intestinal absorption). Relative urinary excretion ranges from 0.3% to 43% of the ingested dose depending on the subclass; isoflavone urinary yields are high, followed by some of the flavan-3-ols, flavanones, and quercetin glucosides (flavonols) but urinary excretion rates for procyanidins, galloylated tea catechins, and anthocyanins are low. However, it is worth noting that the emphasis of previous bioavailability studies has been on the intact parent flavonoids, and for some flavonoid subclasses it is possible that currently unidentified metabolites (arising from spontaneous breakdown or microbial catabolism) may be bioavailable and potentially responsible for significant health effects. The key role of the gut microflora in metabolism of some flavonoid compounds may explain why some exert biological effects *in vivo* even though their apparent bioavailability is low.

To date the isoflavone class has been most widely studied, and from the available evidence it is clear that in healthy adults, isoflavones are absorbed rapidly and efficiently. Following the consumption of either pure compounds, isoflavone-rich extracts or foods/beverages rich in isoflavones, the parent compounds and their metabolites can be detected in plasma and urine of human volunteers. After ingestion, isoflavones are hydrolyzed by intestinal glucosidases, which release the aglycones, daidzein, genistein, and glycitein. These may be absorbed or further metabolized to many specific metabolites including equol and *p*-ethyl phenol. Numerous studies attest to the fact that following ingestion, soy isoflavones attain maximal plasma concentrations within 4–8 h, and are then eliminated from the body through the bile and kidneys with a mean terminal elimination  $t_{1/2}$  (half-life) that is approximately 8 h on average. There is evidence from several studies that high concentrations of isoflavones can be found in tissues: breast tissue of premenopausal women and in prostate glands of men. Our knowledge of the bioavailability of other flavonoid subclasses is less well-studied to date.

As with pharmacological compounds, demonstrating efficacy and understanding potential risks of flavonoids requires knowledge of their bioavailability. Further knowledge of how factors, including genetic determinants, food matrix, chemical composition, and age affect the bioavailability of flavonoids is an important area for future research.

## Potential Mechanisms of Action

The effect of flavonoids on biological processes has been extensively studied, but few investigations have attempted to determine the actual flavonoid metabolites responsible for the observed effects. Much of the *in vitro* data assumes that biological activity originates from the parent/precursor flavonoids ingested without taking into consideration the biotransformation that may occur following ingestion and metabolism. It is well established that following ingestion they are transformed into a range of structurally distinct metabolic conjugates or degradation products. The majority of *in vitro* research has also been carried out with single flavonoids and few studies have investigated the relative effects of single compounds versus mixtures of compounds or the effects of factors such as matrix on absorption, metabolism, and bioactivity.

When interpreting the present mechanistic data, it is also important to note that little attention has been paid to physiologically relevant concentrations of flavonoids in *in vitro* model systems. Thus, in some instances, biological effects have been shown at concentrations that are unachievable *in vivo* following 'normal' habitual dietary consumption; therefore, the biological relevance of these mechanisms to humans is questionable. Despite these issues, there is considerable evidence to suggest that flavonoids have beneficial biological activities.

Epidemiological and experimental evidence supports the contribution of many dietary flavonoids to improving cardiovascular health, reducing cancer, and neurodegenerative disease risk (refer to bioactivity section below), with specific indications for improvements in vascular blood flow, hypertension, and cell cycle progression. As the pathophysiological processes leading to the development of CVD and cancer are so complex, there are numerous potential mechanisms by which bioactive plant compounds present in food could act and elucidating these underlying mechanisms is a key aim for nutrition research. Given that lipid peroxidation and oxygen free radicals are thought to be involved in conditions such as atherosclerosis, cancer, neurodegenerative diseases, and various inflammatory conditions, and that the flavonoid hydroxylated benzoid ring structure lends itself to radical scavenging, the primary health focus for flavonoids was traditionally thought to be through their direct antioxidant properties. Indeed *in vitro* studies have shown that flavonoids are efficient scavengers of free radicals; however, based on the *in vivo* bioavailability of flavonoids and their blood concentrations relative to other endogenous antioxidants, their mechanisms of action are unlikely to be the result of global radical scavenging. Therefore more recent research has focused on exploring other mechanistic actions of flavonoids using more physiologically relevant concentrations. Some recent examples of these mechanistic activities include: inhibition of cyclooxygenase, which in turn reduces platelet aggregation and thrombosis; inhibition of nicotinamide adenine dinucleotide phosphate-oxidase (NADPH oxidase) and regulation of nitric oxide synthase, which are involved with inflammation and vascular function; immunomodulation, anti-inflammatory, direct effects on enzyme function and gene and protein expression, selective interactions with protein kinase and lipid kinase signalling cascades and transcription factors such as Nuclear factor (erythroid-derived 2)-like 2 (NRF2) and nuclear factor kappa beta (NF- $\kappa$ B).

## Potential Health Effects

There is substantial epidemiological evidence that populations that consume diets rich in plant foods have a reduced risk of CVD, various cancers, and other age-related conditions. Identification of the role of flavonoids in the primary mechanisms that may protect against cellular damage may yield clues to slowing aspects of the aging process and postpone age-related diseases.

Although historically, the biological effects of flavonoids was attributed to their antioxidant actions, through their ability to scavenge reactive oxygen and other radicals, recent evidence suggests that this classic hydrogen-donating antioxidant activity cannot account for the reported *in vivo* bioactivity of flavonoids, and recently attention has been focussed on their other biological effects, including anti-inflammatory effects and effects on cell signalling pathways.

### Cardiovascular Health

Intervention and experimental studies have demonstrated roles of some flavonoids in pathways involved in CVD initiation and progression, including improvement in vascular function, hypocholesterolemic effects, reduction of foam cell formation, thrombosis and inflammation, and protection against ischemia-reperfusion injury and arrhythmia. Differential effects of different subclasses have been observed, and some subclasses have been shown to exert beneficial effects on blood pressure by increasing endothelial derived nitric oxide (NO), either via modulation of endothelial nitric oxide synthase (eNOS) activity/expression, changes in eNOS substrate availability or through the prevention of radical induced NO conversion caused by enzymes such as NADPH oxidase. Together these functions implicate the importance of specific flavonoids in a host of CVD-related conditions, including atherosclerosis, hypertension, congestive heart failure, cardiac hypertrophy, ischemic heart disease, and others.

Results from a recent meta-analysis of randomized controlled trials on flavonoids and flavonoid-rich foods provide evidence that some subclasses of flavonoids are associated with a significant reduction in blood pressure. For example, short-term interventions (1–18 week duration) with cocoa flavan-3-ols significantly reduced systolic and diastolic blood pressure. However, to date, for a number of flavonoid subclasses including anthocyanins, there are very few published studies to systematically examine their potential effects on CVD risk biomarkers, whereas for others the levels of flavonoids administered in the interventions were well beyond the range typically consumed in the diet. Further long-term trials are required to substantiate the potential cardioprotective effects of different flavonoid subclasses.

## Neuroprotective Effects

Many flavonoids can cross the blood brain barrier, and therefore some flavonoids (or their metabolites) are present in the brain and have the potential to exert neuroprotective/neuroinflammatory effects. Ongoing research is therefore examining their relative effects on cognitive function and disorders such as Parkinsons disease.

In experimental studies, administration of flavonoids or flavonoid-rich foods (e.g., berries) protects dopamine neurons from oxidative damage and apoptosis and inhibits formation of  $\alpha$ -synuclein fibrils. Other potential mechanisms for the effects of flavonoids in the brain include interactions with neuronal signalling pathways that are critical in controlling neuronal survival and differentiation and in modulating activity/expression of several oxidative-related enzymes (e.g., eNOS and superoxide dismutase (SOD)), and regulation of mitochondrial function or neuroinflammation. In a review of animal studies, oral administration of blueberry or strawberry extract consistently showed favorable neuroprotective effects including increased dopamine release, alleviating oxidative stress or suppressing neuroinflammation. However, flavonoid subclasses differ in their ability to cross the blood brain barrier and these differences depend in part on the lipophilicity and polarity of the flavonoid compound. During absorption flavonoids are extensively metabolized, with chemical transformations resulting in *O*-methylation and glucuronidation during phase II metabolism, which may have a significant impact on flavonoid bioavailability to the brain. It is therefore possible that the less polar *O*-methylated metabolites, for example *O*-methylated epicatechin metabolites, which are formed in the small intestine and liver, may be more bioavailable to the brain than their parent aglycones.

## Cancer

Some flavonoids have been shown to suppress proliferation and induce apoptosis in cancer cell lines; they have been shown to delete aberrant epigenetic marks, resulting in the re-expression of abnormally silenced genes, and they can inhibit angiogenesis in established tumors. In experimental animals, some flavonoids have been shown to inhibit cancer at various stages in the cancer process from initiation to metastasis. However the available evidence from epidemiological studies remains inconclusive. In a recent systematic review of green tea and cancer prevention, which included 23 cohort studies and 27 case-control studies, the data were equivocal. Results were contradictory, particularly for cancers of the digestive tract although there was some limited evidence for protection against lung cancer.

## Safety

Although flavonoids may have potential health effects, the function of many of these compounds in the plant is to discourage attack by fungal parasites, herbivores, and pathogens. As a result, it is not surprising that many are toxic and mutagenic at high concentrations in cell culture systems, and excessive consumption by animals or humans may hypothetically cause adverse metabolic reactions. However, the concentrations used in cell culture experiments in general tend to far exceed the levels that are achievable *in vivo* following dietary consumption. In addition, all of these compounds have short half-lives and do not appear to accumulate in tissues thus suggesting low toxicity. For the majority of the identified phytochemicals, there are currently limited data on the 'safe level' of intake or optimal level of intake for health benefits, and it is critical that these margins be more clearly defined in future research, particularly given the growing number of flavonoid supplements in the market.

## Conclusions

There is increasing evidence that flavonoids may be protective against a number of age-related disorders. Data suggest that diets high in flavonoids may not only reduce the risk of CVD and cancer but also, by protecting against cellular damage, may slow aspects of the aging process and improve quality of life by postponing age-related diseases. There is still much to be uncovered about their bioavailability, mode of action, and optimal doses or, indeed, the actual compounds responsible for their health effects (i.e., metabolites). Given that there are still significant gaps in our knowledge base of flavonoid bioactivity, there are currently no formal recommended dietary intakes for these phytochemicals, but on the basis of the available evidence, people should consume a wide variety of foods that incorporate the various phytochemicals to maximize disease prevention. Further research is required to define optimal doses for potential health effects and to define safe levels of intakes. Many of these compounds should be viewed as pharmacologically active compounds because although they occur naturally, they still require the same levels of proof of efficacy and safety in use as synthetic pharmaceutical agents or dietary supplements.

## Key points

- Proanthocyanidins are important phytochemicals with diverse dietary sources.
- Proanthocyanidins have broad activity in health promotion by mitigating hyperglycemia, inflammation, and bacterial infection.
- The bioactivity of proanthocyanidins are highly dependent on their specific structural variations.
- Although poorly absorbed, oligomeric proanthocyanidins exert their bioactivity by interacting with the biological targets in the gastrointestinal tract and may act as prebiotics and modulate gut microbiota.

## Introduction

As non-nutrient components of plants dietary phytochemicals have been hotly studied for their health promotion effects as active ingredients in nutraceuticals and functional foods. Among them, dietary organosulfides, terpenoids (including saponins), resin glycosides, and polyphenolic compounds (particularly proanthocyanidins) found in fruits and vegetables have been found to function as radical scavengers, anti-inflammatory agents, and enzyme inhibitors (particularly digestive enzymes) thereby mitigating the chronic diseases such as cardiovascular disease, type-II diabetes, obesity, cancer, and cognitive disorder. In this chapter, the progress of the work related to polyphenolic compounds are accounted to cover the literature in the past decade.

## Dietary sources

Proanthocyanidins (PAC) compose of dimeric and oligomeric flavan-3-ols. Furthermore, some proanthocyanidins also contain gallic acid esters. Depending on the type of interflavonyl bond linkage, there are A-type (two interflavonyl bonds) and B-type (one interflavonyl bond) proanthocyanidins (Le Bourvellec and Renard, 2019). Proanthocyanidins are found mostly in fruits such as berries (e.g., blueberry and cranberry), durian, mangosteen, persimmons, cocoa, coconut husk, apple, and chiku (Cádiz-Gurrea et al., 2017; Rauf et al., 2019; Wang et al., 2012). PAC concentration is high in the skin and in the seeds of the fruits. This is consistent with the biological role of PAC for plant protection. In contrast, PAC are much less common in vegetables with okra seeds being an exception (Lu et al., 2016). In addition, PAC are also found in cereals and pseudocereals including barley, sorghum, millet, amaranth, and buckwheat (Zhu, 2019). Some culinary spices and herbs also are known for PAC and the most commonly known ones are cinnamon barks and hops (Gunawardena et al., 2014; Li and Deinzer, 2006). The basic building blocks for PAC are (epi)afzelechin, (epi)catechin, and (epi)galocatechin, PAC found in different plants have structural variations on the type of flavan-3-ols, interflavonyl linkages, and degree of polymerizations. Fig. 1 highlighted some food sources of PAC. The intake of PAC in our daily diets is not known and vary greatly based on the individual dietary habits. The estimated mean daily proanthocyanidin intake in the United States is 53.6 mg/person/day excluding monomers and 57.7 mg/person/day including monomers. Proanthocyanidin intake also varies with age and gender (Aron and Kennedy, 2008).

## Absorption and metabolites

The monomers of PAC have high bioavailability. For example, (+)-catechin in plasma could reach 76.7 nM in humans after consumption of 121  $\mu$ mol catechin in dealcoholized red wine (Bell et al., 2000). Intake of 137 mg of (–)-epicatechin in PAC-rich chocolate could lead to a peak plasma (–)-epicatechin concentration of 260 nmol/L (Rein et al., 2000). However, flavan-3-ol dimers can only be absorbed ten times less. PAC with degree of polymerization equal or larger than four cannot be absorbed due to their high molecular weights and sizes and selectivity of the gut barrier (Vazquez-Flores et al., 2018). *In vitro*, PAC are subjected to acid mediated depolymerization into monomers in the presence of nucleophiles (such as thiols). However, under the acidic gastric juice media, little depolymerization was observed. The PAC are known to chelate metal ions such as ferrous ion, zinc, and calcium ion and reduce their bioavailability. Therefore, PAC are considered as antinutrients. In addition, binding to proteins and thus it can act as inhibitors of digestive enzymes such as pancreatic alpha-amylase and reduce the digestion rates of starch (Chen et al., 2022). This feature would be taken advantage of for development of starchy foods with low glycemic index. The monomers and oligomers (degree of polymerization <3) of flavan-3-ols could passively diffuse into the enterocytes are metabolized to their respective conjugates with sulfate, gluconates, and O-methylation on B-ring, PAC are not broken down in the small intestine and would reach the colon intact (Márquez Campos et al., 2020). On the other hand, the microbe in the gut were found to degrade extensively the PAC into fragments formed from the ring cleavage reactions (Márquez Campos et al., 2020). B-Type PAC underwent series of reactions including C-ring cleavage, A-ring oxidation and interflavan bond breakage followed by decarboxylation, dihydroxylation and lactonization to yield 5(3′4′-dihydroxy-phenyl)- $\gamma$ -valerolactone (for procyanidins) in the case of grape seed extracts (fermented with human fecal microbiota) containing catechins and oligomeric PAC (Sánchez-Patán et al., 2011). Apparently the A ring of the flavan-3-ols were fragmented through unknown mechanisms in order to give such product (Ou and Gu, 2014). Procyanidin A1 [epicatechin-(4 $\beta$ →8, 2 $\beta$ →O→7)-epicatechin] and A2 were found to be absorbed in the small intestine of rats with absorption rates higher than B-type dimer (Appeldoorn et al., 2009). A2 dimer of PAC, found in cranberry, was detected in human plasma and urine (Zampariello et al., 2012). A study using  $^{14}$ C labeled procyanidin B2 showed that after an oral dose, 58% ingested procyanidins were detected in 24 h urine and 40% were found in feces, suggesting high bioavailability of B2 dimer (Stoupi et al., 2010). However, besides B-type procyanidins, there are no study on the gut microbiota metabolites of A-type PAC and other oligomeric PAC such as polygallo catechins which are found in chiku and lady's finger seeds. As PAC may exert their bioactivity both through absorbed metabolites into human circulation systems, or act by modulation of gut microbiota. Full characterization are needed to understand the fates of ingested dietary PAC.

## B-type PAC, poly(catechin), for cardiovascular health

PAC are credited for promoting cardiovascular health benefits of intake of food rich in PAC (Kruger et al., 2014). These include food and beverage (e.g., tea, wine, and dark chocolate) and dietary supplements (e.g., grape seed extracts and pine bark extracts) (Kruger et al., 2014). PAC are claimed to be the active ingredient in pine bark extracts that have been sold as pycnogenol (pine bark extracts) or grape seed OPCs in the marketplace for long time (Weber et al., 2007). However, despite good number of clinical studies, the recent systematic review on pine bark extract concluded that it the evidence of very weak for pine bark extract in lowering blood pressure, increasing HDL cholesterol, or decreases LDL cholesterol (Robertson et al., 2020). Grape seed PAC are slightly different from that of pine bark extracts because it contains significant amount galloyl esters through the C3-OH groups of the (epi)catechin units (Unusan, 2020), and therefore one would expect that they have similar bioactivity. Another B-type PAC is from cocoa, which was believed to be responsible for the extraordinary heart health of Kuna Indian whose diet included daily drinking five cups of high flavanols cocoa with flavonoid intake of 900 mg per day. A small but thoughtfully designed clinical study suggested that the epicatechin monomer was responsible for enhancing endothelial function measured by flow mediated dilation and decreased blood pressure of healthy young individuals (Rodriguez-Mateos et al., 2018). The Cocoa PAC with monomeric flavan-3-ol removed did not show such activity but was able to reduce total cholesterol level. Epicatechin metabolites, not the gamma-valerolactones from oligomeric PAC were suggested to be responsible for the health benefits of cocoa PAC. The European Food Safety Committee approved the health claims on cocoa flavanols for maintenance of normal endothelium-dependent vasodilation, which contributes to normal blood flow at daily dosage of 200 mg flavanols per day (Efsa Panel on Dietetic Products and Allergies, 2012).

## Antibacterial activity of A-type PAC

Traditionally, cranberry has been used for relieving urinary tract infection, which is a common problem in females. However, the components that are responsible for such activity have been under debate because the complex phytochemicals found in cranberry. Scientific evidences have suggested that A-type proanthocyanidins uniquely found in cranberry may be responsible for anti-urinary tract infection activity (Howell et al., 2010). There is only trace amount of PAC found in common cranberry juice and thus not possible to achieve effective dosage by drinking cranberry juice or eating cranberry fruits. High purity cranberry PAC (>18% based on DMAC assay) was suggested to be needed to achieve recommended dose of 36 mg PAC for preventing adhesion of bacteria on urinary tract. Studies found that the mannose found in cranberry might synergize with PAC to enhance the anti-adhesion activity. However, A-type PAC are poorly uptaken by Caco-2 cells than “B-type” PAC (Ou et al., 2012). Therefore, it is unclear how mechanistically, the unabsorbed PAC could reduce the bacteria affinity in the urinary tract. Uropathogenic *E. coli* (UPEC) are the main cause of urinary tract infection. Evidences suggested that UPEC are opportunistic intracellular pathogens, rather than strictly extracellular organisms (Dhakal et al., 2008). Cranberry PAC may inhibit *E. coli* from adhering to uroepithelial cells or alter the pathogenic gut *E. coli* population and thus reduce the chance of infecting the urinary tract (Feliciano et al., 2015).

Recently, studies have suggested that cranberry PAC may be effective in prevention and management of periodontitis, an inflammatory disease of bacterial origin affecting tooth-supporting tissues. In such case, the bioavailability is not an issue (Nawrot-Hadzik et al., 2021; Andersen-Civil et al., 2021). Cranberry PAC may modulate gut microbiota via multiple interactions among them including facilitating the recruitment of immune cells and suppressing the amount of pro-inflammatory cytokines. Research work is needed to characterize the metabolites of the A-type PAC unique to cranberry by gut microbiota and investigate the antimicrobial activity of these metabolites.

## PAC, poly(gallicatechin), and mitigation of starch digestion

PAC have been suggested to be active in modulating glucose homeostasis and the mechanisms could be due to absorbed monomer or dimers, and perhaps their metabolites, which may act *in vivo* as antioxidants and inhibitors of epithelial NADPH oxidase (Sun et al., 2020). PAC are also intensively studied and proven to be potent inhibitors of digestive enzymes, which could be the purpose of synthesizing PAC by plants for their protection against invaders including microbes and animals (Sun et al., 2020). The anti-nutrient activity of PAC could be utilized to mitigate starch digestibility of staple foods and reduce their glycemic index. To this end, PAC known for strong inhibitors of alpha-amylase include those isolated from persimmon, unripe *Manilkara zapota* (chiku), Malay cherry (*Lepisanthes alata*) leaves and fruits, and okra seeds (Lu et al., 2016; Wang et al., 2012; Zhang et al., 2016). The extracts from *L. alata* PAC is more potent than acarbose (based on equal weight), which is the most common antidiabetic drug working via inhibiting alpha-amylase in the gastrointestinal tract (Zhang et al., 2016). Acarbose is a better inhibitor against alpha-glucosidase in the small intestine surface, while PAC are better inhibitors against pancreatic alpha-amylase. This may offer advantage because intake of acarbose lead to side effects such as flatulence and diarrhea, which are due to accumulation of undigested fermentable oligo-saccharides. In theory, inhibition of alpha-amylase instead of alpha-glucosidase, would result in undigested starch, instead of fermentable sugar (dextrin, maltose, and maltotriose) that would stimulate gas formation by the microbiota in the gut. Among the various PAC, the ones show strong inhibitors of alpha-amylase share some common features i.e., they are B-type oligomers of gallicatechin with relatively high mean degrees of polymerization (Wang et al., 2012; Zhang et al., 2016). The PAC from Malay cherry leaves, chiku, and lady's finger are poly(gallicatechin) and this may explain their strong inhibition activity against alpha-amylase. Clinical study is thus needed to illustrate the effectiveness of the PAC for controlling of hyperglycemia.

## Conclusions

Although monomeric dietary polyphenolic compounds have been recognized to play positive role in our health, PAC used to be treated as anti-nutrient factor in foods. Recent studies as we summarized herein suggested otherwise. Many biological targets for PAC are in our GI tract and this makes poor bioavailability of PAC not a concern. The structural diversity of PAC from different edible plants enable us to explore their property specifically for functional foods in controlling hyperglycemia, cardiovascular health, gut health, and anti-microbial activity. PAC are found abundantly in agri-food by products such fruit peels and seeds, grain shells (e.g., coconut shell), and leaves (e.g., Malay cherry leaves), exploiting PAC for human health promotion demands green and cost-effective extraction technology that can selectively separate PAC from the complex biomass matrix. At molecular level, flavanol monomers also include much less studied (epi)afzelechin, (epi)fisetinidol, (epi)guibourtinidol, (epi)mesquitol, and (epi)robinetinidol (Structure shown in the Figure). Their dimers and oligomers may have their unique bioactivity waiting for us to explore. We shall leave no stone unturned in the effort to find bioactive constituents for disease prevention through functional foods.

## Key points

- Prebiotics and probiotics are approaches to modulate the composition and function of the host's microbiota in ways that are beneficial to the host.
- Basic science, in-vitro, in-vivo, and observational studies provide clear and robust evidence of host-microbe interactions which support the rationale for probiotics and prebiotics to enhance health.
- Specific benefits with specific pre- and probiotics on particular health outcomes have been well documented.
- However, the strength and consistency of the clinical evidence in the field so far is extremely variable. Conclusions and guidance should be driven by specific outcomes with a specific probiotic candidate, in a particular population, and replicated beyond a single clinical trial.
- Pre- and probiotics in use today are safe for the general population, and specific benefits have been reported in some high-risk groups, including premature infants, immunocompromised individuals, and the elderly.
- Continued emphasis on rigorous research should help close the translational gaps that still exist between concept, science, and application.

## Introduction

The human microbiota is a set of complex microbial ecosystems which develop and change over the life cycle. These microbes constantly interact with the host, driving and modulating a large set of physiologic responses which are major determinants of

host health. The microbiota of the respiratory tract, skin, vagina, and particularly that of the gastrointestinal (GI) tract play a major role in host immune development, protective and inflammatory responses, metabolic and gastrointestinal functions, as well as in neurocognitive function via the gut-brain axis.

An explosive increase in knowledge of the microbiota has been accompanied by a parallel interest in approaches to modify its composition and modulate its effects, via probiotic microbes and prebiotic substances, as a means of supporting health and preventing or managing disease processes. Such beneficial effects relate to infection, allergy, GI motility, inflammatory disorders, metabolic disorders (glucose control, dyslipidemia, obesity), and possibly mood and other central nervous system dysfunction. Other interventions that can modulate the microbiota and its interactions with the host include specific diets, fecal microbiota transplants, synbiotics, and postbiotics, which are not covered in this section.

This increased understanding of host microbial interactions comes from basic science, in-vivo and in-vitro experimentation, and the accelerated development of new methodologies, such as enhanced microbial genome sequencing techniques. Evidence from human clinical trials that specific pre- and probiotics can yield specific positive clinical outcomes has continued to mount. The need for improved rigor in developing clinical evidence, and the unclear and inconsistent regulatory frameworks for communicating health-related benefits, continue to be significant challenges to the broader application of pre- and probiotics for health and nutrition.

## Probiotics

### Definition

The most widely accepted definition of the term probiotics is: “Live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.” The first version of this definition was put forth in 2001, by consensus from an Expert Consultation of the Food and Agricultural Organization of the United Nations and the World Health Organization (FAO/WHO), and it was espoused in a statement from the International Scientific Association for Probiotics and Prebiotics (ISAPP) at an expert consensus in 2013. The definition implicitly excludes non-live or viable microorganisms and their metabolic products or derivatives, and microbes strictly used as food processing aids.

Most microorganisms described as potential probiotics in the scientific literature include multiple species of bacteria (mainly the genus *Lactobacillus* and *Bifidobacterium*) and yeasts (specifically the genus *Saccharomyces*). Probiotics are generally given orally to reduce the risk or manage specific diseases or related pathologic mechanisms. Today most available probiotic products are commercialized in oral supplements and foods containing probiotic microorganisms, although some products for topical -skin or vaginal applications are available (FAO/WHO, 2001, Hill et al., 2014).

### History

The fermentation of foods, including dairy products, grains, and other plants, using bacteria or yeast has been a technique of food preservation used for thousands of years. These foods have been consumed in all parts of the globe for their nutritional value and, in some instances, for their purported health benefits. However, the modern-day scientific link between the consumption of specific microorganisms and their potential role in health can be attributed to the Russian scientist Élie Metchnikoff. Based on laboratory and field observations while working at the Pasteur Institute, in 1907 he published his “Optimistic Studies” on the “Prolongation of Life”. At the time, it was known that the activity of “putrefactive” microbes such as *Clostridium* produced “potentially toxic substances” including phenols, indols, and ammonia from protein digestion; and that milk fermented with lactic acid bacteria could inhibit the growth of these proteolytic bacteria due to the low pH resulting from lactose fermentation. Metchnikoff also noted that rural populations in Bulgaria and Russia, who consumed yogurt and fermented milks regularly, had longer lives. He postulated that phagocytes, which are important for health in earlier life, hasten cell death from vital organs in old age. And that the products of “putrefactive microbes” are responsible for “intestinal intoxication,” which rendered cells particularly vulnerable to phagocytes. Moreover, he proposed that taking “skimmed milk which has been boiled and rapidly cooled, and on which pure cultures of the recently characterized *Bulgarian bacillus* (now *Lactobacillus bulgaricus*) have been sown”, can inhibit these mechanisms of aging. He himself consumed milk soured with *L. bulgaricus* and believed it benefitted his health (Metchnikoff, 1907; Vaughan, 1965).

However, the term “probiotic” denoting “for life” was not used until decades later and traversed a circuitous path to its current definition. Until now, the first documented use of the term appears to be that proposed by W. Kollath in 1953 to refer to a broader set of “active substances that are essential for a healthy development of life,” contrasting it to harmful substances such as “antibiotics.” A more focused view was expressed by F. Vergin in 1954, referring to the detrimental effects of antibiotics and other antimicrobial substances on the gut microbial population, versus “probiotics,” referring to factors favorable to gut microbial populations. H. Kolb and others formed an Association for Microbial Therapy. They advanced the concept in 1955, suggesting, “Antibiotic therapy causes flora damage. In such cases, we administer cultures of symbionts. In this way, deleterious effects of antibiotics are prevented by probiotic therapy” (Rusch, 2002; Hamilton-Miller et al., 2003).

In the '60s and '70s, the use of the term became more specific. Lilly and Stillwell (1965) used the term to describe protozoan microorganisms or factors which stimulated in vitro the growth of other protozoa. Fujii and Cook (1973) used the term for “compounds that build resistance to infection in the host but do not inhibit the growth of microorganisms in vitro,” referring

to synthetic chemicals that protected mice against infection with *Staphylococcus aureus*. Parker (1974) used it to refer to “organisms and substances which contribute to intestinal microbial balance.”

In 1989 Fuller proposed greater specificity to the use of the term as “a live microbial feed supplement which beneficially affects the host animal by improving its intestinal microbial balance”, limiting it to only “live microorganisms” (not “substances”) that benefit the host, and specifying an “improved microbial balance” as the attendant mechanism. Throughout the 90s several other research and consensus groups put forth definitions which included various criteria for a “probiotic” microbe, including restrictions on “origin” (i.e., human vs. animal), the capacity to “colonize” the intestinal lumen, demonstration or documentation of safety, and mechanism of action (e.g., “by promoting microbial balance,” or “by an immune-modulating effect”). As the knowledge of the composition and the multiple effects and relationships between the host and the intestinal microbiota exploded in the last decades, such limiting definition criteria became less useful or relevant (Fuller, 1989, Hamilton-Miller et al., 2003).

Today’s most widely accepted definition is that proposed by FAO/WHO in 2001–2002: “Live microorganisms that, when administered in adequate amounts, confer a health benefit on the host.”, also adopted by the International Scientific Association for Probiotics and Prebiotics at an expert consensus in 2013. And although not explicit, the definition implies that such live microorganisms are well characterized taxonomically (including genus, species, and strain). This definition excludes non-viable microorganisms, their metabolites, or other substances, and also excludes previous criteria used to denote a probiotic, such as the original source from which it was isolated or identified (human or other), specific level of safety, or mechanism of action. In addition, the definition is expressly vague in terms of type or route of administration, type of microorganisms (phylum, species), and type of “health benefits.” Nevertheless, it has been generally regarded as practical, “relevant, and sufficiently accommodating” for current and anticipated applications of probiotics (FAO/WHO, 2001, Hill et al., 2014).

## Probiotic microorganisms

### Microbes in foods

The current concept of probiotics needs to be differentiated from the presence of bacteria and yeast in foods primarily for the purposes of processing and preservation by fermentation. Used for millennia, bacterial and yeast fermentation allowed not only food preservation but the production of organoleptically and culturally desirable products. Species of *Lactobacillus*, *Streptococcus*, *Leuconostoc*, *Lactococcus*, *Weissella*, *Saccharomyces*, among others, have been used to ferment vegetables (sauerkraut, pickled vegetables, kimchi), legumes (tempeh, miso, soy sauce), cereals (bread, sourdough), fruits (wine, spirits), meats (sucuk and other sausages), tea (kombucha), and dairy (yogurt, kefir, buttermilk). It is estimated that more than 5000 varieties of fermented foods (and beverages) are currently produced and consumed globally. There is consensus today that probiotic microbes require appropriate identification (genus, species, and strain) and documentation of a specific beneficial effect on the host. In most of these traditionally or industrially made and commercialized products, live or viable microbes may or may not be present or viable at the end of processing or through shelf-life. In most cases, the amount or concentration of microbes will vary; in many cases the viability is unknown or changed by warming or cooking, the strain specificity will not be known or noted, and the benefit related to the bacterium or yeast itself may not be documented. So, while many of these food products may be nutritionally adequate or beneficial, it is accepted that for a “probiotic” effect, a benefit must be at least partially attributable to the microbes when consumed, and the benefit should extend beyond the nutritional benefit of the food matrix that contains it. Thus, the mere presence of microbes in traditional fermented foods would not qualify them as a “probiotic foods,” and it would be preferable to describe some of these as a “food containing probiotics,” assuming the specific bacterium or yeast in the food product fulfills the definition of a probiotic (Marco et al., 2021).

### Early identification of probiotic microbes

Historically, the identification of specific microorganisms with potential health-related benefits started at the turn of the last century with the characterization of lactobacilli which produce lactic acid as a major metabolic end-product of carbohydrate fermentation—lactic acid bacteria (LAB). In 1900, Ernst Moro presented the first bacteriological characterization of *L. acidophilus*. Around that time also, S. Grigorov described *Lactobacillus bulgaricus* (today known as *Lactobacillus delbrueckii* subsp. *bulgaricus*), which was central in the work of E. Metchnikoff proposing beneficial health-related effects by specific LAB. Improved microbiologic methods gradually enhanced the characterization and refined the taxonomic designation of multiple species. And better-defined species and strains of lactobacilli and bifidobacteria began to be studied for potential health benefits.

In the 1930s in Japan, Minoru Shirota isolated and described *Lactobacillus casei shirota* (later reclassified as *L. paracasei shirota*). He documented growth inhibition of intestinal pathogens and other potential probiotic benefits with this bacterium, leading to the first commercially marketed fermented dairy drink, Yakult, still sold worldwide today. Around 1900, working at the Pasteur Institute, H. Tissier described the genus *Bifidobacterium*. First isolated from a breastfed infant in 1899, he named it *Bacillus bifidus communis*. Tissier found that bifidobacteria are the dominant species in the gut of breastfed babies and postulated they had a protective effect on the intestinal health of breastfed infants.

Aside from multiple lactobacilli and bifidobacteria, one specific strain of *Escherichia* (*E. coli* nissle 1917) was isolated by A. Nissle from feces of a German soldier who was not affected during an outbreak of shigellosis in 1917. Relatedly, the French microbiologist H. Boulard, during a cholera epidemic in 1920 in Indochina, noticed that individuals drinking tea from the outer skins of lychee and mangosteens appeared to be protected. From it, he isolated a *Saccharomyces* (now *S. cerevisiae* *boulardii*), which was patented in

1947 for its potential medicinal use. Strains of *E. coli nissle 1917* and *S. boulardii* continued to be used and today are commercialized as probiotics (McFarland, 2010; Zommiti et al., 2020; ISAPP, 2019).

A significant leap in the understanding of probiotics has benefitted from the explosive interest and progress in the characterization of the human microbiota. This has been possible due to improvements in genomic sequencing technology and decreased costs. The first bacterial genomes were completely sequenced in the mid-'90s, and the first *Bifidobacterium* in 2002. Thanks to next-generation sequencing techniques, more than 200,000 bacterial and archaeal complete or draft genomes, including hundreds of lactobacilli and bifidobacteria, have been uploaded to public databases. This has allowed for better identification of strains, maintaining adequate control of cultured microbes for commercial purposes, and identifying genetic characteristics to select candidate probiotics (Zhang et al., 2020).

### Commonly used probiotics

Probiotic microorganisms should always be identified by their genus, species, subspecies (if applicable), and an alphanumeric strain designation. The nomenclature used for strain designation follows authentication and preservation by repositories such as the ATCC (American Type Culture Collection—US); CNCM (National Collection of Microorganisms Cultures -France); or NCIMB (National Collection of Industrial and Marine Bacteria—UK). Examples: *Lactobacillus* (genus) *reuteri* (DSM 17,938) (strain) or *Bifidobacterium* (genus) *animalis* (species) subsp. *lactis* (subspecies) (Bb-12) (strain) or.

In the last few decades, the great majority of species and specific strains studied and documented as having health-related benefits belong to the genus *Lactobacillus* and *Bifidobacterium*. These include strains of *Lactobacillus*, *Bifidobacterium*, and *Saccharomyces*, including those below, which are among those better studied. Other lactobacilli and bifidobacteria have also been proposed as probiotics; and in recent years, less well-studied species from the genus *Roseburia*, *Akkermansia*, *Propionibacterium*, and *Faecalibacterium* are emerging as probiotic candidates.

Most probiotics today are commercialized as supplements in a powder form, containing freeze-dried or lyophilized bacteria, which allows for maintaining viability for extended periods of time. This is the case for most probiotics found in capsules, sachets, or powdered products, including infant formulas. However, heat and humidity will gradually reduce bacterial viability over time, so it is critical that the target effective bacterial counts (colony forming units or CFUs) in the product be maintained throughout shelf life, and that storage conditions be followed. More novel methods, such as suspending the bacteria in lipid emulsions, allow extended shelf life in a liquid format. Most probiotics added to liquids, including milks and dairy products such as yogurt, have a much shorter shelf life than dry products and require refrigeration (Hill et al., 2014; Zommiti et al., 2020; Sanders et al., 2018).

Most commonly used probiotics used in clinical trials:

Lactobacilli	Bifidobacteria
<ul style="list-style-type: none"> <li>• <i>L. acidophilus</i></li> <li>• <i>L. casei</i>,</li> <li>• <i>L. helveticus</i></li> <li>• <i>L. johnsonii</i></li> <li>• <i>L. paracasei</i></li> <li>• <i>L. plantarum</i></li> <li>• <i>L. reuteri</i></li> <li>• <i>L. rhamnosus</i></li> </ul>	<ul style="list-style-type: none"> <li>• <i>B. adolescentis</i></li> <li>• <i>B. animalis</i> subsp. <i>lactis</i></li> <li>• <i>B. breve</i></li> <li>• <i>B. infantis</i></li> <li>• <i>B. longum</i></li> </ul>
	Saccharomyces <ul style="list-style-type: none"> <li>• <i>S. cerevisiae</i> boulardii</li> </ul>

Only the probiotic genus and species listed. Many of them have more than one specific subspecies or more than one strain with beneficial effects studied in clinical trials. Some clinical effects are expected to be strain specific.

### Mechanisms of action of probiotics

The rationale for probiotics to deliver health benefits arises from the dramatic improvement in our understanding of the mechanisms by which the host microbiota is a major determinant of health. These mechanisms and effects of the microbiota have been documented in several key functional domains:

- Effects on the gastrointestinal luminal environment (e.g., microbial digestion of macronutrients—particularly carbohydrates, with production of short-chain fatty acids (SCFA), luminal pH, and change in composition of gastrointestinal contents and stools)
- Maintenance of gut barrier function and host protection (nutrient and adhesion competition and bacteriocins to inhibit pathogens), enhancement of barrier function of gut epithelium (e.g., stimulating mucus and mucin production, enhancement of function of tight junctions),
- Development of gut-associated and systemic immune response of the host (e.g., stimulation of secretory antibody production, particularly IgA, modulation of systemic T and B cell responses)

- Metabolic effects (salvage of energy from the diet by absorbing bacterial fermentation products like SCFA, and effects on enterohepatic circulation, and lipid absorption and metabolism)
- Gut-brain axis interactions (e.g., bidirectional neuroendocrine signaling which affects gut motility, permeability, pain perception, and neurocognitive function).

Alterations in the development, composition, and function of the microbiota and its symbiotic relationship with the host are generically described as “dysbiosis”, and this has been associated with adverse health consequences related to the health-related functional domains mentioned above. There is no consensus on what constitutes a “dysbiotic” microbiota profile. However, low presence of bifidobacteria and lactobacilli and elevated clostridia appear to be one of multiple markers of microbiota profiles associated with adverse health consequences. Several “risk factors for dysbiosis” have been associated with these deleterious alterations of the microbiota at different times of the life cycle, including birth by cesarean section, lack of breastfeeding, use of antibiotics, “poor” bacterial exposure or experiences (e.g., urban instead of rural living), and inadequate diets. And these variations have, in turn, been associated with short- and long-term risk of adverse clinical conditions, including infections, allergic disease, immune disorders, chronic inflammatory conditions, and functional gastrointestinal disorders. Emerging evidence suggests dysbiosis may increase risks for metabolic conditions such as dyslipidemia, metabolic syndrome, obesity, as well as neurologic, behavioral and mood disorders. The concept of probiotics is essentially the introduction of specific microorganisms, non-indigenous to the host, to alter the health risks associated with dysbiosis (ISAPP, 2019; Bermudez-Brito et al., 2012; Zommiti et al., 2020).

Most effects described and documented by probiotics relate to their interaction with the host’s microbiota (microbial communities) and the complex gut luminal environment (microbial metabolites, toxins, and other organic molecules), which together compose the broader “microbiome.” (Note: the term microbiome is used here as the microbiota plus its environment. The term is used in other contexts as to refer to the combined genetic material of the microorganisms in a particular environment). The interaction of specific microbes, including probiotics, with other microbes and the host’s tissues and cells, occurs through signaling mechanisms that are exerted by:

- Microbial structural elements (such as bacterial pili and bacterial components including lipids, exo-polysaccharides, lectins, glycoproteins, and other proteins and polysaccharides),
- Microbial metabolites (organic and inorganic signaling molecules, toxins), and
- Mobile microbial genetic elements between microorganisms

The clinical effects on the host result from microbial-host signaling through these mechanisms, which bring about physiologic changes and their clinical consequences. These molecular interactive mechanisms are specific to different microbes. While some mechanisms may be shared among members of a particular taxonomic group (e.g., fermentation, production of SCFA, competitive exclusion of pathogens), others can be strain-specific (e.g., immunologic and neuroendocrine signaling, production of antimicrobial and other bioactive molecules).

**Table 1** summarizes the physiologic mechanisms of action that have been documented in in-vitro, in-vivo, and in clinical trials, which have been associated and linked to clinical benefits from the use of probiotics. Most of these parallel the types of interactions described between host resident microbiota and health. As expected, specific probiotic microorganisms will have particular signaling and interactive mechanisms, and therefore specific effects on the host. As a result, many interactions and effects are strain-specific. These effects and their magnitude will also vary by the characteristics of the host and its environment, including their diet. Therefore, the final clinical outcomes observed in the host will be a “sum” of the multiple microbe-host interactions, influenced by multiple external factors.

The intestinal microbiota is established very early in life by microorganisms that colonize the gut lumen. In each period of the life cycle, these “indigenous” or “commensal” communities remain relatively stable. Thus, most ingested probiotics will not permanently “colonize” or be integrated into the host’s microbiota communities. In fact, probiotic microorganisms will only be present in intestinal contents as long as they are ingested, and most effects will be exerted only while they conform part of the host microbiome. Furthermore, because most human studies are limited to studying and analyzing fecal microbiota, there is still very little understanding of the direct and indirect mechanisms by which they modify the microbiome in different parts of the human digestive tract (Bermudez-Brito et al., 2012; Lebeer et al., 2018; Berg et al., 2020; ISAPP, 2019).

### Health outcomes reported with probiotics

The identification and selection of a bacterium for its clinical use as a probiotic requires.

- The specification of the microorganism (genus, species, and strain),
- Viability (“live microorganisms”) in the product containing the probiotic at the time of ingestion
- A defined amount or “dose” at time of production and consumption (shelf life)
- The characteristics of the host or population ingesting the probiotic (e.g., age, diet, disease risk factors).
- A “defined benefit” (e.g., prevention or treatment specific pathologic condition(s) in that population

**Table 2** summarizes the most studied health outcomes reported with the use of specific probiotics. The best documented positive outcomes reported in children are for prevention and management of gastrointestinal infections, infant colic, antibiotic-associated diarrhea, and necrotizing enterocolitis in premature infants. In adults, there is efficacy reported for lactose intolerance, constipation,

**Table 1** The mechanisms listed include effects at cell, tissue, and organ system level. Their documentation derives from in-vitro, in-vivo, and ex-vivo studies as well as clinical trials. Some mechanisms may apply to broad microbial taxa; some are more strain specific. And various mechanisms may act in concert to yield specific clinical effects. Documentation of specific mechanisms may explain, and not necessarily predict a clinical outcome in the host, which needs to be demonstrated in clinical trials.

---

*Physiologic mechanisms documented with the use of probiotics, which can be associated to clinical outcomes*

---

**Gastrointestinal functions**

Lactase production by specific probiotics, aiding in lactose digestion

Modulation of stool composition and consistency, GI motility and bowel movement frequency

**Modulation of the composition and activity of the microbiota**

Competitive pathogen displacement, competition for nutrients, competitive adhesion to intestinal mucosa

Intestinal pathogen inhibition through luminal content acidification (production of SCFA)

Production of bacteriocins and other antimicrobials, inhibitors of bacterial adherence and virulence

Alteration of intestinal metabolome and immune mediated responses (see below)

**Enhancement of gut epithelial barrier function**

Decrease in epithelial permeability

Enhanced mucus and mucin production

Enhancement of tight junction functionality between epithelial cells

Improved epithelial cell proliferation and inhibition of apoptosis

**Modulation of immune development and response**

Modulation of cell- mediated and humoral immune functions through multiple mechanisms, including interaction with pattern recognition receptors of the immune system such as toll receptors, interactions with monocytes, macrophages, and dendritic cells,

Enhancing B-cell activity and secretory immunoglobulin production, particularly IgA

Effects on cells of the innate and adaptive immune system, modulating the balance of T-helper and T-regulatory cells, and inducing regulatory T-cell function, thus enhancing protection but decreasing inflammatory responses or tissue damage

**Effects on systemic metabolic responses**

Metabolic responses in the gut including modulation of bile salt hydrolase activity and enterohepatic circulation

Energy scavenging by absorption of products of fermentation in the lumen

Systemic metabolic responses from endocrine mediators, through potential probiotic stimulation and modulation of gut hormonal secretion, e.g., effects on intestinal secretion of ghrelin, gastrin, CCK, peptide YY

**Effects on the central nervous system (via the gut-brain axis)**

Bidirectional signaling to the central nervous system (CNS), affecting intestinal secretion, gut motility, intestinal permeability, immune response, and pain perception

Effects on production of neurochemicals: short-chain fatty acids (SCFA), oxytocin, gamma- aminobutyric acid (GABA), serotonin, tryptamine, noradrenaline, dopamine, acetylcholine, and other neurotransmitters,

Effects on gut hormone secretion and CNS signaling, including modulation of ghrelin, gastrin, CCK, peptide YY secretion

Modulation of gut related inflammatory markers which can have CNS effects, e.g., inflammatory cytokines IL-8, CCL4, CCL2, TNF-alpha, INF, IL-6

Nociceptive effects, e.g., blocking pain receptors in the GI tract

---

*C. difficile* colitis, ulcerative colitis/pouchitis, and Traveler's diarrhea with certain probiotics. There is less evidence for other conditions, including respiratory infections, eczema, and *H. pylori* infection. Evidence is emerging for dyslipidemias, urogenital infections, and neurobehavioral or mood disorders (Merenstein et al., 2020; Sanders et al., 2018; Szajewska, 2016; Pobio, 2022; Zommiti et al., 2020)

The clinical research literature on the "efficacy" of probiotics continues to grow and accumulate, albeit with significant limitations. Early studies in the late 80s and 90s were often less rigorous in specifying the microorganisms used in clinical trials, nor were the amounts, dose, or viability rigorously controlled or documented. This has improved significantly in the last 20 years, and the microorganisms and dosing of viable organisms (CFUs in the product) are adequately reported in most clinical trials today. Still, some studies use products that are not always well manufactured or controlled.

Other limitations in the scientific literature come from the breadth of organisms used, and different health benefits studied, with few confirmatory studies for efficacy of a specific probiotic, for a particular benefit, in a particular population. Studies of a specific bacterium will also vary significantly by design, dose, duration of intervention, etc. And there are almost no studies comparing one probiotic intervention with another. In addition, the risk profile for the subjects for the outcome studied may often not be accounted for or controlled. Today, based on a better understanding of the development of the microbiota and variables that influence risk for dysbiosis and disease, we recognize factors that should be controlled for, and most often are not. For example, a clinical trial done in a population of children may not control for antibiotic use prior to the trial, or for vaginal birth vs. by cesarean section, which we know now are clear confounders in the potential for dysbiosis and a clinical response to the intervention. Lastly, some studies use combinations of bacteria, which tests the effect of the combination but makes it difficult to establish individual bacterial components as probiotics.

The way that the accumulated literature is assessed regarding "efficacy" also has major limitations. Multiple systematic reviews and meta-analyses have evaluate the "efficacy of probiotics" for a particular clinical outcome. However, these analyses combine

genus, species, strains, dose, duration, etc., as if the trials addressed a similar, consistent, or homogeneous intervention targeting a particular health outcome, which is simply not appropriate. Such analyses of the clinical trial literature may help identify potential benefits broadly and may suggest the potential for use of any or all probiotics for certain clinical benefits; however, they make it very difficult, and in fact hinder, the development of specific clinical recommendations.

The high level of safety associated with most lactobacilli and bifidobacteria in most populations has worked for and also against the study and use of probiotics. Their relative safety has allowed for a large number of trials, but often done with less rigor than usually applied to a potential drug or similar intervention. In addition, the less-than-ideal regulatory frameworks increase the difficulty for communicating disease-related benefits when there is evidence. On the one hand, poor regulation facilitates poorly informed use or recommendations, even when positive data is not strong or rigorous. On the other, in some regulatory environments, the level of evidence needed to communicate a benefit is as high as it is for a drug. These limitations have created both “hype” as well as skepticism in different circles of scientists, academics, businesses, and consumers. Ultimately, a specific outcome with a specific intervention, using a specific probiotic candidate, in a particular and reasonably homogeneous population and replicated beyond a single clinical trial, should drive recommendations (Merenstein et al., 2020; Sanders et al., 2018; ISAPP, 2019; Zommiti et al., 2020).

### Safety of probiotics

There is a broad and robust consensus that most microorganisms used as probiotics today are safe for most populations. Most safety concerns arise from three potential risks: bacteremia or infection, production of toxins or metabolites of concern, and transfer of genetic material (e.g., for antibiotic resistance) from probiotic bacteria to potential pathogens. Reassurances come from a long history of safe use, clinical trials, epidemiologic assessments, and increased understanding of bacterial metabolism and their genetics.

#### Infectious risk concerns

Most species of lactobacilli and bifidobacteria used today have a very long history of use in the food supply and as supplements, consumed by millions of individuals globally every day. Only a few epidemiologic and surveillance studies have been done to assess safety concerns, but none have shown any evidence of increases in adverse events with increased consumption. Many genera, species, and some strains of probiotics in use are present in human commensal microbiota, and many probiotics have been originally isolated from healthy humans.

No significant concerns of adverse effects have been identified in hundreds of clinical trials, although most of these trials are focused on efficacy and not specifically designed for detecting safety issues. Clinical trials in high-risk populations, including preterm infants, the elderly, patients with HIV, cancer, and other immunocompromised conditions, have not identified any significant risks. Somewhat paradoxically, some of the better-documented benefits of probiotics have been shown in populations at particularly “high risk”, such as premature infants. Specific probiotics have demonstrated significant reductions in risk of necrotizing enterocolitis, with no adverse effects from the probiotics used.

Other concerns include the effects of D-lactate produced by probiotic strains (and potential risk of metabolic acidosis), and consequences from deconjugation of bile salts. Similarly, outside very rare cases of acidosis reported in patients with short bowel syndrome, there has been no significant or reliable documentation of other adverse effects from probiotic metabolic activity. Another theoretical concern with probiotics has been their potential for genetically transferring resistance to potential pathogens. There have been no adverse events reported based on this potential risk. Finally, concerns have also been raised following adverse events due to contaminants in probiotic products, not related to the probiotic itself. This is in part associated with poor manufacturing practices of supplements and health products, and lax oversight or regulatory controls in many countries.

However, risk is never zero, and some populations are of greater concern than others. Very rare cases of bacteremia and sepsis have been reported in patients with serious underlying conditions, including reports with use of lactobacilli and bifidobacteria. The safety record is sparser for non-lactobacillus and non-bifidobacterial strains used as probiotics (e.g., *Enterococcus* and *Saccharomyces*). The most commonly reported type of adverse event has been fungemia with *S. boulardii*. Patients with central line catheters appear to be at particular risk (Sanders et al., 2010; Doron and Snyderman, 2015; ISAPP, 2019).

#### Safety regulation

FAO/WHO guidelines recommend that for probiotics used in foods, safety be always assessed for side effects in human studies, for metabolic activities of concern, e.g., if the strain under evaluation belongs to a species known to produce toxins in mammals, it must be tested for toxin production. They should also be assessed for antibiotic resistance patterns, and epidemiological surveillance for adverse incidents should be done in consumers (aftermarket surveillance). These guidelines have generally been adopted, although the level of global compliance varies significantly. The European Food Safety Authority (EFSA) has adopted a premarket system for safety assessment of microbial species used in food and feed production. Once positively assessed, they are granted a “Qualified Presumption of Safety” (QPS) status. Most of the bacterial species used as probiotics have QPS status. In the United States, safety for use of ingredients in foods, including probiotics, requires petitioning and qualification by FDA as having “generally recognized as safe” (GRAS) status if the probiotic was not marketed in the United States prior to 1994. The US FDA requires that dietary supplements be manufactured under “good manufacturing practice” or GMPs standards. It is the manufacturer’s responsibility to meet safety requirements and to provide documentation when required. There is no indication that probiotic dietary supplements in

**Table 2** The conditions listed are those for which there is published evidence of efficacy of probiotics. See sources below for specific strains and doses indicated. The level of evidence is variable for various conditions as well as for the specific probiotics for each condition.

<i>Clinical conditions for Which positive outcomes have been reported with the use of probiotics</i>		
<i>Condition</i>	<i>Population</i>	<i>Probiotic</i>
<b>Gastrointestinal</b>		
Acute infectious diarrhea (prevention <sup>1</sup> & management <sup>2</sup> )	Infants, children & adults	<i>L. rhamnosus</i> , <i>B. lactis</i> , <i>L. casei</i> , <i>L. plantarum</i> , <i>L. reuteri</i> , <i>S. boulardii</i> , others <sup>3</sup>
Antibiotic associated diarrhea (prevention)	Children & adults	<i>L. rhamnosus</i> , <i>L. reuteri</i> , <i>L. plantarum</i> , <i>L. casei</i> , <i>B. lactis</i> , <i>S. boulardii</i> , others, combinations <sup>4</sup>
<i>C. difficile</i> colitis (management)	Children & adults	<i>L. rhamnosus</i> , <i>L. plantarum</i> , <i>L. casei</i> , <i>L. acidophilus</i> + <i>L. casei</i> , <i>S. boulardii</i> , combinations
Colic (management)	Infants	<i>L. reuteri</i>
Community acquired infectious disease (GI & respiratory)	Children & adults	<i>B. lactis</i> , <i>L. casei</i> , <i>L. reuteri</i> , <i>L. rhamnosus</i>
Constipation (management)	Adults	<i>B. lactis</i> , <i>L. rhamnosus</i> , <i>L. reuteri</i> , <i>L. casei</i> , <i>Shirota</i>
<i>H. pylori</i> infection (management)	Children & adults	<i>L. rhamnosus</i> , <i>S. boulardii</i> , <i>L. casei</i> , <i>Shirota</i> , <i>L. reuteri</i> , <i>L. plantarum</i> , <i>L. johnsonii</i> , others, combinations
IBS (management)	Adults	<i>B. lactis</i> , <i>B. longum</i> , <i>L. plantarum</i> , <i>L. rhamnosus</i> + <i>L. helveticus</i> , Combinations
Lactose intolerance (management)	Children & adults	<i>L. bulgaricus</i> + <i>S. thermophilus</i> , <i>L. acidophilus</i> , <i>L. delbrueckii</i>
Necrotizing enterocolitis (prevention)	Preemies	<i>L. breve</i> , <i>L. reuteri</i> , Others, Combinations
Recurrent abdominal pain (management)	Children	<i>L. reuteri</i> , <i>L. rhamnosus</i>
Traveler's diarrhea (prevention)	Adults	<i>L. rhamnosus</i> , <i>S. boulardii</i>
Ulcerative colitis, pouchitis (management)	Adults	<i>L. rhamnosus</i> , <i>S. boulardii</i> , <i>E. coli</i> Nissle
<b>Skin</b>		
Eczema/Atopic dermatitis (management)	Infants & young children	<i>L. reuteri</i> , <i>L. rhamnosus</i> , <i>B. breve</i>
Mastitis (management)	Adult women	<i>L. fermentum</i>
<b>Urogenital</b>		
Bacterial vaginosis & vulvovaginal candidiasis (management)	Adult women	<i>L. rhamnosus</i> + <i>L. reuteri</i> , other combinations
<b>Metabolic</b>		
Dyslipidemia, (reduction in total cholesterol and LDL)	Adults	<i>L. acidophilus</i> , <i>B. lactis</i> , <i>L. reuteri</i> , others
<b>Mood</b>		
Depression & anxiety (management)	Adults	<i>B. longum</i> + <i>L. helveticus</i> , <i>L. casei</i> , <i>Shirota</i> , others

(1) "Prevention" refers to risk reduction of development of a condition. (2) "Management" refers most often to adjuvant use of the probiotic in the clinical management of the condition, to improve signs and symptoms, not as sole or primary treatment. (3) "Others" refers to additional individual probiotics reported. (4) "Combinations" refers to positive outcomes reported with combinations of multiple probiotics.

Sources: Sanders et al. (2018), Merenstein et al. (2020), Zommiti et al. (2020), Probio (2022).

compliance with these GMPs pose a safety concern to the general population (FAO/WHO, 2001; Degnan, 2008, Koutsoumanis, 2020).

## Regulation of probiotics

Beyond the regulatory aspects of safety of probiotics, the regulation of claims regarding the benefits of commercialized probiotic products remains a complex and unresolved issue. Challenges arise from the lack of adequate or consistent regional or national regulatory frameworks, compounded by the limitations in quality and quantity of the scientific documentation for a positive health outcome. Some challenges relate to the type of purported benefit, how it is stated, and how it is applied to different product categories (foods, supplements, drugs). In addition, independent of a scientifically documented clinical effect, there is no universal agreement as to what constitutes a "benefit", a "health benefit", or a "health claim."

As an example, in the European Union in Europe, the word "probiotic" in a supplement or food is itself understood to be a "health claim", not a "nutrition claim." Therefore, inclusion of the word "probiotic" on a product label requires a "health claim approval" by the European Food and Safety Authority (EFSA). Given the EFSA's high level of evidence requirements, since 2006, there have been no claims approved by the Authority, and the use of the word "probiotic" remains essentially unauthorized. However, there is variability among EU Member States in interpreting and enforcing this regulation. On the other hand, the US FDA allows the use of the term "probiotic", and restrictions on claims depend on the classification of the product (e.g., a dietary supplement, food ingredient, or a drug). Dietary supplement labels can claim how the product affects the structure or function. Structure-function claims, e.g., "to support gut health" or "improves microbial balance", can be made without FDA approval. But manufacturers cannot make "health claims", that indicate the use to prevent, treat, or mitigate a disease. The use of claims

related to a disease, even if well documented, would essentially require the product to be classified as a drug and meet very different regulatory requirements than foods or supplements, or undergo a very complex route to receive a “qualified health claim”, which has not happened in the United States (Degnan, 2008; Nyanzi et al., 2021; Rijkers et al., 2011; de Simone, 2019).

## Prebiotics

### Definition

The most recent and increasingly used prebiotic definition is “a substrate that is selectively utilized by host microorganisms conferring a health benefit”, proposed by the International Scientific Association for Probiotics and Prebiotics (ISAPP). The concept of prebiotics was initially proposed by Gibson and Roberfroid in 1995 as a way to modify the intestinal microbiome to benefit the host by using dietary substrates that are selectively utilized by potentially beneficial species in the host microbiota (Gibson and Roberfroid, 1995; Gibson et al., 2017).

### History

The concept of prebiotics is in many ways tied to that of probiotics, and both follow the growth in knowledge of the relationship between a host and its microbiota as a major determinant of health [see section on Probiotics]. In 1921, Rettger & Cheplin published experiments in animals and humans demonstrating that lactose and dextrins (less absorbable sugars than glucose or sucrose) led to an “enrichment with lactobacilli following consumption.” And “when given in sufficient amounts” together with *L. acidophilus* dextrins “bring about a marked transformation of the intestinal flora in which *B. acidophilus* assumes particular prominence and may even completely supplant all other types of bacteria”, an observation which heralded the concepts of prebiotics and synbiotics (the combination of pre- and probiotics).

In the '70s and '80s, there was a significant development in the understanding of dietary fiber: edible substances that are not digested by human enzymes and will undergo varying levels of fermentation by bacteria in the distal gut. Beneficial outcomes with certain dietary fibers included effects on gastrointestinal health (e.g., improved intestinal regularity and risk reduction of colorectal cancer), lipid and metabolic status (e.g., lowering cholesterol, modulating blood sugar levels), and healthy weight maintenance. Research in the '90s showed that some of these non-digestible carbohydrates, particularly fructooligosaccharides found in common foodstuffs such as artichoke and chicory, were selectively utilized by bifidobacteria and lactobacilli. This gave way to the designation of these as “prebiotics” by Gibson and Roberfroid, who defined the term as “non-digestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria already resident in the colon.” This definition gradually evolved in the literature. Initially, it referred to “food ingredients”, since these substances were mostly non-digestible carbohydrates of vegetable origin (e.g., inulin, fructooligosaccharides). Today various other substances, including human milk oligosaccharides, non-carbohydrate substances, and synthesized substances, are considered as having this selective effect on microbiota. Other definitions limited the term to “effects in the colon”, or “in the gut.” However, this did not address potential changes or effects on other microbial habitats such as skin, oral cavity, respiratory tract, and vagina. The type of effects of these substances on specific species has also evolved, from “selectively stimulating the growth and/or activity”, or “selectively fermented”, to “utilized.” And finally, the “selective utilization” has, for the most part, referred to preferential substrate use by *Bifidobacterium* and *Lactobacillus* species. In practice, the term has been commonly and less rigorously used to describe “bifidogenic” substances. Today, emerging evidence suggests growth promotion of other species may be beneficial (Gibson et al., 2017; Davani-Davari et al., 2019).

Parallel to these developments, in the '50s, P. György and R. Kuhn described the presence in human milk of a “bifidogenic” substance, which they called “*L. bifidus* growth factor.” They showed it was present in much greater concentrations in human versus cow milk and in higher concentrations in human colostrum. This explained the predominance of bifidobacteria in the distal intestine of healthy infants. Subsequent work showed that these were a large family of structurally complex unconjugated glycans which are not digested by human enzymes, eventually called human milk oligosaccharides (HMOs). HMOs are selectively utilized by bifidobacteria and have well-documented beneficial health effects, thus fulfilling the definition of prebiotics (Walsh et al., 2020).

The current ISAPP definition, “a substrate that is selectively utilized by host microorganisms conferring a health benefit,” broadens the concept to include non-carbohydrate substances, categories other than food, and applications other than the gastrointestinal tract; but retains the requirement for documentation of a health benefit via selective microbiota-mediated mechanisms. On the one hand, this enlarges the concept for research, inclusion, and exploration of many substances as candidate prebiotics (Sanders et al., 2019; Gibson et al., 2017). On the other hand, it requires the demonstration, not only of a health benefit, but also documentation that such benefit is linked to a specific microbial-mediated mechanism. The strict demonstration of such a link has consequences in terms of classification, communication, and regulatory challenges for using the term.

### Prebiotic substances

To be substrates “selectively utilized” by the microbiota, prebiotics are non-digestible, non-absorbable substances, mainly carbohydrates. Historically they have been associated with, or defined by, their ability to promote the growth of *Bifidobacterium* and *Lactobacillus* species; however, some more recent work suggests that other species of “potentially beneficial” microorganisms like

*Faecalibacterium*, *Akkermansia*, *Ruminococcus*, and *Roseburia*, could be increased by prebiotic substances. Prebiotics may be present naturally in foodstuffs, or they can be synthesized. Research has focused on components isolated from plants or synthesized substances rather than whole plant foods, allowing for tighter control of substance and dose. Most prebiotic substances studied can also be qualified as dietary fibers (all of which are non-absorbable, and thus available to gut luminal bacteria), particularly soluble fermentable fibers. However, some but not all soluble fibers have a prebiotic effect, and some proposed “candidate” prebiotics are not saccharides, such as polyphenols and polyunsaturated fatty acids. Structurally, most prebiotics are saccharides of varying size and complexity. The best-studied categories include fructans (fructooligosaccharides), galactans (galactooligosaccharides), and human milk oligosaccharides.

### Fructo-oligosaccharides (FOS)

FOS are glycans composed of linear chains of fructose units linked by  $\beta(2-1)$  glycosidic bonds. The number of fructose units ranges from 2 to 60 and often terminate in a glucose unit.

FOS occur naturally in small concentrations in plants such as onion, garlic, asparagus, banana, and artichoke. However, most FOS used today in supplements or food ingredients are primarily inulin and inulin-derived fructooligosaccharides. Inulin is found at high concentrations in chicory root, artichoke, or agave, from which long it is extracted. Shorter chain fructooligosaccharides (FOS) are usually obtained through partial enzymatic hydrolysis of inulin and have a typical DP of less than 10 fructose units. FOS can also be manufactured by enzymatic synthesis using fructosyltransferases.

### Galactooligosaccharides (GOS)

GOS, also called oligogalactose, oligolactose, or trans galactooligosaccharides (TOS), occur naturally in some mammals' milk, particularly the milk of marsupials, but is found in negligible concentrations in human milk. These galactose polymers typically have  $\beta(1-6)$  bonds ( $\beta$  GOS). GOS can also be naturally found in plants, particularly pulses, like chickpeas, in which the bonds are  $\alpha$  bonds ( $\alpha$  GOS), including  $\alpha(1-6)$ ,  $\alpha(1-4,6)$  type bonds.

GOS can also be obtained ( $\alpha$ -GOS) by extraction from plants, mainly from pulses such as soybean, lentil, and chickpeas. However, most GOS used today as supplements or food ingredients are enzymatically synthesized from lactose using  $\beta$ -galactosidases. They typically have chains of 2–10 molecules of galactose, the final product and DP depending mainly on the type of galactosidase used.

### Human milk oligosaccharides (HMOS)

After lactose and fat, HMOS constitute the third-largest solid component by weight in human milk; and their concentration is highest in colostrum and decreases in mature milk. They comprise approximately 200 structurally different structures, composed primarily of lactose (glucose and galactose connected by a  $\beta(1-4)$  glycosidic bond), and chains of varying complexity which include fucose, N-ethylglucosamine, and sialic acid. These glycans can be linear or branched, and the sequences can have fucose or sialic acid. They can be categorized into fucosylated, sialylated, and neutral core HMOS. Of all HMOS, the most abundant oligosaccharide is 2'-fucosyl-lactose (2'FL), which is present in the milk of most women. Some mothers have lower concentrations of 2'FL and other fucosylated HMOS in their milk. This is genetically determined by the absence of specific fructosyltransferases (FUT) in the mammary gland, particularly FUT 3.

Despite being a major solid component of human milk, due to their particular glycosidic bonds, HMOS are not digested by human enzymes, and thus have no nutritional value for the infant. 1% is absorbed into the circulation; the rest transit through the intestine and serve as substrate for bacteria in the gut lumen. HMOS are a highly selective substrate for a number of species of bifidobacteria, which are consequentially predominant in the microbiota of breastfed infants. This predominance is absent in infants fed infant formulas. Compared to FOS or GOS, HMOS are more selectively utilized by bifidobacteria. Some *Bifidobacterium* species, like *B. infantis*, have entire gene clusters that control the expression of specific glycosidases and transporters dedicated to HMO utilization.

About 20% of mothers have lower concentrations of 2'FL and other fucosylated HMOS in their milk. This is genetically determined by the absence of specific fructosyltransferases (FUT) in the mammary gland, particularly FUT 3, and has allowed for observational studies related to these differences. In otherwise healthy infants, a lower concentration of fucosylated HMOS, particularly low 2'FL in mother's milk, is associated with decreased bifidobacteria in the gut, and an increased risk of infectious diseases, and potentially atopic diseases. Thus, HMOS fulfill all the criteria to be considered a prebiotic. In addition, outside their effect on the microbiota, they also have direct effects related to pathogen protection, epithelial integrity, and immune modulation in the infant. Over the last few years, chemical and enzymatic synthesis have made possible the commercial production of some HMOS, like 2'-fucosyl-lactose, lacto-N-neotetraose, and 3- and 6-sialyllactose, which has allowed further research to document clinical benefits of specific HMOS (Sprenger et al., 2022; Wiciński et al., 2020).

### Prebiotic candidates

Many other substances are being increasingly assessed for their potential effect as prebiotics. These include simple and complex non-digestible saccharides which behave like dietary fibers and have variable documentation of selective utilization by specific species. And they have varying levels of evidence on health benefits, including improvements in blood sugars and lipids, digestive health

benefits, laxation, and beneficial changes to immune markers. Others, like polyphenols and polyunsaturated fatty acids, are novel prebiotic candidates with alternate mechanisms of action. These include:

### Saccharide prebiotic candidates

- Beta-glucans
- Resistant starch (RS)
- Guar gum.
- Polydextrose (PDX)
- Lactulose
- Xylooligosaccharides (XOS)
- Isomalto-oligosaccharide (IMO)
- Lactosucrose

### Non-saccharide prebiotic candidates

- Polyphenols
- Polyunsaturated fatty acids

(Gibson et al., 2017; Wiciński et al., 2020; Sprenger et al., 2022; Davani-Davari et al., 2019; Hutkins et al., 2016).

### Health outcomes reported with prebiotics

Many benefits reported in clinical trials with prebiotic substances parallel those documented with probiotics. Some of these benefits are associated with, and potentially driven by, increases in lactobacilli, bifidobacteria, or other beneficial species (an “indirect” probiotic effect). Some outcomes observed with these substances may also result from other potentially beneficial effects and mechanisms.

The best documented compositional effects of FOS, GOS, and HMOS on the host microbiota are growth promotion of bifidobacteria and lactobacilli, with variable decreases in other less desirable species such as *Clostridium*. Positive health outcomes reported in clinical trials using prebiotics are summarized in Table 3. The strength of the evidence so far is higher for digestive-related effects, e.g., constipation and stool regularity, which have been well documented for inulin, FOS, GOS, and other saccharides; and have been allowed as claims by some regulatory bodies. Lowering of total and LDL cholesterol and glycemic control have been shown with inulin, some FOS, and some GOS, as well as other soluble fibers. Improved calcium absorption

**Table 3** The conditions listed are those for which there is published evidence of efficacy of prebiotics. With some exceptions, the overall level of evidence so far is quite limited and highly variable for most outcomes. See article text.

Clinical conditions for which positive outcomes have been reported with the use of prebiotics			
Condition	Population	Effect	Prebiotic
<b>Gastrointestinal</b>			
Constipation	Children & adults	Increase in stool weight, and frequency, softer stool consistency,	Inulin, FOS, GOS
Infectious diarrhea	Infants & adults	Risk reduction	FOS, GOS, HMOS
Necrotizing enterocolitis	Preemies	Decreased risk of developing NEC	FOS + GOS
Traveler's diarrhea	Adults	Risk reduction	GOS
Ulcerative colitis	Adults	Marginal improvement of symptoms	FOS
<b>Respiratory</b>			
Respiratory infections	Infants, children and adults	Risk reduction	FOS, GOS <sup>a</sup> , HMOS
<b>Skin</b>			
Eczema/Atopic dermatitis	Infants	Risk reduction and amelioration of symptoms	FOS + GOS
<b>Urogenital</b>			
Bacterial vaginosis	Adult women	Improvement in efficacy of antibiotic treatment	GOS
<b>Metabolic</b>			
Dyslipidemia,	Adults	Reduction in total and LDL cholesterol	Inulin, FOS
Glucose control	Adults	Improved glucose control	Inulin, FOS
<b>Bone health</b>			
Improved calcium absorption	Children & adults	Improved bone mineralization Potential for managing osteoporosis in adults	Inulin, FOS

<sup>a</sup>Most often in combination with a probiotic.

Sources: Gibson et al. (2017), Carlson et al. (2018), Sanders et al. (2019).

has been demonstrated with some saccharide prebiotics. The evidence for other outcomes, including infections (gastrointestinal, respiratory, urogenital), and other inflammatory conditions (eczema, ulcerative colitis, etc.) is still quite limited, and results are inconsistent.

This literature on clinical health effects has consistently increased, but also has significant limitations. The number of prebiotic substances being studied, with different compositions (type of saccharides, degree and complexity of polymerization, physicochemical properties, etc.), is very large. However, with some exceptions, the number of confirmatory studies for specific individual prebiotic candidates is generally low. Studies also vary greatly in design, dose, duration of intervention, and definition of populations studied. As with probiotics, assuming part or all of the effect is driven by improvements in microbiome composition, adequate control for factors affecting the microbiota in the populations being studied is needed, and not always accounted for. Lastly, many systematic reviews and meta-analyses assess “prebiotic interventions” for a particular health outcome, assuming it is a single or homogeneous form of intervention. They report on the “efficacy of prebiotics” as a whole for a particular outcome. Such analyses do not help define the efficacy of a specific intervention, and actually, make consensus and guidance more difficult. Recommendations should be driven by evidence for a specific intervention, for a specific outcome, with a specific prebiotic candidate, in a specific, reasonably homogeneous population, and which is replicated beyond a single clinical trial (Gibson et al., 2017; Sanders et al., 2019; Carlson et al., 2018; Walsh et al., 2020).

### Mechanisms of action of prebiotics

As with most soluble dietary fibers, saccharide-based prebiotics will generally be fermented by bacteria in the distal gut. This leads to production of SCFA and other organic acids, increased intestinal gas, lower gut lumen pH, increased water stool content, and decreased stool consistency. These mechanisms explain the effects of certain dietary fibers on stool consistency, and bowel movement regularity, which have been reported with inulin, FOS, and GOS. Emerging evidence on prebiotic effects on immunity may be indirectly related to similar mechanisms. How much of these effects relate to actual “selective” microbial utilization by host microbiota, as would be required to be defined as a prebiotic, is less well defined, and probably very variable.

Prebiotics like inulin and FOS have also been shown to help decrease fasting glucose levels and decrease LDL and total cholesterol in individuals with dyslipidemia. The mechanisms for reducing lipid levels, blood glucose control, and immune protection modulation attributed to some prebiotics are not yet totally clear and have mainly been studied in vitro and in animal models. It is postulated, for example, that the generation of particular SCFA by prebiotics, such as propionate, may modulate hepatic gluconeogenesis. SCFAs could also influence appetite regulation and food intake by triggering a release of the gut hormones like GLP-1 and PYY, and stimulating glucose-dependent insulin secretion, inhibiting glucagon release in the pancreas, slowing gastric emptying, as well as directly suppressing appetite in the brain.

The absorption of minerals, particularly calcium and magnesium, appears to be enhanced by some prebiotics. It has been proposed that SCFA production and lower luminal pH can increase the solubility of mineral salts and improve mucosal function and absorptive surface, increasing mineral absorption. The potential mechanisms for protective and immune-related effects of prebiotics on infection and inflammatory conditions such as allergy are still unclear. These include increased bacterial production of SCFA, which lowers pH and inhibits pathogens, and support gut mucosal integrity. An “indirect probiotic effect” could also enhance mucosal integrity, immune function, and regulate expression of pro- or anti-inflammatory cytokines.

HMOs can, in part, behave mechanistically like other saccharide-based prebiotics. They are utilized in a highly selective way by specific genera and species, lower pH, and increase SCFA in the distal gut lumen, which inhibits pathogens, modulates the microbiota composition, and enhances epithelial protective barrier function. In fact, they have been described as “the fiber of breast milk.” However, it is also clear HMOs have multiple other direct effects on resident microbiota (e.g., serving as decoys for pathogens) and on epithelial and immune function, not directly related to their bifidogenic or fermentative capacity (e.g., interacting directly with toll receptors and dendritic cells in the gut mucosa.) (Carlson et al., 2018; Gibson et al., 2017; Wiciński et al., 2020; Sanders et al., 2019)

### Safety

The safety profile for most naturally occurring and synthetic prebiotics or prebiotic candidates is very good, and for many of them, well supported by a long history of safe use. Inulin, FOS, and GOS were used in the EU before 1997 and are considered safe food ingredients. However, prebiotic substances created and introduced after 1997 (e.g., synthesized HMOs) are considered novel and require safety assessment for commercialization. In the US, the FDA permits food manufacturers to self-affirm GRAS (Generally Recognized as Safe) status for products included as supplements or food ingredients, which has been the case with most inulin, FOS, GOS, polydextrose, HMOs, and other potential prebiotic substances (Sanders et al., 2019; Davani-Davari et al., 2019).

### Regulation of prebiotics

To date, no major regulatory body has established a definition for the term prebiotic. All related health claims allowed by the US Food and Drug Administration (FDA) and the European Food Safety Authority (EFSA) relate to specific dietary substances, whether they could be considered a prebiotic or not. For example, “Chicory inulin contributes to maintenance of normal defecation by increasing stool frequency” and “non-digestible carbohydrates contribute to a reduction in post-prandial glycemic response” are

claims allowed by EFSA. However, in Europe or Canada, the term “prebiotic” itself is considered a health claim. Thus, to be allowed, requires a very high level of evidence for addressing a disease or pathologic condition. Furthermore, any potentially beneficial modification to the intestinal microbiota resulting from prebiotic use is generally not acceptable as a health claim or benefit.

Similarly, the US FDA has allowed claims for specific dietary fibers (potential prebiotics), such as oat fiber and whole-grain barley, which contain beta-glucans for improving cholesterol levels and reducing risk of coronary heart disease. However, it is unclear how much selective growth of specific species is needed to achieve these clinical outcomes (to be considered a “prebiotic effect”); and the term “prebiotic” remains undefined by the FDA. Any health claims of a substance related to prevention or management of disease must be submitted to the FDA through a health claims petition process. Currently, there are no health claims, i.e., no disease-related claims allowed specifically for any prebiotics. Nevertheless, the term is used in supplements and food ingredients in practice, with similar claims used for some dietary fibers, e.g., “for maintaining digestive health” and “helping increase levels of good bacteria in the large intestine.” In Japan, the Foods for Specified Health Use (FOSHU) permits claims on some foods and beverages that provide health benefits if valid scientific proof is provided to support such claims. Prebiotics are not explicitly mentioned or defined but can be categorized as FOSHU, which includes some oligosaccharides, lactose, dietary fiber, polydextrose, and guar gum (Sanders et al., 2019; Hutkins et al., 2016).

## Conclusion

The explosion of knowledge on the relationship between human health and its microbiota is mirrored by the volume of scientific work focused on approaches to modulate the composition of these microbial ecosystems in ways that are beneficial to the human host. Basic science and in-vitro studies provide clear and robust evidence of the host-microbe interactions which mediate these interactions and support the rationale for probiotics and prebiotics to enhance health. Specific benefits with specific pre- and probiotics on particular outcomes have been well documented. Pre- and probiotics in use today are safe for the general population, and specific benefits have been reported in some high-risk groups, including premature infants, immunocompromised individuals, and the elderly.

However, the strength and consistency of the evidence are extremely variable, and there are a great many trials, with varying levels of rigor, with many pre- and probiotics, rather than less, more rigorous studies, on specific microbes or prebiotic substances, for specific outcomes. And attempts to assess pre- or probiotic “efficacy” as a whole category are not helpful. This has hindered consensus on efficacy and made guidance more difficult. Less than ideal and inconsistent regulatory frameworks have also created challenges in communicating potential benefits when evidence exists and allowing communication of unsubstantiated benefits in some product categories.

Pre- and probiotic interventions to promote health have a strong basis, some benefits are well demonstrated, and much potential remains untapped. Continued emphasis on rigorous research should help close the translational gaps that still exist between concept, science, and application.

### Key points

- The nutritive value of proteins depends both on the amount of protein provided, on the amino acid composition and concentration, and on the bioavailability of nitrogen and amino acids.
- Protein quality is assessed in humans by measuring nitrogen balance, by biological assay in animal models, or from amino acids using the amino acid scoring corrected by the digestibility.
- Protein quality matters because there are differences in the quality of protein from the different food sources and some forms of food storage and processing can also affect protein quality.

### Glossary

**Amino acid score (or “chemical score”)** Value of the limiting amino acid with the lowest score in a protein (i.e., the “most limiting amino acid”). A protein is assigned a percentage score of 100 (or a fractional score of 1.00) when one of its EAAs are limiting

**Amino acid scoring pattern** Amino acid composition of a hypothetical reference protein that contains all EAAs in the amounts necessary to satisfy requirements

**Amino acid scoring procedure** Calculation of the proportion of each EAA in a protein or diet relative to the scoring pattern. It can be expressed as percentage or as a fractional value

**Essential amino acids (EAAs)** Also called “indispensable.” Amino acids that the diet must provide because humans cannot synthesize them from other components at a rate commensurate with normal body needs

**Limiting amino acids** EAAs in food proteins that are present in lower proportions than in the reference protein (i.e., with fractional value  $\leq 1.00$ , relative to the reference protein)

**Nitrogen balance** The average amount of nitrogen that is retained or lost from the body. It is calculated from measurements of dietary, urinary, and fecal nitrogen and estimates of integumental (sweat, skin, nails, and hair) nitrogen losses

**Protein (or nitrogen) or amino acid digestibility** The proportion of dietary nitrogen or amino acid that is absorbed. “True” protein or amino acid digestibility is calculated correcting for endogenous or obligatory fecal or ileal nitrogen or amino acids losses (i.e., nitrogen or amino acid in epithelial cells, gastrointestinal secretions, and intestinal flora)

### Introduction

Proteins are essential nutrients in human diets, and an adequate protein supply is required to meet the body's nutritional needs (WHO/FAO/UNU, 2007). Protein quality is related to the capacity of protein from foods and diets to provide nitrogen and dietary essential (or indispensable) amino acids (EAAs) to achieve nitrogen balance and support body composition and functions for growth, maintenance, and in different physiological situations in humans. The nutritive value of proteins from food and diet depends both on the amount of protein provided, but also on the amino acid composition and concentration, and on the bioavailability of protein-derived nitrogen and amino acids. This quality influences the quantity of protein intake required to meet dietary nutritional needs—the lower is the quality, the higher is the required dietary protein intake. Protein quality matters because there are differences in the quality of protein from the different food sources and some forms of food storage and processing can also affect protein quality. This article examines the ways of assessing the protein quality of foods and diets and the quality inherent to various protein source.

### Protein content and amino acid composition

#### Protein concentration

Protein concentration or density (i.e., the amount of protein per unit of food) is a factor of a food's protein quality. Protein content in food products and food ingredients is determined either by measuring nitrogen content, by measuring amino acid content, or by direct measurement of protein by colorimetric methods, spectrophotometric methods, or infrared spectroscopy (Tome et al., 2019). The different methods have some limitations and measuring nitrogen content with the Kjeldahl or Dumas methods and using a Nitrogen to Protein Conversion Factor remains the more frequently used approach for protein content in foods. The conversion factor used for a mixture of protein sources is 6.25, corresponding to a nitrogen content of 16%. Specific protein conversion factors range from 5.7 (17.5% nitrogen) to 6.4 (15.6% nitrogen) for the major protein sources in the diet.

#### Protein/energy ratio

The percentage of protein energy in the diet (P/E ratio) has been used to describe whether a diet provides adequate amounts of protein. The reasoning is that energy requirements are the main driving force for food intake. Therefore, a diet is adequate if it satisfies the requirements for all nutrients when it is eaten in amounts that will satisfy energy needs. P/E ratio is calculated by dividing the amount of metabolizable energy derived from dietary protein (grams of protein 16.7 kJ or 4 kcal) by the total amount of metabolizable energy in the diet, multiplied by 100 to avoid using fractional values. The P/E ratio indicates the amount of protein that the diet provides relative to energy but does not imply a constant relationship between protein and energy requirements. Obviously, the critical modifiable factor is the energy requirement, which is linked to the habitual energy expenditure level. Therefore, in adults with a lower energy requirement, such as the older subjects, the P/E requirement ratio will be higher, while in adults with a high energy expenditure and energy requirement the P/E requirement ratio will be lower. Diets, especially those eaten by adults, often provide protein in amounts that surpass requirements, which elevates the P/E ratio.

### Amino acid analysis of food proteins

Modern methods that involve acid or alkaline hydrolysis of the protein followed by separation and quantification of the released amino acids by ion-exchange chromatography, gas chromatography, high-performance liquid chromatography and its ultra-fast variant, and electrophoresis, and other chemical and microbiological methods for specific amino acids, such as lysine, methionine, cysteine, and tryptophan, provide data with a repeatability within laboratory of approximately 5% and a reproducibility between laboratories of approximately 10% (Tome et al., 2019). Not all amino acids are fully released or are partially destroyed under conditions of standard acid hydrolysis and acid hydrolysis after performic acid oxidation or alkaline hydrolysis are performed for sulfur amino acids or tryptophan, respectively. Although several national and international food composition tables include amino acid contents of foods, it is preferable to use analytical results from a reliable laboratory owing to technical shortcomings in the preparation of some tables and to the considerable variability between the reported values, especially for tryptophan, cysteine, and methionine. Amino acid data are usually calculated as milligrams amino acid per gram of protein. If they are reported as milligrams amino acid per gram of nitrogen, they are converted to the protein equivalents by multiplying by specific protein conversion factors. To calculate the amino acid content of a combination of food proteins, as in a processed food based on several protein sources or in a mixed diet, a weighted mean of the published or analytical results of each component should be used.

### Assessment of protein quality in human and animal

#### Metabolic studies

The most accurate assessment of protein quality of foods for humans is through clinical or metabolic studies that measure nitrogen balance (WHO/FAO/UNU, 2007). Different amounts of food protein are fed to a group of individuals and to calculate nitrogen losses for each amount excreta are collected and analyzed for their nitrogen content until a steady state is reached and integumental nitrogen losses generally estimated at approximately  $5 \text{ mg N kg}^{-1} \text{ day}^{-1}$ . At that point, the relationship between nitrogen intake and nitrogen balance is evaluated (Fig. 1). The slope of the line before nitrogen balance reaches a plateau and the amount of dietary protein needed to attain zero nitrogen balance are indicators of protein quality; the steeper the slope and the lower the amount of dietary protein to achieve balance, the higher the quality of the protein being tested.

#### Influence of energy intake on nitrogen balance

When food energy intake is insufficient to satisfy energy needs, amino acid oxidation increases in an effort by the human body to satisfy energy requirements. This raises urinary nitrogen excretion and reduces nitrogen balance. However, increased energy intake may reduce amino acid oxidation and urinary nitrogen excretion, thereby improving N balance until it reaches a plateau. This response, known as the protein-sparing effect of dietary energy, can be attenuated if the quantity or quality of food protein intake is inadequate. It has been postulated that the protein-sparing effect of dietary carbohydrates is mediated by increased insulin secretion, which inhibits proteolysis, hepatic gluconeogenesis, and renal ammonia genesis. The protein-sparing effect of dietary fat may be due to a reduction of amino acid oxidation through an effect of free-fatty acid oxidation in the liver, whereby the increase in NADH/NAD inhibits branched-chained keto-acid dehydrogenase. For these reasons nitrogen

Fig. 1 Relation of N balance to protein intake.

balance must not be used to estimate protein quality when the amount of dietary energy is such that it produces weight loss or gain in an otherwise well-nourished individual. Because of their high cost and experimental complexity, metabolic studies are done mainly to evaluate new, nonconventional protein sources and novel food processes that may affect protein quality. Other methods that can predict protein quality for humans rapidly and at low cost are used to evaluate diets and conventional foods routinely.

### Assays in laboratory animals

Biological assays in laboratory animals have been used to assess food protein quality, based either on a protein's ability to support growth in young rats (protein efficiency ratio (PER)) or on nitrogen retention (net protein utilization (NPU)). However, these assays often underestimate the quality of some vegetable and animal proteins for humans. For example, the proteins of pulses and milk casein have a lower quality for rats than for humans because rats have a higher requirement of sulfur-containing amino acids. Thus, application of rat assay for human nutrition can result in quantitative errors. The discrepancy usually has economic rather than public health implications because rat assays generally err by underestimating protein quality for humans, but the value of certain animal proteins can be overestimated because of higher efficiency of utilization by the rat. Nevertheless, the PER and NPU remain useful model for screening food protein quality and to validate theoretical models based on the amino acid composition of the protein in question.

## Assessment of protein quality by amino acid scoring

### Amino acid scores

The concept of assessing protein quality based on a protein's constituent amino acids was introduced in the late 1940s and was further discussed and developed (Lee et al., 2016; Shivakumar et al., 2020; WHO/FAO/UNU, 2007). Amino acid chemical scores are defined as the content of each of the 9 indispensable amino acid in the test protein over the content of the same amino acid in an indispensable amino acid scoring reference pattern.

Chemical score = EAA in the protein/same EAA in the reference pattern.

It was later suggested that the calculations be corrected by the protein's digestibility. In the protein digestibility-corrected amino acid score (PDCAAS) used to assess protein quality, the amino acid score is corrected for true ileal or fecal nitrogen digestibility of the test protein. In the digestible indispensable amino acid score (DIAAS), more recently proposed, the amino acid score is corrected by true ileal digestibility of each indispensable amino acid (Lee et al., 2016; Tomé et al., 2014).

$$\text{PDCAAS} = \text{Chemical score} \times \text{true faecal or ileal Protein digestibility}$$

$$\text{DIAAS} = \text{Chemical score} \times \text{true ileal EAA digestibility}$$

Significant scientific and technological advancements now allow the use of an amino acid scoring procedure adjusted for digestibility as a good and practical predictor of protein quality for humans. This method is recommended by expert committees of WHO, FAO, UNU, and CCVP, as well as by regulatory agencies of several countries, for routine evaluation of protein quality for humans. The elements required for its application are knowledge about the amino acid composition and digestibility of the food protein(s) under evaluation and a scoring pattern based on human amino acid requirements.

### Amino acid scoring reference pattern

Table 1 shows the internationally accepted patterns for amino acid scoring applicable to infants and to persons after 0.5 years of age (WHO/FAO/UNU, 2007; Shivakumar et al., 2020); the composition of high-quality animal foods is shown for comparison. For infants younger than 0.5 year, the scoring pattern is based on the amino acid composition of breast milk, even if some EAAs in human milk exceed minimum requirements for infants of this age. For example, infants consuming cow's milk proteins, which have less sulfur-containing amino acids than human milk, show adequate growth and nitrogen balance. Thus, although the use of a scoring pattern based on human milk composition may somewhat underestimate the composition of the maintenance requirement and of tissue deposition in children of different ages. This was because published nitrogen balance studies to determine the EAA requirement in older children and adults have experimental flaws. In adults, EAA requirements have now largely been determined by amino acid oxidation techniques, which are more accurate, and coupled with the adult protein requirement, allow for an adult scoring pattern to be established. Because proteins with amounts of EAAs that satisfy the needs of young children will probably be adequate for older children, the scoring pattern for preschool children is currently used for all children after 0.5 years of age. All EAAs present in proportions that exceed the value in the reference pattern are assigned a fractional score of 1.00 (or a percentage score of 100%), even if mathematical calculation gives a higher value. The EAA with the lowest value (i.e., the most limiting amino acid) determines the protein's amino acid score. The main EAAs that are likely to limit the protein

**Table 1** Mean protein requirement and Amino acid scoring patterns for catch-up growth 0.5–4.9 year, infants under 0.5 year, preschool children, and adults (Shivakumar et al., 2020; WHO, 2007). Composition of animal proteins shown for comparison.

	<i>Catch-up growth 0.5–4.9 y</i>	<i>Infant 0–0.5 year</i>	<i>Preschool children 0.5–2 year</i>	<i>Adult</i>	<i>Egg, cow's milk, and beef protein</i>
	<i>(g protein/day)</i>				
<i>Mean protein requirement</i>	2.82	–	0.86	0.66	–
	<i>Amino acid scoring pattern (mg amino acid per g protein)</i>				
Histidine	24	20	18	15	22–34
Isoleucine	34	32	31	30	47–54
Leucine	70	66	63	59	81–95
Lysine	65	57	52	45	70–89
Methionine + cysteine	31	28	26	22	33–57
Phenylalanine + tyrosine	63	52	46	38	80–102
Threonine	36	31	27	23	44–47
Tryptophan	10	8.5	7.4	6	12–17
Valine	46	43	42	39	50–66

quality of mixed diets for humans are lysine, the sulfur-containing amino acids (methionine and cysteine), threonine, and tryptophan (WHO/FAO/UNU, 2007). Consequently, when information on all EAAs is not available, protein quality can be estimated based on its score for these four amino acids.

### Correction for protein digestibility

A protein may have a good amino acid composition relative to the scoring pattern, but if it is not fully digested and its constituent amino acids are not absorbed, its capacity to provide nitrogen and EAAs for human function will diminish. Consequently, amino acid scores as predictors of protein quality must be adjusted for protein digestibility and amino acid availability. Protein and amino acid digestibility are a measure of the amount or proportion of dietary protein derived nitrogen and amino acids that are made available to the organism after digestion and absorption. Digestibility is determined by measuring the digestive losses of nitrogen or amino acids at the level of the terminal ileum (ileal digestibility) or in the feces (fecal digestibility). This apparent digestibility must be corrected by the amount of endogenous protein nitrogen and amino acid losses to calculate the true digestibility. As intestinal amino acid absorption is practically complete at the end of the small intestine, oro-ileal disappearance is considered to represent dietary protein-derived nitrogen and amino acid absorption more accurately than oro-faecal disappearance. The True Ileal Digestibility assay is the best currently available approach to assess nitrogen and amino acid absorption. Digestibility measurements at the ileal level may provide a better measure of amino acid digestibility, however this may pose significant challenges (Shivakumar et al., 2020). True Ileal amino acid digestibility is assessed by different invasive or minimally invasive procedures in human, or alternatively in animal pig or rat models (Devi et al., 2018; Fuller and Tomé, 2005; Gaudichon et al., 2002; Kashyap et al., 2018; Lee et al., 2016; Moehn et al., 2005; Shivakumar et al., 2020; Tomé et al., 2014). *In vitro* procedures have also been developed using combinations of trypsin, chymotrypsin, peptidase, and bacterial pro-tease. Further research is needed to validate their use as predictors of protein digestibility in humans.

## Protein quality and dietary sources

### Differences in protein content, amino acid profile and digestibility

Table 2 illustrates the protein concentration in different food protein sources. Animal product protein sources such as meat, milk, eggs, and some animal products are rich in protein with protein content of 30–70% dry weight. Legume seeds are a source of protein with protein content (dry weight) of 35–38% for soybeans and lupines, and 20–25% for peas and beans. Cereal seeds have a protein content of 15–20% dry weight. Among vegetables, pulses have the highest protein concentrations, ranging from 20% to 25% in most raw beans and peas to approximately 36% in soya beans. Most nuts and edible seeds contain 8–18% protein. Many oil seeds have 12–20% protein, and the cake that remains after oil extrusion can have as much as 30–40% protein. Evaluation of a food's protein concentration must be done for ready-to-eat preparations because food processing and cooking can result in significant changes relative to raw foods. Meats, poultry, and fish usually have a higher concentration of protein after cooking or frying, whereas vegetable food preparations contain more water and less protein than the raw products. Protein-dense foods are especially important for young infants, whose small gastric capacity limits the amount they can eat, and for older people with poor appetite.

**Table 2** Protein content of various animal and plant products.

	Average protein content per food family	
	% Wet matter	% Dry matter
<b>Animal product</b>		
Meats, poultry	30	50–70
Fishes and amphibians	25	50–70
Insects	30	40–60
Cold cuts and cured meats	16	30–60
Eggs and derivatives	12	40–50
Cheeses	20	30–50
Milk and dairy products	3–15	20–50
<b>Plant product</b>		
Oil seeds and chestnuts	18	25–35
Legume seeds	9	20–25
Cereals and pasta	8	15–20
Potatoes and related products	3	–
Legumes	2	–
Fruits	1	–
<i>Protein concentration in raw and ready-to-eat foods (g protein per 100 g wet food)</i>		
	Raw	Ready-to-eat
Beef, lean	21.4	36.8 (cooked)
Fish	20.0	31.8 (fried)
Wheat flour	11.0	12.0 (white bread)
Egg, hen	11.3	11.3 (hard-boiled)
Lentils	23.7	7.1 (cooked)
Common beans	22.0	6.2 (cooked)
Maize	9.40	4.2 (tortilla)
Milk powder, cow	26.1	3.2 (12% in water)
Rice	7.20	2.5 (boiled)
Potato, no skin	1.80	1.1 (cooked)

Not all food proteins are digested, absorbed, and utilized to the same extent because of inherent differences in their source (e.g., inside vegetable cells with indigestible membranes), their physicochemical nature (e.g., protein configuration and amino acid binding), the presence of food constituents that modify digestion (e.g., dietary fiber, tannins, and other poly-phenols), the presence of antiphenological factors that interfere with protein breakdown (e.g., trypsin inhibitors and lectins), and processing conditions that alter the nature or release of amino acids (e.g., Maillard reaction and formation of polyamino acids and methylmercaptan). Protein nitrogen digestibility values and more recently ileal amino acid digestibility values of specific foods and well-defined diets may be taken from reliable published data or must be determined, preferably in humans. When cost and practicality do not permit metabolic studies in humans to be performed, standardized methods in animal models are used (Shivakumar et al., 2020). Nevertheless, animal data must be used with caution for foods and diets that are known or suspected of being handled differently by the human and animal intestines. When data are not available for a mixed diet, a weighted average can be calculated from the true digestibility of its constituent protein sources.

Examples for PDCAAS and DIAAS values of different food protein are reported in Table 3. Foods of animal origin, such as milk and milk products, eggs, meats, poultry, and fish, have excellent amino acid composition, true protein or amino acid digestibility of 95–98%, and a score of 100%. In addition, their protein concentrations often increase after cooking. Almost all vegetable foods have one or more limiting amino acids. In general, proteins in natural vegetable foods have digestibility of 70–85%. Vegetable protein isolates, flours, and extruded products have higher digestibility. Pulses usually have limiting sulfur-containing amino acids. Cereals and cereal products are the largest sources of protein in most areas of the world. Cereal grains and flours contain approximately 7–12% protein with a quality that is limited by their lysine content and, in many instances, also by threonine or tryptophan. Although deficient in lysine and threonine, rice has one of the best amino acid compositions among cereals, whereas sorghum and native maize (i.e., not genetically improved) are among the lowest.

### Improvement of protein concentration, amino acid profile and digestibility

Protein concentration can increase by genetic selection of protein sources, as in improved varieties of rice that have approximately 30% more protein than native rice, using nitrogen-concentrating fertilizers that can raise the protein contents of several cereals or by

**Table 3** Examples of lowest non-truncated PDCAAS and DIAAS values calculated for adult for various animal and plant protein sources.

Protein sources	Limiting amino acid	PDCAAS		DIAAS	
		Non-truncated	Truncated	Non-truncated	Truncated
<b>Animal product</b>					
Whey protein isolate	His	97–112	97–100	107–109	100
Whey protein concentrate	His	99–107	99–100	97–107	97–100
Skimmed milk powder	SAA	112	100	105	100
Beef meat	Leu	114	100	112	100
Egg	His	115	100	113	100
Whole milk powder	SAA	116	100	116	100
Milk protein concentrate	SAA	121–125	100	118–120	100
Average animal	–	115	100	114	100
<b>Plant product</b>					
Corn grain, silage	Lys	47	47	42	42
Wheat	Lys	46–51	46–51	40–45	40–45
Sunflower cake	Lys	54	54	46	46
Triticale	Lys	55	55	50	50
Sunflower expeller	Lys	58	58	49	49
Rice	Lys	59	59	48–56	48–56
Barley	Lys	59	59	47	47
Wheat bran	Lys	60	60	49	49
Pea protein concentrate	SAA	71–86	71–86	62–82	62–82
Peas	SAA	78	78	65	65
Soya protein isolate	SAA	86–95	86–95	84–90	84–90
Rapessed expeller, cake	Ileu	92	92	70	70
Soya flour	SAA	93	93	89	89
Soyabean cake	SAA	99	99	97	97
Soyabean expeller	SAA	102	100	100	100
Soybean	SAA	102	100	100	100
Average plant	–	70	70	61	61

All EAAs present in proportions that exceed the value in the reference pattern are assigned a fractional score truncated to 1.00 (or a percentage score of 100%), even if mathematical calculation gives a higher value (non-truncated score). The EAA with the lowest value (i.e., the most limiting amino acid) determines the protein's amino acid score.

His, histidine; Ile, isoleucine; Leu, leucine; Lys, lysine; SAA, sulfur-containing amino acids; PDCAAS, protein digestibility-corrected amino acid score; DIAAS, digestible indispensable amino acid score; EAA, essential amino acid.

Values from Ertl et al. (2016), Mathai et al. (2017), Sosulski and Sarwar (1973), Rutherfurd et al. (2015), Herreman et al. (2020).

industrial and home processing that reduce the water content of food preparations. Protein fortification by addition of concentrated protein sources, such as casein, soya protein isolates, soya flour, milk powder, or dehydrated egg, will also increase the protein concentration of foods and diets, as well as their amino acid score in some instances.

The amino acid profile of a food or diet can be improved by increasing the amount of constituent amino acids in its proteins, adding specific amino acids, or combining foods in proportions that result in a better amino acid pattern. In cereals genetic handling resulted in higher contents of the amino acids that limit their protein quality. For example, varieties of Opaque-2 corn have approximately 50% more lysine and 35% more tryptophan than native corn, both of which are limiting amino acids in this cereal. The addition of synthetic amino acids by fortification and enrichment eliminates or reduces the magnitude of limiting amino acids, for example, in lysine-enriched wheat flour. For complementation, the combination of a food that has one or more limiting EAAs with another food(s) that has a surplus of these amino acids results in an improved combined amino acid profile. A double complementation effect has been achieved in the formulation of vegetable mixtures based on protein sources in which one has a surplus of the EAA that is limiting in the other and vice versa (Fig. 2).

Various food processing procedures can improve protein digestibility by removing food constituents that reduce digestibility (such as dietary fiber), breaking down poorly digestible vegetable cell membranes, destroying or neutralizing antiphenological factors, and increasing the food surface area in contact with gastrointestinal enzymes. For example, soya protein isolate, polished rice, and refined wheat flour have higher protein digestibility than soya flour, whole rice, and whole wheat, respectively. Food storage and processing in adverse circumstances can reduce protein quality by making some EAAs unavailable for use in the human body. These conditions should be avoided to preserve protein quality. Some examples are the storage of dried milk under mild to moderate heat and humidity, which renders lysine side chains unavailable after reacting with the reducing sugar, lactose (Maillard or "browning" reaction); the severe treatment of protein with alkali, which causes lysine and cysteine residues to react and form lysinoalanine; and the treatment of proteins with oxidizing agents, which can result in a loss of methionine. Severe heating conditions in the presence of reducing sugars or oxidized lipids can make some food proteins resistant to digestion, thereby reducing the availability of all their amino acids.

**Fig. 2** The effect of combining proteins on the amino acid score of the dietary protein intake.

## Conclusion

Different methods and approach have been used to assess the nutritive value of protein from food and diet. Significant scientific and technological advancements and development make the amino acid scoring procedure adjusted for digestibility as an accurate predictor of protein quality for humans. This method is recommended by most expert committees and regulatory agencies.

## Key points

- Dietary protein intakes can vary markedly throughout the life cycle within healthy diets according to the balance between plant-based or animal-source foods so that identifying the lower limit of the healthy range is challenging.
- The metabolic model for the protein requirement identifies the cellular metabolic demand, which includes obligatory and adaptive components. The dietary requirement is an intake which meets the demand after adjusting for digestibility and amino acid-dependent biological value. Dietary allowances are set at the upper end of the range of interindividual variation.
- Obligatory demands comprise amino acids used for synthesis of various nitrogenous metabolites, for net synthesis of proteins lost from the body and in children, pregnancy and lactation, the net protein deposition during tissue and fetal growth and breast-milk secretion.
- Adaptive components of the metabolic demand comprise amino acid oxidation at a rate set by the habitual protein intake which occurs to minimize increases in the potentially toxic branched-chain, aromatic and sulfur amino acids.
- The minimum protein requirement, defined as the lowest intake that will maintain nitrogen balance in healthy adults and provide for special needs of children or pregnant or lactating women, derive from a meta analysis of nitrogen balance studies in adult men and women, in which the median intake for nitrogen equilibrium in individual subjects, was independent of age gender or dietary protein composition. The range of overall variation was large, possibly due to non-intended variation in energy intakes between studies and in incomplete adaptation to the test diets.
- A factorial model of requirements in children, pregnancy and lactation assumed similar obligatory demands per kg body weight as the adult value plus special needs adjusted for an assumed efficiency of dietary protein utilization deriving from nitrogen balance studies. The efficiency values used are low and arguably underestimates of the true biological values so that intakes for special needs are likely to be overestimated, markedly so in pregnancy. Thus recommended intakes for pregnant women may be associated with health risks.
- The metabolic demand includes requirements for indispensable amino acids and dispensable amino acid nitrogen and can be met by mixtures of plant source proteins as well as animal source proteins. The amino acid profile of many traditional and novel plant proteins satisfies the amino acid requirement profile, with the main difference between animal and plant dietary protein sources reflecting a lower digestibility.

## Introduction

Discussions in the area of nutritional recommendations are seldom without some degree of controversy and protein is an exemplar of the difficulties and debates which can occur. The amount and type of dietary protein needed to allow optimal genomic expression during growth and development is poorly understood. There are virtually no effective markers of protein deficiency in adults or children, and clinical manifestations long thought to reflect a protein-deficient diet, such as edematous infantile malnutrition, are now generally recognized as reflecting the combined effects of infection and micronutrient-deficiency. At the other end of the spectrum of public health issues, within health clubs worldwide, more money is spent on protein and amino-acid supplements than on any other ergogenic aid, even though the effectiveness of such expense is poorly documented to say the least.

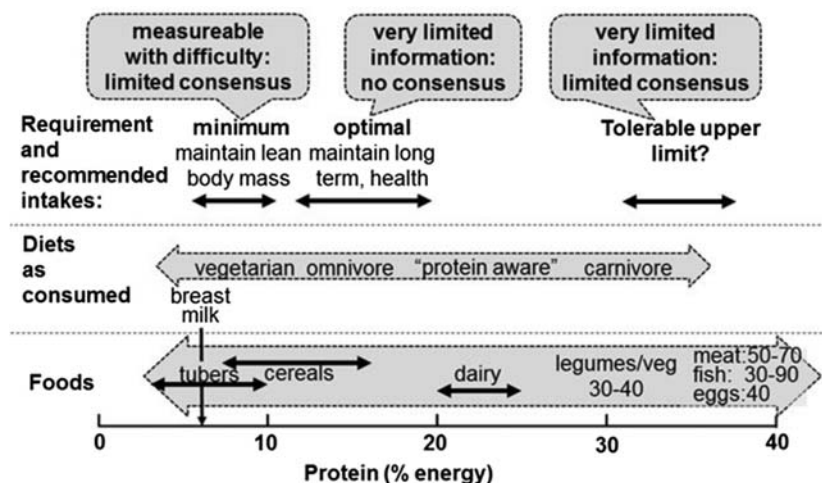

Values for protein and amino-acid requirements derive from nitrogen (N) balance and growth studies which began early in the 20th century and identified estimates of dietary requirements and the pattern of amino-acid essentiality. From the 1970s research expanded to include stable isotope tracer studies of human protein and amino-acid metabolism and turnover. However the 2007 expert report from WHO on human protein and amino-acid requirements ([World Health Organization, 2007](#)) concluded that, of the methodologies available, N balance remains the only available method for estimating the requirement for total protein (N), and no current method is entirely reliable for determining the dietary requirement for indispensable amino-acids (IAAs). However because of these limitations, the latest recommendations for protein and amino-acid requirements are not entirely satisfactory, yet their limitations are by no means widely recognized.

It is the case, as indicated in [Fig. 1](#), that dietary protein intakes can vary markedly even within diets which would be judged “healthy”, and between population groups who choose plant-based rather than animal-source foods. In fact given  $\geq 3$  fold variation in dietary protein content indicated in [Fig. 1](#), overall protein intakes can vary over a 5 fold range if variation in lifestyle and food energy intake is taken into account in ostensibly healthy individuals. The challenge is to identify the intake at the lower end of this range which satisfies the criteria of a requirement value.

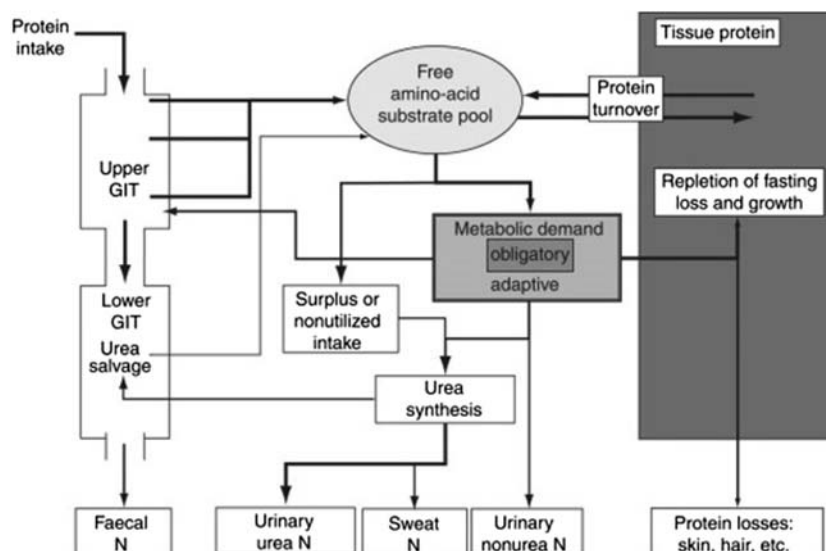

In general terms the dietary protein requirement is the amount of protein in an otherwise nutritionally adequate diet, necessary to maintain the desired structure and function of the organism and to provide for any special needs. In a 2007 WHO report the minimum protein requirement, (MPR), was defined as: the lowest level of dietary protein intake that will balance the losses of nitrogen from the body, and thus maintain the body protein mass, in persons at energy balance with modest levels of physical activity, plus, in children or in pregnant or lactating women, the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health. This has the benefit of being conceptually straightforward with N-balance as its main focus. While several stable-isotopic approaches based on different paradigms have been described no consensus has been reached on any specific alternative approach, with one approach identified as deeply flawed ([Millward and Jackson, 2012](#)). However the nitrogen balance approach is beset by major design and practical difficulties of which the problem of metabolic adaptation is especially difficult as will be described here.

## Terminology

Protein requirements can be discussed in terms of metabolic demand, dietary requirement, and dietary allowances. Metabolic demand is the cellular requirement for amino-acids of a pattern which matches their metabolic consumption in metabolic pathways which vary with the phenotype and the developmental and physiological state of the individual. The dietary protein requirement is the amount of protein that must be consumed in order to satisfy the metabolic demand. If digestion and absorption is incomplete (with dietary N lost in the feces), the digestibility is less than 100%, and if the absorbed amino-acid pattern does not exactly match cellular needs (with some absorbed amino-acid N lost as urea), the biological value is less than 100%. In each case the efficiency of

**Fig. 1** Relationships between protein content of foods, dietary intakes and current status of knowledge about requirements (see [Millward, 2013](#)).

**Fig. 2** Schematic representation of the metabolic demands for amino-acids.

utilization will be less than 100% and the dietary protein requirement will be greater than the metabolic demand. Dietary allowances are a range of intakes derived from estimates of individual requirements taking into account variability between individuals. They are designed to meet the dietary requirements of almost all individuals or the majority of the population. The most recent values of safe intakes for individuals and populations are those published by (WHO) ([World Health Organization, 2007](#)) values which have been reproduced in the 2012 EFSA report ([European Food Safety Authority, 2012](#)) (although the terminology varies).

### Metabolic demands for amino-acids: the metabolic model

Current evidence supports the representation of the metabolic demands as in [Fig. 2](#). The metabolic demand for amino-acids is to maintain tissue protein at appropriate levels and to provide for all amino-acid derived metabolites and any additional needs during growth, rehabilitation, pregnancy, and lactation. The ~20 K proteins encoded in the human genome are diverse, including structural or fibrous insoluble types and soluble globular species, with characteristic properties and functions that are determined by their amino-acid sequence. All proteins are in a dynamic state of constant turnover (i.e., breakdown to constituent amino-acids and resynthesis), although for the structural proteins this is slow or minimal. Nonprotein products include nucleic acids and a diverse range of smaller molecules, such as creatine, taurine, glutathione, hormones (e.g., catecholamines and thyroxine), neurotransmitters (serotonin and dopamine), and nitric oxide, a key regulator of blood flow and other physiological processes.

The metabolic demand is supplied from the free amino-acid pool, the size of which, for most amino-acids, is regulated within narrow limits. This regulation involves supply from three sources: dietary proteins after digestion and absorption from the upper gastrointestinal tract (GIT), tissue protein after proteolysis during protein turnover, and urea salvage in the large bowel, (discussed below). Within the free amino-acid pool there are also interconversions of several amino-acids, especially during transfer between organs and in the course of the absorption of dietary amino-acids and ammonia. Removal of free amino-acids occurs by reactions in which they act as substrates, and these reactions are shown as three pathways, one of which is the metabolic demand. This pathway involves a number of irreversible pathways, including net protein synthesis, and other irreversible metabolic transformations of individual amino-acids with the N ultimately excreted as urea and other end products. The second and quantitatively largest pathway is the removal for protein synthesis during protein turnover. However at N equilibrium, the removal of amino-acids for synthesis is balanced by their replacement through proteolysis so turnover does not exert a significant net metabolic demand. The third pathway is the irreversible removal of amino-acids by oxidation and nitrogen excretion provoked, for example, by the transient increases in some or all free amino-acids after a protein meal. This would represent an inefficient utilization. Terminal removal of N by urea synthesis is not entirely irreversible because of urea salvage in the lower GIT. Thus, the rate of urea synthesis is usually in excess of the rate of urea excretion because some urea enters the large bowel and is hydrolyzed by bacteria. Most of this nitrogen is utilized by bacteria, and since little is lost as faecal N, it is eventually returned to the systemic pool as mainly ammonia, which can contribute to the *de novo* synthesis of dispensable amino-acids, and possibly some amino-acids after bacterial death and proteolysis.

### Obligatory and adaptive components of the metabolic demand (see [Millward, 2003](#))

The obligatory component of the demand for amino-acids for subjects at N equilibrium, (i.e., at maintenance), comprises conversion of some individual amino-acids into important metabolites that are further transformed into nitrogenous end products, mainly urea and other compounds in urine, feces, or sweat, as well as net synthesis of proteins lost from the body as skin, hair, and any other secretions including that within the upper GIT involving mucin proteins lost into the large bowel. These diverse

biological demands for amino-acids for maintenance represent an essential but small intrinsic metabolic demand for an equivalent amount of protein, assumed empirically to be equal to the obligatory nitrogen loss (ONL). This is the sum of all N losses from the body observed in subjects fed a protein-free but otherwise nutritionally adequate diet after 7–14 days, by which time nitrogen losses have declined to a stable and reproducible low level with subjects losing body protein at a constant daily rate. In normal adults, the daily obligatory urinary, fecal, and subcutaneous and other N losses are approximately 32, 10.5, and 4.8 mg N kg<sup>-1</sup>, respectively, i.e., 47.1 mg kg<sup>-1</sup> d<sup>-1</sup>, in total equivalent to about 0.3 g protein kg<sup>-1</sup> d<sup>-1</sup> tissue protein mobilized to meet such demands. The ONL is a function of body weight, is assumed not to vary with age, and can be assumed to derive from net tissue proteolysis at a rate determined by the metabolic consumption of the rate-limiting amino-acid, the amino-acid with the highest ratio of molar proportion in the metabolic demand to molar proportion in protein. In fact because the amino-acid pattern of the obligatory metabolic demand is unlikely to match that of tissue protein, the N content of the metabolic demand is likely to be less than the ONL because only some of tissue amino-acids mobilized to provide for the metabolic demand will serve useful functions with the remainder oxidized and their N excreted. Thus the ONL falls in response to feeding selective amino-acids, such as threonine, tryptophan, and methionine, and it is generally assumed that methionine is the rate-limiting amino-acid driving the ONL. In addition to these metabolic demands for maintenance, any net protein synthesis associated with growth, pregnancy, and lactation also constitutes an obligatory metabolic demand.

The adaptive component of the metabolic demand represents amino-acid oxidation at a rate varying with the habitual protein intake that occurs as a result of the adaptive changes in capacity and activity of the pathways of oxidation of amino-acids that regulate free amino-acid pool sizes. Although this aspect of amino-acid metabolism is least understood, it is likely to occur as a consequence of the fact that humans grow slowly or maintain constant weight on diets that contain protein considerably in excess of minimum needs. Thus, to be able to rapidly dispose of excess protein and maintain the very low tissue concentrations of those amino-acids that may be toxic at higher concentrations, (the branched chain, aromatic, and sulfur amino-acids), pathways of oxidative amino-acid catabolism adapt (change their  $V_{\max}$ ), enabling them to operate at the appropriate rate set by habitual protein intakes. Importantly, this adapted rate of amino-acid oxidation changes only slowly in response to either a change in dietary protein intake level or to feeding and fasting. This has two main consequences.

First, when intake falls below habitual intake mobilization of tissue protein occurs with a negative N balance for as long as it takes to adapt to the lower level of intake. This was previously identified as the labile protein reserves. It can be assumed that for intakes greater than the minimum protein requirement (MPR), full adaptation to the new level will include not only a change in the adaptive metabolic demand to match intake but also repletion of tissue N lost during the adaptive transition, i.e., a period of positive N balance.

Second, because the adaptive rate of amino-acid oxidation continues to some extent into the postabsorptive state, there are varying postabsorptive losses of tissue protein and nitrogen excretion with varying habitual intake—that is, a diurnal cycle of post-absorptive losses and postprandial gains with an amplitude that changes with changes in the habitual level of protein intake as shown in Fig. 3. As such, the adaptive metabolic demand includes a component of net protein synthesis that repletes postabsorptive losses. The magnitude of this varies in a complex way with eating pattern and with the amount and quality (amino-acid score) of the habitual protein intake.

There are several practical implications of the adaptive metabolic demands model.

1. The true MPR will be that associated with the lowest possible adaptive metabolic demand. However, it is not known with any certainty how long such adaptation would take. Evidence suggests it is likely to be considerably longer than the two-week periods employed in short-term balance studies. This implies our current estimate of the MPR, from short-term balances, is likely to be an overestimate and that some of the variability in protein requirements between studies may reflect variable completeness of adaptation to the test diets.

Fig. 3 Schematic representation of balance regulation throughout the diurnal cycle with increasing habitual protein intakes (see Millward, 1995).

2. Within an adaptive demand model, intakes and requirements are correlated, which has implications for the definition of risk of deficiency and safe intakes.
3. In N-balance studies the slope of the regression of N-intake on balance will underestimate the efficiency of protein utilization. This is discussed further in the next section.

### Nitrogen balance studies in practice

N balance studies have been central to the definition of protein requirements within a model of nutrient balance: i.e., an intake which balances all losses observed in a healthy weight-stable subject. N is the proxy measure of protein intake and losses, and health is identified only in terms of an appropriate lean body mass at a healthy body weight. Thus, the MPR, is determined as the intake for N equilibrium, (zero balance), as indicated in N balance studies. There are no other measurable physiological or biochemical indicators of health which are exclusively and unequivocally indicators of protein intake and no disease states which have been identified as having a quantifiable relationship with protein intakes.

The aim of N balance studies is simple—to define the relationship between intake and all losses (urinary, fecal, and surface—mainly sweat, skin, hair, breath ammonia, nail clippings, etc.) in subjects fed 3 or preferably more intakes, usually at or below the expected intake for equilibrium. This allows the intake ( $I$ ) which matches all losses ( $L$ ) and maintains N equilibrium to be identified as the requirement ( $R$ ). Thus,

$$\text{when } I = R, \quad \text{balance} = I - L = 0.$$

Subjects adapted to a protein-free diet excrete the ONL which equates to a daily loss of about 0.3 g protein/kg/day. On refeeding with protein, balance improves as the dietary protein provides for some of the metabolic demand, but N losses also increase so that the required intake for balance is more than the ONL. This is a crucial part of the problem of interpretation of N-balance studies. The increasing N losses with intake have been assumed to reflect an inefficiency of utilization of dietary protein to meet the metabolic demand, (quantified by the slope of the regression of intake on balance). However, such increased losses with intake would be expected as part of the adaptive metabolic demand which increases with intake, and these cannot be identified separately in N-balance studies from losses due to an actual inefficiency of intake, so the slope underestimates the true efficiency of utilization to an unknowable extent.

The 2007 WHO report adopted a meta-analysis of acceptable N balance studies in adults aimed at estimating both the ONL and the requirement (Rand et al., 2003). All the reported individual balance points from this meta analysis and the analytical principle is shown in Fig. 4. In this figure the protein intake which will balance all losses and produce N equilibrium, the maintenance requirement is identified by linear regression of balance against intake, as intercept/slope. In practice the currently accepted MPR for adults, (0.66 g/kg/day), is the median value of all individual subject linear regressions of the three or more levels of protein intake. Although the majority of the studies were young men studied with animal proteins, some studies with mixed plant proteins,

**Fig. 4** Illustration of the results obtained and their analysis in a meta-analysis of N balance studies. Data from Rand et al. (2003).

**Table 1** Potential problems relating to N balance methodology (see Millward, 2001).

---

Imprecise: balance is small difference between two much larger amounts
Systematic errors: intake overestimated, loss underestimated due to difficulty of accounting for all losses: e.g.,
Skin surface and secretions
Loss of nitrogen as gas
Expired ammonia
Endogenous NO production gives urinary nitrate, fecal ammonia, and nitrite (not always measured)
Changing size of the body urea pool
Design: balance influenced by
Dietary energy intake and physical activity
Extent of adaptation of amino-acid oxidation
Analysis: linear regression slope markedly underestimates efficiency of utilization

---

with women and with older adults were included. However no significant influences of gender, age or dietary protein source were observed. Subsequent to this meta-analysis, N balance studies examining age and gender specifically have confirmed that these factors do not influence the MPR.

### Inherent difficulties with nitrogen balance studies

This apparently simple but laborious approach is beset with a large number of quite serious problems, as listed in Table 1 (see Millward, 2001).

The lack of precision results in large overall errors and systematic errors appear to result in an overestimate of balance with unrealistic positive balances (protein gains) at high intakes as is apparent in Fig. 4. Of the various difficulties relating to the design and interpretation of N-balance studies the most important are (a) ensuring subjects are at energy balance, (b) allowing sufficient time for adaptation of amino-acid oxidation rates to the change in protein intake with the test diets, and (c) the interpretation of the slope of the regression as a true measure of the efficiency of protein utilization.

### Energy balance and N balance

Ensuring that energy intakes match energy expenditure is the major difficulty with either weight and lean body mass loss or gain a consequence of any mismatch. This means that the protein requirement is a function of the state of energy balance with the influence quite marked (Millward, 2004). Thus the relationship between nitrogen balance (NB), intakes of energy (EI; kcal kg<sup>-1</sup>) and of N (NI; mg N kg<sup>-1</sup>) indicated

$$NB = 0 : 171NI + 1.006EI - 69 : 13.$$

This implies that the intake for N equilibrium (the requirement) will vary from 1.4 to 0.32 g kg<sup>-1</sup> d<sup>-1</sup> according to whether energy intakes are low (equal to the resting metabolic rate RMR), or high, (equal to twice the RMR). In fact, most, (85%), of the estimated between individual variability used to calculate the safe protein intake shown in Fig. 5 could be accounted for by an error of only  $\pm 10\%$  of basal metabolic rate (BMR) in estimating the true energy needs of a subject (Millward, 2004, 2012a). Such errors might not be observed in terms of weight change during the few days in which nitrogen balance is measured and it is likely that many of the positive N-balances shown in Fig. 4 reflect excess energy intake.

Since N-balance varies as a function of energy intake, it may be argued that protein requirements can only be defined in terms of a specified energy intake level, but what is the appropriate energy intake? Should populations with low protein staples consume more energy to achieve body protein equilibrium? Will this predispose to obesity? To what extent does variation in energy intakes at energy balance (i.e., with increasing levels of physical activity) influence nitrogen balance? These are difficult and currently unanswered questions.

### Adaptation to changes in protein intake

With the metabolic demand for amino-acids including both fixed and variable demands, the relationship between intakes and balance will be a function of time and the rate of adaptation, a major cause of the difficulty in the determination of human protein requirement by N balance. In practice, most balance studies are short term, i.e., 2 weeks at each intake studied and with diet periods randomized to minimize metabolic carryover of prior diets. The actual time taken for complete adaptation amino-acid oxidation and urea excretion rates to the new intakes is poorly understood but it is likely to be much longer than the time allocated in balance studies (Millward, 2003). Certainly studies in which the order of the test diets are varied indicate different N balances for the same intake according to the previous intake level. While two weeks allows N excretion to stabilize in subjects fed a protein-free diet, (i.e., during studies of the ONL), it appears that this adjustment to the extreme metabolic change of a protein-free diet occurs

**Fig. 5** Histogram showing distribution of individual reported values for the protein requirements assessed by nitrogen balance, with values for estimated average requirement (EAR), safe individual and population intakes and tolerable upper limit indicated. Requirements determined as intakes for nitrogen equilibrium observed in multilevel balance studies, analyzed by linear regression for each individual studied, ( $n = 224$  individual subjects from  $n = 32$  studies, after a 5% trim of outliers), expressed as protein equivalents. The values in the box indicate the magnitude of the total and between individual variation used in calculating the safe individual intake. Data from a meta analysis of N balance data reported by [Rand et al. \(2003\)](#). The minimum requirement after full adaptation is not known but likely to be less than the median value within the range shown.

more rapidly than the adjustment from one intake to another. The evidence suggests changes in N excretion continue over several months after reduced protein intakes. Incomplete adaptation to a reduced intake at the end of a two week dietary change will result in a more negative N-balance, increasing the apparent protein requirement.

### Adaptation and the efficiency of protein utilization

Because of a lack of sufficient N-balance studies in children and pregnant and lactating women, their protein requirements have been derived with a factorial model: i.e., estimates of the additional needs during growth, pregnancy and lactation are added to the maintenance requirement assumed to be the same as for adults per kg body weight. The factorial model involves adjusting measured rates of protein deposition, in children or during pregnancy, or rates of breast milk production, by an efficiency factor to determine the dietary intake to meet these special needs. Historically these efficiency factors were decided somewhat arbitrarily at 0.7. However in the 2007 WHO report, much lower specific values were chosen from the slopes of the linear regressions of the limited N balance studies reported for the different population groups. Thus the calculated special needs added to the maintenance requirement are now much larger than previously identified.

Clearly most balance studies are performed with high quality protein sources and this raises the question as to why protein utilization should be so inefficient in healthy adults. In fact direct studies of the efficiency of utilization of proteins with  $^{13}\text{C}$ -1 leucine oxidation balance studies have shown that the true efficiency of utilization of dietary protein is as would be expected, i.e., 95–100% for milk and high quality proteins and lower (60–70%) for wheat ([Millward, 2003](#)). The shallow slope (low efficiency) of the N-balance regression has been explained in terms of the adaptive metabolic demand, which results in increasing oxidative losses and consequent metabolic demand above the ONL (the intercept) with increasing intakes, i.e., the slope is unrelated to the efficiency of utilization. The slope of the regression is only of value in terms of defining the intake for equilibrium (i.e., the requirement = intercept/slope = intake for zero balance). This means that the special needs for children, pregnant and lactating women discussed below are all markedly overestimated in the current WHO report and these values have been adopted by other international and national bodies which invariably tend to adopt the WHO values.

## Interpretation of N balance studies in the current WHO recommendations

### Dietary protein allowances for individuals and populations

Nitrogen balance studies determine experimentally an individual MPR, while allowances for protein are calculated from the distribution and interindividual variability of these values within the relevant population as shown in [Fig. 5](#). The EAR or average/median requirement, is the mid point of the range of individual requirements. The safe individual intake (Recommended Nutrient Intake in the UK) is defined as the 97.5th percentile of the distribution, nominally the average + 2SD. Thus any individual receiving such an

intake will have a very low, ( $\leq 2.5\%$ ), risk of deficiency (intake < requirement). However it is not generally appreciated that the safe intake for a population will differ from the safe individual intake. This is because calculation of a safe population intake, needs to take into account the distribution of individual intakes as well as requirements. Because the variability of intake is usually greater than that of the requirement, the safe population intake is greater than the safe individual intake, usually approximating to the average requirement +2SD of intakes or plus 3–5SD of requirements. In fact some argue that the EAR is the most important measure which can be used to judge the adequacy of intakes of populations because the prevalence of deficiency approximates to the proportion of the population with intakes below the EAR, with 2.5% usually an acceptable risk level, (this is called the cut point method of calculating the approximate deficiency prevalence). Thus dietary adequacy would involve most individuals with an intake above the EAR. A tolerable upper limit (TUL) has not been identified for protein but the evidence suggests that intakes of 3–4 times the safe individual intake are consumed without obvious harm. This would suggest that the TUL may be quite high and certainly higher than the value of  $2 \times$  safe intake often assumed in the past.

The serious implication of lack of complete adaptation in short term multi-level balance studies is that because of the very wide range of protein intakes in the human diet, mainly through variable meat intake, the apparent requirement indicated in a study may still reflect the prior habitual diet: i.e., the actual metabolic demands are higher than minimum levels because of the adaptive component of amino-acid oxidation set to balance previous intakes. This may explain the very wide range of reported apparent requirements shown in Fig. 5 from below 0.4 to greater than 1.1 g protein per kg per day. If adaptation does account for the variability rather than variation in actual protein requirements then a quite different analytical model would be implied in which the MPR and safe intake are much lower. In this case risk of deficiency for fully adapted individuals would remain low until intakes fell to quite low levels. Such adaptive models pose difficult questions for public health nutrition.

### Protein requirements for growth and special needs

For infants, children, and pregnant and lactating women, protein requirements are derived by a semi-factorial analysis of the maintenance and special needs, with an assumed efficiency of utilization, all adjusted for individual variation to give the safe intake. The main components of the protein requirements for infants children and adults are shown in Fig. 6. The metabolic demands are for maintenance, assumed to be the ONL as derived for adults (Rand et al., 2003), and assumed to be the same for all age groups, and the demand for growth derived from measured rates of protein accretion in infants and children. The additional amounts needed to account for the low dietary efficiency of utilization to meet these metabolic demands come from balance studies in adults and children which indicate efficiencies of 47% and 58% respectively. To account for interindividual variability, the safe intakes includes the addition of 2 SDs for maintenance and dietary growth needs, calculated from a coefficient of variation (CV) that is the weighted mean of the CVs for maintenance and growth. Overall the safe intake falls from  $1.31 \text{ g kg}^{-1} \text{ d}^{-1}$  at 6 months to  $0.83 \text{ g kg}^{-1} \text{ d}^{-1}$  in adults. The values for infants are validated against protein intakes of healthy breast-fed infants.

**Fig. 6** Histogram showing components of the protein requirements throughout the lifecycle within the factorial model. Overall values are averages of the separate values for boys and girls. Values from WHO/FAO/UNU (2007).

## Pregnancy requirements

The values reported by WHO/FAO/UNU allow for protein retention in the products of conception and in the maternal tissues associated with an average gestational weight gain in a healthy women of 13.8 kg, estimated from body composition analyses, and for the increased maintenance costs of the increased body weight. The efficiency of dietary protein utilization to meet these growth costs is assumed to be 42% a value observed in nitrogen balance studies in primiparous teenagers, and the safe intake is calculated assuming a CV of 12%. This equates to additions of 0.7, 9.6, and 31.2 g protein per person per day. Lactation requirements of 19 g d<sup>-1</sup> and 12.5 g d<sup>-1</sup> derived from the demand observed as average milk protein output of well-nourished women exclusively breastfeeding for the first 6 months and partially breastfeeding after this time adjusted for an efficiency of utilization of 47% as observed in the meta-analysis of N balance studies in adults (Rand et al., 2003).

## Areas of uncertainty

### Requirements for infants and children, pregnancy and lactation

Definition of protein requirements has historically been problematic and successive reports have never been without new areas of controversy. In the most recent report a major consequence of the difficulty associated with interpreting nitrogen balance studies is not only uncertainty about the true adult MPR but also the possibility of overestimation of requirements for the other population groups through calculations within the factorial model. The problem derives from application of very low efficiency figures of  $\approx 50\%$  with no biological explanation for their values other than their derivation in a few balance studies. As is apparent in Fig. 6 for children and adolescents the identifiable metabolic demand for maintenance and growth accounts for only half of the average requirement because the assumed efficiency of dietary utilization is only about 50%. An even lower efficiency is assumed in calculating the requirements for pregnancy. If the actual efficiency is higher, as assumed in previous reports, then the true requirement values would be lower. Although overestimation of requirements for infants and children is unlikely to result in harm, this may not be the case for pregnancy. In fact there is evidence that excessive protein intakes in pregnancy can have adverse effects on pregnancy outcomes so that if any additional dietary intakes are recommended for pregnant women these should comprise of a normal healthy diet. In the WHO/FAO/UNU report advice is given that the additional protein during pregnancy should consist of additional normal food, rather than high protein supplements. During the third trimester an extra 31 g d<sup>-1</sup> of protein would represent an extra 3.6 MJ of a mixed diet assuming it contains 15% protein energy. This is considerably more additional energy than is recommended at this stage of pregnancy by any agency. Indeed given the concern for adverse influences of overweight and obesity on pregnancy outcomes and given that pregnant women often have successful pregnancy outcomes without any increase in food intake, it is likely that this amount of additional food would result in excessive weight gain.

### The amino-acid pattern of the metabolic demand: plant versus animal sources

With continuous and extensive amino-acid interconversion, the pattern of amino-acids in dietary protein need not exactly match the amino-acid pattern of the demand. This is because of some interconvertibility of dietary amino-acids although this is not entirely straightforward. Firstly while the indispensability of nine of the 21 amino-acids in protein is clear (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), as is the dispensability of five amino-acids, (aspartic acid, asparagine, glutamic acid, alanine, and serine), which can be replaced by nitrogen from other amino-acids or sources of nonessential N such as ammonium compounds, there is also an intermediate class of conditionally dispensable amino-acids (DAAs). These (cysteine, tyrosine, glycine, arginine, glutamine, and proline) can be formed from other amino-acids but under specific physiological or pathological conditions their formation may be inadequate. Secondly it appears that the indispensable amino-acids (IAAs) are a poor source of amino nitrogen for the DAAs after their oxidation and that dietary amino-acid mixtures rich in IAAs like egg protein are less effective in meeting the demand than mixtures with added non-essential N. Such diluted mixtures maintain overall balance with lower levels of IAAs, indicating that the metabolic demand for amino-acids includes an absolute need for non-essential N.

Historically growth studies with laboratory animals gave rise to the view of marked differences in the ability of plant compared with animal sources of protein to support growth resulting in classification of dietary proteins according to their nutritional value (quality) in terms of their IAA content. Thus compared with animal source proteins, cereal proteins generally have low levels of lysine and in some cases tryptophan because of the structure of the main storage proteins—the prolamins—e.g., gluten in wheat and zein in maize. In legumes while the main storage proteins, the globulins contain much higher levels of lysine than cereals, they often have relatively lower levels of the sulfur amino-acids, methionine and cysteine. However when different plant protein sources are combined in these assays, such as cereals and legumes, near maximal animal growth can be observed and this gave rise to the concept of complementation, in which the appropriate balance of essential amino-acids is provided from combinations of plant proteins. In fact, apart from cereals, legumes and some starchy roots, most other plant proteins, such as Irish potatoes and leaves such as spinach or oilseeds, and the novel protein sources such as marine microalgae, aquatic plants, blue-green algae and mycoprotein, have balanced amino-acid profiles.

However it is insufficiently appreciated that in human nutrition, with the rapid growth of the newborn infant slowing markedly after weaning, the nutritional demand for IAAs for tissue growth becomes a minor component of the metabolic demand after the first year of life. Little metabolic demand for amino-acids is generated by protein turnover because of amino-acid recycling. Some net protein synthesis is associated with skin and hair growth and with gastric secretions (e.g., threonine-rich mucus glycoproteins) that pass into the colon to be utilized for bacterial metabolism, and with the post prandial replacement of post absorptive tissue protein losses as shown in Fig. 3. The metabolic demand for maintenance of normal function and composition is a poorly understood pattern of amino-acids utilized in the various metabolic pathways other than protein synthesis, but it has long been known that this pattern differs from that required for growth (the tissue protein pattern) and contains a much lower overall amount of IAAs. The currently recommended amino-acid pattern for human adults, the maintenance pattern, contains 28% IAAs compared with 42% in tissue proteins. Furthermore nitrogen balance studies of different plant protein sources has consistently failed to show marked differences between plant-based compared with animal protein based diets. Indeed long term studies of healthy active adults on diets where wheat provided most of the protein have shown that body composition and physical fitness is maintained over periods of several months (see Millward, 2012b). This means that protein quality in terms of the amino-acid profile may be less relevant in human nutrition at least after the first few years of life when the rapid growth of infancy has subsided.

In fact it is likely that the main difference between animal and plant dietary protein sources reflect the lower digestibility of some plant protein sources due to a combination of tough plant cell walls which reduce the accessibility of plant proteins to digestive enzymes and antinutritional factors which can inhibit digestion.

The currently accepted amino-acid pattern of the maintenance requirement for IAAs defined in the 2007 WHO report is not entirely satisfactory (see Millward, 2012b). Each value was chosen from several values which derived from different methodologies on the basis of the consultations judgment as to which was likely to be the most accurate. While the chosen value for lysine (30 mg/kg per day) was derived from tracer studies using the 24 h indicator amino acid method, which were considered to provide the best stable isotope data currently available, it was also stated that the possibility of a lower value intermediate between 22 and 30 could not be ruled out. This means that considerable uncertainty remains about the amino-acid requirement pattern which is used to judge the quality of dietary protein sources.

### Conclusions: implications of adaptation for nutrition policy

In general, protein requirements serve two purposes. One is as a basis for prescription (i.e., advice on safe diets through recommending appropriate dietary intakes). Adaptation implies a low but difficult to define MPR. Indeed, since natural diets, providing sufficient energy and other nutrients, usually provide considerably more than the currently defined MPR, especially the case for young children, so that the magnitude of the MPR becomes to some extent an issue of scientific curiosity only. Formulation of policy in relation to prescriptive matters will inevitably and correctly be most concerned with satisfying the upper range of demands for protein and, where there is uncertainty, include positive margins of error. In this case, it is arguably unwise to adopt an adaptive model and reduce the MPR, even if agreement could be reached on the likely lower limit of adaptation. Indeed, an adaptive model does not imply that protein is an unimportant nutrient for the maintenance of human health and well-being but that indicators other than balance (nitrogen, protein, or amino-acid) need to be identified. Thus, the most relevant measure is an optimal requirement allowing balance and supporting both optimal body function and minimum risk of chronic disease. Unfortunately, it remains the case that there is mixed evidence about the overall long term health effects of protein at intakes at or above the current MPR with no overall consensus. The most widely discussed issue is the suggestion that intakes above the MPR can protect the elderly from the muscle wasting-disease sarcopenia. This is based on the observed anabolic resistance of muscle protein synthesis to essential amino acids together with a number of dietary intake-sarcopenia studies. However the evidence base from these studies that increased protein intakes limit sarcopenia is minimal or based on studies in which the authors interpretation of the results has been identified as misjudged (Millward, 2012c). This results in a dilemma for those attempting to frame prescriptive dietary guidelines. From this perspective, it is probably wise to retain current values as an operational expedient until it becomes possible to quantify the benefits (and any risks) of protein intakes within the adaptive range.

The other purpose of requirement recommendations is as a diagnostic indicator of deficit risk, often within an epidemiological context in which population groups rather than individuals are considered. In this case, indicators used to estimate prevalence of disease states or deficit risk are carefully chosen so as to strike an acceptable balance between false positives and false negatives. The main implication of adaptation for estimating risk of deficiency as intakes become less than requirements is a dramatic reduction in the prevalence of risk for most populations compared with that assessed according to the traditional model, which does not account for adaptation. This occurs because the requirement and intake can be assumed to be correlated and because the actual MPR and safe intake calculated from it will be lower. As in the prescriptive context, this low risk of deficiency applies only to that of being unable to maintain nitrogen balance after full adaptation with otherwise nutritionally adequate diets satisfying the energy demands. Whether such populations, (likely to be rare), enjoy optimal protein-related health in terms of immune function, bone health, or any other function is a separate issue and needs to be addressed as such. From this perspective, it follows that maintenance of nitrogen balance can no longer be used as a surrogate of adequate long term protein-related health, and that current lack of quantifiable alternative indicators is no excuse for ignoring the issue of adaptation.

## Key points

- Sodium chloride (salt) is an essential nutrient required for numerous physiological functions. It is naturally present in many foodstuffs; it is also added in food processing, at the table and in cooking process.
- Urinary sodium excretion is generally considered as a useful surrogate parameter for sodium intake, with spot urine samples being less reliable than 24-h urine samples, and multiple urine samples more representative of a person's usual sodium intake than a single sample.
- Sodium chloride is but one among many factors which are involved in the control of blood pressure. Individuals are more or less sensitive to salt in terms of blood pressure.
- While numerous observational studies in general population have shown associations between salt intake and blood pressure, many others failed to demonstrate such an association. Differences in confounding factors probably account for the discrepant results.
- Observational studies are merely hypothesis generating. Causal relationships can only be proven by intervention studies. Unfortunately, the number of well conducted intervention studies is much smaller, and again reported findings have remained inconclusive, both as regards the effect of salt intake on blood pressure and its role in cardiovascular events and mortality.

## Introduction

"Salt" is a commonly used term. It is composed of sodium and chloride although strictly speaking there are numerous other salts containing sodium or chloride such as sodium carbonate, sodium fluoride, potassium chloride, and magnesium chloride. Sodium does not naturally occur in isolated form. It represents only one of the two elements necessary to form the most common form of "salt" (NaCl). Both in the medical and general literature the terms sodium and salt are often used interchangeably.

Sodium is required for a large number of physiological functions, including the maintenance of body fluid volumes and their distribution, skeletal and cardiac muscle contraction, and nerve conduction velocity. Salt also plays a role in growth and development, general appetite, sexual performance, reproduction, and pregnancy, to name just a few. Chloride participates together with sodium in most of these functions. Chloride also is involved in the digestion of meals in the stomach via hydrochloric acid.

Increased needs of salt are caused by changes in external conditions and enhanced cutaneous sodium losses such as in hot climate and at high levels of physical activity. They can also be caused by disease states such as salt losing endocrinopathies and nephropathies. In other disease states there may be decreased needs of salt. Examples are salt-sensitive hypertension, chronic heart failure, chronic kidney disease, the nephrotic syndrome, and decompensated liver cirrhosis. The latter are clinical conditions associated with salt and water retention leading to symptoms of volume overload. In these conditions controlling salt intake is key for a successful therapeutic strategy. However, a number of randomized clinical trials have shown that salt restriction also stimulates sympathetic nervous system activity (thus stimulating sodium retention), increases serum cholesterol and triglyceride levels, activates the renin-angiotensin system (thus promoting cardiovascular damage and risk), decreases insulin resistance and alters aldosterone secretion (Graudal et al., 2020). These stimulations are not necessarily beneficial, they may be even harmful. Thus in each individual, potential benefits of a more or less severe salt restriction must be weighed against potential harms.

Dietary salt is naturally present in many foodstuffs, but salt is also added in food processing and at the table or cooking process (discretionary salt). Natural sources make up 1–1.5 g and discretionary salt 2–3 g of daily ingested sodium chloride. The main amount stems from salt added to food by food manufacturers. It represents roughly 3–4 g per day. Since the body has only limited reserves of sodium and chloride, it depends on the regular intake of salt. The minimum daily requirement compatible with life has been estimated to be 1–2 g sodium chloride. However, this minimum amount is not compatible with normal physical and mental activities. Total salt intake estimates derived from 24 h urine samples are in the range of 7–9 g per day in the Western world (Muntzel and Drüeke, 1992), with the majority of samples being comprised between 6 and 14 g per day in high and middle income countries according to one source (Intersalt Cooperative Research Group, 1988) and between 6.5 and 12 g (2.6–4.8 g sodium) per day according to another, more recent source (McCarron et al., 2013). Table 1 shows an update of the amount of dietary salt intake in various countries worldwide. The relative importance of assumptions about both discretionary salt used by the cook, at the table, and salt added by the industry has to be stressed, keeping in mind that a significant proportion of the salt used during preparation of meals is not ingested, but discarded.

Urinary sodium excretion is generally considered as a useful surrogate parameter for sodium intake. Note that in hot climates or under sustained physical exercise up to 50% (or even more) of the absorbed sodium chloride can be lost by sweating, that is via the cutaneous route. This needs to be taken into account when relying on urinary sodium as a proxy of sodium consumption. There is an ongoing debate on the relative merits of 24 hr urine collections as compared to spot urine samples for the indirect assessment of sodium intake. A recent study compared the sodium excretion and blood pressure relationships from measured 24 h urinary sodium vs. formula-estimated spot urinary sodium values, using restricted cubic spline plots for adjusted multilevel linear models (Naser et al., 2021). According to this analysis all spot urine formulas overestimated 24 h sodium at lower levels but underestimated 24 h sodium at higher levels. There was a linear relationship between measured 24 h urinary sodium excretion and systolic blood pressure, while estimated sodium excretion from all 3 spot urine formulas had a J-shaped relationship with systolic blood pressure. Although 24 h urinary sodium excretion is more reliable the collection of spot urine is more convenient and less expensive (John et al., 2016). While single measurements lack accuracy on an individual level (Ginos and Engberink, 2020) repeat measurements better reflect average sodium intake (Sun et al., 2017), especially when used for population-level estimates in large epidemiologic studies (O'Donnell et al., 2020). This is true for both spot urine and 24 hr urine collections. Food questionnaires are not reliable in assessing dietary salt intake (Ginos and Engberink, 2020) since food tables are rather incomplete and not regularly revised and updated and thus not very useful.

**Fig. 1** Mean and  $\pm$ SD 24 h UNaV from 13 published surveys in the UK between 1984 and 2008 with essentially equal representation of women and men ( $n = 6343$ ). Trend line equation  $y = -0.097x + 150.4$ ;  $R^2 = 0.0026$ ; UNaV, urinary sodium excretion; UK, United Kingdom; NDS, National Diet Survey; NDNS, National Diet and Nutrition Survey. From McCarron et al. (2009) (reproduced with permission).

In the past decades numerous attempts have been made to decrease salt intake in the general population. These attempts have not been successful in most instances. Dietary sodium intake has varied minimally in the UK over 25 years on the turn of the 20th century, encompassing several surveys from the UK and also the Intersalt data (Intersalt Cooperative Research Group, 1988), as reported by McCarron et al. (2009) (Fig. 1). This analysis did not support pronouncements by the British Foods Standards Agency that their national campaign directed at sodium reduction had achieved a significant reduction in the population. Similarly, according to a subsequent report by Bernstein and Willett based on the analysis of 38 studies dating from 1957 to 2003, sodium intake in the US adult population appeared to be well above current guidelines and did not decrease with time (Bernstein and Willett, 2010). It is interesting to note that the consumption of sodium and also that of potassium present specific seasonal variations, as demonstrated by a recent study from Switzerland (Marti-Soler et al., 2017). However, other studies, even in high salt consuming countries, did not show a large seasonal intake variations, or variations were only found in certain subgroups of the population (such as older women).

### Salt (sodium) intake and blood pressure

As already mentioned, sodium and chloride are indispensable for maintaining body fluid volumes in the normal (physiological) range, both outside and inside the cells of the organism, that is in the extracellular and intracellular space, respectively. The extracellular volume comprises the blood space and the interstitial space. Maintaining blood volume within physiological limits is essential for the control of blood pressure, in concert with fine tuning of cardiac output (i.e. "stroke volume"  $\times$  "heart rate") and peripheral vascular resistance, that is the degree of openness (vasoconstriction vs. vasodilatation) of the peripheral arteries and arterioles. The healthy organism (in contrast to patients with heart or kidney failure, who show an impaired natriuresis) closely adapts salt and water excretion to salt and water intake, guaranteeing a neutral balance. In most healthy people, the kidneys are capable of excreting large amounts of sodium when intake is high, and of excreting little sodium when intake is low. It is noteworthy that the kidneys' ability to excrete sodium is impaired in the presence of low potassium diets (Krishna and Kapoor, 1991). This tight control helps to prevent increases or decreases of blood pressure beyond the physiological range.

Sodium chloride is but one among the numerous factors which control blood pressure. The maintenance of normal blood pressure requires a subtle interplay between endogenous factors including age, gender, the cardiovascular system, the kidneys, the endocrine system, neurohumoral factors and genetically determined predisposition including ethnicity, and exogenous factors including dietary factors, physical activity, body mass index, and psychosocial stress. Among the dietary factors, sodium chloride plays an important, although frequently overemphasized role as compared to potassium and other factors. Although the accumulation of sodium chloride favors arterial hypertension and depletion favors hypotension its effects should not be regarded in isolation, especially not without considering the concomitant intake of potassium, the overall health status, body weight status, insulin resistance and many other still ignored factors such as a circadian rhythm misalignment.

However, since the majority of studies aimed at examining the effect of sodium have been done without considering concomitant potassium intake and other determinants of salt sensitivity we shall present reports on sodium in the first place, and only briefly mention reports on potassium and sodium/potassium ratio in the second place.

## Salt sensitivity

An important question is what is excessive and what is insufficient salt intake? The short answer is that this depends on the individual sensitivity to exogenous salt as regards its effect on blood pressure. **Table 2** summarizes the factors commonly incriminated in salt sensitivity and salt resistance, respectively. Salt sensitive individuals exhibit a blood pressure decrease in response to salt restriction, and a blood pressure increase in response to salt overload. Several different methods have been proposed to assess salt sensitivity but there is no commonly accepted definition. As an example, salt sensitivity can be assessed by putting subjects on a high or low salt diet for several days and measuring subsequent blood pressure changes. In the general population, approximately 40% of people are considered to be "salt-sensitive." Consequently, 60% among them are "salt-resistant." Young individuals are more often salt-resistant than older individuals. A minority of young people may even be "reverse reactors." They exhibit an increase in blood pressure in response to reduced salt intake. **Fig. 2** shows a histogram of salt sensitivity in normotensive individuals, that is changes in mean blood pressure in response to salt depletion ([Weinberger et al., 1986](#)).

Not only lay people but also many physicians continue to be confused about the effects of salt on blood pressure. As already mentioned, several disease states as well metabolic-neuroendocrine constellations are associated with a reduced sodium excretory capacity of the kidneys and arterial hypertension, and limiting salt intake in such disease states can reduce blood pressure. But those observations cannot be used to impose a reduction of salt intake on healthy subjects.

The assumption of a close relation between salt intake and blood pressure in the general population actually has a historical basis ([Muntzel and Drüeke, 1992](#)). First, in the early decades of the 20th century no efficient antihypertensive treatments were available other than a severe reduction of salt intake. The well-known amazing blood pressure reduction by the Kempner rice diet is most likely the first well documented evidence of the effect of a severe salt reduction on blood pressure as well as morbidity and mortality in highly selected patients. Usually it is ignored that while under this diet the patients lost more than 20 kg (obviously part of this weight loss was due to edema reduction and thus volume depletion). Nevertheless one can dispute whether the salt restriction or the body weight reduction was of greater physiological importance for their clinical improvement. In view of the global obesity pandemic weight reduction would most likely be favored as the main mechanism. Second, in the 1950s and 1960s Dahl developed the concept that dietary salt is a major factor responsible for increased blood pressure, based on experimental studies in salt-sensitive rats, with his first landmark report dating back to 1958 ([Dahl, 1958](#)).

**Table 2** Salt sensitivity: variable individual response to changes in dietary salt intake.

Relative salt-sensitivity	<ul style="list-style-type: none"> <li>* Old individuals</li> <li>* Black subjects</li> <li>* Some hypertensive subjects (30–40%)</li> <li>* Baseline level of blood pressure</li> <li>* Calcium deficiency</li> <li>* Expansion of extracellular volume and increase of Atrial Natriuretic Factor (ANF)</li> <li>* Stimulation of sympathetic nervous system</li> <li>* Biochemical and genetic markers: <ul style="list-style-type: none"> <li>– Low plasma renin activity</li> <li>– Increased plasma ANF</li> <li>– Decreased urinary kallikrein</li> <li>– Decreased urinary endothelin-1</li> <li>– Haptoglobin 1-1 phenotype</li> <li>– 17<math>\alpha</math>-hydroxylase deficiency</li> <li>– Impaired nitric oxide synthase activity</li> <li>– Mutations of sodium channel genes</li> <li>– Genetic polymorphism of <math>\alpha_2</math>-adrenergic receptor</li> </ul> </li> </ul>
Relative salt-resistance	<ul style="list-style-type: none"> <li>* Young individuals</li> <li>* White subjects</li> <li>* Most hypertensive subjects (60 à 70 %)</li> <li>* Biochemical and genetic markers: <ul style="list-style-type: none"> <li>– Elevated plasma renin activity</li> <li>– Low plasma ANF</li> <li>– Haptoglobin 1-2 and 2-2 phenotypes</li> <li>– Genetic polymorphism of <math>\alpha_2</math>-adrenergic receptor</li> </ul> </li> </ul>
Variable salt sensitivity during lifetime, potential factors	<ul style="list-style-type: none"> <li>* Age</li> <li>* Baseline level of blood pressure</li> <li>* Obesity</li> <li>* Pregnancy</li> <li>* Several disease states</li> <li>* Some medications</li> </ul>

Certain biochemical and genetic markers may be used to assess salt sensitivity. For example the activities of several plasma enzymes and the amounts of certain proteins in plasma and tissues are related to salt sensitivity.

**Fig. 2** Blood pressure response to salt depletion of normotensive subjects. Changes in Mean Arterial Blood Pressure (MABP) in normotensive adults after dietary sodium restriction. Sodium sensitivity was defined as a decrease of at least 3 mmHg, and sodium resistance as an increase of at least 3 mmHg. From [Weinberger et al. \(1986\)](#) (reproduced with permission).

### Epidemiological studies

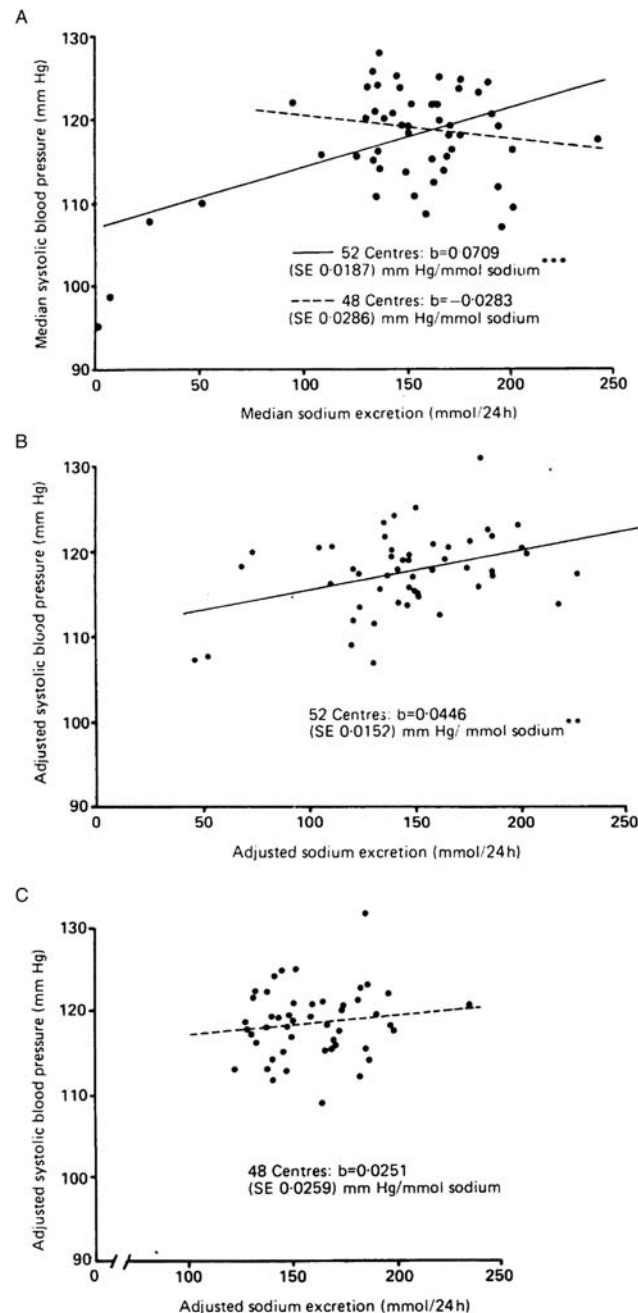

Following this experimental evidence, numerous epidemiological studies done in general population showed associations between salt intake and blood pressure. This started with reports of studies in Northern and Southern Japan, which suggested an association between high salt intake and high blood pressure, although the evidence was rather weak, if not entirely speculative ([Muntzel and Drüeke, 1992](#)). Since the 1980s, the results of better designed epidemiological studies were reported which aimed to definitively establish the presumed relationship between salt intake and blood pressure. The largest early effort in this field has been undertaken with the Intersalt study ([Intersalt Cooperative Research Group, 1988](#)). It included 10,079 volunteers in 52 participating centers worldwide and showed a weak positive association between urinary sodium excretion (reflecting salt intake) and blood pressure. Specifically, systolic blood pressure augmented by 2.2 mm/Hg for every 100 mmol per day increase in habitual sodium intake (6 g salt per day). However, the association disappeared when four centers of non-acclimated populations in Brazil, Kenya and New Guinea were excluded from the analysis, as shown in [Fig. 3](#), which also shows associations after adjustment for various confounders. People of these non-acclimated populations had unusually low salt intakes and blood pressures, unlike the people in industrialized countries. Further they all had a normal body weight, a high potassium intake, plenty of physical activity and a complete lack of acculturation induced stress biomarkers. Moreover, the generally limited life span of these populations did not enable any information on the possible development of hypertension with age. Another observational study of large sample size was performed at same time in Scotland. It failed to identify a relationship between urinary sodium excretion and blood pressure ([Smith et al., 1988](#)).

Differences in several confounding factors probably account for the discrepant results. It is well known that when age, body mass index (BMI), physical activity, potassium intake and alcohol consumption are taken into account the relation between sodium intake and blood pressure becomes weaker or even disappears.

The largest study ever done in this field is the PURE trial ([Mente et al., 2014](#)). The authors studied 102,216 adults from 18 countries. Estimates of 24 h sodium excretion were made based on spot urine measurements as surrogates for sodium intake. Regression analyses showed increments of 2.11 mm Hg in systolic blood pressure and 0.78 mm Hg in diastolic blood pressure for each 1 g increment in estimated sodium excretion ([Fig. 4](#)). The slope of this association was steeper with higher sodium intake. Further, the slope of the association was steeper for persons with hypertension than for those without hypertension and was steeper with increased age.

A very recent observational study of large sample size showed that treatments with effervescent or soluble acetaminophen (paracetamol) formulations containing high amounts of sodium, as compared to sodium-free acetaminophen formulations, were associated with increased risks of cardiovascular disease and all-cause mortality ([Zeng et al., 2022](#)). This was true for both in individuals with hypertension (1-year risk, 5.6% vs. 4.6%) and without hypertension (1-year risk: 4.4% vs. 3.7%). It must be pointed out, however, that the effervescent and soluble formulations of 0.5 g acetaminophen contain 0.44 and 0.39 g of sodium, respectively. Thus, the intake of maximum daily dose (i.e. 4 g/day) of sodium-containing acetaminophen corresponds to the considerable amount of an additional ingestion of respectively 3.5 and 3.1 g of sodium (8.75 and 7.75 g of salt) per day. In this context it is important to mention that a randomized controlled trial recently showed that regular daily intake of 4 g acetaminophen (with a negligible sodium content of only 0.04 mg per capsule) increased systolic blood pressure per se in individuals with hypertension by  $\approx 5$  mm Hg when compared with placebo and hence increased cardiovascular risk ([MacIntyre et al., 2022](#)).

Several other studies showed that excessive alcohol consumption and obesity are more important lifestyle factors than salt intake for the development or degree of severity of hypertension and modulation of salt sensitivity but because of space limits some of

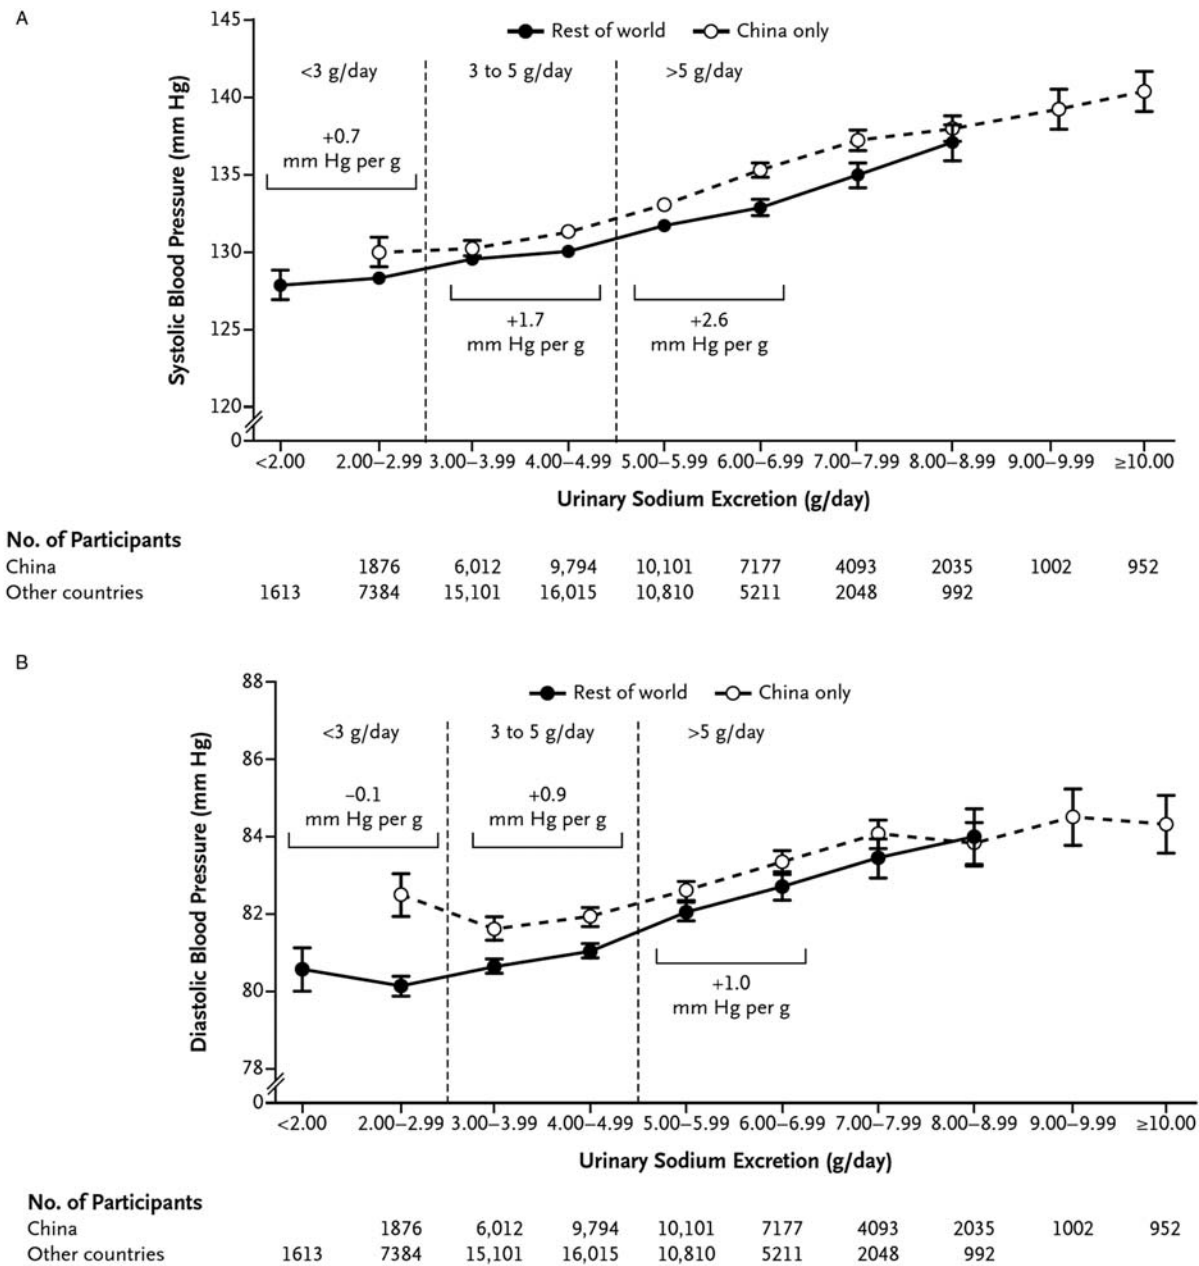

**Fig. 3** INTERSALT 1988—within population studies. them are merely mentioned here by referring to recent reviews and meta-analyses ([Fuchs and Fuchs, 2021](#); [Roerecke et al., 2017](#); [Babu et al., 2018](#); [Zhou et al., 2018](#); [Arabshahi et al., 2014](#)) but not discussed any further.

There is ample epidemiological evidence from the literature that high potassium intake is protective against hypertension. As an example, an observational cross-sectional study of 1996 done in 3239 elderly people in The Netherlands showed that an increase in dietary potassium intake of 1 g/day, based on food frequency questionnaires, was associated with a 1.2 mmHg lower systolic and a 0.8 mmHg lower diastolic blood pressure ([Geleijnse et al., 1996](#)). Note that dietary recalls are more reliable for the assessment of potassium intake than of sodium intake. A very recent cross-sectional analysis of the NHANES database in the US involving 16,684 adults aged  $>20$  years confirmed a correlation between the highest quartile of potassium intake and hypertension ([Cheteu Wabo et al., 2022](#)). This was also true for the sodium/potassium ratio. The study with the largest sample size in this respect is PURE,

**Fig. 4** Mean systolic and diastolic blood pressure according to sodium excretion (Mente et al., 2014). The analysis was adjusted for age, sex, body-mass index, educational level, alcohol intake, and geographic region. Changes in blood pressure are shown for sodium excretion of less than 3 g per day, excretion of 3–5 g per day, and excretion of more than 5 g per day. Persons with extremely low or extremely high sodium excretion are included in the figure. In China, 218 persons with excretion of less than 2 g per day were included in the group with excretion of 2.00–2.99 g per day, and 482 persons with excretion of more than 11 g per day were included in the group with excretion of 10.00 g or more per day. In other countries, 235 persons with excretion of 9.00–9.99 g per day and 112 persons with excretion of 10 g or more per day were included in the group with excretion of 8.00–8.99 g per day. I bars indicate 95% confidence intervals. From Mente et al. (2014) (reproduced with permission).

a worldwide observational study done in 102,216 adult subjects, mean age 50 (Mente et al., 2014). Based on spot urine samples, the authors found a significant inverse correlation between urinary potassium and blood pressure. For each increment of 1 g in estimated potassium excretion per day, there was a decrement of 0.75 mmHg in systolic blood pressure.

### Intervention studies

Epidemiological studies are able to identify associations between lifestyle factors and disease but cannot demonstrate causal relationships. Therefore, several intervention studies were subsequently performed, albeit their number is much smaller than that of

published epidemiological studies. Not surprisingly, even the intervention studies led to conflicting results in that some of them found significant reductions in both normotensive and hypertensive people when salt intake was reduced, whereas others failed to observe an effect. Potential explanations include differences in sample size, age, initial blood pressure, study duration, and last but not least compliance with dietary counseling and educational intervention. We present here three conflicting reports.

The TOHP-II trial is the largest to examine the effect of long-term sodium reduction on blood pressure, with a mean follow-up of 36 months (Anonymous, 1997). The trial was done in the 1990s. The authors recruited 2382 people, aged 30–54 years. Baseline diastolic blood pressure was 83–89 mmHg, and systolic blood pressure < 140 mmHg. The participants had a body mass index representing 110%–165% of desirable body weight. A  $2 \times 2$  factorial design was used to evaluate an intervention for weight loss concomitantly. Mean daily intake was 3.1 g sodium (7.8 g salt) at 18 months, and 3.2 g sodium (8 g salt) at 36 months despite targeting a sodium intake of <1.8 g (4.5 g salt) in the intervention group. This indicated that the target of <2.3 g (5.8 g salt) has not been achieved even in this controlled setting of a clinical trial in which substantial efforts were made to lower sodium intake. In the control group, the mean daily intake of sodium was 3.9 g (9.8 g salt) at 18 months, and 4.0 g (10 g salt) at 36 months. The mean difference in systolic blood pressure between sodium intake groups was 2.9 mmHg at 6 months, 2.0 mmHg at 18 months, and 1.2 mmHg at 36 months. In the intervention group, the reduction in prevalence of hypertension also diminished over time. The primary outcome measure in TOHP-II, mean change in diastolic blood pressure, was no different between sodium reduction and control groups at 36 months.

The TONE trial (Whelton et al., 1998) was another counseling/educational intervention. It included 975 elderly individuals, age 60–80, whose hypertension was controlled by a single antihypertensive drug. More than half of the participants were obese. The authors evaluated both sodium reduction and weight loss in  $2 \times 2$  factorial trial design, with the inclusion of control subjects. In the non-obese group, the effect of sodium reduction was compared to corresponding controls. After 90 days, systolic blood pressure was significantly reduced by 3.4 mmHg in the intervention group. Antihypertensive therapy withdrawal began after 90 days of the intervention. Thirty months later, more patients in the sodium intervention group were off antihypertensive therapy or had a systolic blood pressure <150 mmHg and a diastolic blood pressure <90 mmHg. Specifically, average systolic and diastolic BPs were 131 and 74 mmHg, respectively, for the 127 remaining participants assigned to sodium reduction, as compared to 134 and 75 mmHg for the 83 remaining participants assigned to usual care. Thus here again, achieved differences were rather modest. There was no evidence of a difference in cardiovascular disease.

That compliance is a major issue has been demonstrated in a controlled intervention trial conducted in two towns of Belgium. The trial was aimed at exploring the feasibility of reducing salt intake in the general population by means of simple and inexpensive intervention techniques (Staessen et al., 1988). A total of 2211 people accepted to participate at the study, which lasted 5 years. The inhabitants of the intervention town underwent multiple types of instruction how to reduce salt intake, whereas those of the control town remained on their usual unrestricted salt consumption. The intervention led to a reduction of urinary sodium excretion by 17 mmol/24 h (1.0 g salt/24 h) in adult women in the intervention town, which differed significantly from the concurrent trend of an increase by 8 mmol/24 h (0.5 g salt/24 h) in women of the control town. However, both systolic (-7.5 compared with -7.9 mmHg) and diastolic (-2.3 compared with -3.0 mmHg) blood pressures declined to the same extent in women of the two towns. A decrease in urinary sodium excretion of 12 mmol/24 h (0.7 g/24 h salt), and in systolic and diastolic blood pressures of 5.6 mmHg and 2.4 mmHg respectively was observed in adult men of the intervention town. However, these trends were the same in the control town, with a decrease in urinary sodium excretion of 12 mmol/24 h (0.7 g/24 h salt) and in blood pressure values 4.9 mmHg and 0.2 mmHg, respectively. The authors concluded that salt intake in the long-run cannot be restricted to less than 5 g/24 h. While a more moderate salt restriction might constitute a more realistic goal its influence on blood pressure in the community at large would probably be trivial.

Post-hoc analyses allow a more systematic examination of intervention trials although the quality of many among them is frequently questionable. In one post-hoc analysis of the 1990s (Law et al., 1991), salt reduction was efficacious in studies lasting 5 weeks or longer (33 of 78 trials analyzed) but not in those lasting less than 5 weeks (45 of 78 trials analyzed). However, in another analysis where the author took care to include only those studies that had an appropriate design, he reached the opposite conclusion (Swales, 1991). There was no effect of salt reduction in studies which lasted more than 4 weeks, a conclusion reinforced by three subsequent meta-analyses (Graudal et al., 1998; Hooper et al., 2002; Midgley et al., 1996). However, meta-analyses by other groups reached opposite conclusions (Dickinson et al., 2006; He and MacGregor, 2006; Strazzullo et al., 2009). Therefore one should exercise extreme caution when relying on observational data alone, given the complexity of the interaction with numerous other endogenous and exogenous confounding variables.

The results of the prospective randomized DASH-2 trial reported in 2001 were considered by its authors to solve this issue definitively (Sacks et al., 2001). The authors allocated 412 adult volunteers from USA to six different treatment groups. The subjects ingested for a 1-month period either a typical, high caloric US diet or a diet enriched in vegetables, fruits and low-fat dairy products ("DASH diet"). In addition, they were allocated to a salt intake of either 9 g, 6 g or 3 g per day. The most marked decrease in blood pressure was obtained with the DASH diet together with usual sodium intake. The additional blood pressure reduction induced by concomitant salt restriction was much smaller (Fig. 5). Specifically, the decrease of systolic blood pressure achieved with the DASH diet, as compared to that on standard US diet, was 5.9 mmHg. The decrease observed in response to a reduction of salt intake from 9 g to 6 g per day was only 1.3 mmHg, and the decrease in response to a reduction of salt intake down to 3 g per day was 1.7 mmHg, knowing that the latter drastic restriction is unacceptable for most people in the long run. It is also noteworthy that the DASH study has been performed in a selected cohort of US individuals with high salt sensitivity, i.e. a percentage of black and overweight subjects strikingly higher than in the population at large. Extrapolations from these findings to general population and to people outside the US may therefore not be justified. Finally, the primary criterion of evaluation was blood pressure, i.e. an intermediary

**Fig. 5** Sodium reduction, the DASH diet, and changes in systolic blood pressure. Beneficial effects of the DASH diet and reduced intake of sodium on systolic and diastolic blood pressure in 412 patients with mild hypertension, age >45 years. The participants were randomly assigned to follow a DASH diet or a typical U.S. diet for 30 days. During that period, each group consumed, in a crossover design, three versions of the diet adjusted for daily sodium content: high, 8.8 g NaCl/day; intermediate, 5.8 NaCl/day; low, 3.0 NaCl/day. Body weight was held constant. The two downward-sloping arrows on the left depict the effect of intermediate sodium intake as compared with higher sodium intake, and the two downward-sloping arrows on the right depict the effect of lower sodium intake as compared with intermediate sodium intake. The dotted lines show the effect of the DASH diet as compared with the typical U.S. diet at each level of dietary sodium. Numbers shown represent the mean changes with 95% confidence intervals. From [Sacks et al. \(2001\)](#) (reproduced with permission).

endpoint, not a hard endpoint such as cardiovascular morbidity or mortality. DASH-2 compared a diet rich in fruits and vegetables, and consequently rich in potassium, to the usual US diet less rich in these nutrients. The observation of a more marked blood pressure decrease with the diet rich in fruits and vegetables as compared to the two reduction steps in salt intake is in line with the view that potassium may be a more important dietary factor than sodium in controlling blood pressure. In fact numerous prospective trials have shown that a high potassium intake is protective against hypertension, whereas a low intake favors its development or aggravates already existing hypertension, as summarized in a recent meta-analysis by [Filippini et al. \(2020\)](#).

Nutrients such as calcium and magnesium also contribute to the regulation of blood pressure ([Cheteu Wabo et al., 2022](#)). Sufficient to high intakes of these nutrients are possibly protective against high blood pressure but here again, literature reports are highly controversial. The role of diet in blood pressure regulation involves a number of interrelated nutrients and, as food intake varies widely, the arbitrary modification of one or the other among them may be beneficial or detrimental, especially when considering hard outcomes

such as cardiovascular events and mortality (see below). Several other exogenous factors play a role as well, either via an interaction of salt in controlling blood pressure or independently (see above). As an example, regular physical activity is protective whereas stress, obesity, and excessive alcohol consumption and many others favor arterial hypertension ([Muntzel and Drüeke, 1992](#)).

### Salt intake and cardiovascular outcomes

In the last decade, attention has shifted from the relationship between salt intake and hypertension to that between salt intake and hard clinical outcomes, i.e. cardiovascular events, cardiovascular mortality and global mortality. Although randomized controlled trials with morbidity and mortality endpoints are the gold standard they are highly impractical to address this issue. Only few such trials have been conducted in studies with small sample size, relatively short duration, and most importantly poor protocol adherence. Before discussing these trials we shall present the major observational studies in this field. Some among them are presented individually, all the others are summarized in meta-analyses.

In 2010, Alderman examined the association of sodium consumption with clinical outcomes in 13 observational cohort studies, including more than 100,000 participants and more than 800 morbidity and mortality events ([Alderman, 2010](#)). The results were conflicting, as shown in [Table 3](#). In two studies whose participants ingested high amounts of sodium (Finland, mean value 4600 mg/day; Japan, mean value 5428 mg/day corresponding to 11.6 and 13.7 g salt per day), there was a positive association between salt intake and cardiovascular disease events ([Nagata et al., 2004](#); [Tuomilehto et al., 2001](#)). In the eleven other studies with lower mean sodium intakes comprised between 2070 and 3680 mg/day (corresponding to salt intakes between 5.2 and 9.3 g salt per day), two also detected a positive association between salt and cardiovascular disease events, but each of them was a post hoc subgroup analysis with findings not entirely consistent with the overall study results ([Hooper et al., 2002](#)). In five among the studies, there was no association between salt intake and clinical outcome. Remarkably, in the four remaining studies sodium intake was inversely associated with cardiovascular disease events. A J-shaped curve, in which the most favorable dietary sodium range would be around 3450 mg/day (8.5 g salt/day)—with possible cardiovascular risk above and below this level—might best explain these apparently contradictory observations ([Alderman, 2007](#)).

In another meta-analysis including several of the observational studies examined by Alderman, but without stratification taking into account differences in daily sodium intakes, Strazzullo et al. detected a positive association of sodium intake with stroke, a finding driven by studies in people with high salt intake ([Strazzullo et al., 2009](#)). However, the authors failed to observe an association between sodium consumption and cardiovascular events. Total mortality was not reported. Not surprisingly, given different populations, different diets and sodium intakes, different methods and conflicting results, more than one explanatory hypothesis has emerged.

Bibbins-Domingo et al. performed yet another meta-analysis at that time, based on the above mentioned and other observational data ([Bibbins-Domingo et al., 2010](#)). Using a computer-simulation model to estimate the effects of low sodium intake they postulated that a reduction of daily dietary salt intake by 3 g might reduce the annual number of new cases of chronic heart disease by 60,000–120,000, stroke by 32,000–66,000, and myocardial infarction by 54,000–99,000, and allow the annual number of deaths from any cause to fall by 44,000–92,000. However, these estimates rely on several unverified assumptions, in particular the assumption that reducing salt intake lowers blood pressure and hence the risk of stroke and chronic heart disease ([Appel and Anderson, 2010](#)).

More recent observational studies found either a negative, a U-shaped, or a J-shaped association between salt consumption and mortality, both in general population and in patients with diabetes or heart failure. We discuss several among them here.

Stolarz-Skrzypek et al. found a negative association (Stolarz-Skrzypek et al., 2011). They examined 3681 participants from two European studies on the effects of genes vs. environment on hypertension. None of the participants had cardiovascular disease, 2096 were normotensive at baseline, and 1499 had blood pressure and urinary sodium excretion measured at baseline and after a median follow-up of 7.9 years. Cardiovascular disease deaths decreased across increasing tertiles of 24 h sodium excretion, from 50 deaths in the low, 24 in the medium, and 10 in the high sodium excretion group, resulting in respective death rates of 4.1%, 1.9%, and 0.8%. Baseline sodium excretion predicted neither total mortality nor fatal combined with nonfatal cardiovascular events. Remarkably, the risk of hypertension did not increase across increasing urine sodium tertiles. However, in multivariable-adjusted analyses, a 100-mmol increase in sodium excretion was associated with a significant, albeit only 1.71 mmHg increase in systolic blood pressure. Thus although systolic blood pressure changes over time associated with urinary sodium changes, this did not translate into a higher risk of hypertension or cardiovascular complications. Most importantly, lower sodium excretion was associated with higher cardiovascular mortality.

O'Donnell et al. observed a J-shaped association in a first observational study (O'Donnell et al., 2011). In this post hoc analysis of 28,880 patients with cardiovascular disease or diabetes, who had been enrolled in two different drug trials, they found that both high and low sodium intakes, based on spot urine sodium samples, were correlated with an increase in cardiovascular events, corresponding to a J-shaped curve. As compared to participants with a baseline daily sodium excretion of 4–6 g (10–15 g salt), those participants who excreted more than 6 g sodium (15 g salt) and those who excreted less than 4 g sodium (10 g salt) exhibited an increase in cardiovascular deaths, strokes, or heart attacks.

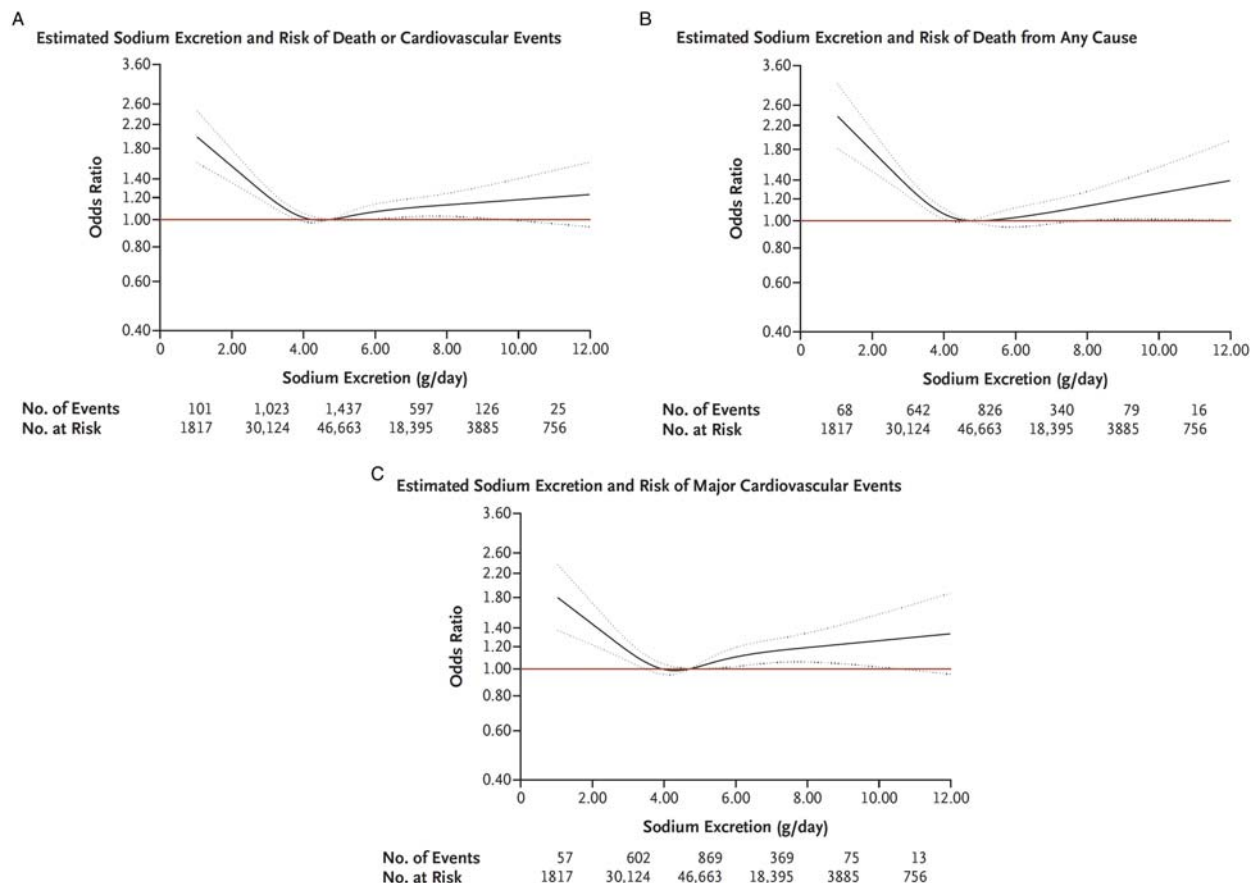

The same group of authors from McMaster in Canada subsequently devoted three other observational studies of very large sample size on this issue. In the first, O'Donnell et al. examined the association between urinary sodium and potassium excretion and the composite outcome of death and major cardiovascular events in 101,945 persons from 17 countries (O'Donnell et al., 2014). Daily sodium and potassium excretion was estimated based on morning fasting urine samples. Mean follow-up was 3.7 years. Compared with an excretion of 4.00–5.99 g sodium (10–15 g salt) per day (reference range), a higher excretion ( $\geq 7.00$  g sodium or 17.5 g salt per day) was associated with an increased risk of the composite outcome, as well as increased risks of death and major cardiovascular events (Fig. 6). The association between a high sodium excretion and the composite outcome was strongest among participants with hypertension, with an increased risk at an excretion of 6.00 g sodium (15 g salt) or more per day. As compared with the reference range, an excretion that was below 3.00 g sodium (7.5 g salt) per day was also associated with an increased risk of the composite outcome. As compared with a potassium excretion that was less than 1.50 g per day, higher potassium excretion was associated with a reduced risk of the composite outcome.

In the second study of the McMaster group, Mente et al. aimed to explore whether the association between sodium intake and cardiovascular disease events and all-cause mortality was modified by hypertension status (Mente et al., 2018). In a pooled analysis, they included 133,118 individuals (63,559 with and 69,559 without hypertension), median age 55 years, from 49 countries in four large prospective studies and estimated daily urinary sodium excretion based on spot urine sampling. Median follow-up was 4.2 years. They found that increased sodium intake was associated with greater increases in systolic blood pressure in hypertensive than in normotensive people, with a 1.22 mmHg change per g sodium (2.5 g salt). In the hypertensive patients a daily excretion of 7 g sodium (17.5 g salt) or more and less than 3 g sodium (7.5 g salt) were both associated with increased risk compared with a daily excretion of 4–5 g sodium (10–12.5 g salt). In the normotensive individuals, higher sodium excretion was not associated with risk of the primary composite outcome when compared with 4–5 g sodium (10–12.5 g salt) excretion, whereas an excretion of less than 3 g sodium (7.5 g salt) was associated with increased risk. These findings are again in keeping with the view of a U-shaped relationship between salt consumption and hard clinical outcomes.

In the third study from the McMaster group, O'Donnell et al. evaluated the joint association of sodium and potassium urinary excretion with cardiovascular events and mortality, in the context of current World Health Organization recommendations for daily intake ( $<2.0$  g sodium,  $>3.5$  g potassium). They used data from an international prospective cohort study of 103,570 adult individuals people who provided morning fasting urine samples (O'Donnell et al., 2019). Mean daily estimated sodium and potassium urinary excretion were 4.93 g and 2.12 g, respectively. After a median follow-up of 8.2 years, 7884 (6.1%) participants had died or experienced a major cardiovascular event. Increasing urinary sodium excretion was positively associated with increasing potassium excretion, and only 0.002% had a concomitant daily urinary excretion of  $<2.0$  g sodium ( $<5$  g salt) and  $>3.5$  g potassium. The authors observed a J-shaped association of sodium excretion and inverse association of potassium excretion with death and cardiovascular events. For joint sodium and potassium excretion categories, the lowest risk of death and cardiovascular events occurred in the group with moderate sodium excretion and higher potassium excretion (21.9% of cohort). Compared with this reference group, the combinations of low potassium with low sodium excretion and low potassium with high sodium excretion were associated with the highest risk, followed by low sodium excretion and high sodium excretion among those with potassium excretion greater than the median. Higher potassium excretion attenuated the increased cardiovascular risk associated with high sodium excretion. The authors stated that the simultaneous target of low sodium intake ( $<2$  g/day) with high potassium intake ( $>3.5$  g/day) is extremely uncommon. They concluded that combined moderate sodium intake (3–5 g/day) with high potassium intake is associated with the lowest risk of mortality and cardiovascular events.

More recently, Messerli et al. again examined the hypothesis that dietary sodium intake is a risk factor for cardiovascular disease and premature death (Messerli et al., 2021). Their analysis was done in 181 countries worldwide, using several sources of data. Sodium intake was estimated according to a previous study of global, regional and national sodium intakes based on either urinary

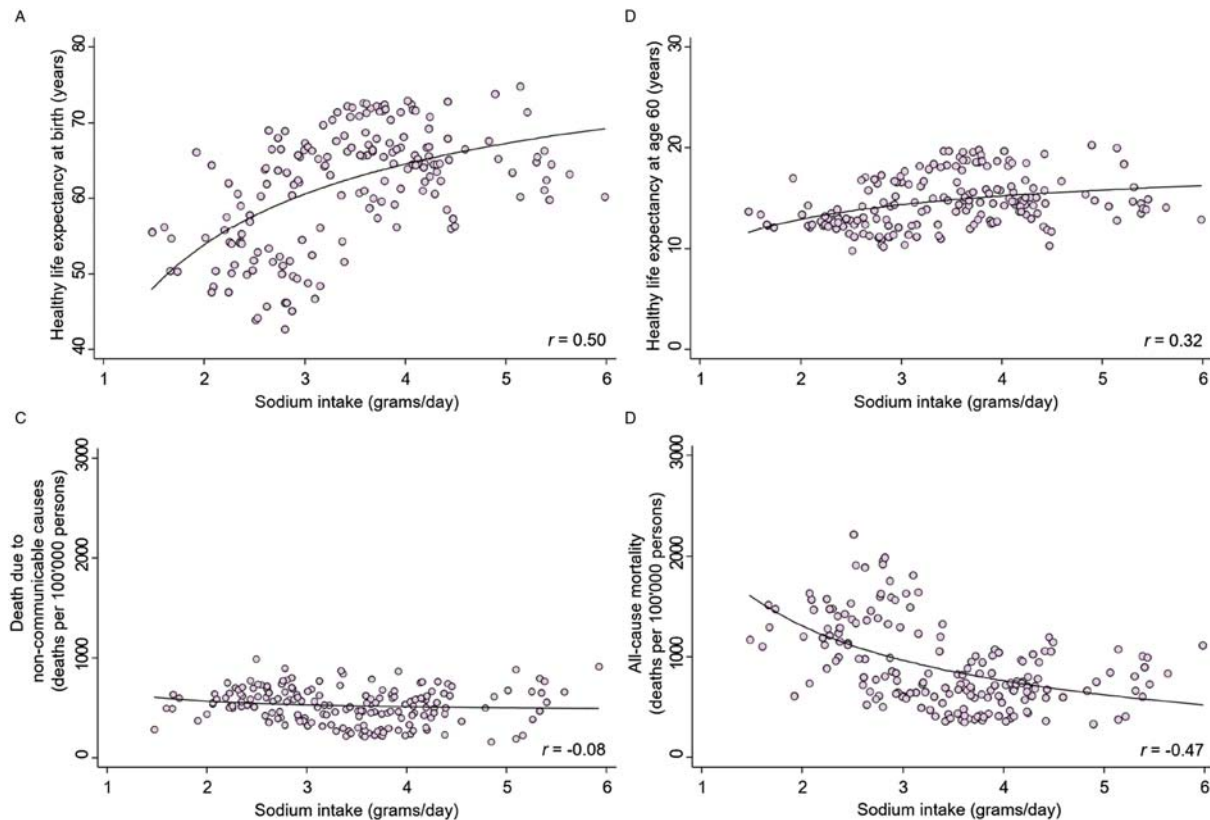

**Fig. 6** Association of estimated 24 h urinary sodium excretion with risk of death and major cardiovascular events. Panel A shows a restricted-cubic-spline plot of the association between estimated 24 h urinary sodium excretion and the composite outcome of death from any cause and major cardiovascular events. The spline curve is truncated at 12.00 g per day (event rate among participants with sodium excretion >12.00 g per day, 8 events in 305 participants). Panel B shows a restricted cubic-spline plot of the association between estimated sodium excretion and death. The event rate among participants with sodium excretion of more than 12.00 g per day was 5 events in 305 participants. Panel C shows a restricted-cubic-spline plot of the association between estimated sodium excretion and major cardiovascular events (defined as death from cardiovascular causes, myocardial infarction, stroke, or heart failure). The event rate among participants with sodium excretion of more than 12.00 g per day was 6 events in 305 participants. All plots were adjusted for age, sex, geographic region, educational level, ancestry (Asian vs. non-Asian), alcohol intake, body-mass index, and status with respect to diabetes mellitus, history of cardiovascular events, and current smoking. Dashed lines indicate 95% confidence intervals. The median sodium excretion (4.72 g per day) was the reference standard, indicated by the red line. To convert the values for estimated sodium excretion to salt intake in grams per day, multiply by 2.5. From O'Donnell et al. (2014) (reproduced with permission).

sodium or dietary sodium recall data (Powles et al., 2013). The authors correlated age-standardized estimates of country-specific average sodium consumption with healthy life expectancy at birth and at age of 60 years, death due to non-communicable diseases, and all-cause mortality for the year of 2010, after appropriate adjustments. They found a positive correlation between sodium intake and healthy life expectancy at birth, as well as healthy life expectancy at age 60 but not for death due to non-communicable diseases. Conversely, all-cause mortality correlated inversely with sodium intake (Fig. 7). In a sensitivity analysis restricted to 46 countries in the highest income class, sodium intake continued to correlate positively with healthy life expectancy at birth and inversely with all-cause mortality. They concluded that the observation of sodium intake correlating positively with life expectancy and inversely with all-cause mortality worldwide, and also in high-income countries alone, argued against dietary sodium intake being a culprit of curtailing life span or a risk factor for premature death.

Two other studies of more modest sample size examined this issue in persons with type 1 and type 2 diabetes, respectively. Ekinici et al. measured 24 hr urinary sodium excretion at a single visit in 638 patients with type 2 diabetes who were subsequently followed for 10 years (Ekinici et al., 2011). Mean baseline urinary sodium excretion was 184 mmol (10.7 g salt) per day. At end of follow-up, they recorded 175 deaths with 43% among them having a cardiovascular cause. All-cause mortality was lower by 28% for every 24 hr sodium excretion higher by 100 mmol. Cardiovascular mortality also inversely associated with sodium excretion. This led to them to hypothesize that low salt intake might cause adverse effects. However, as pointed out by Lambers Heerspink et al. (2012), patient characteristics were not balanced since the low salt group had longer diabetes duration, lower body mass index, lower glomerular filtration rate, higher prevalence of macrovascular disease, and received less frequently renin-angiotensin-aldosterone blockade and insulin treatment.

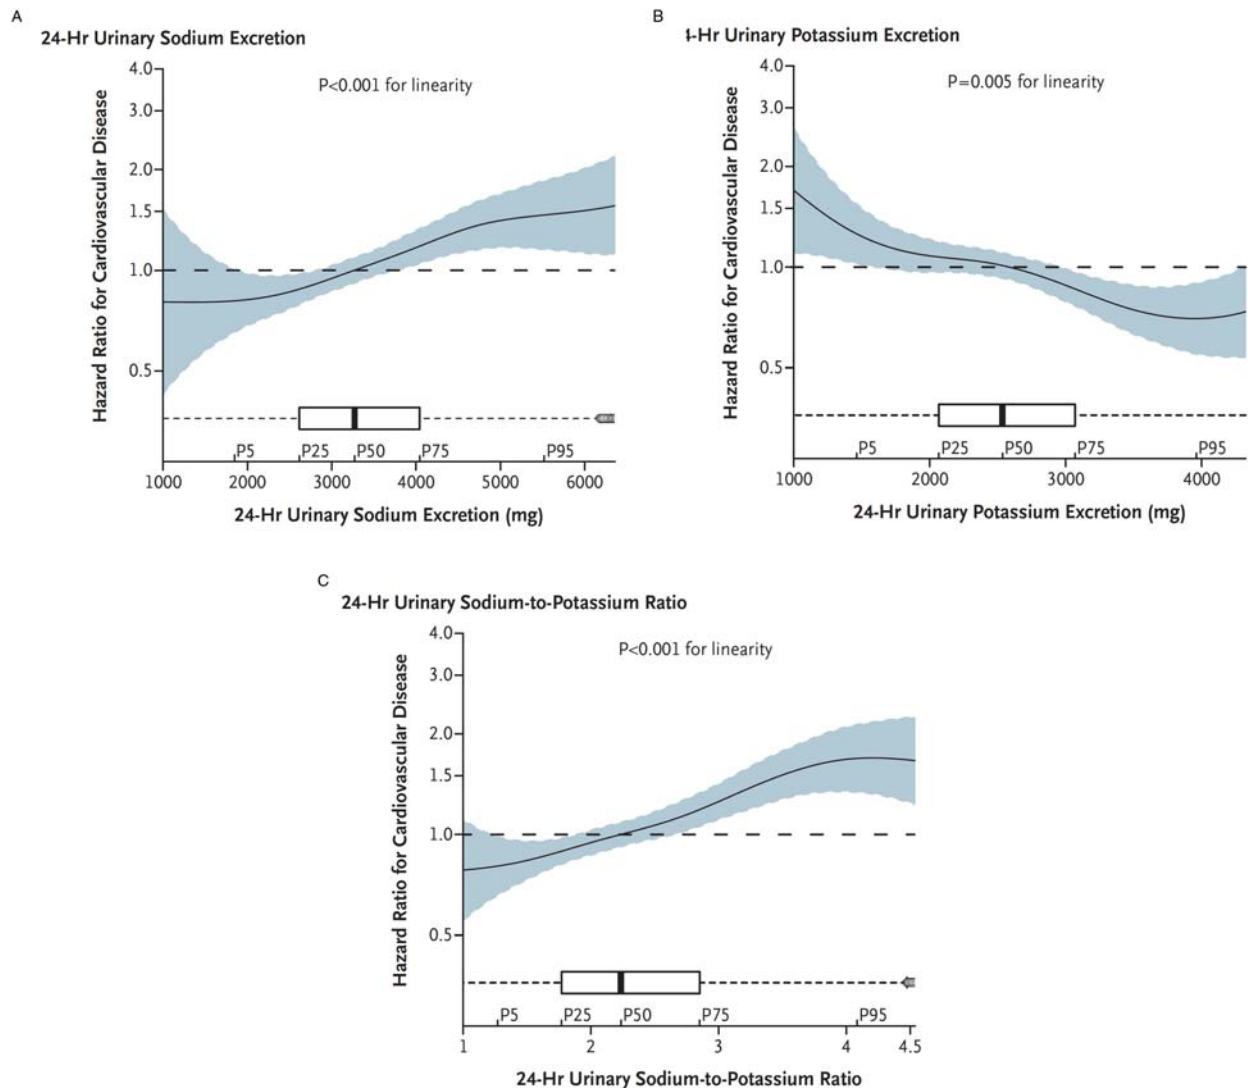

**Fig. 7** Scatterplots of sodium intake (g/day) for the year of 2010 and healthy life expectancy at birth, healthy life expectancy at age 60, age-standardized death rates of death due to non-communicable diseases and all-cause mortality in 181 countries worldwide (A–D, respectively). From Messerli et al. (2021) (reproduced with permission).

Thomas et al. examined the role of salt intake in outcomes of 2807 adult patients with type 1 diabetes who participated at the Finn Diane cohort and were followed for 10 years (Thomas et al., 2011). The authors found that urinary sodium excretion was non-linearly associated with all-cause mortality in that both low and high urinary sodium excretion was associated with higher mortality. The nadir of mortality was at a daily consumption of 100 mmol sodium (5.8 g salt). The association persisted after adjustment for confounders including age, gender, diabetes duration, glomerular filtration rate and albuminuria. Lambers Heerspink et al. criticized this study as well, stating that the low salt cohort included more females, patients with lower BMI, less anti-hypertensive medication and more macrovascular disease, all findings being consistent with a higher cardiovascular risk (Lambers Heerspink et al., 2012).

Taken together, these observations demonstrate that studies of possible associations between salt intake and hard clinical outcomes done normotensive people of the population at large should not be lumped together with studies done in patients with hypertension, diabetes or other diseases. They further show that changes of cardiovascular and global outcomes in response to changes in salt intake do not necessarily parallel changes in blood pressure. As already mentioned, a major criticism of the studies from the McMaster group is that spot urine analyses are less reliable than 24 h urine collections since the former tend to overestimate sodium excretion at lower levels and to underestimate sodium excretion at higher levels (Naser et al., 2021).

In the year 2022, two additional major studies on the relation between sodium intake and cardiovascular outcomes were reported.

First of all, Ma et al. reported the results of an observational study on the relation between sodium intake and cardiovascular disease. They combined individual data from 10,709 participants of six different cohorts (Ma et al., 2022). Mean age was 51.5 years, 54.2% were women, and the majority among them had normal blood pressure at baseline. All participants had at least two 24 h urine samples. The authors ascertained 571 cardiovascular events during a median study follow-up of 8.8 years. Median 24 h urinary sodium excretion was 3270 mg (8.2 g salt). Higher sodium excretion, lower potassium excretion, and a higher sodium-to-potassium ratio were all associated with a higher cardiovascular risk in analyses that were controlled for confounding factors (Fig. 8). In analyses that compared quartile 4 of the urinary biomarker (highest) with quartile 1 (lowest), the hazard ratios were 1.60, 1.19 to 2.14 for sodium excretion, 0.69 for potassium excretion, and 1.62 for the sodium-to-potassium ratio. Each daily increment of 1000 mg sodium excretion (2.5 g salt excretion) was associated with an 18% increase in cardiovascular risk, and each daily increment of 1000 mg potassium excretion was associated with an 18% decrease in risk. Thus higher sodium and lower potassium

**Fig. 8** Spline plots for the associations of 24 hour urinary sodium and potassium excretion and sodium to- potassium ratio with cardiovascular risk. The spline analysis of pooled data supported a linear association over the range of sodium excretion (Panel A; 5th to 95th percentile, 1846–5520 mg) and potassium excretion (Panel B; 5th to 95th percentile, 1462–3961 mg) within the overall study population. The sodium-to-potassium ratio (Panel C) was assessed on the basis of the sodium and potassium excretion measured in millimoles. Hazard ratios were estimated from Cox models stratified according to study cohort with adjustment for age, sex, race, educational level, height, body-mass index, alcohol consumption, smoking status, physical activity, history of diabetes and elevated cholesterol status, family history of cardiovascular disease, and mutual adjustment for 24 h urinary potassium and sodium excretions. Shaded areas indicate 95% confidence intervals, and the dashed line at 1.0 indicates the reference. Box plots at the bottom of the graphs show the distributions of the urinary biomarker. The vertical bar indicates the median, and the ends of the box the interquartile range; the whiskers (dashed lines) extend to values no farther than 1.5 times the interquartile range (which may be past the graphed area), and dots indicate values that are farther than 1.5 times the interquartile range. The 5th, 25th, 50th, 75th, and 95th percentiles (P5, P25, P50, P75, and P95, respectively) are shown at the bottom of each graph. From [Ma et al. \(2022\)](#) (reproduced with permission).

intakes, as measured in multiple 24 h urine samples, were associated in a dose–response manner with a higher cardiovascular risk. The authors concluded that their findings supported reducing sodium intake and increasing potassium intake from current levels. However, although the urinary sodium measurement method appeared to be optimal in the combined cohort studies examined by [Ma et al. \(2022\)](#), the post-hoc character of the analysis had major limitations including the inclusion of very heterogeneous study cohorts and an observation time period spanning 2 decades. Most importantly, the mean value of the lowest quartile of urinary sodium excretion was 2212 mg (5.5 g salt). This means that half of the participants in the lowest quartile had a daily sodium intake above the one recommended by WHO (<2300 mg sodium or 5.8 g salt). Thus the study by Ma et al. fails to inform the impact of the presently recommended very low salt intake on cardiovascular events and mortality. This means that the left side of a potential U-curve relationship has not been adequately assessed. It is noteworthy that the report by Ma et al. does not provide any information on the relation between sodium intake and blood pressure.

Second, Ezekowitz et al. reported the results of an open-label, randomized, controlled clinical trial to test the effects of dietary sodium reduction for patients with heart failure on the incidence of future clinical events (Ezekowitz et al., 2022). They randomly assigned 397 patients to a low sodium diet (<100 mmol/day [ $<3.8$  g salt/day]) and 409 patients to usual care. Adherence to the diet was not based on urinary sodium measurements, but only estimated by 3-day food records. The authors found that dietary sodium restriction did not reduce the clinical composite outcome of all-cause mortality, cardiovascular-related hospitalization, or cardiovascular-related emergency department visits compared with usual care over 12 months. An improvement in the patient reported outcome of quality of life and clinician assessed New York Heart Association functional class was noted; however, no significant between-group difference was seen in 6 min walk distance. It must be noted that the study was prematurely stopped due to futility, and therefore only 806 (81%) of the estimated 992 patients needed were included in the trial. The authors concluded that in ambulatory patients with heart failure, a dietary intervention to reduce sodium intake did not reduce clinical events.

## Conclusions

In agreement with O'Donnell et al. (2020) we would like to conclude that the aim of the WHO recommendation to reduce daily sodium (salt) intake to amounts below 2.3 g (5.8 g) in the long run seems unrealistic based on the results of numerous intervention trials conducted at the individual, community, or national level. More modest reductions of salt intake do not allow achieving clinically meaningful reductions of blood pressure, as compared to the efficacy of antihypertensive agents. Although a number of observational data suggest an association of salt intake with blood pressure, cardiovascular risk, and/or mortality risk convincing evidence for this claim is lacking to date. Moderate salt intake in association with higher potassium intake is probably achievable by many people. However, the association with low cardiovascular risk as suggested by some observational studies is at best hypothesis generating. Whether this translates to real life conditions in general population has to be shown in definitive intervention trials. It does not seem that a low sodium diet is able to reduce clinical events in patients with chronic heart failure. For the time being the advice to focus on the established classical risk factors and risk markers seems to be more promising.

## Key points

- The worldwide ingestion of added sugar/sucrose is still very high
- Sucrose is an important source of calories and promotes weight gain
- Energy independent negative effects of sucrose on metabolism are likely to exist
- Added sugars are suspected to dilute the intake of other nutrients
- The oral and intestinal microbiome interacts with added sugar
- Sugar/sucrose consumption by the ingestion of fruits is not harmful
- A reduction of the intake of added sugar is recommended

## Introduction

While the diet of our ancestors was not completely free of sugar, the amount of simple carbohydrates ingested was low, refined sugar was not available and only few natural sources provided the disaccharide sucrose as such (e.g., fruits), and even fewer sources contained some “free” sucrose as defined by the WHO (e.g., honey). In contrast, modern western diets provide a large amount of the

daily energy intake in the form of sugar, mostly sucrose. In Europe, where sucrose is by far the most important form of added sugar, recent summaries of analyses from different countries report a daily total sugar intake of 76–117 g/day, resulting in up to 20% of calories which are consumed as sugar (Azaïs-Braesco et al., 2017). The amount of added sugar is reported to figure between 42 and 76 g per day, with up to 12% of the daily energy intake provided by added sugar. 60–80% of the total amount of added sugar that is ingested is provided by sweet products and sugar-sweetened beverages.

Sucrose is a disaccharide, consisting of one molecule of glucose and one molecule of fructose that are linked via an ether bond. When ingested, sucrose is hydrolyzed by the enzyme sucrose, an intestinal  $\alpha$ -glucosidase, to its component monosaccharides, which then are absorbed. While glucose and fructose contain the same caloric content, they enter different metabolic pathways and exert different effects regarding human health and disease.

In this article, different aspects of the impact of sucrose or its components on human disease are highlighted. First, sucrose provides a significant amount of calories, and thus, its effect as a caloric sweetener on metabolism is discussed. However, there are also calorie-independent effects that are proposed, which are highlighted in a second part. Third, it is of importance to understand how sucrose may influence the ingestion of other nutrients and is thus indirectly targeting health. In a fourth article, recent advances in the understanding of the interaction of dietary sucrose with the microbiome are highlighted. Finally, the impact of the ingestion of naturally occurring sucrose, in contrast to sucrose in the form of added sugar, is briefly discussed, with the latter being the main source of human sucrose intake nowadays.

## Sucrose as a caloric sweetener

### Sucrose and other added sugars

Sucrose, mostly derived from sugarcane and sugar beets, has been the main added sugar for centuries. During the past 50 years, the use of high-fructose corn syrup (HFCS) as caloric sweetener became popular as an alternative to the industrial use of sucrose as added sugar. HFCS is produced from cornstarch, which is enzymatically cleaved into glucose molecules and further processed by D-xylose isomerase in order to convert some of the glucose to fructose. The use of HFCS became popular because it is easier to handle and cheaper than sucrose.

Thus, like sucrose, high-fructose corn syrup consists of glucose and fructose, but the two monosaccharides are present in their “free” form. HFCS is mainly used as “HFCS 42” (containing 42% fructose) or “HFCS 55” (containing 55% fructose). Therefore, the ratio of fructose and glucose in sucrose and HFCS is comparable. The use of HFCS was suspected to have specific adverse effects, e.g., its consumption was linked to the development of obesity (Bray et al., 2004), and thus, the question about differences between this sweetener and sucrose became important. However, so far it was mostly concluded that there is no evidence for different effects of sucrose ingestion as compared to the ingestion of the corresponding monosaccharides glucose and fructose, as long as their ratio (50% each) is not dramatically altered (Melanson et al., 2007; Tappy and Lê, 2010).

### Sugar-sweetened beverages

The consumption of sugar in the form of sugar-sweetened beverages (SSBs), providing a high amount of calories in liquid form, is suspected to have particular deleterious effects on health. Although the qualitative and quantitative sugar composition of SSBs varies (e.g., use of sucrose or HFCS, which may differ by region), the association of their consumption with weight gain and obesity was almost univocally reported by many observational studies from different places, independently of their country of origin and the time they were conducted. Such studies include cross-sectional studies that show an association of SSB consumption with higher body weight/BMI, but also prospective cohort studies demonstrating larger weight gain and obesity in adults as well as in children being associated with a higher intake of SSBs (Malik et al., 2006).

Furthermore, interventional trials were conducted in individuals of different age in order to explore a possible direct causal relationship of the intake of sugar-sweetened beverages with weight gain. In such a trial, overweight adult subjects were provided either sucrose sweetened beverages (80% of supplement) and food (20% of supplement) for 10 weeks, or similar amounts containing artificial sweeteners. As a result, body weight increased in the sucrose group and decreased in the sweetener group during the intervention (Sørensen et al., 2014). Another intervention was conducted in children for a total duration of 18 months. More than 600 children were randomly assigned to receive 250 mL of a beverage which was either artificially sweetened (with sucralose and acesulfame; sugar-free group) or a similar beverage containing 26 g of sucrose (104 kcal per day) (de Ruyter et al., 2012). As a result, in the sugar group statistically significant more weight gain as well as an increase in skinfold-thickness, waist-to-height ratio and fat mass was observed.

### Sucrose intake and reduced satiety

The above-mentioned observed effects of caloric sweeteners as sucrose on weight gain/obesity led to the hypothesis that they are not able to induce effects of satiety that are sufficient to maintain total caloric intake at a constant level. This hypothesis was consecutively tested in interventional trials comparing the effects of different sugars (with the same content of calories) on satiety. In a recent

study with healthy young adults, different hormones that affect appetite and energy homeostasis were measured after ingestion of 75 g of either sucrose or glucose (Yunker et al., 2021), including the hormones glucagon-like peptide (GLP-1), peptide YY (PYY), and ghrelin. In addition to lower plasma insulin levels, also responses in GLP-1 and PYY (both providing satiety feelings) were significantly lower after sucrose ingestion as compared to glucose, providing evidence for a reduced effect of sucrose on satiety as compared to other sugars.

The reason for this effect of a reduced satiety induction was suggested to be based on the composition of sucrose, containing 50% fructose and 50% glucose. Many trials have shown that fructose has a satiating effect which is clearly inferior as compared to glucose. When MRI was performed in healthy adults who ingested either glucose or fructose, different changes in cerebral blood flow were observed in brain regions involved with appetite and reward pathways (Page et al., 2013). Similarly, in another interventional trial, it was shown that ingestion of fructose compared with glucose resulted in greater brain responses to food cues in the visual cortex and left orbital frontal cortex, and led to greater hunger and desire for food—and even greater willingness to give up long-term monetary rewards to obtain immediate high-calorie foods (Luo et al., 2015).

Thus, the reduced induction of satiety after sucrose consumption—as compared to pure glucose—is very likely to be a result of the composition of sucrose, containing 50% fructose, which may be the driver for a higher promotion of feeding behavior.

## Conclusion

Sucrose, together with high-fructose corn syrup, is one of the most important added sugars and a source of a high amount of calories, contributing to weight gain and obesity. A reduced induction of satiety feelings may be one of the factors contributing to this effect.

## Metabolic effects of sucrose

### Metabolism of sucrose

As stated above, sucrose is hydrolyzed in the intestine into equal amounts of glucose and fructose, which then are absorbed by the intestinal epithelial cells separately. Glucose, on one hand, is the preferred substrate and energy source of most eukaryotic cells. Apart from its direct use for energy production, it can be stored in the form of glycogen, primarily in the cells of the liver and the skeletal muscle, or as lipids (mainly in the adipose tissue) after entering the pathways of lipogenesis (Wasserman, 2009). The uptake into these organs is mainly mediated by insulin. On the other hand, fructose cannot be directly metabolized in many cells. Thus, it is first metabolized in the liver by distinct pathways. Apart from the possibility of being converted to glycogen, it enhances fatty acid synthesis as a lipogenic substrate as well as being a potent inducer of lipogenic enzyme expression (Geidl-Flueck and Gerber, 2017).

Thus, one of the most important questions addressed by many studies during the past years was whether the ingestion of glucose or fructose (or its co-ingestion as sucrose or HFCS) is—due to these distinct metabolic pathways—resulting in specific, different effects on health and disease.

### Association of sucrose consumption with metabolic diseases

With all the evidence that an increase in sucrose intake leads to weight gain, increased fat mass and obesity, it was concluded that these unfavorable effects were inevitably linked to consecutive metabolic disturbances resulting from obesity, as non-alcoholic fatty liver disease, dyslipidemia, or type 2 diabetes—regardless of the possibility of additional direct metabolic effects that are confined to sucrose due to its specific properties.

Like for obesity itself, the association of type 2 diabetes with sugar consumption was explored by many observational studies which mainly tested the hypothesis of this relationship by assessing the consumption of sugar-sweetened beverages and the concomitant diabetes incidence in selected populations. In a meta-analysis of such studies, including more than 300,000 Individuals and more than 15,000 cases of type 2 diabetes, a clear increase of the risk to develop type 2 diabetes was identified in people consuming a high amount of sugar-sweetened beverages (Malik et al., 2010). In contrast, a later meta-analysis which analyzed data of a similar number of individuals, but assessed specific differences of different sugar types, was not able to detect an association of a higher incidence of type 2 diabetes with total sugar, fructose, or sucrose consumption (Tsilas et al., 2017). However, this analysis concluded that confidence in the estimates was limited by evidence of serious inconsistency between studies, and serious imprecision in the pooled estimates for the different sugar categories.

Similarly, the assessment of effects of sugar intake on the development of non-alcoholic liver disease, another severe metabolic disturbance associated with a Western Diet, provided some insights, but there are also remaining questions. Current evidence of observational studies was summarized as supporting the hypothesis that sugar intake, but in particular fructose intake, increases hepatic lipid accumulation (Jensen et al., 2018). However, other authors concluded that the apparent association between indexes of liver health and fructose or sucrose intake appears to be confounded by excessive energy intake, thus rendering available evidence insufficiently robust to draw conclusions regarding effects of fructose or sucrose consumption on non-alcoholic fatty liver disease (Chung et al., 2014).

Data regarding an association of further cardiovascular risk factors with sugar consumption are also derived mostly from studies that search for associations of these risk factors with sugar sweetened beverage consumption. A systematic review including different prospective cohort studies reported that all included studies examining vascular risk factors found direct associations between SSB consumption and change in blood pressure, blood lipids or blood sugar (Keller et al., 2015). Such prospective cohort studies are supported by large cross-sectional studies as the Health Professionals Follow-up Study (HPFS) (de Koning et al., 2012) and Nurses' Health Study (NHS) cohorts (Yu et al., 2018), where an association between SSB consumption and higher plasma triglycerides, but also inflammatory cytokines and other cardiometabolic risk factors was detected. Regarding hypertension, a systematic review and meta-analysis found, despite heterogeneity of the studies that were examined, a risk of developing hypertension associated with SSB consumption (Jayalath et al., 2015).

Finally, direct assessment of cardiovascular disease was also performed by many studies. A recent report of the California Teachers Study presented the prospective association of baseline SSB consumption with incident cardiovascular disease in more than 100,000 women. After adjusting for potential confounders, an increased risk for the development of cardiovascular disease, revascularization and stroke was found to be associated with the consumption of SSB (Pacheco et al., 2020). Finally, one of the latest reports of the above-mentioned HPFS and NHS prospective cohort studies examined total and cause-specific mortality in almost 120,000 men and women. Here, after adjusting for major diet and lifestyle factors, consumption of SSBs was associated with a higher risk for total mortality. The association was observed for cardiovascular and, to a somewhat lesser, but statistically significant extent, for cancer related mortality (Malik et al., 2019).

Regarding cardiovascular disease, it is debated whether the consumption of specific sugars promotes inflammation independently of overfeeding (where an increase in inflammatory markers is probably associated with an expansion of adipose tissue). Indeed, there are observational studies that confirmed an elevation of CRP in heavy SSB drinkers even after adjusting for BMI (Lin et al., 2020).

Taken together, most observational data on the association of sugar consumption and cardio-metabolic risk factors (up to total mortality) is derived from studies on the consumption of sugar sweetened beverages. As described, most of these observational studies adjusted this risk for confounding factors as weight gain, suggesting a calorie-independent effect. However, the question remained whether such diseases are not only the result of the increase in (caloric intake driven) adipose tissue expansion, and not of a specific calorie-independent effect of the sugars that were investigated. To differentiate such effects of sucrose on metabolism (as compared to other nutrients), interventional trials using iso-caloric diets were needed. Such studies were conducted during the past decades and discussed below.

### Direct effects of sucrose on glucose metabolism

Early studies conducted around 1980 used diets with large differences in sucrose content to explore the effects of sucrose consumption on metabolism in healthy subjects. In one of the first trials, a very high proportion (30% of total energy intake) of an isocaloric diet was either provided as sucrose or as wheat starch in order to assess the effect of these two different carbohydrates on glucose metabolism (Reiser et al., 1979). Indeed, fasting insulin and glucose levels were significantly elevated after 6 weeks of sucrose consumption compared to the consumption of starch, and the insulin response as well as the insulin to glucose ratio after a sucrose load were increased after sucrose consumption. As a confirmation of the isocaloric composition of these diets, there was no change in weight gain observed. Thus, a disturbance of glucose metabolism, mediated probably by a reduction in insulin sensitivity, was proposed, and confirmed in a second study applying isocaloric diets with different sucrose content (2–30% of total energy intake) in individuals who were already hyperinsulinemic at baseline. Again, an increase in fasting glucose as well as in glucose and insulin levels after a sucrose load was observed after a 6 week diet with high sucrose content compared to starch consumption (Reiser et al., 1981).

However, these early observations were challenged by later studies. In such a trial, somewhat smaller differences in sucrose consumption, which probably reflect better the usual span of sucrose intake in daily live, were investigated during a similar period of 6 weeks (Black et al., 2006). With an eucaloric diet over 6 weeks designed to result in weight maintenance but containing 10% or 25% of total daily energy intake as sucrose, no differences in glucose metabolism were observed in healthy subjects, despite a thorough investigation using euglycemic clamp technique as well as a continuous glucose monitoring system. Furthermore, a study conducted in mostly obese, already moderately insulin resistant subjects, could not detect any beneficial effect on insulin resistance with a lower sucrose intake of 5% (vs. 15%) of daily energy intake, despite a slightly lower fasting plasma glucose (Lewis et al., 2013). A study that compared different sugars regarding their effect on insulin sensitivity did see an effect of pure fructose feeding, but not of sucrose feeding (Aeberli et al., 2013). Thus, it might be hypothesized that fructose is the main driver of insulin resistance, and that the fructose content of sucrose is not sufficient to induce such insulin resistance—unless sucrose is provided in very high quantities.

In summary, these trials provided no clear evidence of biologically significant effects of sucrose consumption on glucose metabolism, at least when consumed in an eucaloric diet for some weeks, unless very high amounts of sucrose are ingested. Nevertheless, the question remained whether sucrose ingestion induces subtle metabolic changes that may have long-term negative effects on glucose metabolism that are not detectable after short-term ingestion.

### Direct effects of sucrose on serum lipids and inflammation

Similar as for glucose metabolism, first interventional studies examining lipid metabolism were already conducted around 1980 and provided evidence for unfavorable effects of sucrose on serum lipids. Here again, the consumption of sucrose was compared to the consumption of wheat starch (30% of daily energy intake). While serum fatty acids were not changed, there was an increase in triglycerides (by 33%) as well as total cholesterol (Reiser et al., 1979). Again, the feeding with such very large dosages was adapted in later studies, when more moderate amounts of calories were replaced by sucrose. In a recent trial conducted in individuals with a different genetic background regarding the presence of the apolipoprotein E2 allele (which is involved in the metabolism of triacylglycerol-rich lipoproteins), 40 g/day of sucrose was used in an isocaloric adaptation of the usual diet for 8 weeks. No changes in any of the conventional serum lipid parameters (total, HDL- and LDL-cholesterol as well as triglycerides) were observed (Erkkilä et al., 2007). Another interventional cross-over study came to the same conclusion, when sugar-sweetened beverages containing glucose, fructose or sucrose were used (80 g per day of each) (Aeberli et al., 2011). However, in this study, additional and more subtle changes in LDL-cholesterol particles were investigated. Of interest, it could be shown that the intervention with sucrose and fructose, but not with glucose, promoted the generation of small, dense LDL-particles which are known to be associated with a high cardiovascular risk (Gerber and Berneis, 2012), again pointing to a specific unfavorable effect of fructose (as part of sucrose) on lipid metabolism.

Regarding a general inflammatory response as an additional cardiovascular risk factor, the effect on CRP (as one of the most important indicators of inflammation) of different sugars was summarized in a systematic review and meta-analysis of intervention studies. Here, no difference between the effects of different sugars (e.g., fructose, sucrose, glucose and HFCS) was detected (Della Corte et al., 2018). One possible reason for this might be that some intervention studies were conducted over a very short time (e.g., 1 week (Kuzma et al., 2016)), which was probably insufficient to reveal significant differences in an outcome as chronic inflammation.

### Direct effects of sucrose on hepatic lipid metabolism

Due to the high prevalence of non-alcoholic fatty liver disease and the suspected association of sugar intake with this disease that was reported at least in some observational studies, interventional studies were conducted to investigate a possible causality of this association. A systematic review and meta-analysis identified more than 20 studies that reported data on the effects of the consumption of different sugars on prespecified indexes of liver health as liver fat or liver enzymes (Chung et al., 2014). One result of the study was, here again, that it is very difficult to differentiate effects of overfeeding from effects that are directly associated with the quality of the sugar ingested.

However, one trial assessed the effect of different test drinks containing either sucrose or semi-skim milk in isocaloric quantities, with an aspartame-sweetened drink and water. Of interest, the study was conducted for an extended period of 6 months. In the sucrose-sweetened beverage group, the fat content not only of the liver, but also of skeletal muscle and visceral fat was significantly increased (Maersk et al., 2012). An even closer look at sugar quality was provided by a recent study investigating the effects of isocaloric amounts of glucose, fructose and sucrose (80 g/day for each, ingested as sugar-sweetened beverages for 7 weeks) on hepatic de-novo lipogenesis using tracer-based methods (Geidl-Flueck et al., 2021). An increase in hepatic de-novo lipogenesis was observed after the consumption of fructose and sucrose, but not glucose.

### Conclusion

In conclusion, observational as well as interventional studies provided varying results regarding the effect of added sucrose consumption on different metabolic parameters. In interventional studies, adverse effects on metabolic health were seen mostly when either large dosages of sugars were used, or when subtle changes in metabolism were examined. Thus, it can be hypothesized that adverse effects of sugar consumption probably exist, but that they need a certain time until they become clinically relevant.

### Interaction of sucrose consumption with the intake of other nutrients

Considering the composition of food rich in added sugars as sucrose, there was increasing concern that a high intake of such food might compromise the intake of other macro- and micronutrients. Thus, many cross-sectional or prospective studies evaluated the association between the intake of sugar and diet quality as well as nutrient intake.

As for other questions regarding sucrose intake, most data available is derived from sugar-sweetened beverage intake, with sucrose being one of the most widely used sugar.

### Sucrose consumption and micronutrient intake

Most systematic reviews that were conducted around 10 years ago concluded that the evidence available at the time did not allow for firm conclusions regarding the hypothesis of a general micronutrient dilution mediated by the ingestion of nutrients rich in added sugar (Gibson, 2007; Livingstone and Rennie, 2009; Rennie and Livingstone, 2007). Data from a recent European report on the

association of sugar-sweetened beverage consumption and micronutrient intake derived from 3-day food records suggested a decrease of calcium, iron, and magnesium intake with increasing consumption of SSBs (Mullie et al., 2018). Another study presenting data from the Australian Health Survey reported a peak intake of 16 out of 19 micronutrients when 5–15% of energy was consumed as free sugar. For higher sugar intake, a decreasing trend was seen, including the intake of fiber, folate and magnesium (Mok et al., 2018). One of the latest studies, a cross-sectional analysis in two Swedish adult populations, reported again a significant inverse association between the intake of added sugar and the intake of nine micronutrients (calcium, folate, iron, magnesium, potassium, selenium, vitamin C, vitamin D and zinc) in both populations (González-Padilla et al., 2020).

Despite these data, caution regarding the hypothesis of micronutrient dilution by sugar intake in general is advised since the effect of different sugar containing nutrients on micronutrient ingestion might be much more complex, given the large differences in individual diet patterns.

### Sucrose consumption and macronutrient intake

In addition to adverse effects on micronutrient ingestion, it is also suggested that the ingestion of a high amount of calories in the form of sugar may adversely affect the intake of other important macronutrients as protein.

Indeed, such a reduction was observed in the past—cross-sectional studies reported a reduction of all macronutrients other than carbohydrates (e.g., fat, protein, fiber) being associated with added sugar intake (González-Padilla et al., 2020). Of importance, the reduction of protein intake was also found in a study performed in older people, where a sufficient supply with proteins is highly important (Jyväkorpi et al., 2017). Furthermore, the reduction of protein intake after the introduction of sucrose-sweetened beverages was also confirmed in interventional trials (Geidl-Flueck et al., 2021).

### Conclusion

A reduced intake of important micro- and macronutrients due to an increased consumption of nutrients with a high content of added sugar is a serious concern, however, such risk is likely to be significantly influenced by individual diet patterns.

## Sucrose metabolism by components of the microbiome

### Sucrose and dental health

Sucrose has been known to affect dental health for a long time, and experimental data dates back to the time before 1950 when an association between sucrose consumption and dental caries was first demonstrated (Shafer, 1949). Dental caries is still one of the most prevalent noncommunicable chronic diseases, with estimates of a global prevalence of some 2.5 billion people in 2015 (Kassebaum et al., 2015), and with an enormous medical and economic impact on societies (Righolt et al., 2018). The prevalence of untreated caries in the USA was recently reported to be more than 20% in the adult population (Bashir, 2021).

The pathophysiology of caries is based on the fermentation of dietary sugars by bacteria of the oral flora as *Streptococcus mutans* or *Lactobacillus* species which are normally present in dental plaque. With the intake of high amounts of sugar, their presence and activity increases, producing a high amount of acid when metabolizing dietary carbohydrates, and in particular sugar. The landmark Vipeholm studies, conducted almost 70 years ago, underscored the importance of both the frequency of sugar consumption, as well as its consistency (Gustafsson, 1954; Gustafsson et al., 1954; Hojer and Maunsbach, 1954; Krasse, 2001). These data could be reproduced over the past decades (Touger-Decker and Van Loveren, 2003).

Early childhood caries is a particular worrisome consequence of high sugar intake in children. Multiple studies have shown a strong correlation of the intake of added sugar and the development of caries early in life. Here again, sugar-sweetened beverages are of particular importance in the development of dental caries. Despite the efforts to reduce childhood caries during the past decades, recent data from two German birth cohorts still showed a significantly increased caries burden in children/adolescents 10 and 15 years old being associated with the consumption of SSB (Pitchika et al., 2020). In addition, the results of a prospective study among Scottish young children provided evidence that the introduction of SSBs during the 1st year of life can put children in a trajectory of high levels of dental caries (Bernabé et al., 2020). Of importance, four categories of social determinants were identified to have an impact on added sugar intake in children. These are socioeconomic disadvantage, household dietary habits, the location of added sugar sources and peer influence (Chi and Scott, 2019). Thus, any efforts to reduce added sugar intake in children should address these important factors.

Despite a focus on the burden of caries in early life, it is important to acknowledge the fact that the association of sugar (as from SSBs) with dental disease is still present in adulthood. A recent report of cross-sectional data from the US National Health and Nutrition Examination Survey (NHANES) reported an adjusted prevalence for untreated decay of 30% to be associated with the consumption of 47 g of added sugar from SSBs compared to those reporting no sugar from SSBs, and the number of untreated decayed teeth increased with sugar intake from SSBs (Moss et al., 2021). A clear dose-response gradient regarding the association of SSB consumption and dental disease was also observed by a very recent systematic review and meta-analysis, underlining the suggestions that the association is likely to be causal (Valenzuela et al., 2021).

Finally, although there was much attention on the association of SSBs and caries during the past years, it is important to mention that added sugar also in solid form is associated with dental disease, as demonstrated by a recent analysis of data from the UK

Children's Dental Health Survey (CDHS), were the ingestion of drinks and foods with added sugar were analyzed separately (Hong et al., 2018). It was shown that the frequent consumption of foods and drinks with added sugars was associated with the presence of dental caries among 12- and 15-year-olds.

### Sucrose and the intestinal microbiome

The intestinal microbiome consists of a very diverse consortium of different bacteria, archaea, fungi, protozoa, and viruses that inhabit the gut of all mammals. Many studies in humans, but also in other species have demonstrated that the microbiome plays a pivotal role in a broad variety of fundamental biological processes impacting human health and disease locally (e.g., gut epithelial health), but even more important systemically (e.g., control of energy homeostasis, metabolic processes, immunologic activity or neurobehavioral development) (Barko et al., 2018). Thus, the gut microbiome is an active participant in host physiology, and any disturbances regarding its composition may affect the whole individual.

When the interaction of sugar consumption with the microbiome is evaluated, we must be reminded that the disaccharide sucrose is enzymatically hydrolyzed into glucose and fructose, which then are metabolized in significant amounts by the microbiome. The effect of fructose on the microbiome is of particular interest and seems to exhibit significant differences as compared to the effect of glucose. Thus, the intake of sucrose, providing both glucose and fructose, is suggested to affect the microbiome quite differently as compared to the intake of food providing mainly glucose molecules (e.g., starch) or fructose alone (Rosas-Villegas et al., 2017).

So far, our understanding about possible interactions of different sugars with the microbiome is still incomplete and mainly derived from experimental data in rodents. One important question, which was addressed in many studies during the past years, is whether the impact of sucrose and fructose on hepatic lipid metabolism is, at least in part, mediated by interactions with the microbiome. In one of the first studies assessing this question, fructose (and sucrose), but not glucose, were shown to induce hepatic triglyceride accumulation in rodents (Bergheim et al., 2008). This effect was accompanied by a concomitant increase in portal vein endotoxins. Of interest, liver lipid accumulation could be reversed by the administration of an antibiotic therapy together with fructose consumption. This led to the hypothesis that a fructose-induced increased translocation of bacterial toxins might be the reason for this observation. While the importance of disruption of the gut vascular barrier as a prerequisite for non-alcoholic steatohepatitis was further emphasized (Mouries et al., 2019), the role of different sugars on this remained unclear, since further studies on this topic provided conflicting results. Another study showed that glucose, but not fructose, alters the intestinal paracellular permeability in association with gut inflammation and dysbiosis in mice (Zhang et al., 2021). Furthermore, and in contrast to these rodent studies, a clinical cross-over pilot study in obese humans who were provided 75 g of fructose or glucose (substituted isocalorically for complex carbohydrates) for 14 days did not show any difference between the glucose and fructose intervention regarding changes in the gut microbiome, metabolome, and permeability as well as endotoxemia (Alemán et al., 2021). However, the question remains whether obese people exhibit an already altered gut microbiome, which is not significantly changed by further interventions, and further studies are needed to clarify these questions. As another hypothesis, latest experimental evidence suggests that the interaction of the microbiome with ingested fructose regarding hepatic lipid accumulation relies probably on the conversion of dietary fructose to acetate by the gut microbiota, which then supplies lipogenic acetyl-CoA (Zhao et al., 2020). Depletion of the microbiota in this study potentially suppressed this effect.

### Conclusion

The causal effect of sucrose and other sugars on dental disease, mediated by oral microbiota, is well established. In contrast, the role of the intestinal microbiome in mediating adverse effects of sugars regarding the development of metabolic (as fatty liver) disease is still incompletely understood and targeted by many current studies.

### Effects of naturally occurring sucrose

#### Sucrose in fruits

With the increasing evidence for harmful effects of fructose (and thus, sucrose, which provides fructose as well), the question about possible adverse effects of the consumption of high amounts of fruits, containing fructose and sucrose in different amounts, arose. However, corresponding evaluations that were performed in large meta-analyses of prospective cohort studies consistently provided evidence for a protective role of fruit consumption (at least up to 5 servings per day) regarding cardiovascular disease, cardiovascular mortality, and all-cause mortality (Wang et al., 2014; Zhan et al., 2017). Correspondingly, interventional studies could not show any benefit of a reduction of fructose/sucrose consumption by reducing the intake of fruits regarding cardiovascular risk factors (Aeberli et al., 2011).

It is hypothesized that a possible harm of the moderate amount of fructose and sucrose that is ingested when consuming fruits is clearly outweighed by the beneficial effects of fruits, providing many protective nutrients as fibers or vitamins.

## Conclusion

So far, there is no evidence of negative effects of sugar consumption by the ingestion of fruits in moderate amounts.

## Summary, conclusion and outlook

### Summary

In most parts of the world, sugar consumption is very high, in particular when compared to the dietary sugar intake that was present in prehistorical diets. Most of the added sugar consumed nowadays consists of sucrose and thus, of a mixture (50/50) of the two monosaccharides glucose and fructose. High-fructose corn syrup is often used as added sugar as well, with a comparable glucose and fructose content, and most of the existing evidence suggests similar effects of sucrose and high-fructose corn syrup regarding health and disease.

Five important topics regarding sucrose consumption and human health must be considered.

- (1) Sucrose is a source of energy. A reduced ability of sucrose to induce satiety after consumption is suggested, in particular because of its fructose component. Thus, overfeeding induced by sucrose consumption is likely to occur.
- (2) Sucrose is very likely to have energy independent negative effects on human metabolism. Again, these effects are probably mainly mediated by the fructose component, but may be facilitated by glucose. They include the induction of lipogenic activity in the liver, a metabolic switch which may pave the way for further changes negatively affecting metabolic health.
- (3) The consumption of food rich in sucrose may result in a reduced intake of other micro- and macronutrients which are important for maintaining health, but this effect depends on the individual diet pattern.
- (4) Fermentation of sucrose and/or its components by the oral and intestinal bacterial flora results in either fermentation products or changes in the microbiome which may have adverse effects on health.
- (5) The consumption of sugar (fructose, sucrose) containing fruits does not seem to be associated with adverse effects on health as compared to food containing added sugar.

## Conclusion

Current evidence derived either from larger cross-sectional or prospective cohort studies, or from smaller interventional trials suggests that the consumption of sucrose in the form of added sugar contributes to the development of different diseases. The call to reduce the intake of free sugars to at least less than 10%, better less than 5%, as suggested by the WHO, should be emphasized.

## Outlook

There is still a need to further clarify the role of sucrose regarding clinical endpoints. While conducting interventional studies that introduce additional sucrose to the diet are precluded by ethical considerations, interventional trials that reduce the intake of added sugar in a randomized manner would help to further clarify the impact of sucrose on human health and disease.

## Introduction

In 2004, global sales of dietary supplements represented a significant business. Worldwide sales have been estimated at \$70–250 billion. The demand for herbal products worldwide increased at an annual rate of 8% from 1994 to 2001, although this growth has slowed in recent years.

Issues and controversies in the dietary supplement market are related to defining exactly what is a dietary supplement, understanding how sales and marketing data are derived, defining the regulatory environment, safety issues, product quality issues, labeling and health claim issues, and scientific evidence for benefit. This article describes some of these controversies and provides examples to illustrate these issues.

## How is the Sales Data Derived?

Global sales have been estimated to be between \$70 billion and \$250 billion. This approximately three-fold difference in estimates is due to the variation in what products are actually included in product sales results. As will be discussed, the definition of dietary supplements varies greatly from country to country; therefore, deriving sales data is complex.

Another difficulty in assessing sales of dietary supplements is the source from which sales data are gathered. Many business surveys rely on only one or two of the following sales outlets to derive their results:

- Supermarkets and mass merchandisers
- Natural food and health food stores
- Direct sales from Internet, mail order, practitioners, and multilevel marketing
- Pharmacies and drugstore chains

## What is a Dietary Supplement? How are they Regulated in Different Countries?

Each country has developed regulatory definitions and systems that place dietary supplements, particularly botanicals, into categories of drugs, traditional medicines, or foods. However, in the late 1980s, many countries launched major changes in regulations that may or may not have been approved at the time of this writing. Many regulations are still in draft form.

The US Congress defined the term 'dietary supplement' in the Dietary Supplement Health and Education Act (DSHEA) of 1994. A dietary supplement is a product, taken orally, that contains a 'dietary ingredient' that is intended to supplement the diet. The dietary ingredient includes vitamins, minerals, herbs or other botanicals, amino acids, a dietary substance for use by man to supplement the diet by increasing the total dietary intake (e.g., enzymes or tissues from organs or glands), or a concentrate, metabolite, constituent, or extract. Dietary supplements may be found in many forms, such as tablets, capsules, softgels, gelcaps, liquids, or powders. They may also be produced in other forms, such as a beverage, spread, or bar, in which case information on the label must clearly state that the product is a dietary supplement and it is not represented as a conventional food or a sole item of a meal or diet.

Whatever their form, DSHEA places dietary supplements in a special category under the general umbrella of 'foods,' not drugs, and requires that every supplement be labeled a dietary supplement and carry a Supplement Facts Label.

In UK, there is a distinct separation of food supplements and herbal medicines. The Food Standards Agency developed the Food Standard Act of 1999 and is responsible for protection of public health. The Food Supplement Directive 2002/46/EC, which harmonizes European Community legislation on food supplements, was published in 2002. This directive is stricter than existing UK standards and regulations but is relatively more liberal than that which exists in other European countries. The directive defines the term 'food supplements,' contains a list of vitamin and mineral sources that may be used in the manufacture of food supplements, states labeling requirements, and, in the future, will provide a framework for maximum and minimum levels for vitamins and minerals in food supplements. Herbals and botanicals are not discussed in this directive.

The Foods Supplement Directive defines a food supplement as any food the purpose of which is to supplement the normal diet and which is a concentrated source of a vitamin or mineral or other substance with a nutritional or physiological effect, alone or in combination, and is sold in dose form. Dose form means capsules, pastilles, tablets, pills, and other similar forms, and also powders, ampoules, drops, or other similar forms of liquids or powders, designed to be taken in small measured quantities. Because the directive defines a food supplement as something to supplement the diet, products that are not meant to supplement the diet (e.g., a weight loss product) are outside the scope of the regulations. There remains a complex legal area between food supplements and medicinal products, although the directive indicates that if a product is used for treating or preventing disease, or restoring, correcting, or modifying a physiological function, then it falls under the Medicines Directive 2001/83/EEC, Medicines Act 1968, or Medicines for Human Use Regulations 1994.

The Transatlantic Business Dialogue (TABD) approved a position statement regarding dietary supplements in 2002. The TABD is a group of corporations that promote closer commercial ties between the European Union and the United States. This position statement established industrywide consensus on standards and definition of permissible claims, as well as defining what is necessary for substantiation of those claims. In keeping with the Foods Supplement Directive, the TABD dealt only with vitamins and minerals, with the understanding that some of the conclusions may be revisited when warranted for herbals, botanicals, or other dietary supplements.

Herbal medicines, however, are regulated by the Medicine and HealthCare Products Regulatory Agency based in London. A herbal remedy is defined as

a medicinal product consisting of a substance produced by subjecting a plant or plants to drying, crushing or any other process, or of a mixture whose sole ingredients are two or more substances so produced, or of a mixture whose sole ingredients are one or more substances so produced and water or some other inert substance.

There are two alternative regulatory routes in UK for herbal medicines: Licensing and exemption from licensing requirements:

- Licensed herbal medicines: To receive a product license before marketing, herbal medicines are required to meet safety, quality, and efficacy criteria in a similar manner to any other licensed medicine.
- Herbal remedies exempt from licensing requirements: The exemption applies to herbal remedies meeting certain conditions set out in Section 12 of the Medicines Act 1968. Section 12 allows a person to make, sell, and supply a herbal remedy during the course of his or her business provided the remedy is manufactured or assembled on the premises and that it is supplied as a consequence of a consultation between the person and his or her patient. Section 12 also allows the manufacture, sale, or supply of herbal remedies where the processing of the plant consists only of drying, crushing, or comminuting; the remedy is sold without any written specification as to its use; and the remedy is sold under a designation that only specifies the plant and the process and does not apply any other name to the remedy.

Canada has been estimated to have approximately 3% of the market share of the global nutritional market. Health Canada established the Office of Natural Health Products. Premarket assessment, labeling, licensing, and monitoring of herbal supplements are items in its mandate. The definition of a natural health product includes products for the use in 'diagnosis, treatment, mitigation, or prevention of a disease, disorder, or abnormal physical state or its symptoms in humans; restoring or correcting organic function in humans; or modifying organic functions in humans, such as modifying those functions in a manner that maintains or promotes health.' These products include homeopathic preparations, substances used in traditional medicine, a mineral or trace element, a vitamin, an amino acid, an essential fatty acid or other botanical-, animal-, or microorganism-derived substance. Foods are not included in this product category called natural health products. Canada's Food and Drugs Act of 1953 regulates foods and drugs but does not specifically deal with natural health products. Therefore, these types of products are regulated as either a food or a drug depending on the type and concentration of active ingredient and whether claims are made on the products.

Germany regulates vitamins and minerals as food if they are sold to complement the nutritive value of the diet and do not exceed safe levels. However, if the vitamin or mineral is used for disease treatment or prevention and is used at pharmacological levels, then it is considered a drug. Safety and efficacy of drugs must be established by clinical research. Medicinal plants are regulated differently depending on what plant and in what form it is sold. In general, extracts of plants are considered drugs and must be prescribed. Teas, however, are sold over-the-counter in pharmacies. Other teas, such as those that contain alkaloids, must be sold by prescription only. Beginning in 1980, an extensive analysis of the literature on more than 300 herbal remedies was undertaken by the German Kommission E. Approximately two-thirds of the herbals were listed as safe and at least minimally effective. The results were published as a series of monographs by the German Kommission E, and this body of work was summarized and translated into English

by the American Botanical Council. These substances are generally purchased at the pharmacy and are reimbursable through health insurance. One caveat regarding the German herbal preparations is that they are not likely to be the same preparations that are produced by other countries; thus, the safety and efficacy statements in the Kommission E are only for the preparations that are prepared in German pharmacies.

Australia regulates therapeutic goods under the Therapeutic Goods Act of 1989. Therapeutic goods include vitamins, minerals, plants and herbals, nutritional food supplements, naturopathic and homeopathic preparations, and some aromatherapy. The Therapeutic Goods Administration (TGA) developed the Office of Complementary Medicine to evaluate new substances and products. Basically, the TGA regulates these therapeutic goods as they do pharmaceutical products, and thus their criteria are more rigorous than the criteria of other countries. Most of the therapeutic goods are 'generally listed' rather than regulated. Listed medicines are considered to be relatively harmless, so the regulations allow for manufacturers to 'self-assess' their products in some situations. The majority of listed medicines are self-selected by consumers and used for self-treatment, and they are all manufactured with well-known established ingredients, such as vitamin and mineral products or sunscreens. These are assessed by the TGA for quality and safety but not efficacy. This does not mean that they do not work; rather, it means that the TGA has not evaluated them individually to determine if they work. It is a requirement under the act that sponsors have information to substantiate all of their product's claims.

The Japanese Ministry of Health and Welfare does not define or recognize a distinct category known as dietary supplements. Instead, there are only two classifications, food and drugs. In 1993, Japan defined a group of foods known as Foods for Specific Health Use (FOSHU). As of 2004, approximately 342 foods had been approved as FOSHU. The dietary ingredients are sold in the form of foods, not in the form of capsules, tablets, or powders.

The herbal supplements market in Japan has been strongly influenced by the practice of *Kampo*. *Kampo* (or *Kanpo*) is the adaptation of Chinese herb formulas to Japanese medicine. Approximately 25 years ago, the Japanese Ministry of Health formally recognized that certain traditional Chinese herb formulas (and a few formulas of similar nature developed in Japan) were suitable for coverage by national health insurance. These formulas are prepared in factories under strict conditions.

In summary, developing global data on dietary supplement sales depend on how they are defined. (Table 1) summarizes the differences in regulatory categories of different countries.

## Product Quality and Safety Issues

Product quality is an issue derived from the explosive growth of the industry in the post-DSHEA world. Quality issues revolve around products that contain wrong ingredients, incorrect claims, contamination, or incorrect amounts – either too much or not enough.

An example plant misidentification was published in 1998 by Slifman *et al.* Two patients were admitted to hospital emergency rooms with palpitations, vomiting, nausea, and chest pressure, among other symptoms. Both individuals, having been admitted 1 month apart, had each consumed a program of dietary supplements, one containing 14 herbs, a tablet containing 11 herbs, liquid clay, a bulking powder, and capsules containing microorganisms. Of the five supplements, the one made up of 14 herbs tested positive for cardiac glycosides. The investigators determined that *Digitalis lanata* was present in the supplement. *D. lanata* contains cardiac glycosides, which resulted in the cardiac symptoms. Further investigation revealed that raw material labeled as plantain (genus *Plantago*) had been contaminated with *D. lanata* due to misidentification in the field.

Another quality issue that has safety manifestations was an incorrect claim on a product. PC-SPES, a combination of eight herbs, is claimed to be a nonestrogenic treatment for prostate cancer. However, several of the herbs used in this preparation do in fact have estrogenic activity. In 1998, DiPaola *et al.* showed a significant amount of estrogenic activity in both *in vitro* (yeast) and *in vivo*

**Table 1** Regulatory categories of different countries

Country, act	Definition
United States, DSHEA	Vitamins, minerals, herbal, other botanical, amino acid, enzymes, organs, glands
Europe, Food Supplement Act	Vitamin and minerals
United Kingdom, Medicine and Health Care	Medicinal plants
Canada, Office of Natural Products	Mineral; trace element; vitamin; amino acid; essential fatty acid; botanical-, animal-, or microorganism-derived substances; homeopathic preparation; traditional preparations
Germany, Kommission E	Vitamin and mineral as both foods and drugs, botanicals (approved and not approved), teas as prescription and as over-the-counter
Australia, Therapeutic Goods Administration	Vitamin and mineral, plants, herbs, nutritional food supplements, naturopaths and homeopathic preparations, aromatherapies
Japan, Ministry of Health and Welfare	No definition of dietary supplements, regulations for foods, drugs, and <i>Kampo</i>

studies (mice and humans) with PC-SPES. Use of the supplement by men with prostate cancer resulted in similar side effects as would develop with estrogen therapy and theoretically could confound the results of standard therapy.

By law (DSHEA), the manufacturer is responsible for ensuring that its dietary supplement products are safe before they are marketed. Unlike drug products that must be proven safe and effective for their intended use before marketing, there are no provisions in the law for the US Food and Drug Administration (FDA) to 'approve' dietary supplements for safety or effectiveness before they reach the consumer. Also unlike drug products, manufacturers and distributors of dietary supplements are not required by law to record, investigate, or forward to the FDA any reports they receive of injuries or illnesses that may be related to the use of their products. Under DSHEA, once the product is marketed, the FDA has the responsibility to show that a dietary supplement is 'unsafe' before it can take action to restrict the product's use or remove it from the marketplace.

In 2003, the FDA banned all products containing ephedra alkaloids. Ephedra-containing products were, until the ban, marketed in conjunction with enhancing athletic performance and/or promoting weight loss. Recent studies provided enough additional evidence that ephedra presents a significant and unreasonable risk of illness and injury that the FDA banned all ephedra-containing products from the market and advised consumers to stop taking such supplements. Strong statements were issued cautioning about the use of ephedra-containing products, especially when strenuously exercising or in combination with other stimulants, such as caffeine.

## Interactions

An issue that has become of concern is the interaction of dietary supplements with herbs and other dietary supplements, drugs, foods, lab tests, and diseases or other conditions. There are literally hundreds of potential interactions that have not yet been recognized. Both practitioners and consumers must be aware of the possibilities. In some cases, knowledge about interactions comes from documented reports. However, in other cases, the knowledge is theoretical, based on the pharmacological profile or mechanism of action of the supplement and the drug, food, test, or condition. For example, ginkgo biloba contains ginkgolides in the leaf that competitively inhibit platelet-activating factor (PAF). PAF inhibition decreases platelet aggregation among other many other physiological effects. Inhibition of PAF may increase cardiac contractility and coronary blood flow. Concomitant use of herbs and supplements that affect platelet aggregation could theoretically increase the risk of bleeding in some people due to ginkgo's effects on platelet aggregation. Spontaneous hematomas (broken blood vessels) and hemorrhaging in the anterior chamber of the eye have been reported in ginkgo users, although it is not known what other drugs or supplements these individuals were taking.

Herbs and supplements that promote platelet inhibition include angelica, anise, capsicum, celery, chamomile, clove, fenugreek, feverfew, fish oil, garlic, ginger, horse chestnut, horseradish, licorice, meadowsweet, onion, Panax ginseng, red clover, vitamin E, and willow. Similarly, concomitant administration of drugs, including aspirin, clopidogrel (Plavix), dalteparin (Fragmin), enoxaparin (Lovenox), heparin, indomethacin (Indocin), ticlopidine (Ticlid), and warfarin (Coumadin), may increase the risk of bleeding in some people. This is just one example of the interactions between drugs with herbals and herbals with other herbals. There may be an infinite number of interactions.

Currently, there are no mandated US federal guidelines to report adverse events or consumer health complaints associated with the use of dietary supplements. MedWatch reporting is voluntary. In 2004, the Life Sciences Research Office published a report, *Recommendations for Adverse Event Monitoring Programs for Dietary Supplements*.

## Label Claims

Label claims regarding dietary supplements are a complex issue that varies from country to country. Yet no matter what specific claims are allowed or disallowed by a country, it is reasonable to assume that any global regulation requires that the claim be true, not misleading, and be clear to the consumer. A summary of US label claims follows.

The Nutrition Labeling and Education Act (NLEA) was passed in 1990 as a result of a pre-1984 FDA position that prohibited making any therapeutic or disease-related claims on a food or dietary supplement label. The NLEA permits certain claims describing a positive relationship between a supplement and a health-related condition (or disease). These claims are considered 'health claims' in order to distinguish them from nutrient content claims. A health claim must be authorized by the FDA, and the FDA can only authorize a claim if there is 'significant scientific agreement among qualified experts' or by the 1997 amendment that permits a manufacturer to rely on a statement from an 'authoritative scientific body' of the US government or the National Academy of Sciences. This is a rigorous assessment and only 14 claims have been authorized to date.

In addition to health claims, dietary supplement labels are permitted to have qualified health claims or structure-function claims. The rationale behind the development of a qualified health claim was the idea that the First Amendment should allow disclaimers to be considered as solutions to making claims nonmisleading (Pearson vs Shalala). In other words, the First Amendment does not allow the FDA to reject health claims unless it shows that disclaimers would fail to remedy harm from misleading statements. The criteria for a qualified health claim were released in 2003 and in this context the FDA will not take enforcement action against a manufacturer using the following specified qualifiers provided the FDA is satisfied that the qualifiers are not misleading:

- “Although there is scientific evidence supporting the claim, the evidence is not conclusive.”
- “Some scientific evidence suggests.... However, FDA has determined that this evidence is limited and not conclusive.”
- “Very limited and preliminary scientific research suggests.... FDA concludes that there is little scientific evidence supporting this claim.”

Qualified health claims for dietary supplements recognized by the FDA as part of its enforcement discretion include such examples as the relationships between phosphatidylserine and cognitive function, B vitamins and cardiovascular disease, omega-3 fatty acids and cardiovascular disease, selenium and cancer, and antioxidant vitamins and cancer.

Dietary supplements are not permitted to carry labeling statements that imply such issues as ‘cure,’ ‘mitigate,’ ‘treat,’ or ‘prevent disease’ because these statements are considered within the definition of a drug and drugs are subjected to a rigorous premarket approval process. However, under DSHEA, structure-function claims are permitted on dietary supplements because dietary supplements may have effects on the structure or function of the body without the implication that they act as a drug and/or are related to disease. Structure-function claims include those that describe the role of the dietary supplement in affecting the structure or function in humans or the documented mechanism in which a dietary supplement acts to maintain such structure or function. In addition, dietary supplement label claims allow statements of benefits related to classical nutritional deficiency or statements regarding the general feeling of well-being derived from consumption.

## Potential Benefits of Dietary Supplements

The 2000 *Dietary Guidelines for Americans* (new release due 2005) emphasizes choosing foods sensibly, maintaining a healthy weight, and exercising regularly. It acknowledges that some people may need a vitamin–mineral supplement to meet specific needs. Similarly, the Food and Nutrition Board and the American Dietetic Association also recognize that dietary supplements may be desirable for some nutrients and for some individuals. The following is a compilation of recommendations by these groups:

- Folic acid supplements for women of childbearing age due to the risk of neural tube defects
- Vitamin B<sub>12</sub> supplements for people older than age 50 years due to inefficient absorption
- Vitamin B<sub>12</sub> supplements for vegans who eat no animal products
- Calcium for people who seldom eat dairy products
- Vitamin D for elderly people who do not consume fortified dairy products and for others with little exposure to sunlight
- Iron supplementation for pregnant women
- Multivitamin-mineral supplement for people who are following a severely restricted weight-loss diet.

Specifically for athletes, the position of the American Dietetic Association, Dietitians of Canada, and the American College of Sports Medicine is that physical activity, athletic performance, and recovery from exercise are enhanced by optimal nutrition. These organizations recommend appropriate selection of food and fluids, timing of intake, and supplement choices for optimal health and exercise performance. In sports, athletes who are at greatest risk of micronutrient deficiencies are those who restrict energy intake or use severe weight-loss practices, eliminate one or more food groups from their diet, are sick or recovering from injury, or consume high-carbohydrate diets with low micronutrient density. In practice, athletes should consume diets that provide at least the Recommended Dietary Allowances/Direct References Intakes for all micronutrients from food. It follows that, in general, no vitamin and mineral supplements are required if an athlete is consuming adequate energy from a variety of foods to maintain body weight. Supplementation may be necessary under conditions of inadequate food intake. Athletes, as for the general population, should follow supplementation recommendations unrelated to exercise, such as folic acid in women who may become pregnant.

## Conclusions

One of the difficulties in assessing the nature of the worldwide dietary supplement industry and its regulations is largely in understanding what products are considered dietary supplements. In the United States, only pills, capsules, tablets, and the like are considered dietary supplements. Globally, it is sometimes difficult to discuss dietary supplements without discussing functional foods or nutraceuticals. Functional foods are similar in appearance to conventional foods but have demonstrated physiological benefits beyond the traditional nutritional value. Nutraceuticals may go so far as to declare not only health benefits, but also medical benefits that reduce the risk of chronic disease beyond basic nutritional functions. Canada regulates functional foods, nutraceuticals, and dietary supplements under one regulatory agency. The United States clearly distinguishes between foods and dietary supplements, although both fall under the category of food, which is distinct from drugs. UK distinguishes between herbal medicines and dietary supplements containing vitamins and minerals. Japan regulates functional foods as FOSHU and has no regulatory definition for dietary supplements as defined in the United States. Moreover, these regulations are in a constant state of flux as the industry changes and develop over time. Issues that must be monitored regarding dietary supplements consumption are product quality and potential harmful interactions among supplements, foods, and drugs. Health claims that have been approved by regulatory agencies worldwide stress that the claims be truthful, clear, and not misleading to the ultimate consumer. Current scientific

expertise acknowledges that dietary supplements, specifically some of the vitamins and minerals, have potential benefits in certain populations.

## Key points

- Sustainable diets encompass health, environmental, social and economic dimensions of the way food is produced and consumed
- There are often trade-offs between the different dimensions (health, environmental, social and economic) of sustainable diets
- Measuring sustainable diets in a comprehensive way is challenging, with the emphasis most often being placed on health and environmental aspects of diets
- Shifting global diets toward more plant-based foods (e.g., Planetary Health Diet) will be critical to achieving more sustainable consumption patterns
- Both consumer-facing and upstream food systems solutions will be needed to promote and support sustainable diets
- Social movements, local government actions and chefs have the potential to increase the awareness and adoption of sustainable diets

## Introduction

The United Nations (UN) Sustainable Development Goals (SDGs) were adopted in 2015 with the view of providing a blueprint “for peace and prosperity for people and the planet, now and into the future” (United Nations, 2015). SDG 2—to “end hunger, achieve food security and improve nutrition and promote sustainable agriculture”—highlights the importance of food and nutrition in meeting the 2030 goals (United Nations, 2015). In addition to the SDGs, there are several global goals aimed at tackling food insecurity, suboptimal diets and malnutrition (e.g., World Health Organization (WHO) global target 2025 to improve maternal, infant and young child nutrition, WHO Non-communicable Disease targets). Alongside these global goals, the UN Food Systems Summit 2021 resulted in a myriad of commitments to transform the way the world produces and consumes food, highlighting the need to shift toward more sustainable consumption patterns. These international goals and actions highlight the growing prominence of sustainable diets on the global agenda. Global shifts toward sustainable diets could help to achieve SDG 2 and beyond; however, the world is currently off track to meet most of the global nutrition goals (FAO et al., 2021).

In 2020, between 720 and 811 million people were undernourished, a number that has been increasing since 2014 and is projected to increase even further due to the COVID-19 pandemic (FAO et al., 2021). At the same time, billions of people worldwide experience malnutrition in one or more of its forms: 149 million children under five are stunted, 45 million are wasted, over two

billion adults are overweight or obese, and approximately 2 billion people worldwide are deficient in key micronutrients (FAO et al., 2021). Moreover, 3 billion people globally cannot afford a healthy diet (FAO et al., 2021).

Consuming diverse, nutritious diets has the potential to help address the burden of malnutrition. However, current global diets are suboptimal and are among the top risk factors contributing to the global burden of disease (Afshin et al., 2019). While there are differences in dietary intakes across countries, much of the global population is under-consuming whole grains, legumes, nuts, fruits and vegetables while over-consuming red meat and starchy vegetables (Willett et al., 2019). However, this masks the inequality in dietary intakes and malnutrition across populations globally, and within given countries (Bell et al., 2021).

In many countries, the populations with the highest burden of poor-quality diets and malnutrition are employed within the food system. Subsistence farmers, particularly in Sub-Saharan Africa and Asia, are often malnourished and experience high levels of food insecurity. Their livelihoods are also at risk due to increased climate variability, including shocks. In high-income countries like the United States, people working in food production, harvesting, processing and service are often paid below a living wage with insufficient access to social safety nets, increasing their risk of food insecurity, poor quality diets and disease. In order to ensure that all populations have access to affordable, nutritious and sustainably produced food, real changes are needed in the way we produce food, how it moves through the food value chain, and how we consume it.

## Defining sustainable diets

In 1986, Gussow and Clancy first introduced the concept of sustainable diets (Gussow and Clancy, 1986). They proposed that the nutrition community should go beyond focusing solely on the relationship between food and human health and also consider the health of the planet (Gussow and Clancy, 1986). While little progress was made to move this agenda forward for many years, over the past decade it has begun to receive considerable attention. While sustainable diets have been described in a variety of ways, the Food and Agriculture Organization (FAO) defines them as “those diets with low environmental impacts that contribute to food and nutrition security and to healthy life for present and future generations. Sustainable diets are protective and respectful of biodiversity and ecosystems, culturally acceptable, accessible, economically fair and affordable, nutritionally adequate, safe, and healthy, while optimizing natural and human resources” (FAO, 2012). The definition is comprehensive, including health, environmental, social and economic dimensions. However, given the breadth of dimensions of sustainable diets there will undoubtedly be trade-offs among them.

Fig. 1 provides an overview of the key principles of sustainable diets (FAO and WHO, 2019). While these principles are helpful in terms of providing insight into the elements of sustainable diets, it remains difficult to conceptualize what a sustainable diet looks like in practice, particularly among different populations and contexts. As such, there are challenges to providing an overarching definition of sustainable diets, given that so much of what makes diets sustainable are context specific.

## Rationale for promoting sustainable diets

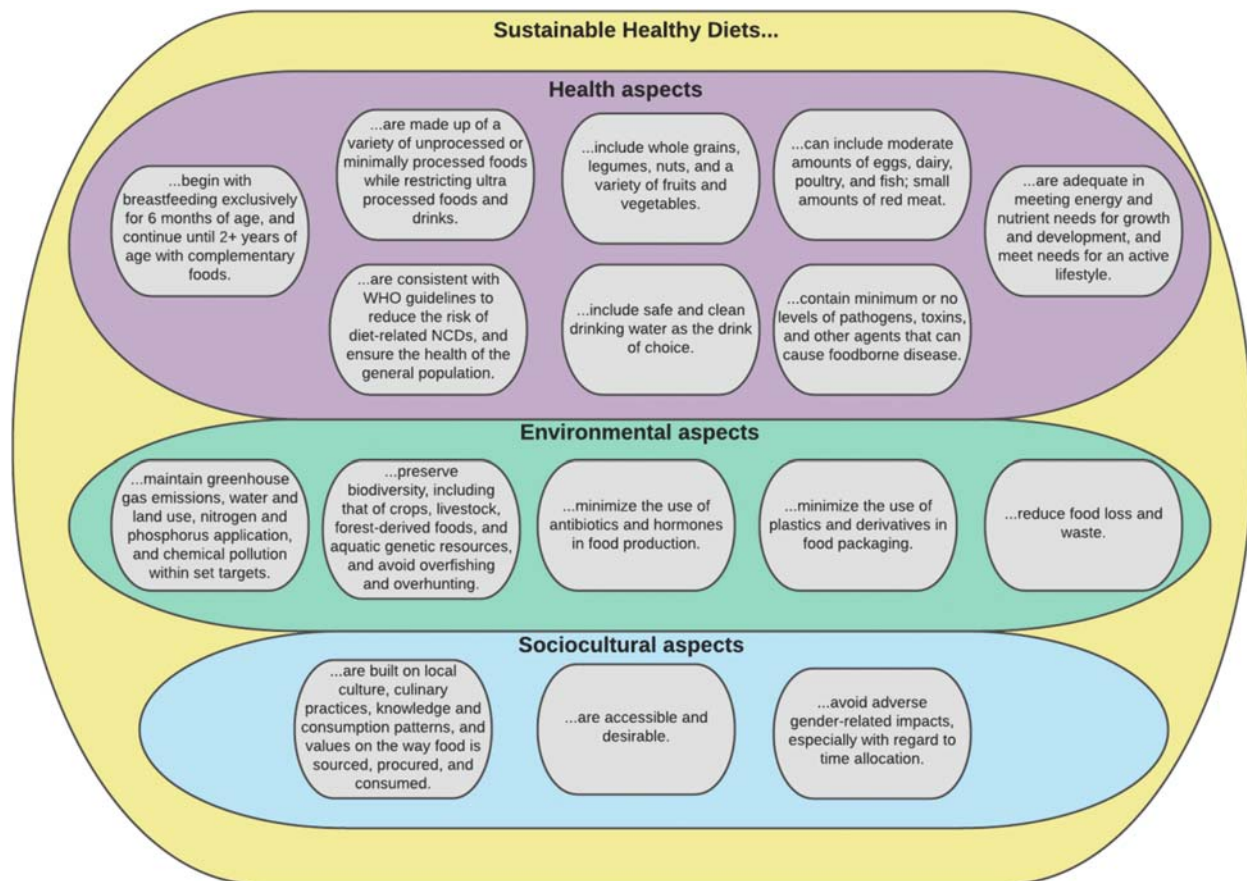

The food we consume, and how it is produced and moves along the food value chain, has serious implications for the health of people but also for the planet. The food system is responsible for approximately a third of greenhouse gas emissions, 30% of freshwater use and the largest contribution to biodiversity loss globally (Willett et al., 2019). It is putting immense pressure on the Earth's systems, leading us to surpass planetary boundaries (Willett et al., 2019).

Animal source foods, and ruminant meat (e.g., beef, lamb, etc.) in particular, are the main contributors to environmental degradation attributed to food systems (Willett et al., 2019). Fig. 2 depicts the environmental effects of consuming different foods and food groups. While the environmental impact of animal source food consumption is already high, this is being exacerbated by increasing global intakes. Fig. 3 describes the changes in animal source food availability (used as a proxy for consumption) over time based on socio-demographic Index (SDI), a metric that takes into account incomes per capita, average educational attainment, and fertility rates. While egg and fish availability has remained relatively stable since the early 1960s, milk and meat consumption has been growing particularly among higher SDI countries.

Given that ruminant meat production has the largest impact on the environment of any food group, and its intakes are currently increasing, it's clear that intakes need to decrease in order to stay within planetary boundaries. However, it is important to acknowledge the significant inequality in the availability of animal source food across countries globally. Approximately one-fifth of the global population consumes less than 10% of their energy from animal source foods (Bell et al., 2021). This is important given that animal source foods can be critical sources of key nutrients, particularly for young children. Increasing animal source food consumption among the lowest-income consumers globally, and decreasing consumption among the highest, has the most potential to lead to significant improvements in both health and environmental outcomes (Willett et al., 2019).

## Moving toward a global sustainable diet

In recognition that global diets need to shift both from a health and an environmental perspective, the EAT Lancet Commission described a healthy reference diet that provides a blueprint for a global diet that sustains health while protecting the planet (Willett et al., 2019). The “Planetary Health Diet” emphasizes the consumption of plant foods, while limiting consumption of meat and

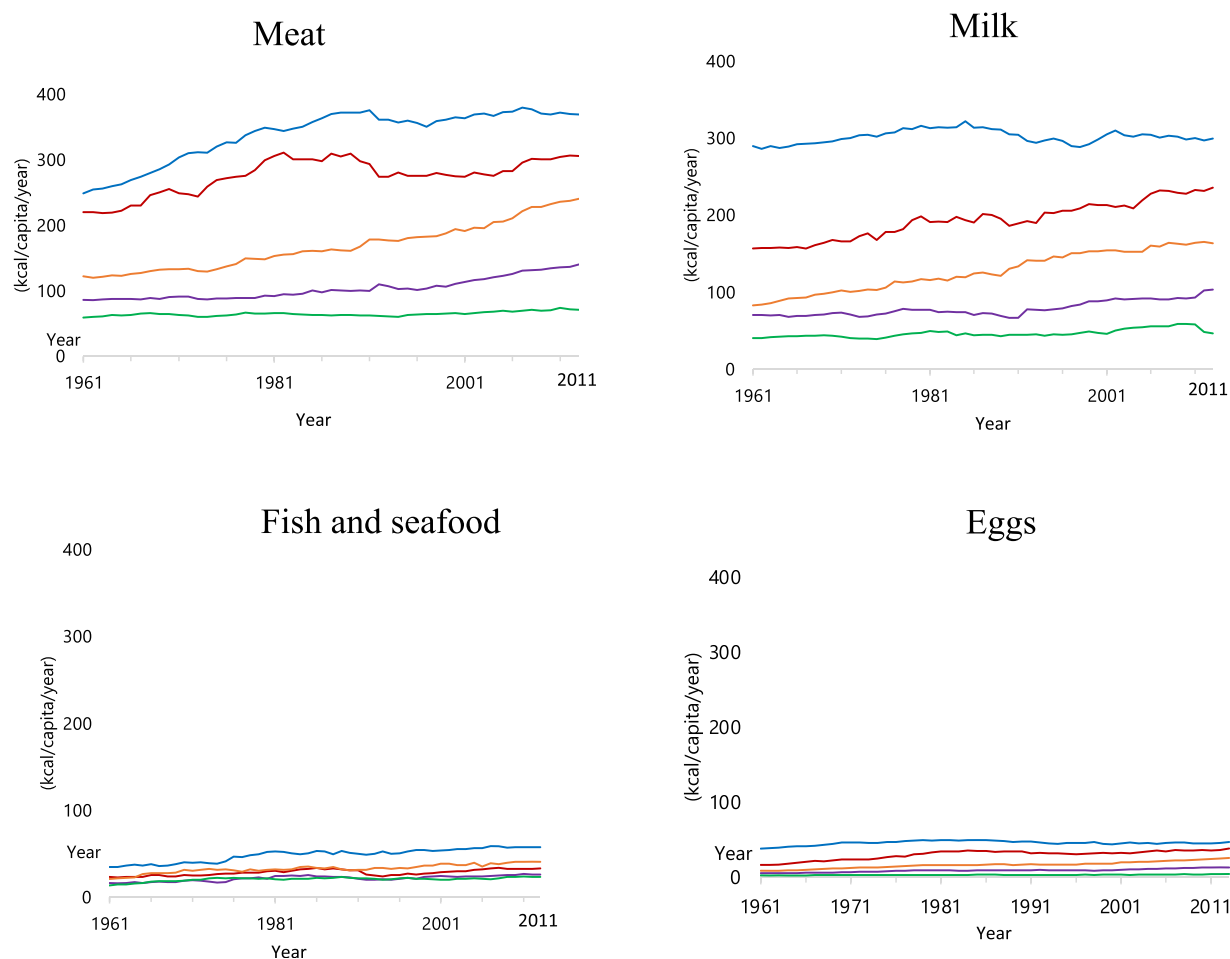

**Fig. 1** An overview of the principles of a sustainable diet. Adapted from [FAO and WHO \(2019\)](#).

**Fig. 2** Environmental effects per serving of food produced. Source: EAT Lancet. Permission has been obtained to reproduce.

**Fig. 3** Shifts in the availability of food over time (1961–2013) by SDI grouping. Source: FAOSTAT, <https://www.fao.org/faostat/en/>.

dairy (Fig. 4). It provides recommendations for the quantity of each food/food group to be consumed per day. While the diet is not designed to be prescriptive it provides guidance on a way forward to eat in a way that is healthy for people and for the planet. Current diets are not aligned to the “Planetary Health Diet,” with most regions overconsuming animal source foods and starchy vegetables while under consuming fruits, vegetables, legumes, nuts and whole grains (Willett et al., 2019).

While the “Planetary Health Diet” takes into consideration the health and environmental principles of sustainable diets, it fails to sufficiently account for social and economic aspects of diets. An analysis of the affordability of the diet found that it would be affordable for the average household in high-income countries (Hirvonen et al., 2020). However, it would exceed household per capita income for 1.58 billion people globally (Hirvonen et al., 2020), highlighting the need for sustainable diets to be assessed in a more comprehensive way.

### Measuring sustainable diets

Given the complexity of sustainable diets, and the breadth of elements that are included within its definition, identifying ways to measure them has been challenging. Most of the studies measuring sustainable diets that have been conducted to date have focused on the greenhouse gas emissions associated with dietary patterns (Jones et al., 2016; Eme et al., 2019). Fig. 5 summarizes the ways in which sustainable diets have been measured in the existing literature. In a systematic review conducted in 2016, 73% of papers focused on environmental outcomes, with less than a third focused on social or economic outcomes (Jones et al., 2016). A review conducted in 2019 found a similar pattern where the majority of studies focused on human and/or health outcomes, with fewer than 15% focusing on social and economic outcomes (Eme et al., 2019). In addition, most studies have focused on high income countries (Jones et al., 2016; Eme et al., 2019).

While studies examining both health and environmental outcomes can help in terms of assessing the environmental sustainability of our diets, social and economic considerations are important components of food choice. Without comprehensive

methodological approaches that include the social and economic dimensions of sustainable diets it will be difficult to weigh the trade-offs associated with the different dietary dimensions.

There are several gaps that remain regarding how to best measure sustainable diets in practice. Given the breadth of sustainable diets principles, an index that provides an overall composite score across the health, environmental, social and economic dimensions of sustainable diets could prove valuable. However, these types of indicators currently do not exist. Moreover, few studies have examined how to measure sustainable diets at the local level using comprehensive approaches that cut across the multiple dimensions of sustainable diets. However, the city of Milan has developed a monitoring framework that includes a myriad of indicators focused on enabling effective action (governance), sustainable diets and nutrition, social and economic equity, food production, food supply and distribution and food waste to monitor progress toward attaining its urban food policy pact. This monitoring framework provides a useful starting place for developing comprehensive assessments of local food and sustainability initiatives.

### Shifting consumption toward sustainable diets: what are the challenges?

As with the difficulties in measuring sustainable diets, there are also challenges related to promoting their consumption among consumers. While there are many strategies that can be adopted across the food system to reorient food systems toward more sustainable production and consumption, dietary change will also be necessary. Consumers will need to make significant changes to the way they procure, prepare and consume food in order to shift diets toward sustainable consumption patterns, such as the “Planetary Health Diet.” Promoting sustained shifts to diets is difficult. Even when there are direct benefits to personal health, individuals have a difficult time instituting long term lifestyle change. People have a difficult time evaluating and acting on trade-offs between present and future costs and benefits. Whereas most benefits of unhealthy options are certain and immediate, many potential costs are uncertain and far in the future.

Tackling embedded social and cultural norms within the everyday eating practices of individuals presents a plethora of challenges. Consumption is largely framed by the norms and social expectations of an individual’s various perceived in-groups: religious, ethnic, social, etc. (Vermeulen et al., 2020). Foods and meals also play multiple important social functions, often serving as a central point of human bonding, cultural preservation and bridging social cohesion. Adapting to new dietary norms often presents a conflict to longstanding foodways and cultural norms. For example, in many societies the consumption of animal products is deeply entrenched in socio-cultural practices and has long been equated with affluence, success and stability (Klaudia and Wojciech, 2018). This has been highlighted in recent years by the way that the global growth of the middle class, and overall increases in incomes, has driven significant increases in meat consumption as well as highly processed foods. While the importance of mainstreaming more plant-based diets has been identified by experts as a key step toward sustainability, the deeper psychological underpinnings that influence food choice need additional consideration (Klaudia and Wojciech, 2018).

Decisions about which foods to consume are influenced not only by socio-cultural and psychological factors but also the food environments that we interface with. Individual capacity to access healthy diets from sustainable food systems differs drastically across the globe based on geographic, political, environmental, and economic contexts.

Even where healthy foods produced within sustainable food systems are physically available, ensuring equitable access presents an additional challenge due to economic constraints. Along with taste, cost is one of the most important factors influencing food choice. While plant-based foods are often less expensive than animal products, consumers often pay a premium for value added foods (e.g., local, organic, animal welfare considerations, etc.). Local foods are one example of “value-added” foods (see Box 1). Given that many low-income populations are already spending a higher proportion of their income on food, and their food choices are already economically constrained, the price premium of foods that are produced in a more sustainable way may be prohibitive.

#### Box 1 Local food: its definition and sustainability characteristics

“Local food” is often considered as a geographic concept, referring to the distance from production to consumption. However, the definition of “local” varies by country and state. In 2008 the Food, Conservation, and Energy Act in the United States required that a locally or regionally produced agricultural food product must travel less than 400 miles from its origin, or within the State in which it is produced. Meanwhile, a growing number of people globally (especially in the USA and European Union) consider local to denote a closer geographic range: 100 miles. The French Ministry of Agriculture officially defines “short circuit” food as coming from within 150 km but sees it in the form of marketing which is done either by direct sales from producers to consumers or through indirect sales through no more than one intermediary between the operator and the consumer. In an example of even stricter guidelines, the state of Vermont legally defines local food as food produced within 40 miles. Currently, many countries do not have established guidelines for defining local foods, and the concept has been more prominent in the global north. Population density also strongly influences perceptions of local: individuals in dense urban centers have a different perception of distances needed to travel to access foods than those in sparsely populated and/or rural areas. Additionally, when considering a diet, the question of the quantity of food which must or should be local also arises.

However, “local” and “sustainable” cannot be treated as equivalent. Local doesn’t guarantee minimal environmental impact beyond transportation distance—which is not the only factor, nor is it one of the major factors, contributing to a food’s carbon footprint. Furthermore, short distance food supply chains don’t guarantee food security or social sustainability, as they are not always complex or dense enough to guarantee availability, or affordability (Stein and Santini, 2021).

At the crux of the issue related to equity and sustainable diets is that those with less income have more difficulty consuming foods which meet more stringent quality and environmental standards (organic, local or fresh vs. those from further fields and from increasingly industrial production methods). Moreover, consumers are often not paying the true cost of food—many of the externalities of food production such as environmental degradation or the health system costs associated with the food we consume are not reflected in the prices paid by consumers.

Consuming a sustainable diet, and promoting policies that support them, is further complicated by competing interests. The vested interests of agricultural organizations and commercial food companies are often in direct conflict with health and sustainability recommendations. Furthermore, in some countries such as the United States, the agencies providing dietary guidelines are the same agencies charged with supporting farmers and fostering stronger markets. This can create tensions in relation to advocating that populations reduce their meat consumption or for including sustainability considerations in dietary guidelines (Ahmed et al., 2019). Policy coherence across the food system as a whole is needed in order to ensure better alignment between food system incentives and dietary recommendations.

## Solutions to help support sustainable diets

The most effective strategies to shift diets toward sustainable diets will involve multiple approaches that deliberately aim to influence consumers as well as to incentivize all actors in the food systems to produce foods in a better way, while taking into account multiple agendas and values (Vermeulen et al., 2020). Both consumer-facing strategies as well as those targeting the more upstream drivers of food production and consumption will be necessary.

Three main categories of consumer-facing interventions to promote sustainable diets were previously identified, which include: (1) informing and empowering, (2) guiding and influencing, and (3) incentivizing, discouraging or restricting (Bailey and Harper, 2015) (see Fig. 6).

### Consumer-facing solutions

#### Inform and empower

Providing consumers with information about the sustainability of the foods they have access to, such as environmental labeling, can enable them to make more informed food choices (Bailey and Harper, 2015). Interventions that aim to inform and empower are the least intrusive strategies aimed at shifting consumers toward sustainable diet (Bailey and Harper, 2015). Two key ways in which policies and interventions have been used to inform and empower consumers to make more sustainable food choices is through the inclusion of sustainability in food based dietary guidelines and environmental food labeling.

	Inform and empower 	Guide and influence 	Incentivize, discourage or restrict 
Private Sector 	<ul style="list-style-type: none"> <li>•Product labeling with nutrition and sustainability information</li> </ul>	<ul style="list-style-type: none"> <li>•Positive positioning of healthy and sustainable foods within retail settings</li> <li>•Reduced plate/portion size in food outlets to encourage lower consumption</li> </ul>	<ul style="list-style-type: none"> <li>•Voluntary commitments to use sustainable ingredients (e.g., sustainable palm oil)</li> </ul>
Multi-stakeholders 	<ul style="list-style-type: none"> <li>•Public-private agreement on standardized labeling</li> <li>•Multi-stakeholder certification schemes</li> </ul>	<ul style="list-style-type: none"> <li>•Public-private agreement to reduce sales and marketing of unhealthy and unsustainable foods</li> <li>•Provide more tasty plant-forward foods in food outlets (e.g., Menus for Change Initiative)</li> </ul>	<ul style="list-style-type: none"> <li>•Public-private agreements to reduce content of desirable ingredients (e.g., sodium reduction targets)</li> </ul>
Public Sector 	<ul style="list-style-type: none"> <li>•Social marketing campaigns about sustainable diets</li> <li>•Advertising regulation</li> <li>•Labeling regulations</li> <li>•Food based dietary guidelines</li> <li>•Deliver culturally appropriate nutrition and sustainability education, sustainable food literacy and skills training</li> </ul>	<ul style="list-style-type: none"> <li>•Change default food options in public institutions to be more sustainable (e.g., Meatless Mondays)</li> <li>•Implement comprehensive school food programs that include healthy and sustainable school meals, standards combined with nutrition and sustainability education, school gardens, etc.</li> <li>•Adopt public procurement policies that prioritizes purchasing from small scale farmers, local, family and/or sustainable food producers</li> <li>•Restrict marketing of unhealthy and unsustainable foods to children</li> </ul>	<ul style="list-style-type: none"> <li>•Banning or restricting sale of unhealthy and unsustainable foods</li> <li>•Taxing unhealthy and unsustainable foods and subsidizing those that are healthier and more sustainable</li> <li>•Exclusion of unhealthy and unsustainable foods from public procurement</li> </ul>

Fig. 6 An overview of the points for intervening to shift consumption toward sustainable diets. Adapted from Bailey and Harper (2015).

- *Food based dietary guidelines*

One of the ways in which sustainable diets have been incorporated into government policies to date are through dietary guidelines. The FAO/WHO have released guiding principles for sustainable healthy diets (see Fig. 1) “to be further translated into clear, non-technical information and messaging to be used by governments and other actors in policy-making and communications” (FAO/WHO, 2019).

While guiding principles for sustainable healthy diets have been developed at the global level, individual countries develop their own food based dietary guidelines. Only a few of the nearly 100 countries globally with dietary guidelines include aspects of sustainability within them (Ahmed et al., 2019). Fig. 7 summarizes the sustainability considerations included in the dietary guidelines of countries globally (Rose et al., 2019). One of the most consistent messages across the dietary guidelines of countries that have included sustainability considerations is to consume a plant-based diet (Rose et al., 2019).

Given that dietary guidelines can have important implications for the implementation of government programs (e.g., school lunch programs), including sustainability considerations within them has the potential to make a significant impact on diets and environmental outcomes. Shifting toward adopting national food based dietary guidelines in their current state would lead to a reduction in environmental resource demand, including greenhouse gas emissions, by an average of 13% (Springmann et al., 2020). However, most dietary guidelines are incompatible with environmental targets in their current form (Springmann et al., 2020) and by including sustainability considerations they could have an even greater impact on environmental outcomes. For example, adopting the “Planetary Health Diet” would lead to a more than three times greater decline in greenhouse gas emissions and better attainment of environmental targets as compared to adopting current dietary guidelines (Springmann et al., 2020).

While it is clear that incorporating sustainability in dietary guidelines, particularly providing advice on limiting beef and dairy consumption, is important from an environmental perspective, it is often politically contentious. In the United States there was significant political backlash after the 2015–2020 Dietary Guidelines Advisory Committee included sustainability considerations in their report, leading to removal of sustainability considerations from the final guidelines. However, it may be possible to include aspects of sustainable diets in food based dietary guidelines without explicitly referring to sustainability in an effort to limit political opposition. A study examining the inclusion of ecological, economic, social and health dimensions of sustainable diets in food based dietary guidelines found that some countries that had not explicitly framed their dietary guidelines as including sustainability considerations still addressed many aspects of sustainable diets within their guidelines (Ahmed et al., 2019). For example, Brazil’s dietary guidelines covered the widest range of dimensions of sustainable diets without explicitly referring to sustainability within them (Ahmed et al., 2019).

Given the global need to shift food choices toward more plant-based diets, there is a clear need for dietary guidelines to begin to include aspects of sustainable diets, whether explicit or not, within them. This then has the potential to influence public and institutional procurement policies providing incentives for changes to the food supply as well as food environments.

- *Environmental food labels*

Food labels have the potential to influence food choices; however, the evidence of health and nutrition labels leading to changes in purchasing behavior has been mixed (Hawkes et al., 2015). Labels appear to fill an information gap for people who already

Fig. 7 Sustainability considerations in dietary recommendations in various countries. Adapted from Rose et al. (2019).

have healthy preferences but are limited by the lack of point-of-purchase information to make choices aligned with their preferences (Hawkes et al., 2015). Environmental sustainability or eco labeling has recently become more popular. However, unlike nutritional labeling, most environmental labeling schemes are certification initiatives rather than providing information about the environmental impacts of particular foods (Bailey and Harper, 2015). These labels assure consumers that the food meets specific minimum sustainability standards. While high quality studies are needed to evaluate the impacts of environmental labeling, there is some evidence to suggest that these approaches can influence consumer food choices (Potter et al., 2021). However, there are gaps in the current evidence base related to the types of labels that have the greatest impact on consumer food choices.

### **Guide and influence**

Interventions that nudge or provide cues to consumers to consume specific foods could be employed to increase consumption of sustainable diets. Setting defaults as the healthier option have shown some success in terms of improving the nutritional quality of foods purchased. Institutions such as schools, hospitals and government buildings can be ideal settings for these types of interventions. Meatless Mondays and the Menus of Change, which has developed principles of healthy, sustainable menus, are other examples of ways in which consumers can be nudged toward more sustainable food choices.

### **Incentivize, discourage or restrict**

Interventions that incentivize, discourage or restrict can help incentivize consumption of foods that are more sustainable, while discouraging those that are not. There is strong evidence to suggest that the use of taxes and subsidies can change consumer purchasing behavior (Thow et al., 2018). Overall, the strongest evidence relates to taxes on sugar-sweetened beverages and subsidies on fruits and vegetables (Thow et al., 2018). Given that beef contributes disproportionately to the environmental footprint of food production and consumption, adopting taxes aimed at reducing its consumption has the potential to improve environmental outcomes. While there is little evidence of the impact of fiscal policies targeting beef consumption, modeling studies have found that taxing red meat would lead to benefits from a health and environmental perspective (Springmann et al., 2018). Denmark is one of the only countries to date to have implemented a tax that would apply to red meat. In 2011, they implemented a tax on saturated fat that applied to foods high in saturated fat, including red meat (Jensen et al., 2015). While the tax was rescinded shortly after its implementation due to political backlash, it led to a 13–16% increase in the price of high fat varieties of minced beef and cream products which yielded a 4–6% decrease in intake of saturated fat from minced beef and regular cream (Jensen et al., 2015). While these findings imply that fiscal policy could be used to incentivize consumption of sustainable diets, there are several limitations of its use.

A sustainable diet includes a variety of different foods which makes it difficult to identify which foods should be targeted in fiscal policy approaches. While there have been studies that have modeled the effects of taxes across all foods based on GHG emissions (Latka et al., 2021), this type of approach may not be politically feasible. Moreover, to reach nutrition and environmental sustainability targets, considerably high tax levels are required (Latka et al., 2021). Sugar sweetened beverage taxes have led to shifts in consumption at relatively low levels (~10%), whereas modeling studies examining taxes on red meat have suggested that taxes would need to be upwards of 100% or higher (Latka et al., 2021; Springmann et al., 2018).

Another challenge associated with the use of taxation to incentivize the consumption of sustainable diets is that these taxes tend to be regressive (Thow et al., 2018). Red meat contains many key nutrients (e.g., iron, zinc, etc.), as do many other animal source foods. Moreover, consuming animal source foods could help to reduce stunting and other forms of malnutrition among populations living in low resource settings globally. There are thus ethical implications related to increasing the cost of accessing these key nutrients by low-income populations. This creates challenges in terms of the way in which taxes aimed at increasing consumption of sustainable diets are framed. Coupling taxes with subsidies on other nutrient-rich foods (e.g., fruits and vegetables) could help to at least partially address the regressivity of these types of taxes.

### **Supply-side solutions**

The aforementioned consumer-facing strategies aimed at supporting sustainable diets need to be complemented with interventions throughout the food supply chain in order to make foods that comprise a sustainable diet more available, affordable and appealing. Innovative technologies will play a critical role in terms of reorienting food production, and the way it moves through supply chains, toward more sustainable practices. While many of the production practices that are currently used by subsistence farmers are more sustainable than industrial farming practices, such as increased diversity on farms, use of organic fertilizer, etc., there is a large yield gap. Introducing improved farming practices and increasing the adoption of technology and higher quality seed could help to address these gaps, increasing the sustainability of these production systems. Government incentives (including subsidies in some cases), investment in R&D and strengthening of extension services could also help to identify and implement farming, fishing and rearing practices that reduce the environmental impact of food production, including through improved feed, increased diversification of farms, the adoption of circular economy, etc. Improvements in food processing, packaging (i.e., biodegradable, fewer plastics, etc.), and distribution (i.e., use of electric vehicles) will also help increase the sustainability of foods that are available within the food environments that consumers interface with.

## Advancing the sustainable diets agenda: the role of different stakeholder groups

There are various stakeholders that can help to support healthy diets from sustainable food systems. While UN agencies, government and the private sector have an important role to play, we highlight the particular influence of local government and social movements in this section.

### The role of local government

Local governments are in a unique position to adopt innovative policies that support sustainable diets. There are many examples of cities around the globe that are working toward supporting more sustainable food systems in order to mitigate the negative environmental, health, and socioeconomic outcomes associated with current practices. Perhaps most notably, the mayor of Milan, Italy created an international agreement, Milan Urban Food Policy Pact (MUFPP), for cities and urban areas to adopt an action framework for food policy to measure its impact on diet quality and accessibility, as well as its impact on the environment and food supply chain (<https://www.milanurbanfoodpolicycompact.org>). As of April 2021, 211 cities around the world had committed to adopting food policies to tackle at least one of the six areas of focus: governance, sustainable diets and nutrition, social and economic equity, food production, food supply and distribution, and/or food waste. While cities from all continents have signed on to the MUFPP, those who have already planned and activated a food strategy are concentrated in Europe, North- and Latin America. Two-hundred and eleven cities around the world have committed to adopting food policy to tackle at least one of the six areas of focus. While cities from all continents have signed on to the MUFPP, those who have already planned and activated a food strategy are concentrated in Europe, North- and Latin America.

While many of the examples of local government approaches to supporting sustainable diets and food systems are from high-income countries (see [Box 2](#)), there are also examples from low- and middle-income countries. Arusha, Tanzania joined the MUFPP in 2015 and in 2018 launched its first food policy initiatives. The city has intentions of matching rapid urbanization with environmental protection policies in order to promote food safety while mitigating inefficient agriculture practices such as inappropriate use of crop protection products, like overuse of pesticides. By partnering with the MUFPP, partnerships with various NGOs have fostered the establishment of over 200 gardens and a wet market in order to promote biodiversity and food access, demonstrating the potential for cities around the world to put sustainable diets on the agenda and make a real impact on their communities.

### The role of social movements and role models

Consumer organizations, grassroots movements and non-governmental organizations have an important role to play in promoting sustainable diets. Given the necessity of societal buy-in and bottom-up action to achieve dietary shifts, there is a strong potential role for social movements and local organizing to influence behavior and drive social change toward sustainable diets. Past environmental movements have relied heavily on the power of social movements to carry their messages, and to drive broad spread action, policy change and reframe social norms. In 2019, the UN Secretary-General directly named “people action”—including by youth, civil society, the media, the private sector, unions, academia and other stakeholders, to generate an unstoppable movement pushing for the required transformations—as one of the three necessary levels to accelerate sustainable solutions to key global issues.

#### Box 2 Examples of approaches to support sustainable diets and food systems by local governments

New York City (NYC) is one local municipality where multiple strategies have been underway to encourage sustainable practices, including: animal welfare practices and waste management, dietary recommendations and their relation to sustainability, reducing air pollution and greenhouse gas emissions from food transport and storage, promoting innovation in food and sustainability research and public procurement guidelines stipulating the inclusion of local and state grown produce. Additionally, since 2011 NYC releases annual Food Metrics reports to track and realign progress toward its food and sustainability goals. In February 2021, the city released a 10-year food policy plan that refines and expands the previous 2011 plan and includes a school education program focused on sustainability, as well as encouraging private sector partnerships with community stakeholders to promote sustainable food campaigns. Additional information can be found here: <https://www1.nyc.gov/site/foodpolicy/index.page>.

Similarly, the city of Toronto, Canada launched the Toronto Food Strategy in 2010 to continually develop innovations to promote resident and environmental health through their food system. The plan defines a sustainable diet as one that is able to provide people nutrients without negatively impacting the environment and ensuring equity. Additionally, Toronto has adapted a food system monitoring framework in order to keep track of their sustainability goals over time. The Toronto Food Strategy is unique in that it emphasizes a multifactorial approach toward sustainability goals focusing on not only ecological/environmental and health impacts, but also promoting social justice as a necessity to meet those goals. Additional information can be found here: <https://www.toronto.ca/community-people/health-wellness-care/health-programs-advice/toronto-food-strategy/background/>.

Birmingham, UK partnered with Pune, India to join the MUFPP in 2016 as “Food Smart Cities” to utilize data and invest in innovation in order to make the food system more sustainable. The partnership between the two cities aims to develop policies that encourage the consumption of safe, healthy, and sustainable foods. By having similar approaches to issues such as COVID-19 and malnutrition, the cities are able to work together with compiled data to form their best mitigation approaches moving forward. Additional information can be found here: <https://commonwealthsustainablecities.org/europe/nutrition-smart-cities-birmingham-india-nutrition-initiative-in-birmingham-and-pune/>.

Social pressure is one of the strongest motivators when it comes to behaviors related to sustainability and the environment. For example, highlighting the increasing normality of eating less meat, telling people that most other people recycle, or use less energy (Vermeulen et al., 2020) have all been shown to have impacts on individual behavior when communicated by peers. Grassroots movements and social campaigns therefore present strong inroads to drive social change.

Starting in the 1980s, the Slow Food movement began modeling how food, and the choices made within and about the food system, can be used to protect communities, preserve culture and biodiversity and protect the environment. In subsequent decades we have seen the growth of these global social campaigns focused on changes to diet and food choices as drivers of human and environmental health. Increasingly, these movements, such as the Food Justice Movement, have focused on racial and economic disparities.

The resurgence of the urban agricultural and community garden movements in the global North presents an opportunity to promote personal and community food growing, and to adopt more neighborhood centric models of food production and distribution. The local food growing movement and its related platforms create strong entry points to conversations about changing dietary needs as well as a deeper understanding and interest in sustainable food production. Importantly, it also serves to normalize the idea and acceptability of urban food growing and engages people in a stronger understanding about where food comes from.

Food, Beverage and Hospitality have taken on a new status in the past decade with the exponential expansion of food media and content across all platforms (from socio-cultural cooking podcasts like “Good Foods” to food adventure travel like Anthony Bourdain’s *Parts Unknown*, and Chef and Server Memoirs ala *Bittersweet*). This has increased the visibility and opportunities for chefs, restaurants and companies to inform and influence opinions and habits connected to food systems. Increasingly, celebrity chefs are highlighting the importance of sustainability, from NYC Blue Hill (NYC) and NOMA (Copenhagen) restaurants ongoing focus on regional, seasonal foods and sustainable sourcing to bolster local supply chains, to Eleven Madison Park’s (NYC) post pandemic rebirth as a vegan based fine dining experience. Chefs are centering their menus on more sustainable models and introducing these ideas to consumers. We have seen the growth of the “farm-to-table” and “eat local” movements, which has increased the number of restaurants focusing on local, sustainable and seasonal foods, including some fast casual chains (e.g., Digg In and Sweetgreen in the United States). There are also encouraging opportunities to model behavior and drive change being brought about through corporate socio-environmental responsibility and a focus on more environmentally friendly and healthy foods. Examples of this include: Epicurious’ move to no longer publishing new meat recipes; Burger King’s launch of vegan “chicken” sandwich in the UK and meatless Impossible burgers throughout the US and UK; Chipotle’s ongoing drive to increase its local and organic ingredients, etc. While these examples are mostly from the United States, this trend toward more environmental consciousness is also being seen in other parts of the world. However, it is important to note that much of the messaging around sustainability continues to target energy-dense foods of low nutritional value leading to concerns related to “greenwashing.”

## Research gaps and recommendations for moving toward sustainable diets

There are many gaps in the way in which sustainable diets are measured, particularly as it relates to the ways in which trade-offs among different dimensions of sustainable diets are considered. Moving forward, additional research is needed to provide guidance on the most appropriate ways to measure the multiple dimensions of sustainable diets, including how to weigh and balance trade-offs. Sustainability considerations have largely been missing from the food environment literature but given that it is the place within the food system that consumers interact with to make decisions about the foods to acquire and purchase, improved understanding regarding how best to measure sustainability properties within the food environment will become increasingly critical. Identifying a suite of indicators that could be used to measure the different dimensions of sustainable diets, at different scales (including national, regional and local level) would help to provide researchers and practitioners with the necessary measurement tools to comprehensively assess sustainable diets in different contexts as well as how they change over time.

Another key gap in the current evidence base that merits additional research relates to the most effective ways to influence populations to consume sustainable diets. Of the interventions aimed at increasing consumption of sustainable diets that have been conducted to date, few have included strong evaluations of their impact and implementation (Bailey and Harper, 2015). The majority of studies that have examined the impact of interventions aimed at increasing plant-based diets have focused on fruits and vegetables, which limits our understanding of the impact of interventions aimed at reducing consumption of animal source foods with high environmental footprints (Taufik et al., 2019). Changing consumer food choices is difficult. It is therefore imperative that consumer-facing interventions aimed at increasing demand for sustainable diets are combined with supply-side policies and interventions aimed at increasing the availability, affordability and appeal of sustainable healthy foods.

## Summary

In summary, shifting global diets toward more plant-based foods (e.g., Planetary Health Diet) would lead to considerable reductions in the environmental impact of our diets. However, interventions aimed at shifting consumption toward plant-based diets need to also consider the economic and social considerations that influence their consumption. Interventions across the food system as a whole will be needed to incentivize food system actors and consumers to produce and consume a sustainable diet. While there is some evidence to suggest potential approaches to support and promote sustainable diets, significant research gaps remain.

Future research should focus on identifying better ways to measure sustainable diets in a comprehensive way and to develop innovative solutions targeting various food system actors to reorient food production and consumption toward more sustainable practices.

## Key points

- There is one primary sweet taste receptor that is activated by both nutritive sweeteners and low calorie sweeteners (LCS).
- Sweeteners vary in the intensity of the sweetness they impart and LCS also elicit various side tastes, LCS are not sweeter than sucrose, they just achieve this sweetness intensity at low concentrations.
- Sweeteners vary in their digestion, microbial fermentation, and peripheral distribution with uncertain metabolic and health implications.
- Sweeteners are inherently pleasant, but their appeal and consumption are determined more by dietary experience and culture.
- While multiple health organizations have recommended that added/free sugar intake should not exceed 10% of energy intake, data suggest that many people fail to meet these recommendations.
- Use of LCS has grown globally and is projected to continue; there is considerable consumer interest in “natural” LCS compared to synthetic LCS.
- Several policy approaches have shown promise in reducing added sugar consumption.
- Sugar intake is associated with the risk of overweight, obesity, cardiovascular disease (CVD), type 2 diabetes mellitus (T2DM) (in the form of sweetened beverages), and dental caries. The association with cancer risk is inconclusive.

- Although LCS intake was positively associated with BMI in some prospective cohort studies, interventional studies consistently reported greater weight reduction with LCS use. There is a lack of association between LCS and CVD, T2DM, and cancer.

## Introduction

Sweeteners comprise a wide variety of substances that produce a sensation of sweetness when consumed. While individuals will differ on their preferred concentration, sweetness is considered to be hedonically pleasing, and sweet foods are readily consumed. Given the associations between dietary intake and chronic disease, sweeteners have come under scrutiny for their role in conditions including obesity, diabetes, and cancer. This chapter discusses sweet taste biology, trends in both nutritive and low calorie sweetener consumption, and the associations between sweetener consumption and disease.

## Sweetener taste, digestion, and appeal

### Receptor

Sweetness is a sensation imparted by a wide range of chemicals (Table 1). Nevertheless, sweetness is transduced (converted from an external chemical signal to an internal electrical signal) primarily by a single sweet taste receptor. This receptor is a heterodimer comprised of the G-protein coupled receptors: taste receptor type 1 receptor 2 (T1R2) and taste receptor type 1 receptor 3 (T1R3). The receptor has three domains, the amino terminal domain (ATD), a cysteine-rich domain (CRD) and a trans-membrane domain (TMD). The diverse chemicals that impart sweetness do so by binding to the different domains on each protein. For example, glucose binds primarily to the ATD of T1R3; aspartame, neotame and D-tryptophan bind to the ATD of T1R2; thaumatin and brassinin bind to the CRD of T1R3; and cyclamate and neohesperidine dihydrochalcone bind to the TMD of T1R3 (DuBois, 2016). T1R3 alone can also serve as a sweet receptor but has lower sensitivity and primarily binds nutritive sweeteners (Damak et al., 2003). Following binding of a sweetener to a receptor on a taste cell, a cascade of cellular events occurs leading to the release of neurotransmitter resulting in the generation of an electrical signal that is conveyed by afferent nerves first to the nucleus of the solitary tract in the brainstem, next to the thalamus and finally to subcortical and cortical areas. These latter sites are reciprocally innervated with other brain centers allowing for integration of multiple sources of input and formation of a hedonic perception and early indication of the stimuli's safety (Chaudhari and Roper, 2010; Vincis and Fontanini, 2019).

An additional sweetener signaling system, that may not produce a cognitively apparent sensation, has also recently been identified and serves a different but inter-related purpose. Sensory stimulation alone by various sources (e.g., vision, olfaction, taste) elicit neurally-mediated physiological responses that mimic those occurring during food digestion and nutrient absorption and metabolism. These responses are termed first or cephalic-phase responses, and they reportedly prime the body to efficiently process ingested foods. For example, a cephalic phase insulin response (CPIR) is documented in humans to foods generally, but also to nutritive and low-calorie sweeteners (LCS) (see Dhillon et al., 2017). This response helps to modulate post-prandial glycemic responses (Calles-Escandon and Robbins, 1987) and is blunted or absent in patients with diabetes (Davies et al., 1994; Del Prato and Tiengo, 2001). Based on rodent studies, the CPIR may be activated by a transporter mechanism involving K<sub>ATP</sub> channels. CPIR-activated taste cells responsive to sweeteners also release GLP-1, which acts as an incretin stimulating pancreatic insulin release (Kokrashvili et al., 2014).

**Table 1** Sweetener types.

<i>Class of stimuli</i>	<i>Effective stimuli</i>	<i>Sweetener examples</i>
Carbohydrate	Monosaccharides	Glucose, fructose, galactose
	Disaccharides	Sucrose, lactose, maltose, isomaltulose
	Short chain oligosaccharides	Inulin, maltotriose
	Sugar alcohols	Mannitol, sorbitol, xylitol, lactitol, isomalt, maltitol, erythritol
Protein	Amino acids	Tryptophan, alanine, asparagine, glutamine, histidine, leucine, serine
	Dipeptides	L-aspartyl-L-phenylalanine methyl ester (aspartame), neotame, advantame
	Polypeptide	Curculin, monellin, brazzein, miraculin, thaumatin
Miscellaneous	Low calorie sweeteners	Steviol, cyclamic acid, saccharin, acesulfam-potassium, alitame, neohesperidine-dihydrochalcone
Heavy metals	Ions	Lead, beryllium

The sensation imparted by sweeteners is, by definition, sweetness, though some sweeteners also activate other taste receptors leading to additional taste qualities, most notably bitterness. For example, saccharin and acesulfame-potassium (Ace-K) bind to the bitter receptors coded by the TAS2R31 and TAS2R43 genes (Kuhn et al., 2004). Such undesirable taste notes can be minimized by reducing the concentration of the sweetener. Mitigating off-tastes is one reason for using blends of sweeteners. Additionally, there is marked individual variability in sensitivity to the bitterness of these sweeteners. At least part of the explanation for this lies with polymorphisms in bitter receptors (Allen et al., 2013). LCS can also stimulate oral, non-taste, receptors leading to metallic, liquorice, and irritancy sensations. Additionally, LCS vary markedly in the temporal pattern of sensations they elicit. Time-intensity profiling indicates the time from stimulus presentation to onset of sensation is: stevia > neotame > aspartame > sucralose, Ace-K. Because of differences in rise and decay times, their duration of sensation follows a pattern of neotame > sucralose and aspartame > stevia > Ace-K (Moraru, 2011; Tan et al., 2019).

The sweetness of LCS are often rank ordered relative to sucrose; examples are provided in Table 2. However, it is important to note that sweetness does not grow linearly with concentration. The relationship is better fit by a power function with an exponent of about 1.3 (Moskowitz, 1970). Thus, the actual sweetness relative to sucrose will vary with concentration. Additionally, the sweetness values for LCS are based on the concentration required to achieve a given level of sweetness. They are not actually capable of eliciting a sweetness intensity greater than high concentrations of sucrose. In humans, the curve relating sweetener concentration with sensation intensity asymptotes at about 10% sucrose in water. Introspection leads to the realization that no two sweeteners impart a sensation that differs by a hundred- or thousand-fold as tables often imply. Interestingly, when matched on sweetness intensity, some studies suggest nutritive sweeteners are more potent activators of brain reward centers (Han et al., 2019) and in taste receptor knock-out mice, ingestion of a sucrose solution is maintained over a sucralose solution (De Araujo et al., 2008). However, a recent systematic review failed to confirm robust differences between sweetener types on brain activation (Yeung and Wong, 2020).

**Table 2** Relative sweetener taste intensity.

<i>Sweetener</i>	<i>Sweetness intensity relative to sucrose</i>
Acesulfam-K	200
Advantame	20,000
Agave syrup	1.56–1.92
Aspartame	180–250
Cyclamate	26–30
Erythritol	0.70
Fructose	1.17–1.75
Galactose	0.35
Glucose	0.74–0.8
Glycyrrhizin	50
High fructose corn syrup	1.2–1.6
Isomalt	0.5
Isomaltulose	0.5
Lactitol	0.4
Lactose	0.16–0.2
Maltitol	0.7
Maltodextrin	0.1
Maltose	0.33–0.5
Mannitol	0.7
Mannose	0.6
Monk fruit (Luo han Guo)	100–250
Neohesperidin dihydrochalcone	340
Neotame	7000–13,000
Saccharin	200–700
Sorbitol	0.6
Steviol glycosides	40–400
Sucralose	600
Sucrose	1
Sugar alcohols	0.25–1
Tagatose	0.8
Thaumatococcus	200–1000
Trehalose	0.6
Xylitol	1
Xylose	0.5

## Toxicology

The safety of LCS has been an ongoing topic of debate. However, the regulatory bodies of many nations have thoroughly reviewed the toxicological evidence and concluded that, when consumed within the acceptable daily intake (ADI) level, they are safe. The ADI is generally calculated as the concentration that is one-hundredth of the no observable adverse effect level. However, the ADI does vary across nations. For example, for Ace-K, it is set at 9 mg/kg body weight by the European Food Safety Agency; 15 mg/kg body weight by the Food and Drug Administration and Joint Commission of Experts on Food Additives of the World Health Organization and the Food and Agriculture Organization; and 40 mg/kg body weight by the Danish Veterinary and Food Administration (Mattes and Popkin, 2009).

## Digestion and absorption

The sweet taste receptor is referred to as a “taste” receptor because it was first characterized in the oral cavity and is the initial site for activation of the sense of taste. However, the identical receptor is present throughout the GI tract and in a variety of peripheral tissues including bladder, pancreas, thymus, brain, testes, and bone (Behrens and Meyerhof, 2019). In these other locations, the receptor does not mediate a taste sensation. Rather, when activated, it stimulates the functions of the cells on which the receptor is located. Thus, binding of a sweetener to the receptor on an enteroendocrine or pancreatic islet cell leads to release of gut peptides or insulin, respectively. Consequently, the potential physiological effects sweeteners may exert will be, in part, a function of their digestion, absorption, and distribution. If a sweetener is not absorbed from the GI tract, it will not be available to bind to a receptor in the periphery. If it is degraded or fully absorbed in the upper small intestine, it will not be available further downstream as a substrate for the microbiota. There is considerable variability in GI processing even within a class of sweet compounds. For example, among the sugar alcohols, erythritol is largely absorbed in the small intestine whereas isomaltulose is only partially absorbed in the small intestine and lactitol is generally not absorbed in that region. The fate of selected sweeteners is outlined in Table 3 and further described below:

## Sugar

The predominant dietary nutritive sweeteners are the disaccharides, sucrose and lactose. Greater than 90% of these energy sources are absorbed. They are digested to their constituent monosaccharides via enzymatic degradation. This is accomplished by the brush border hydrolases, sucrase and lactase. Sucrose yields glucose and fructose while lactose is reduced to glucose and galactose. Glucose and galactose are transported primarily into jejunal enterocytes by the sodium-dependent hexose transporter, SGLT-1. At high glucose concentrations, the low-affinity, high-capacity transporter, GLUT-2, is also recruited. Fructose enters the enterocyte via the hexose transporter, GLUT-5. All three monosaccharides exit the enterocyte and enter the blood stream by GLUT-2. Based on

**Table 3** Sweetener digestion, absorption and metabolism.

Sweetener	Digestion-absorption-excretion
Glucose	>90% absorbed by transporter from intestinal lumen and released as glucose by another transported into the circulation. Used by peripheral cells for energy.
Fructose	Absorbed by intestinal transporter with efficiency determined, in part, by dietary exposure. Variable amounts are converted to glucose in the enterocyte and the balance is released into circulation where it serves as an energy substrate.
Galactose	>90% absorbed by transporter from intestinal lumen and released as glucose by another transported into the circulation. Used by peripheral cells for energy.
Sucrose	Digested to glucose and fructose by brush border sucrase. Each monosaccharide is processed as above.
Lactose	Digested to glucose and galactose by brush border lactase. Each monosaccharide is processed as above.
Aspartame	Hydrolyzed by gut esterases and peptidases to ASP, PHE, and methanol.
Sucralose	Minimally digested and absorbed, 90% enters colon.
Saccharin	Not digested; absorbed and ~95% excreted in urine.
Acesulfam-potassium	Not digested; absorbed and 99% excreted in urine.
Stevioside & rebaudioside A	Enters the colon intact. In the colon, sugar moieties are removed and the steviol backbone is absorbed, conjugated with glucuronide, and excreted in urine.
Neohesperidin dihydrochalcone	Minimally absorbed. Fermented in the colon.
Neotame	Equally excreted in urine and feces.
Cyclamate	Small amount metabolized in the colon, mostly eliminated in feces.
Erythritol	90% absorbed in the small intestine and excreted in the urine.
Isomalt	Up to 10% absorbed in the small intestine; fermented in the colon.
Lactitol	Not absorbed in the small intestine; fermented in the colon.
Sorbitol	Partially absorbed in the small intestine; fermented in the colon.
Mannitol	Up to 25% absorbed in small intestine; fermented in the colon.

isotope tracer studies in mice administered low to moderate concentrations of glucose and fructose in a 1:1 ratio (as would occur with sucrose ingestion and be very similar with high fructose corn syrup intake), approximately 42% of this fructose is converted to glucose, glycerate, and organic acids (Jang et al., 2018). Only 14% of ingested fructose enters the blood intact. At higher fructose intakes, greater than 1 g/kg, fructose enters the circulation at higher concentrations, but some is passed downstream where it can serve as a substrate for the microbiota. The extent of this spill-over is based, in part, on customary fructose intake. High intake increases fructose absorption and concentrations in portal blood, but this is reversible with lower intake. Fructose derived from sucrose or high fructose corn syrup is processed similarly (Jang et al., 2018). Whether these recent findings in mice hold quantitatively for humans remains to be determined, but it is likely the trends are conserved across species.

### Low calorie sweeteners

Reflecting their different chemical structures, low calorie sweeteners undergo diverse digestive and absorptive processes (Magnuson et al., 2016). Examples are provided below:

Aspartame is hydrolyzed in the upper small intestine to aspartic acid, phenylalanine, and methanol. These by-products, but not the parent compound, are absorbed into the circulation. The amino acids are available for protein synthesis and the methanol is oxidized in the liver. Thus, this sweetener does not enter the circulation so cannot bind to peripheral sweet receptors nor pass into the large intestine and serve as a substrate for the microbiota. Any effects of this sweetener on metabolism and health would have to occur by an alternate mechanism, (e.g., cephalic phase responses).

Ace-K is almost completely absorbed through the small intestine and enters the circulation. Absorption efficiency is not determined by level of exposure. Ace-K is not metabolized and is cleared rapidly, primarily by the kidneys, and excreted in the urine. However, low concentrations have also been detected in breast milk (Sylvetsky et al., 2015). Thus, this sweetener would theoretically have the capacity to serve as a ligand for peripheral sweet receptors.

Saccharin is largely (85%–95%) absorbed through the small intestine and enters the circulation. It is not metabolized and is cleared rapidly, primarily by the kidneys, and excreted in the urine. However, low concentrations have also been detected in breast milk (Sylvetsky et al., 2015). Thus, saccharin would have the capacity to serve as a ligand for peripheral sweet receptors. A small fraction (5%–15%) of saccharin passes into the colon. However, given the very low concentration initially ingested (due to its high potency as a sweetener) and efficient absorption, its concentration in the colon is extremely low. Thus, it is unlikely it serves as a meaningful substrate for the microbiota though a role in gut signaling is possible.

Sucralose is primarily (~90–95%) undigested. Seventy to ninety percent is lost in feces with about 14% excreted in urine. It is highly resistant to microbial fermentation or degradation in various tissues. It has been detected in breast milk (Sylvetsky et al., 2015), so it may also be excreted through lactation. Concentrations in the circulation will be low due to the limitations of its intake by its high potency sweet property and the dilution by blood. Sucralose is highly resistant to microbial metabolism. Frequency of exposure to sucralose does not alter its digestion, absorption or excretion. The small fraction entering the circulation would be available to serve as a ligand for peripheral sweet receptors. It may also exert a physiological effect in the GI tract and periphery via neural signaling.

Steviol Glycosides are digested by bacteria in the colon to steviol. Steviol is resistant to further bacterial digestion. The steviol moiety is absorbed slowly and is converted to the glucuronide in the liver. Steviol glucuronide is then transport via the bile duct back to the colon where 95% of an ingested amount is excreted. The balance is excreted in the urine. Concentrations will be limited by its high sweetness potency that will moderate ingestion and its concentration will be diluted in the circulation. Nevertheless, it will be available to bind to peripheral sweet receptors. It may also exert a physiological effect in the GI tract and periphery via neural signaling.

### Gut signaling

It is well established that carbohydrate ingestion stimulates the release of gut peptides such as GLP-1, GIP, and PYY from enteroendocrine cells in the small intestine. These hormones reportedly modulate appetitive sensations, influence GI transit time, and act as incretins, stimulating the release of insulin from the pancreas. With the identification of sweet taste receptors on enteroendocrine K, L, and K/L cells and co-expression of  $\alpha$ -gustducin (a component in the taste transduction system) in several animal models and humans, the possibility was raised that sweeteners could activate these cells with implications for glycemia, appetite, and energy balance (Bryant and McLaughlin, 2016). Moreover, it was demonstrated that sweet receptor regulated SGLT1 expression and glucose absorptive capacity increase in response to luminal sugars and LCS in mice (Margolskee et al., 2007). Early reports based on cell culture (Jang et al., 2007) or rodent models (Mace et al., 2007) indicated that LCS could stimulate GLP-1 release and enhance glucose transport across enterocytes possibly raising post-prandial glycemia. Subsequent rodent studies indicated glucose was effective but not a range of LCS (Fujita et al., 2009). This was followed by several human trials that yielded no robust or consistent effects (e.g., Ma et al., 2010; Pepino et al., 2013; Brown et al., 2009; Steinert et al., 2011; Wu et al., 2012; Bryant et al., 2014; Bryant and McLaughlin, 2016). At present, the findings in rodent models do not appear to translate to humans.

### Microbiome

The microbiome is responsive to short and longer-term dietary intake. Sensory and nutritive properties of foods and beverages influence ingestive decisions and activate neural and endocrine signaling pathways that influence digestion dynamics and, as a result, the

types and quantities of food components that reach the colon. These substrates are then differentially used by the various colonic bacterial species leading to changes in their balance and the metabolic products produced. Understanding of these process is incomplete, hampering predictions of how individual sweeteners will impact the microbiome and health-related outcomes.

### **Sugar**

Except under pathological and specific non-pathological conditions (e.g., disaccharide intolerance), most nutritive sweeteners are efficiently digested and absorbed in the small intestine so are not present in appreciable amounts to serve as substrate for colonic bacteria. Exceptions include selected polyols (e.g., maltitol, xylitol, isomalt, lactitol). Erythritol, sorbitol, and mannitol do not affect the microbiota, and some sweet oligosaccharides are poorly digested (Ruiz-Aceituno et al., 2018). These may be added to foods for their prebiotic properties. They reportedly hold promise for a number of health outcomes (Belorkar and Gupta, 2016) that will require additional study to confirm.

### **Low calorie sweeteners**

There are multiple, recent critical reviews of the evidence linking LCS consumption with the microbiome (Glendinning, 2018; Ruiz-Ojeda et al., 2019; Lobach et al., 2019). Evidence from animal trials reveals different patterns of effects for selected LCS. Alterations of microbial communities have been reported with saccharin, aspartame, sucralose, stevia, and ace-K. The mechanisms for these effects remain to be elucidated since aspartame does not reach the colon and saccharin and Ace-K do so in very minimal amounts. Additional concerns about these findings include the use of non-physiological dosing in some studies; failure to control the total diet, hampering attribution of effects to the sweetener; inconsistency of effects across trials; and extrapolation of such trials to humans with markedly different GI tracks and microbial populations compared to rodent models. Current evidence is mixed. One trial of 172 individuals who completed a food frequency questionnaire reported a positive association between LCS ingestion and various microbial species (Suez et al., 2014). In another trial of 31 individuals, 7 consumed aspartame, 7 consumed Ace-K, and 3 consumed both for 4 days (Frankenfeld et al., 2015). No effects on bacterial abundance were identified though LCS consumers versus non-consumers differed in microbial diversity. However, because background diet was not controlled, it is not possible to attribute even this difference to a sweetener. Well-designed and adequately powered human trials are lacking.

### **Sweet hedonics**

It is widely accepted that there is an inherent liking for sweetness that is demonstrable through a stimulatory effect of in-utero exposure to saccharin on fetal drinking (De Snoo, 1937), as well as early post-natal mimetic reflexes (Steiner, 1973; Rosenstein and Oster, 1988) and sucking responses (Maone et al., 1990) to oral stimulation with sweet stimuli. There is a growing literature that early flavor exposure may hold implications for food acceptance later in life (Mennella, 2014). Very preliminary evidence in human infants is mixed on whether early sweetener exposure is a determinant of later sweet acceptance (Beauchamp and Moran, 1984; Liem and Mennella, 2002). However, dietary experience and cultural influences are the primary determinants of where sweetness is expected in the food supply, when such items are to be ingested, appropriate portion sizes, frequency of ingestion, as well as on the type and concentration of sweetener in an item. There is high inter-individual variability in the preferred sweetness levels of foods (Witherly et al., 1980). In that sweeteners are generally not consumed in isolation, hedonics is not closely associated with concentration, and the context in which sweeteners are ingested modifies their appeal. Taken together, the evidence suggests hedonic responses to sweetness have a biological basis, but are highly individual, context-specific and a reflection of recent exposure.

### **Sweeteners and appetite**

It has been proposed that oral sweetener exposure, particularly with LCS, augments hunger (Blundell and Hill, 1986; Rogers et al., 1988; Tordoff and Alleva, 1990). However, the preponderance of evidence indicates nutritive sweeteners (Steinert et al., 2011) and LCS (Ford et al., 2011; Peters and Beck, 2016) suppress hunger or increase fullness, or, more commonly, have no independent impact on appetitive sensations (Sørensen et al., 2014; Fantino et al., 2018; Mattes and Popkin, 2009). A remaining question concerns the role of expectations on appetite ratings. Knowledge of the type of sweetener consumed may influence appetitive responses such that LCS could be expected by consumers to have a lesser impact on appetite.

### **The biological basis for sweetener intake**

There is a widespread view that humans have a sensitivity to and preference for sweetness to facilitate the identification and ingestion of carbohydrate energy sources. This teleological perspective is supported by evidence that selected vertebrates (e.g., cats, sea lions, whales, pandas, western clawed frog, vampire bats) that do not rely on carbohydrate for energy have limited or no ability to detect sweetness. Additionally, hummingbirds, who feed on nectar, have repurposed the umami receptor to permit detection of carbohydrate again, while other birds have not (Baldwin et al., 2014; Zhao et al., 2010). However, this scenario has been questioned (Feng and Zhao, 2013) and there are other issues that do not support this view. First, the primary effective taste stimuli for sweetness are mono- and disaccharides, which would have been rare and only episodically encountered throughout most of human evolution. A sensory system tuned to starch, the overwhelming form of carbohydrate in the environment, would have held greater survival

value. There is some evidence humans can detect short chain oligosaccharides, but they are not detected by the sweet receptor and are not sweet (Lim and Pullicin, 2019). Second, unlike the case with fat and protein, where the effective stimulus is an essential nutrient, this is not the case for sweet stimuli. Thus, a sensory system tuned to sweeteners holds less salience. Third, sweetness is a very imperfect predictor of energy. Sweet fruits are generally energy dilute and potent sweeteners are consumed in such limited quantity that they contribute little to energy intake. Fourth, sweetness also is a poor indicator of safety. Heavy metals, such as lead, are sweet but neurotoxic. Complications from the ingestion of lead date back to the Romans who used a concoction of lead acetate to sweeten foods, and presently, children are at high risk for lead toxicity because of the appeal of sources like paint chips. These observations, the intake trends noted above, and the health consequences of sweetener ingestion outlined below, suggest sweetener intake is driven more by hedonics than homeostatic mechanisms.

## Consumption trends

### Sugar

Terminology surrounding sugar intake focuses on total, free, and added sugars. Total sugars refer to all sources of mono- and disaccharides in foods and beverages (Mela and Woolner, 2018). Free sugars are defined, per the World Health Organization, as “mono-saccharides and disaccharides added to foods and beverages by the manufacturer, cook or consumer, and sugars naturally present in honey, syrups, fruit juices and fruit juice concentrates” (World Health Organization, 2021). The US Food and Drug Administration (FDA) and agencies in several other countries focus on added sugars rather than free sugars. The FDA defines added sugars as “sugars that are added during the processing of foods (such as sucrose or dextrose), foods packaged as sweeteners (such as table sugar), sugars from syrups and honey, and sugars from concentrated fruit or vegetable juices” (US Food and Drug Administration, 2021a). The FDA excludes naturally occurring sugars from this definition. Despite the slight differences in definitions, free and added sugars are the primary focus of public health recommendations surrounding sugar intake.

Free or added sugars in the diet come from a variety of sources, but beverages are significant contributors. Among American adults, sweetened beverages are the largest source of added sugar intake, followed by desserts (Bowman et al., 2019a). Tea and coffee are the third largest contributor of added sugar, followed by candy and sugars and breakfast cereals and bars. Broken down by age range, desserts are the primary contributor to added sugar intake among individuals ages 2–5 years (Bowman et al., 2019b) and 51–70 years, followed by sweetened beverages; while sweetened beverages are the leading contributor for all other age groups (US Department of Health and Human Services and US Department of Agriculture, 2020). Together, all five food groups mentioned contribute about 70% of the energy from added sugar while beverages provided nearly half. Similar trends have been noted among many other countries (Amarra et al., 2016; Lei et al., 2016; Promdee et al., 2007; Ruiz et al., 2017), and a global survey from 2010 reported that sugar sweetened beverage consumption was highest among Caribbean countries (Singh et al., 2015).

Public health messaging around sugar intake is largely consistent throughout the world, but there are some differences. For example, the World Health Organization (WHO) (World Health Organization, 2015) recommends limiting free sugar intake to less than 10% of total energy. These recommendations apply to both children and adults and were based on the effects of sugar on oral health (World Health Organization, 2015). Health Canada (Health Canada, 2019) also adopted the WHO recommendations. The US Dietary Guidelines align with WHO recommendations but are targeted to added, rather than free, sugar intake (Department and Services, 2020). Other countries, like the United Kingdom (National Health Service, 2018), recommend free sugar intakes of less than 5% of total energy. The WHO also conditionally supports a 5% limit, but this is based on low-quality data that suggest diets with less than 5% of energy coming from total sugars are even more beneficial for oral health than the 10% cut-off (World Health Organization, 2015). The US Dietary Guidelines advisory committee recommended reducing the previous recommendation of added sugar intake from 10% to 6%, but the recommendation was not accepted and remains unchanged in the 2020–2025 version of the guidelines (Thompson, 2020; US Department of Health and Human Services and US Department of Agriculture, 2020). The DGA's original 10% recommendation is based on the fact that meeting all other nutrient recommendations while achieving energy and sodium intake recommendations becomes exceedingly difficult if added sugars are not limited (US Department of Health and Human Services and US Department of Agriculture, 2020). Some argue the science does not fully support a limit as low as 6% (Thompson, 2020), and others doubt if such restrictions are achievable (Erickson and Slavin, 2015). Overall, recommendations to limit energy from free or added sugar to 5–10% of total energy intake are frequently noted.

Trend data on sugar consumption suggest reductions have occurred recently. In the US, increases in intake were observed between the 1970s and 1990s (Chun et al., 2010) where total sugar intake increased by 8% and added sugars by 12%. Nutritive sweetener intake, which includes sugar, honey, and corn syrup, appeared to peak in 1999, when per capita intake reached 422.6 kcal/day (US Department of Agriculture, 2021). However, intake has been gradually decreasing. In 2019, intake was estimated at 344.3 kcal/day (US Department of Agriculture, 2021), which represents a decrease of 18.5%. This trend was also reported based on analysis of multiple cycles of the National Health and Nutrition Examination Survey (7 cycles spanning 2003–2004 to 2015–2016) (Marriott et al., 2019). American children and adults have reduced their total sugar intake over time by 27% and 17%, respectively (Marriott et al., 2019). Reductions in the intake of sugar sweetened beverages (SSBs) over the study timeframe contributed substantially to this reduction. In addition, the US food supply has reduced the number of available products that contain added nutritive sweeteners, like sucrose and fructose (Popkin and Hawkes, 2016). Compared to 2000, when 63% of all food and beverage products sold in the US contained added nutritive sweeteners, by 2013, this was reduced to

55% (Popkin and Hawkes, 2016). Notably, this reduction in added sugars has not been accompanied by lower energy intake or body weight in the US, in part due to increased energy from high-quality carbohydrates, polyunsaturated fats, saturated fats, and plant protein (Shan et al., 2019).

Interest in reducing sugar intake has been documented in many nations. For example, a survey of Kenyan adults reported that 54% of respondents indicated they were trying to reduce sugar intake (Mwenda et al., 2018), and among Polish adults, nearly 100% of those surveyed claimed they were trying to limit sugar intake (Pielak et al., 2019). American adults are also attempting to reduce sugar intake; 80% of respondents in a recent survey indicated they were trying to either limit or avoid sugar intake (International Food Information Council Foundation, 2019). The same survey of over 1000 American adults noted that sugar reduction was the most commonly mentioned dietary change respondents had undertaken in the past 10 years (International Food Information Council Foundation, 2019). Clearly, the public is aware of health messaging regarding sugar.

Despite trends suggesting reduced sugar consumption, sugar intake frequently exceeds recommendations. For example, data from surveys of European countries indicate that total and added sugar intake of adults comprised between 15–21% and 7–11% of dietary energy, respectively; while total and added sugar intake among children ranged from 16 to 26% and 11 to 17% of total energy, respectively (Azaïs-Braesco et al., 2017). Data from the US indicates 54% of American adults and 66% of children consume more added sugars than recommended (Bowman et al., 2017). Broken down by age group, 50% percent of children ages 1–3 years consume more than 10% of their energy from added sugars (Dietary Guidelines Advisory Committee, 2020). Among children ages 4–8 years, 79% of boys and 75% of girls do not meet added sugar intake recommendations (Dietary Guidelines Advisory Committee, 2020). Results are similar among adolescents; 70% of boys and 75% of girls do not meet recommendations (Dietary Guidelines Advisory Committee, 2020). Average per capita intake of nutritive sweeteners was 344.3 kcals/day in the US population in 2019, which far exceeds recommendations of limiting added sugar intake to less than 10% of energy (US Department of Agriculture, 2021). These data suggest that intentions and intakes do not align.

Developing areas also struggle with high sugar intake. For example, a survey of eight Latin American countries reported average added sugar intakes of 13.2% of total energy with a range from 10.3% in Ecuador to 16.4% in Argentina (Fisberg et al., 2018). Among Gaza Palestinians, 44.1% of respondents consumed more than recommended amounts of added sugars (Jebril et al., 2020). Results from the Global School Health Survey indicated that over 45% of students ages 13–17 in Saint Lucia reported consuming sugar sweetened beverages at least once per day while over 55% of students in Guatemala and over 75% in Suriname answered similarly (Pan American Health Organization, 2021). Nearly 14% of adults in Kenya were classified as consuming a diet high in sugar (Mwenda et al., 2018). A high sugar diet was defined as adding “sugar to drinks already served with sugar or intake of processed foods or drinks high in sugar on a daily basis”. Based on current public health recommendations, over consumption of added sugars is a global concern.

### Low calorie sweeteners

One approach used by consumers to reduce sugar intake is to substitute LCS. LCS are substances that produce a sweet sensation but provide minimal energy due to their high potency (hence extremely low concentration) and/or poor digestibility. While different LCS are approved for use in different countries, six synthetic LCS have been approved by the Food and Drug Administration as food additives. These include: acesulfame potassium (Ace-K), advantame, aspartame, neotame, saccharin and sucralose. Three other natural products, steviol glycosides, thaumatin, and luohanguo fruit extracts are also approved. These compounds have undergone rigorous health testing and have been given Generally Recognized as Safe (GRAS) status (US Food and Drug Administration, 2021b).

LCS are widely consumed, and evidence suggests use continues to grow. Based on two 24 h diet recalls collected during the 2009–2012 National Health and Nutrition Examination Survey (NHANES), 41.4% of American adults and 25.1% of children consumed LCS (Sylvetsky et al., 2017). Among adults, individuals who were White, non-Hispanic, female, obese, and from the highest income tertile consumed more LCS (Sylvetsky et al., 2017). Compared to the number of adults (24.1%) and children (12.5%) who reported using LCS in 2007–2008 NHANES survey, numbers from the 2009 to 2012 NHANES survey represent a marked increase (Sylvetsky et al., 2012). The most popular reasons for using sweeteners by US consumers were to reduce sugar intake, lose weight, consume less energy, and control blood sugar (International Food Information Council Foundation, 2019). The most recent US Dietary Guidelines report suggests low- and no-calorie sweeteners may aid in reducing sugar intake and facilitate weight management, at least in the short term (US Department of Health and Human Services and US Department of Agriculture, 2020). From a global perspective, a recent review of worldwide exposure studies that evaluated daily intake of seven different LCS reported variable use by region and LCS, with no data available for African and limited data available for North American consumers in the format required and time period assessed (2008–2017) (Martyn et al., 2018). However, based on the available data, the authors concluded that there is little cause for concern that acceptable daily intakes are being exceeded at present (Martyn et al., 2018). Thus, LCS are commonly used and current exposures do not appear to exceed recommended intakes.

Consumers have several choices for discretionary LCS use. Splenda/sucralose is currently the most popular choice in the US, followed by Sweet'N Low (saccharin), Equal (blend of aspartame and Ace-K), and Stevia in the Raw (Statista, 2020). Twice as many people report using Splenda compared to each of the other top LCS (Statista, 2020). While the global LCS market is expected to grow through 2026 (Statista, 2021b), multiple surveys suggest that consumers are concerned that there are adverse health effects from consuming synthetic LCS, and as a result, some consumers seek to avoid these options (360 Market Updates, 2019; International Food Information Council Foundation, 2018; Strategy Online, 2017). These concerns have likely contributed to the

increasing popularity of naturally-derived LCS, like stevia, around the globe (Research and Markets LTD, 2020; Saraiva et al., 2020; Statista, 2021a; Strategy Online, 2017). While a consensus definition of “naturalness” is lacking, a systematic review of studies from 32 countries concluded that the concept is important to many consumers (Román et al., 2017).

In addition to using LCS to reduce sugar intake, other policy approaches have been implemented. These policies are meant to influence access to sugar-containing foods and beverages as well as LCS. Examples of policy approaches include levying taxes on SSBs and energy drinks (World Health Organization, 2017), bans on sales of SSBs in schools or businesses (Eneli et al., 2014; Epel et al., 2020), manufacturing guidelines to limit sugar in products (Enright and Eskensazi, 2018), and expanded labeling on products (Huang et al., 2019). While various studies reach differing conclusions, there is evidence to suggest these approaches can be effective. For example, an excise tax of approximately 10% reduced beverage purchases in Mexico by 12% over a two-year period (Colchero et al., 2016). A beverage tax was also effective in reducing consumption in the US (Falbe et al., 2016). A meta-analysis also concluded that SSB taxes reduced demand and the authors concluded that taxation improved BMI (Cabrera Escobar et al., 2013). Banning the sales of SSBs has also been associated with reduced consumption (Avery et al., 2015; Epel et al., 2020). Meta-analyses conclude that product reformulation to reduce sugar intake result in decreased sugar intake (Hashem et al., 2019), and that front of package labeling regarding sugar also reduces intake (Crocker et al., 2020). In summary, while there is controversy regarding the best approaches to use to curb added sugar intake, there appear to be a variety of policies that can be used to address sugar intake in order to achieve public health recommendations.

## Sweeteners and health

The effects of sweeteners, both nutritive and non-nutritive, on human health have been extensively investigated and the findings have been synthesized by multiple systematic reviews and meta-analyses. Evidence from these reviews related to overweight/obesity, cardiovascular disease (CVD), type 2 diabetes, cancer and dental caries are presented, first for nutritive sweeteners followed by LCS.

### Sugar

There are concerns about the impact of sugar consumption on human health due to the acute effects sugar has on human ingestive behaviors and physiological responses (as discussed in the previous section). Whether these acute effects translate into long-term health consequences is summarized below.

#### Overweight and obesity

The relationship between free sugar intake and body weight was summarized in a systematic review that included 38 cohort studies and 30 interventional trials (Te Morenga et al., 2013). In adults, 11 of 16 cohort studies reported positive associations between free sugar and weight, BMI, and/or waist circumference. Only one cohort study noted a significant negative association. An increase in sugar intake over time was also associated with increased body weight. The associations from observational studies were confirmed by interventional trials, where a reduction in free sugar intake led to an average weight loss of 0.80 kg ( $n = 5$  studies included in the meta-analysis). In contrast, increasing free sugar intake led to weight gain, and the magnitude of weight gain was positively related to study length (0.52 kg higher in studies up to 8 weeks, and 2.73 kg higher for trials >8 weeks). Meta-analysis of 13 studies that isocalorically replaced free sugars with other nutrients revealed no effect on body weight (mean difference = 0.04 kg, 95%CI -0.04–0.13 kg,  $n = 13$  studies), suggesting that the effects of sugars on body weight may be adequately explained by their energy content. However, a systematic review did not observe an effect of reducing sugar intake on the body weight of children ( $n = 5$  interventional trials). The authors indicated that this could be explained by the poor compliance to reduced free sugar diets in children. Overall, the evidence indicates that free sugar intake is positively associated with body weight in adults while the evidence in children is less clear.

A number of recent systematic reviews also specifically examined the relationship between SSB and body weight in adults and children. In adults, one review that included 11 observational studies reported 18% higher obesity risk (RR = 1.18, 95%CI 1.10–1.27,  $n = 11$  studies) and 20% higher waist circumference (RR = 1.20, 95%CI 1.04–1.37,  $n = 4$  studies) in SSB consumers than non-consumers (Ruanpeng et al., 2017). This was confirmed by another systematic review that included 10 studies (Luger et al., 2017), where eight of the studies did not overlap with those included in the previous review (Ruanpeng et al., 2017). In children, SSB intake has been associated with a higher incidence of adiposity by multiple observational studies (Te Morenga et al., 2013; Luger et al., 2017; Keller and Bucher Della Torre, 2015). Interventional trials conducted in children are limited ( $n = 3$  studies). Among these, interventions were not SSB-specific in two studies, and two studies were secondary analyses (Luger et al., 2017). Considering these limitations, the evidence is insufficient to draw a conclusion (Dietary Guidelines Advisory Committee, 2020).

To summarize, the preponderance of evidence supports a positive association between sugar (free and via SSB) and body weight and risk of obesity in adults and, to a slightly lesser extent, in children. Few studies report a negative association. However, as highlighted by the scientific report compiled by the 2020 Dietary Guidelines Advisory Committee, the risk of bias in SSB studies is high, and generalizability is of concern. For these reasons, evidence relating SSB to obesity was rated by the DGAC as moderate in children, and limited in adults (Dietary Guidelines Advisory Committee, 2020).

### Cardiovascular disease (CVD)

A recent systematic review of 24 prospective studies examined the relationships between free sugar intake and the incidence of CVD (median follow-up of 11 years), and CVD mortality (median follow-up of 13 years) (Khan et al., 2019). Sugar intake (total, sucrose, fructose) was not associated with the incidence of CVD. However, non-linear dose-response positive relationships were observed between total sugar intake (RR = 1.09, 95%CI 1.02–1.17,  $n = 4$  studies) and fructose intake (RR = 1.08, 95%CI 1.01–1.15,  $n = 2$  studies) and CVD mortality. Interestingly, sucrose was associated with decreased CVD mortality (RR = 0.94, 95%CI 0.89–0.99,  $n = 2$  studies), while no association was noted for added sugar intake. These latter findings may be factual, but the authors suggested the unexpected lack of or negative relationships observed for sucrose and added sugar intake and CVD risk may be explained by reverse causation, where individuals with high risk of CVD may avoid sugars as a preventative measure.

The relationship between sugar intake and CVD was also tested specifically for SSB consumption. In a systematic review of prospective studies, every additional serving/day of SSB was associated with higher incident hypertension (RR = 1.10, 95%CI 1.06–1.15,  $n = 6$  studies), coronary heart disease (RR = 1.16, 95%CI 1.06–1.27,  $n = 4$  studies), and stroke (RR = 1.10, 95%CI 1.00–1.20,  $n = 4$  studies) (Xi et al., 2015). In another review, the risk of myocardial infarction was also reported to be 22% higher (RR = 1.22, 95%CI 1.14–1.30,  $n = 2$  studies) with incremental increases in SSB consumption (Narain et al., 2016). Despite these reported associations, the number of studies investigating the relationship between sugar and CVD is still very limited, therefore the 2020 DGAC concluded a firm conclusion cannot be drawn (Dietary Guidelines Advisory Committee, 2020).

### Type 2 diabetes mellitus (T2DM)

The association between free sugar intake and T2DM has been summarized by a systematic review that included 15 prospective studies, with a median follow-up period of 12 years (Tsilas et al., 2017). When individuals with the highest vs. the lowest intake were compared, no association was observed between total sugar or fructose intake and T2DM. The lack of association was, partly, due to the significant heterogeneity in studies included in the meta-analyses ( $I^2 = 76\%$  and  $71\%$  for total sugars and fructose respectively). Although an association was noted between sucrose intake and T2DM, the risk was lower in those with the highest consumption (RR = 0.89, 95%CI 0.80–0.98,  $n = 8$  studies). The studies on sucrose had large study populations (almost 200,000 participants in total) and used validated dietary assessment tools. However, there were some differences between studies in term of study population (five studies included females and one study included males only, only some studies included younger participants) as well as T2DM outcomes (four studies relied upon medical diagnosis and the remaining were self-reported). Therefore, more studies are needed to confirm the relationship between free sugar intake and T2DM.

The evidence is more consistent relating SSB intake to T2DM. A number of meta-analyses have reported higher risk of T2DM (ranging from 18% to 30% higher) in individuals with higher SSB consumption (Wang et al., 2015; Malik et al., 2010; Greenwood et al., 2014; Imamura et al., 2015). Although these reviews included some similar studies, the outcome criteria varied across the meta-analyses, e.g., risk was assessed between the lowest vs. the highest intake (Malik et al., 2010; Wang et al., 2015); per 250 mL/day (Imamura et al., 2015) or 330 mL/day (Greenwood et al., 2014) increase; between geographical regions (Wang et al., 2015), and was also based on different age groups (Imamura et al., 2015). The higher risk was comparable between Asia, Europe, and the US (Wang et al., 2015). After adjusting for BMI, the relationships remained significant, although the reported risks were slightly lower. This is consistent with the scientific report of the 2020 Dietary Guideline Advisory Committee, where intake of added sugars, especially as SSB, was reported to increase the risk of T2DM in adults, though this was partly explained by BMI (Dietary Guidelines Advisory Committee, 2020). In another review that focused on fruit juice, the risk and incidence of T2DM was also reported to be higher, but this occurred only when the fruit juice was sweetened (RR = 1.28, 95%CI 1.04–1.59,  $n = 2$  studies), and 100% fruit juice intake was not associated with T2DM (Xi et al., 2014). It should be noted that studies on fruit juice, to-date, were of mixed quality due to the lack of consistency in how 100% fruit juice was defined and quantified (Dietary Guidelines Advisory Committee, 2020).

To-date, there is evidence linking SSB intake to the risk of developing T2DM, which is not fully explained by adiposity. However, the relationship remains inconclusive for free sugars. The consistent relationship between SSB and metabolic diseases presented so far may be partly explained by the physical forms of sugar being ingested. In a liquid form, sugars are consumed faster, cause rapid fluctuations in blood glucose, and they have poor appetitive effects (Dhillon et al., 2016).

### Cancer

A recent systematic review has summarized the findings of observational studies on the relationship between free sugar intake and cancer risk (Makarem et al., 2018). This review concluded that the evidence was mixed, where the association with cancer risk was not observed in 11 out of 29 studies (38%) that assessed total sugar and sucrose intake. In analyses involving fructose, 8 out of 14 studies (57%) did not observe an association, and mixed findings were reported in the remaining studies, i.e., 2 studies reported negative and 4 studies noted positive associations. Only 5 studies on added sugar were identified in this review. Two of these studies reported an association, but they were in opposite directions, possibly due to different target cancer types (RR = 0.72 for ovarian cancer vs. RR = 1.60 hematological cancer). The explanation for inconsistent findings is unclear as there was no evidence the outcomes were influenced by sample size and follow-up period. The authors of the review highlighted the challenges in accurately quantifying specific sugars in the diet, and the limitation of cross-sectional analysis of intake (not necessarily representative of long-term intake), which may explain the mixed findings (Makarem et al., 2018).

Inconsistent findings were also observed for trials examining fruit juice and SSB intake. In a systematic review of 64 observational studies, SSB intake was associated with higher risk of breast (RR = 1.14, 95%CI 1.01–1.30,  $n = 7$  studies,  $I^2 = 0\%$ ) and prostate (RR = 1.18, 95%CI 1.10–1.27,  $n = 3$  studies,  $I^2 = 0\%$ ) cancer (Llaha et al., 2021). A similar (but weaker) association was reported with fruit juice intake and prostate cancer (RR = 1.03, 95%CI 1.01–1.05,  $n = 4$  studies,  $I^2 = 0\%$ ). However, this review observed no association between SSB or fruit juice and other cancer types such as colorectal, bladder, renal cell, and pancreatic cancers.

Overall, only a very small number of studies reported a link; therefore, the association between sugar intake and cancer risk is considered weak. Additional evidence is required to confirm this conclusion.

### **Dental caries**

A link between SSB intake and dental caries is well-established. In a recent systematic review of 38 cross-sectional studies, higher SSB intake in children was associated with higher risk of dental caries (OR = 1.57, 95%CI 0.38–1.26,  $n = 16$  studies) and erosion (OR = 1.43, 95%CI 1.01–2.03,  $n = 7$  studies). This review also reported that there were 0.82 more decayed, missing, and filled teeth in children consuming moderate vs. low, and high vs. moderate levels of sweeteners compared to children with low SSB intake (Valenzuela et al., 2021). Another systematic review of five cohort studies further suggested that higher risk of dental caries is linked to between-meal consumption of sugars (Hancock et al., 2020).

### **Low calorie sweeteners**

Several mechanisms have been proposed to explain associations between LCS consumption and human health. Some are well-established, but most are still preliminary and require further investigation. These mechanisms relate to appetite regulation (Romo-Romo et al., 2016), energy intake (Rogers and Appleton, 2020), substrate oxidation (Chern and Tan, 2019), glucose metabolism (Romo-Romo et al., 2016; Tucker and Tan, 2017), advanced-glycation end product production (Deo et al., 2020), and effects on the gut microbiome (Walbolt and Koh, 2020).

The link between LCS intake and human health has been widely studied and several systematic reviews have been published. However, most of these reviews are narrative and fail to differentiate between the various LCS and how they are ingested. Some additional challenges in understanding the association between LCS and health include the extensive range of LCS-containing food products that may not be fully captured by nutrient analysis software, hence the lack of ability to accurately identify the types of sweeteners ingested, and to quantify their contributions to the food supply. This limits determination of potential dose-response analyses. The evidence presented below should therefore be interpreted within the context of these methodological limitations. Most trials focused on LCS consumed in beverages; the most common source of LCS. It is also important to note the high possibility of reverse causation in findings related to LCS and human health, where LCS products may be more frequently used by individuals attempting to manage disease risks.

### **Overweight and obesity**

In a review of prospective observational studies, LCS beverage intake was positively, but weakly, correlated with the BMI of children and adults (mean correlation = 0.03, 95%CI 0.01–0.06,  $n = 6$  studies) (Miller and Perez, 2014). However, no association was found between LCS use and body weight. The same review assessed clinical trials, where LCS interventions led to lower BMI (mean difference =  $-0.24 \text{ kg m}^{-2}$ , 95%CI  $-0.41$  to  $-0.07 \text{ kg m}^{-2}$ ,  $n = 6$  studies), fat mass (mean difference =  $-1.10 \text{ kg}$ , 95%CI  $-1.77$  to  $-0.44 \text{ kg m}^{-2}$ ,  $n = 6$  studies), and waist circumference (mean difference =  $-0.83 \text{ cm}$ , 95%CI  $-1.29$  to  $-0.37 \text{ cm}$ ,  $n = 3$  studies) (Miller and Perez, 2014). The effects of LCS, compared to sugars, on body weight was further strengthened by two meta-analyses of interventional studies, where body weight reduction was seen with LCS (standardized mean difference SMD =  $-0.56 \text{ kg}$  and  $-0.35 \text{ kg}$  respectively) (Laviada-Molina et al., 2020; Rogers and Appleton, 2020). Lower weight in the LCS group was observed when the sweeteners were included in unrestricted diets (SMD =  $0.47 \text{ kg}$ , 95%CI  $0.26$ – $0.68 \text{ kg}$ ); were used by people with overweight/obesity (SMD =  $0.51 \text{ kg}$ , 95%CI  $0.29$ – $0.72 \text{ kg}$ ); and were consumed by adults but not children (SMD =  $0.43 \text{ kg}$ , 95%CI  $0.22$ – $0.64 \text{ kg}$ ,  $n = 23$  studies) (Laviada-Molina et al., 2020). The totality of evidence indicates LCS use is associated with lower adiposity when they replace sugars in the diet. Although two reviews questioned the effectiveness of LCS on body weight management (Toews et al., 2019; Azad et al., 2017), the conclusions on these reviews were based on the inclusion of limited or inappropriate studies, as described by Sievenpiper et al. (2017). Finally, non-alcoholic fatty liver disease (NAFLD) is commonly associated with obesity and a systematic review (Green and Syn, 2019) that included 2 interventional trials concluded that LCS had no effect (Maersk et al., 2012), or reduced clinical indicators of NAFLD (Campos et al., 2015) when SSB was replaced with LCS-containing beverages.

### **Type 2 diabetes**

Observational studies suggest elevated risk of type 2 diabetes with higher LCS intake when reported as servings per day (RR = 1.03, 95%CI 1.01–1.05,  $n = 4$  studies) or for comparisons of lowest vs. highest quartile's of intake (RR = 1.14, 95%CI 1.05–1.25,  $n = 9$  studies) (Azad et al., 2017). In a scoping review, positive associations were also reported between LCS consumed in beverages and the risk of T2DM, but findings were mixed when overall LCS intake was considered (Lohner et al., 2017). This highlights the importance of assessing the form of LCS being consumed. Nonetheless, this is an area of particular risk for reverse causation, where people with diabetes are more likely to use LCS to improve glycemic control. Findings are also subject to publication bias, inconsistency, and imprecision in pooled estimates (Sievenpiper et al., 2017).

In a meta-analysis of 26 feeding trials, LCS intake alone did not influence acute postprandial glucose (mean difference =  $-0.02$  mmol/L, 95%CI  $-0.09$ – $0.05$  mmol/L) and insulin (mean difference =  $-2.39$  pmol/L, 95%CI  $-11.83$ – $7.05$  pmol/L) concentrations, regardless of the types and dose of LCS ingested (Greyling et al., 2020). When LCS was compared to other nutritive sugars, there was a smaller or no increase in blood glucose and insulin due to a lower carbohydrate load (Tucker and Tan, 2017). In short-term interventional studies, LCS consumption also did not affect insulin resistance or glycated hemoglobin (HbA1c) (Azad et al., 2017). Considering all evidence and potential reverse causation from observational studies, LCS use does not appear increase the risk of T2DM.

## Cancer

Governmental bodies such as the US Food and Drug Administration as well as its counterparts in many other nations have concluded that LCS are safe for consumption. This was supported by a scoping review that included 51 primary studies that reported limited evidence on the link between LCS use and cancer risk (Lohner et al., 2017).

## Conclusion/summary/outlook

Despite strong recommendations to moderate sugar intake, reductions have been limited and the consumption of LCS is high and trending upward. This reflects the inherent appeal of sweetness and the reinforcing contribution of dietary experience and culture. Concern about the safety and health effects of high levels of consumption have prompted recommendations to moderate intake. To-date this has resulted in only modest success, but new approaches are emerging. While sweeteners share a common property, sweetness, they vary markedly in chemical structure resulting in differences in their taste properties, digestion, absorption, metabolism, and health effects. The strength of evidence implicating nutritive sweetener intake in the onset and manifestations of overweight/obesity, CVD, and diabetes ranges from limited to moderate with a stronger association for dental caries and inconclusive evidence for selected cancers. Much of this may be attributable to the energy contributed by these sweeteners. They are singled out as problematic for this contribution because they are often, though not necessarily, ingested through foods and beverages that provide limited other nutritive value. In contrast, there is a weak, but significant, inverse association between LCS use and overweight/obesity and no significant association with CVD, diabetes, or cancer.

## Conflict of interest

RDM currently serves on the scientific advisory boards of the Grain Food Foundation and Mars, Inc. RMT currently serves on the scientific advisory board of the Central Bottling Company.

## Key points

- African, EurAsian, American, and Australian indigenous and traditional foods (AITFs) around the globe are an undervalued, under-recognized, under-leveraged source of nutrients that, depending upon the specific species and landrace, would be considered “high sources” of one or more nutrients (e.g., vitamins and minerals), which are often limited in the same region. A promotion of their production and consumption could help mitigate malnutrition and food insecurity.
- AITFs, often wild foraged, are generally resilient to changing environmental conditions, and therefore already adapted to the biotic and abiotic stressors found in the area, providing climate smart crops for consumption and production.
- AITFs can contribute toward increasing biodiversity among crop species globally, providing increased solutions to climate sensitivity and subsequently household hunger and food security.
- AITFs are a diverse group of plants that include annuals, perennials, and legumes. Some of these plants, such as the legumes, can fix nitrogen, enhance soil health, and reduce erosion, therefore contributing to environmental protection all while providing communities with fiber and food for household consumption and animal feed.
- AITFs can be used as economic drivers for job creation and income generating opportunities among vulnerable populations (e.g., women, youth) complimenting rather than replacing traditional agronomic staple crops.
- AITFs can be incorporated more formally into agro-forestry systems to enhance economic, environmental, and cultural sustainability.
- A multitude of strategies are urgently needed to address the core issues of food security and sovereignty. The promotion of AITFs could play a significant role in ensuring that nutrient rich foods are more available, affordable, accessible, and acceptable and adopted for production and household consumption.

## Introduction

The world faces a formidable challenge: to feed an increasingly hot and hungry planet where extreme events such as the COVID-19 pandemic and climate shocks can contribute to household hunger and food insecurity. Despite some achievements in meeting the global food demand, the prevalence of malnutrition remains high in some low-to-middle income countries in sub-Saharan Africa (SSA), South Asia, and parts of Central and South America. In 2020, over 50% of the children under 5 were stunted in Asia (FAO, 2021). In addition to undernutrition, many low-to-middle income countries are facing the double burden of malnutrition, at both the household and individual level (Hoffman, 2019; Popkin et al., 2020). Disruptions to the global food supply chain, such as those experienced during the COVID-19 pandemic are expected to worsen under climate change.

Climate change is associated with increased temperatures, atmospheric carbon dioxide, and extreme weather events. Through several causal pathways, it is predicted that climate change will have a negative impact on global nutrition outcomes. Furthermore, the intensity of monoculture farming (e.g., land clearing, high use of irrigation, fertilizer, and pesticide application) is a threat to ecosystem services and a contributor to climate change. In return, climate change and the decline of ecosystem services (e.g., decline in pollinator species, carbon sequestration, pest control) impact agriculture production, creating a vicious cycle where agriculture and the ecosystem are at constant odds (Sunderland et al., 2019).

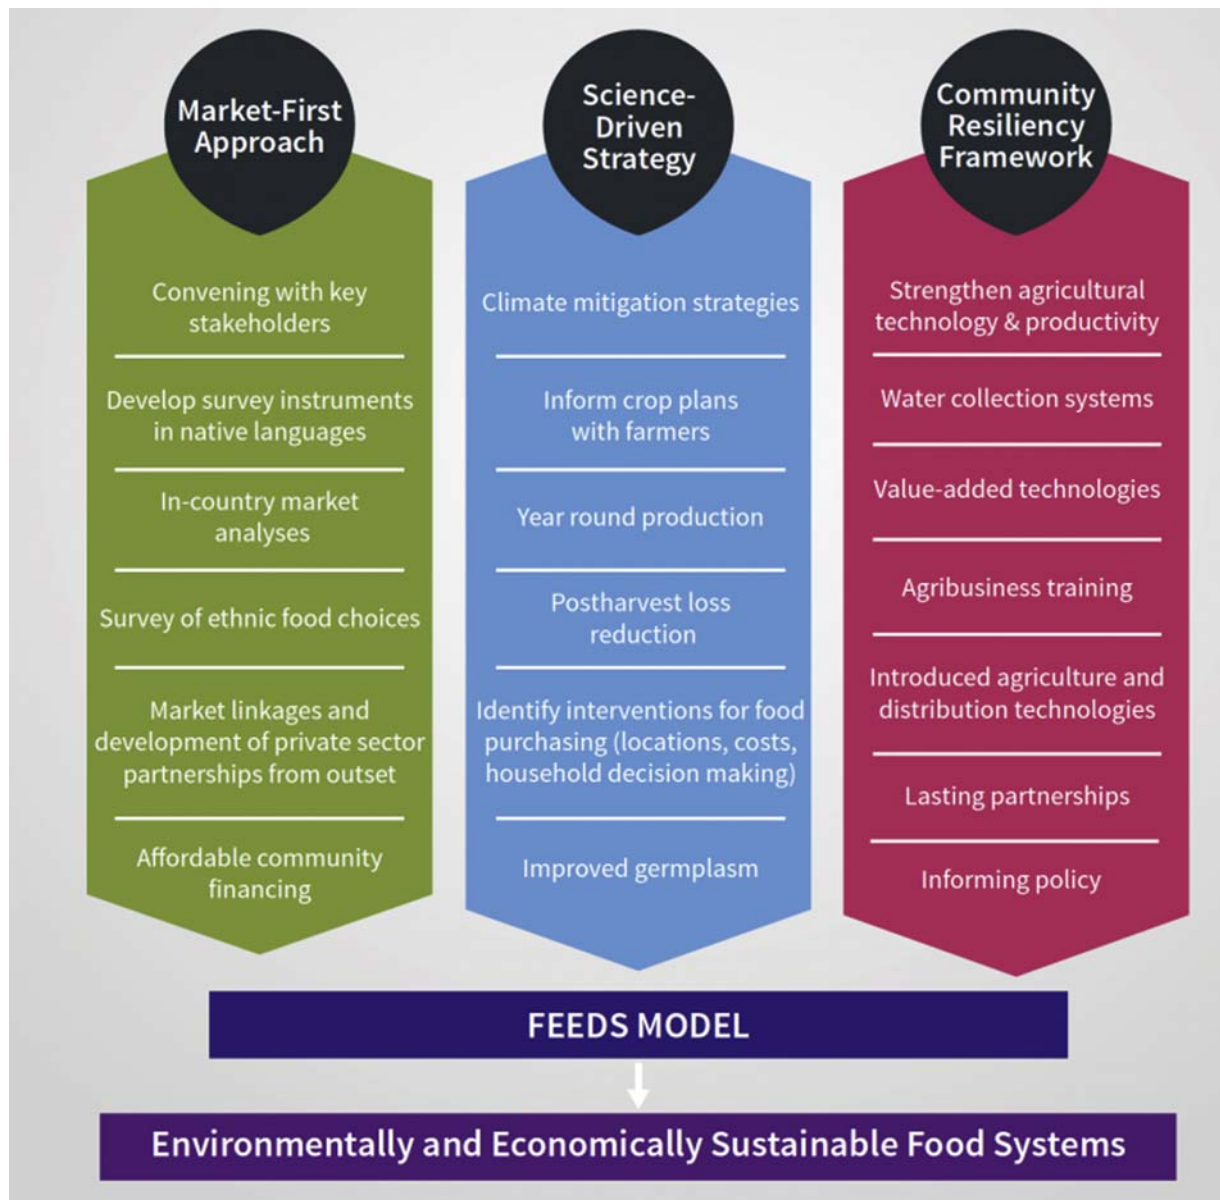

Agroecological issues are further exasperated by the production of fewer food crops. The availability of food supply worldwide is dependent on only a few crop species or “major crops.” It is estimated that only 30 plant species, often widely and intensively cultivated, are used to meet 95% of the world’s food requirements (Leff et al., 2004). Declining biodiversity among fruit and vegetable production worldwide is severely limiting the available food options for a sustainable, healthy food supply. There is a real need to increase biodiversity among food crops and to provide a more diverse diet to feed the ever-growing human population while avoiding dependency on a few major crops, especially under climate change.

The promotion of neglected and underutilized African, EurAsian, American, and Australian indigenous and traditional foods (AITFs) around the globe is one way that agriculture can diversify to better serve human nutrition and ecosystem needs. AITFs either originated in their respective continent or have a long history of being accidentally or intentionally introduced and became naturalized into a new region. Either way, these plants are often wildcrafted and in some cases brought into cultivation and domesticated to grow locally and have become accepted through custom, habit, or tradition. Examples include African nightshade, amaranth, hibiscus, moringa, and spider plant (Li et al., 2020; Towns and Shackleton, 2018). While many of these plants may be considered neglected or underutilized on a global level (e.g., limited international trade or commerce, lack of scientific crop improvement research, little investment and, funding in their commercialization) they are important and highly valued on a local level. AITFs are often culturally preferred (Hoffman et al., 2018; Hunter et al., 2019; Simon et al., 2020, 2021) and nutritionally dense (Abukutsa-Onyango et al., 2010). Furthermore, AITFs are adapted to local environmental conditions and some are even considered “survivor plants” due to their tolerance to temperature and precipitation extremes (Chivenge et al., 2015).

Although AITFs hold significant potential to reduce global malnutrition while strengthening sustainable food ecosystems, they are not without their challenges. In some parts of the world, AITFs are grown as subsistence crops or wild foraged, and have historically carried the social stigma of “famine foods,” which negatively impacts their adoption, promotion, and consumption (Towns and Shackleton, 2018). Addressing this stigma is particularly important in vulnerable communities that may not have access to affordable “Western” introduced vegetables (Hunter et al., 2019). Moreover, the success of any commodity is dependent on support from and linkages into the larger agricultural system, or in this context the food environment. Downs et al. (2020) defines the food environment as: “the consumer interface with the food system that encompasses the availability, affordability, convenience, promotion and quality, and sustainability of foods and beverages in wild, cultivated, and built spaces that are influenced by the socio-cultural and political environment and ecosystems within which they are embedded.” Unfortunately, AITFs are often in disabling food environments that do not promote their widespread production and trade (Ghosh-Jerath et al., 2021). For example, it is common for farmers to shift land allocation from household gardens growing nutritious traditional foods, toward commercial cereal crops for retail-sale (Abdoellah et al., 2020). In contrast to the “conventional food crops”, the AITFs have not had the historical support and recognition by governments, international agencies, and research centers, which has drastically limited research, extension, industry, and public support.

Despite these challenges, AITFs possess strengths and opportunities such as significant unmet economic potential (Simon et al., 2020, 2021). A holistic enabling food environment that utilizes a systems approach is needed for global food security and food sovereignty under climate change conditions. Market-first, science-driven solutions need to incorporate a community resilience framework that rebuilds local economies, regenerates ecosystems, and mitigates climate impact (Simon et al., 2021; Weller et al., 2015). Models such as the Food-systems for Empowerment, Economic Development and Sustainability (FEEDS) (Fig. 1) have produced transformative changes across many regions and communities. This model engages farmers and consumers directly in the formulation of the research agenda by combining concepts from food security and food sovereignty discourse. Furthermore, this model actively engages farmers and consumers in the process of developing and disseminating technological innovation through hands-on demonstrations and storytelling that captures shared experiences, subsequently strengthening local community resiliency and improving nutrition outcomes.

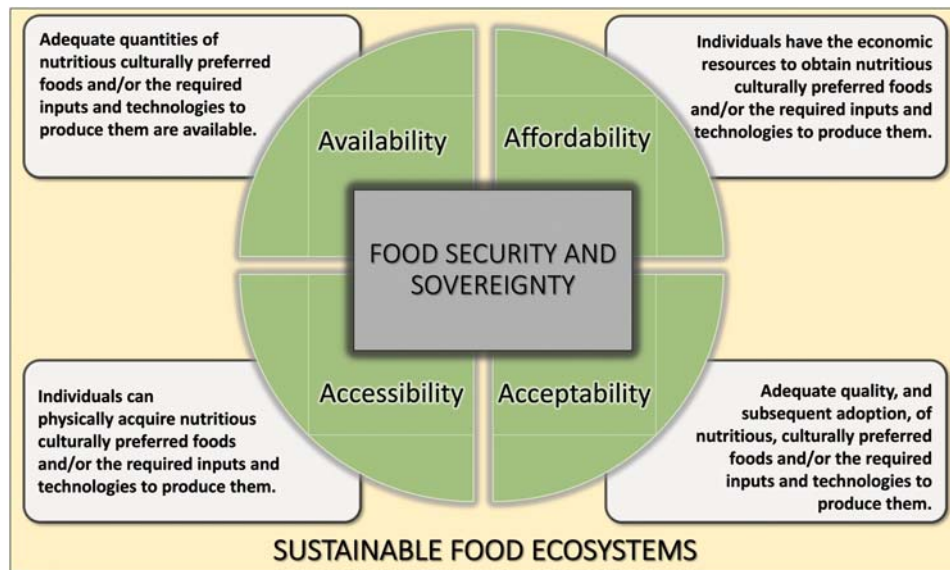

“Double-duty” solutions that combine the food security and food sovereignty discourses are needed to create a global agricultural food ecosystem that harmonizes the environment and the world’s food supply (Jarosz, 2014). While the food security and food sovereignty discourses share some similarities, namely that their primary goal is ensuring that all people have reliable access to sufficient quantity and quality of affordable, nutritious food (Table 1); it is important to look at their historical agendas. The first official definition of “food security” in 1974 was “the availability at all times of adequate world food supplies of basic foodstuffs to sustain a steady expansion of food consumption and to offset fluctuations in production and prices” (United Nations, 1975 cited in FAO, 2001). While today, these agendas are similar at heart, their primary difference can be seen in the historical definition: scale. Food security often includes a primary research and development agenda around exports and global markets with an emphasis on commercial farming. In contrast, food sovereignty tends to focus on small-holder farmers and is often regarded as a “peasant movement.” The development work, research, and discourse around both terms are critical to feeding our global population and research and development work must commit to all scales of the food system.

**Fig. 1** Food-systems for Empowerment, Economic Development and Sustainability (FEEDS) model for global food security and food sovereignty (Simon et al., 2021).

**Table 1** Current or widely used definition of food security and food sovereignty.

Term	Current or widely used definition	Defining agency
Food security	All people, at all times, have physical, social and economic access to sufficient, safe and nutritious food that meets their dietary needs and food preferences for an active and healthy life. With the four pillars of food security: availability, access, utilization, and stability.	Food and agriculture Organization of the United Nations (FAO, 2001)
Food sovereignty	The right of peoples to healthy and culturally appropriate food produced through ecologically sound and sustainable methods, and their right to define their own food and agriculture systems.	La Vía Campesina (Patel, 2009)

**Fig. 2** The four pillars of food security and food sovereignty within a sustainable food ecosystem.

Our paper will use the dual concept of food security and sovereignty as a framework for the promotion of consumption and production for various markets (e.g., local, national, international) of indigenous and tradition foods in EurAsia, Africa, the Americas, and Australia through four pillars: availability, affordability, accessibility, and acceptability (Fig. 2). We will also discuss and illustrate how AITFs serve as one pathway for a sustainable food ecosystem.

## Four pillars of food security and food sovereignty

### Availability

For AITFs to be affordable, accessible, and acceptable, they first need to be available. Availability is defined as a situation when there are sufficient quantities of AITFs, in the built or natural food environment, for household consumption and/or the availability of improved and appropriate technologies and inputs to produce them. This section examines the availability of traditional and indigenous foods within the food environment as well as the availability of agricultural innovations for producers.

#### *Availability of AITFs in the natural and built environment*

The availability of AITFs is critical for food security and sovereignty for many vulnerable populations such as rural, indigenous, and aboriginal communities. Ferguson et al. (2017) reported that among key informants traditional foods significantly contributed to dietary intake, particularly during food insecure times, among aboriginal communities in Australia. While these food types are culturally significant and contribute to healthy dietary intake, their availability, and often affordability, is influenced by factors in the natural and built environment. For example, seasonality and climate change variability can impact the varieties and yield of fruits and vegetables available, both on the farm and in the marketplace (Ochieng et al., 2016). While AITF production is vulnerable to environmental stressors, as a group of plants, they tend to be less sensitive compared to “Western” introduced crops, stabilizing the availability of a variety of AITFs throughout the year.

In addition to the natural environment, aspects of the built environment can further influence the availability of AITFs. A review by Hunter et al. (2019) reported that low recognition of cultural and market value can hinder the availability of AITFs, while limited and fragmented data can restrict the availability of technological and germplasm advances and subsequent training for smallholder farmers. In addition, limited capacity, due to poorly developed infrastructure as well as disabling policies that restrain the production of AITFs, can further limit the availability and increase risk along the value-chain. Despite these challenges, the promotion of cultivation or wild harvesting of AITFs through extension and other outreach services can increase production and harvest and subsequently availability for consumers and smallholder farmers.

#### *Availability of agricultural innovations for producers*

Empowering smallholder farmers with innovations in agriculture such as Good Agricultural Practices (GAP) (e.g., hands-on season-long training in soil preparation, fertilization, water management and irrigation, planting, harvest methods, and more); post-harvest handling that reduces food waste and maximizes post-harvest processing; and improved seeds can promote the growth and availability of high-quality products for rural communities worldwide. This concept is further exemplified when utilized in a market-first science-driven model that combines biocultural knowledge with scientific advances. Moreover, it is essential that these methods are

embedded into the engagement with farmers and subsequently accepted, adopted, and championed by the communities involved for successful and sustainable development. Despite continued population growth, prior to the COVID-19 pandemic, agricultural production was largely meeting global food demand, with the global prevalence of undernutrition declining (FAO, 2021). This achievement was driven largely by technological innovations such as improved germplasm resulting in higher-yielding higher nutrition agronomic and horticulture varieties; synthetic and organic high performing fertilizers and pesticides; and innovative low- and high-tech farm tools such as irrigation systems, tractors, and solar dryers (Byrnes et al., 2017; Simon et al., 2020). Agricultural innovations and subsequent trainings coupled to increase scientific understanding of the drivers and methods that promote sustainable longer-term behavior change, must be made available to farmers on a continual basis, just as they are in developed countries, to be maximized by producers.

Availability of extension or other outreach services and intervention trainings impact the adoption of advanced agronomic practices and technologies improving yield and in turn increasing affordability and accessibility of AITFs to consumers. For example, glutinous rice plays an important role in food and cultural security among smallholder farmers in rural Vietnam. A study by Sattaka et al. (2017) found that extension services, such as extension official site visits, demonstration plots, trainings, and multi-media messaging, played a key role in fostering the sustainable production of culturally preferred glutinous rice and helped to ensure local food and cultural security in Vietnam. While most of the farmers in the study were smallholder, it is essential that policy and programming promote the availability of improved agronomic practices and germplasm for both small- and large-scale farmers.

The availability of improved germplasm and seed stock for producers can improve production and yield and increase supply, having a direct effect on nutrition delivery to consumers. The genetic diversity among AITFs suggests that targeted breeding programs can enhance the agronomic and nutritional characteristics of plants (e.g., yield, flavor, and nutritional quality). For example, Byrnes et al. (2017) found that there was a genotype effect on iron content among several species of *Amaranthus*. The selective breeding efforts in the study led to the development of an *Amaranthus* varietal with relatively high iron. Yet, the selection and breeding of improved germplasm of AITFs as conducted by the World VegCenter, the leading international center in vegetables, can be far more impactful with a stronger commitment by the commercial seed industry and other actors along the value chain that can effectively disseminate, maintain, and make available the genetic materials to farmers. Market-first, science-driven breeding programs can narrow the information gap for effective varietal development serving the goals of both farmers and stakeholders, promoting the affordability, accessibility, and acceptability of indigenous and traditional vegetables, to reduce micronutrient deficiencies. The availability of agricultural innovations can promote the affordability and accessibility of AITFs. The inclusion of grower/farmer participation in the final selection of those AITFs that would be released is also helpful and leads to greater success in the new varieties adoption by those that participated in their field performance evaluation prior to its commercial release.

### Affordability and accessibility

Affordability and accessibility of AITFs is defined by a situation where individuals have the needed resources to obtain adequate quantities of desired and culturally preferred AITFs economically and physically (respectively) and/or the required and appropriate inputs and technologies to produce them. This section examines the affordability and accessibility of AITFs in the market as well as how increased household production can improve food security and food sovereignty through two major pathways.

#### Affordability and accessibility at the market

A lack of economic affordability and market access is a major contributor to food insecurity and loss of food sovereignty. Approximately 25% of the world's population is classified as food insecure, and this number is often higher in vulnerable communities. A study by Lambden et al. (2006), in Arctic Canada, found that 40–70% of the indigenous women surveyed, from 44 tribes, could not afford enough food. In addition, food security and sovereignty are further exacerbated by crises such as the COVID-19 pandemic. Food environment disruptors such as the extreme droughts and locust infestation, such as those currently afflicting east Africa, can cause market disruptions subsequently limiting access and affordability of nutritious foods (FAO, 2021).

The food security and food sovereignty discourse extend beyond sufficient caloric intake and considers the quality of calories ultimately linking the affordability of healthy diets with nutrition outcomes. In 2020, FAO (2021) estimated that 3 billion people, or 42% of the global population, was unable to afford a healthy diet. With a majority of communities in lower-and-middle income countries unable to afford adequate quantities of healthy foods, it is of no surprise that economic affordability is a significant barrier to culturally preferred nutritious foods.

While affordability and accessibility may be a barrier to purchase and consume AITFs, the promotion of household production may assist in increasing household consumption. In low-to-middle income countries, smallholder farming remains a primary livelihood for households, and therefore many rural consumers may serve a dual role also as producers. Nutrition-sensitive agriculture has demonstrated positive contributions to health outcomes for women and children. Constrained affordability and accessibility can limit an individual's ability to acquire production inputs and advanced technologies. Fortunately, AITFs often require fewer inputs compared to introduced vegetables. Since AITFs originated or have a long history of cultivation in the given locale, they are adapted to the local environmental conditions. Thus, this large group of under-utilized crops can provide real benefits to many environmentally vulnerable regions where increased heat, drought and biotic stressors associated with climate change are already noted and where local climate-resilient, culturally preferred, nutritious crops will become even more important. Furthermore, research and development initiatives have demonstrated the success of disseminating innovative production methods and technology through farmer engagement in extension settings (Sattaka et al., 2017; Simon et al., 2020, 2021).

### Pathways between production and food security

Adequate production of nutritionally dense fruits, vegetables, and grains can address household food and nutrition insecurity through two causal pathways: (1) improved access to nutrient-rich foods; and (2) improved household finances either through generating income from the sale of produce or saving income from food expenditures (Korth et al., 2014).

AITFs are traditionally wild harvested or self-produced using home gardens. In both rural or urban settings, AITFs production in home gardens can contribute to household food security and sovereignty, and ecological sustainability through household and community autonomy within the food systems. A study by Márquez and Schwartz (2009) found that home gardens in Petén, Guatemala, which are highly diverse, rich, and productive, contributed to household income, nutrition delivery, and strengthened social bonds and networks. In addition to rural agriculture, urban agriculture can contribute to improved food security and food sovereignty even with limited space. A study by Gallaher et al. (2013) reported that sack gardening in urban communities increased social capital and alleviated household food insecurity improving household dietary diversity, particularly during times of food shortages.

In addition to direct consumption, household-level production of fruits and vegetables impact household economics by decreasing grocery expenditure and generating income from sales. AITFs are popular, highly valuable produce with unmet market potential. A study conducted by Senyolo et al. (2014) reported that due to their historical importance, demand and preference for African ITFs were high among survey participants. In addition, they found that most individuals (80%) were willing to pay a premium for African ITFs. Regional significance is important and can support production among rural and urban producers.

Furthermore, some AITFs, such as quinoa, have successfully expanded to the global market. Access to both regional and export markets is often dependent on supply chain infrastructure (e.g., processing, storage, transportation). Furthermore, as the global popularity for specialty crops increases the balance between production for household consumption and sales can shift favoring income generation over household food security. As research and development frameworks are designed for these markets and commodities, it is important to prioritize food sovereignty among producers.

As demand for AITFs in informal and formal markets increases, it is important that interventions and extension agents continue to emphasize production for household consumption. Furthermore, increased household production is only one pathway to increase the affordability and accessibility of nutritious diets. Affordability and accessibility hinge on stability in the food environment (Downs et al., 2020). Extreme climate events or poor seed stock can cause crop failure or low yields further driving demand and price, limiting the availability of food options for purchase. Moreover, political unrest or regional shocks, such as the COVID-19 pandemic, may limit an individual's ability to access the markets. Hence, policy-level change needs to be enacted to fully address this issue.

AITFs are often in disabling environments that do not promote the production and consumption of these crops. This can further hinder the acceptability of available and accessible agricultural innovations and culinary advances (Ghosh-Jerath et al., 2021). Moreover, in communities that celebrate AITFs with pride, advances may meet cultural resistance in a desire to adhere to traditional norms (Ochieng et al., 2019). To promote acceptability, market-first science-driven solutions need to incorporate a community resilience framework such as FEEDS, which involves farmers and consumers directly in the formulation of the research agenda and actively engages them in the process of technological innovation and dissemination through hands-on demonstrations and storytelling (Fig. 1) (Simon et al., 2021).

### Acceptability

Acceptability of AITFs is defined by a situation when the available nutritious, culturally preferred foods are of sufficient quality (e.g., nutritional, freshness, and other attributes as defined by the community) and/or the production inputs and practices are of sufficient quality, and both are subsequently adopted. In addition to acceptability at the consumer level, it is also essential that AITFs exist in an enabling environment that promotes the production and consumption of AITFs. This section will examine how the superior quality (e.g., nutrition) in general of AITFs, compared to “Western” crops, and an how enabling environment can contribute to the acceptability of traditional and indigenous foods.

### Nutrition

AITFs often contain significantly higher macro-, and micronutrients compared to “Western” introduced crops. This section provides examples of the general health attributes of AITFs and examples of how processing and value-added production can diversity and alter the nutritional properties.

AITFs provide valuable micro- and macronutrients such as vitamins, minerals, carbohydrates, proteins, fats, and bioactive compounds such as antioxidants (Hoffman et al., 2018; Hunter et al., 2019). In Africa, Abukutsa-Onyango et al. (2010) found that priority ITFs (African nightshade *Solanum scabrum*, amaranth *Amaranthus sp.*, spider plant *Cleome gynandra*, cowpea *Vigna unguiculata*, pumpkin leaf *Cucurbita moschata*, slender leaf *Crotalaria sp.*, and jute mallow *Corchorus olitorius*) contained over 70–80% of the recommended daily intake of iron and 18–54% of the recommended daily intake of protein. Furthermore, Ghosh-Jerath et al. (2021) found that traditionally consumed grains, leafy-vegetables, and fungi were rich in macro- and micronutrients such as protein, calcium, iron, folate, Vitamin A and C. For example, the commonly consumed green leafy-vegetable *Crotalaria juncea*, was found to be a high source of calcium and Vitamin A.

To minimize culinary monotony, researchers have assessed more nuanced aspects of nutrition delivery through recipe development and variation in preparation styles. This research is essential to provide communities with more targeted interventions that maximize nutrition delivery. A study by Habwe et al. (2009) reported that cooking (e.g., boiling, pan-frying) traditional leafy

vegetables significantly increased the iron content compared to raw consumption. Moreover, the study found that pan-frying the vegetables with complementary ingredients such as tomatoes and onions significantly increased the iron content. This supports the use of traditional recipes that serve green leafy-greens along-side other vegetables for a complete side-dish. Even more importantly, this study found that boiling the vegetables with lye, which is traditionally done to soften the fibrous leafy greens, significantly decreased the iron content. Context specific nutrition education should focus on the promotion of utilizing complimentary vegetables while minimizing the use of lye for preparation to maximize iron delivery.

Given that numerous AITFs are wild harvested or have little to no domestic cultivation, there may be some concerns as to their potential anti-nutritional properties such as concentrations of alkaloids, oxalates, glycoalkaloids, and saponins. While studies have affirmed the relatively low presence of these compounds, more research is needed in this area as additional value-added products are explored for market sales (Yuan et al., 2019, 2020). For example, varieties of nightshade, which are native to EurAsia, are commonly consumed in South America and Africa where it was introduced. In South America, it is common to consume only the berries and not the leaves, while in Africa only the leaves are consumed and not the berries. The berries contain high levels of glycoalkaloids, anti-nutritional compounds, that if not carefully prepared (e.g., cooked) can be harmful. Furthermore, through selective breeding, a cultivar with relatively low concentrations of these compounds could become available creating “new” products for the AITF supply chain (Yuan et al., 2019) while the “toxic” varieties may have their own value-added application such as uses in pesticides and dye. In addition to consumer acceptability, AITFs must exist in an enabling environment that promotes the production and consumption of AITFs.

### **Enabling environments to promote consumption and production of AITFs**

The promotion and expansion of enabling environments that support the production and consumption of AITFs is critical to increasing the acceptability of AITFs at all levels of the food environment (e.g., local, national, global). Furthermore, enabling environments can help to mitigate barriers to household availability through production for consumption and sales; the accessibility of quality seeds and inputs; affordability and competitive market value; policies that promote the production and consumption of AITF; and women’s empowerment.

An innate contribution to the enabling environment for AITFs is their food heritage. IFTs have a long history of cultivation and use in their respective areas with women often serving as the custodians of the cultural knowledge (Hunter et al., 2019). The promotion of AITFs through historical legacy and pathways, such as storytelling, can contribute to cultural security and reinvigorate the use of AITFs, providing a sense and source of “cultural pride” (Simon et al., 2021). These traditional practices also support ecological services and resources expanding the scope of the enabling environment beyond politics toward sustainability and food ecosystem wellness. However, it is of note that not all AITFs evoke thoughts of cultural pride. In some parts of the world, IFTs are grown or wild foraged as a coping mechanism for food shortages and carry the social stigma of “famine foods” (Towns and Shackleton, 2018). In addition, social folklore can contribute to hesitancy around consumption. For example, crops with dark purple pigmentation (e.g., some amaranths in East Africa) can be incorrectly associated as being poisonous. An enabling environment may help retell the story of AITFs under a different lens that promotes cultural pride.

Governments that support the promotion of AITFs, often through the establishment of initiatives and policy, foster an enabling environment through the development of a clear framework as well as establishing incentives and accountability that integrate AITFs at all levels. To promote the acceptability of AITFs, interventions must balance local needs (e.g., economic, nutritional), market capacity, and cultural practice by enhancing existing community interests and networks.

The Biodiversity for Food and Nutrition Project (BFN) is an example of a multinational program that mainstreamed biodiversity conservation and sustainable use of AITFs for improved nutrition and well-being in the local, national, and global food system. As summarized by Hunter et al. (2019) BFN is based in Brazil, Turkey, Sri Lanka, and Kenya and programmatic work was often built upon pre-existing national initiatives. In Brazil, the work built on several national initiatives such as, but not limited to, *National School Meals Program* and *Food Acquisition Program*, which mandated that school meals are partially sourced from family farmers and paid an incentive for organic or agroecological produce from smallholder farmers.

Community participatory buy-in is important to promote policy-level change. Nutrition-sensitive agriculture interventions, at the household and community level, that take into consideration gender disparities may further promote an enabling environment for AITFs. Women serve as a major custodian in traditional knowledge and food practices. Furthermore, when women control the resources, they are more likely to use it for family consumption improving nutrition outcomes. A study by Ruel et al. (2010) found that nutrition-sensitive agriculture that contains complementary programming such as women’s empowerment as well as sanitation, health, and water, had a greater impact on nutrition outcomes for women and children. Empowering women to use their food heritage and knowledge to produce foods for household consumption and sales can also extend the scope of the “enabling environment” to include sustainability and food ecosystem wellness, as often these behaviors are coupled, both consciously and as proxy, with protecting and promoting ecological services. Furthermore, linking nutrition-sensitive interventions and cultural pride with new and/or improved acceptable ways of preparing foods can create a more inclusive and sustainable approach to nutrition behavior-change.

### **Sustainable food ecosystem**

Current industrial agricultural practices, climate change, and the decline of ecosystem services impact agriculture production. In the global agricultural system, genetic diversity is decreasing (Leff et al., 2004). In addition, the intensity of monoculture farming (e.g.,

large-scale land clearing, irrigation, fertilizer, and pesticide application) is a threat to many ecosystem services (e.g., pollination, pest control, and regulation of disease vectors) and a contributor to climate change. The global food supply chain's ability to feed the growing population depends on high amounts of the earth's natural resources such as land and water. The incorporation of AITFs in sustainable food ecosystems can contribute toward diverse, productive, and resilient agroecosystems (Altieri et al., 2012). This section will examine how AITFs can promote ecosystem services and the importance of genetic diversity for a stable food system.

### ***Tradition and indigenous foods promote ecosystem benefits and genetic diversity***

The incorporation of AITFs into agricultural systems poses several ecosystem benefits. AITFs have a low carbon footprint since are often gathered from cultivated or wild environments in traditional systems with minimal inputs compared to "Western" introduced crops. This is particularly important given that AITFs are adapted to marginal, complex, and difficult environments; environments that would require considerable inputs if they were used to cultivate "Western" introduced crops. In addition, traditional production systems often incorporate aspects of environmental management such as minimizing overharvesting and exploitation of crops as well as environmental benefits such as nitrogen-fixation (Sunderland et al., 2019). Furthermore, there is high genetic diversity among AITFs.

Agriculture diversification (both between and within species) can improve ecosystem services particularly during times of increased environmental stress (Altieri et al., 2012). Increased genetic diversity creates species redundancy, allowing stronger species to withstand environmental stress while sensitive species are lost from the system. This is particularly important for both human and environmental health. As climate variability continues to worsen, diverse genetic stock is critical for breeding nutritious, climate-smart, crops. In addition, crops, particularly those in wild and minimally cultivated environments serve many ecosystem niches such as but not limited to food and habitat. Diversified agricultural systems have been demonstrated to maintain greater biodiversity with high quality ecosystem services. Such climate "smart" crops may also provide greater benefits to communities during seasons and years of intense drought, floods, and/or pest infestations when the commodity crops may fail. This not only has positive ecological outcomes but also contributes to positive economic and social implications.

## **Conclusion**

The success of holistic models that incorporate African, EurAsian, American, and Australian indigenous and traditional foods (AITFs) demonstrates the need to combine concepts from food security and food sovereignty and focus research and development work at all levels of the food system. These AITFs provide an undervalued, under-recognized, under-leveraged source of nutrients (in addition to tastes and flavors) that can be used as economic drivers for job creation and create income generating opportunities among vulnerable populations (e.g., women, youth) complimenting rather than replacing traditional agronomic staple crops, grown so often by smallholder farmers. In addition to human health, AITFs offer climate and environmental sustainability solutions. Overall, AITFs are adapted to the biotic and abiotic stressors of the area and resilient to changing environmental conditions, providing climate smart crops for collection and production. AITFs are a diverse group of plants which include annuals, perennials, and legumes. Some of these plant types can facilitate nitrogen fixation, enhance soil health, reduce erosion, and contribute to increased biodiversity therefore providing environmental protection particularly when incorporated into agro-forestry systems to enhance economic, environmental, and cultural sustainability. Approaches that blend modern agricultural science and indigenous knowledge systems are proving to enhance food security while conserving agrobiodiversity and ecosystem services throughout the world. A multitude of strategies are urgently needed to address the core issues of food security and sovereignty. The development of AITFs need champions as these crops could have serious and contributing roles to ensuring that nutrient rich foods are available, affordable, accessible, acceptable, and adopted for regular home consumption and production.

## **Acknowledgment**

This work has been guided by our work over many years and thus is a synthesis of observations incorporated into the models under which we work. Prior research was made possible by the generous support of the American people through the US Agency for International Development (USAID). The contents are the responsibility of the Horticulture Innovation Lab and do not necessarily reflect the views of USAID or the US Government. This research was in part supported by the Horticulture Innovation Lab with funding from USAID (EPA-A-00-09-00004), as part of the US Government's global hunger and food security initiative, Feed the Future, for project titled "Improving nutrition with AITFs" in eastern Africa (Feed the Future, 2014). We thank Agilent Instruments, Shimadzu Instruments, the New Jersey Agricultural Experiment Station (HATCH project NJ12170), The New Jersey Institute for Food, Nutrition and Health and its Center for Agricultural Food Ecosystems (RUCAFE) and Center for Childhood Nutrition and Health; the World Vegetable Center (WorldVeg). We also thank the Academic Model Providing Access to Health Care (AMPATH), University of Eldoret, Moi University, University of Zambia, Cuttington University, Kenyan Agricultural and Livestock Organization (KALRO), AgriSmart-Zambia, Hantambo Women's Association, the Mitengo Women's Growers Association, and the Mirror of Hope CBO. We would also like to thank Drs. Steve Weller, Daniel Hoffman, Ramu Govindasamy, Xenia Morin, Rodolfo Juliani, and Shauna Downs. In addition we thank Dan Acquaye, Jerry Brown, Carol Wilson, John Bowman and Howard Shapiro as well as the many friends, faculty colleagues and importantly the communities and farmers with whom we have had the privilege of working as each who contributed to the success of our collaborative projects.

## Key points

- The adverse health effects of industrially-produced TFA are well documented in the scientific literature.
- Numerous countries have implemented effective measures to limit or remove TFA from the food supply.
- Intake of TFA has decreased worldwide as a result of public health efforts, although intake still remains higher than recommended in some countries that have not yet enacted policies to reduce TFA.

## Introduction

TFA are a class of fatty acids that contain one or more double bonds in the *trans* configuration. The two dietary sources of TFA are those produced through the partial hydrogenation of oils (industrially-produced), and those that are naturally-occurring, which are produced by ruminant animals (ruminant TFA). Historically, vegetable oils were partially hydrogenated for use in margarines, commercial cooking and frying, and food manufacturing. The presence of TFA results in fats that are solid at room temperature, longer shelf-life of commercial products, and stability of oils at very high temperatures. Elaidic acid (C18:1, t9) typically is the major isomer contained in industrially-produced sources of TFA. Ruminant TFA are synthesized via bacterial metabolism of C18 unsaturated fatty acids in ruminant animals, and found in ruminant-derived products, such as beef, lamb, and dairy. Vaccenic acid (C18:1, t11), the predominant *trans*-monoene isomer in ruminant fats, comprises 50–80% of the total TFA in ruminant fat and is the precursor for the c9,t11 isomer of conjugated linoleic acid (CLA). CLA is a group of positional and geometric conjugated isomers of linoleic acid. The two predominant isomers of CLA with known bioactive properties are c9,t11 and t10,c12.

## Health effects

Numerous studies have demonstrated the adverse effects of industrially-produced TFA on the risk of chronic diseases, including cardiovascular disease, cancer, and diabetes. However, the health effects of ruminant TFA in humans have not been as well-studied, and clinical studies comparing the two sources of TFA are more limited.

### Cardiovascular disease

#### Coronary heart disease

Numerous epidemiological studies have demonstrated an association between intake of TFA and risk of coronary heart disease (CHD). In the early 1990s, results from the Nurses' Health Study, a prospective cohort study, demonstrated that intake of TFA isomers was directly related to risk of CHD (RR = 1.5, 95% CI 1.12–2.00, *p* for trend = 0.001) (Willett, 1993). In contrast, there

was a nonsignificant inverse association with intake of TFA from ruminant sources and risk of CHD. Two meta-analyses have reported similar findings demonstrating that intake of industrially-produced TFA increases total CHD and CHD mortality whereas intake of ruminant TFA does not (Bendsen, 2011; de Souza, 2015).

Overall, these data suggest that intake of ruminant TFA may have differential effects on CHD risk compared with those of industrially-produced TFA; however, both meta-analyses are based on a limited number of studies ( $n = 6$ ). Further research is needed to determine the effects of ruminant TFA on CHD risk.

### Lipids and lipoproteins

Clinical trials consistently demonstrate that consumption of TFA adversely affects lipids and lipoproteins. Studies have demonstrated that these effects are greater than those of saturated fatty acids. Compared with saturated fatty acids, consumption of TFA results in a lower concentration of high-density lipoprotein (HDL)-cholesterol and a higher concentration of low-density lipoprotein (LDL)-cholesterol (specifically small dense LDL particles), triglycerides, and Lp(a).

In a recent systematic review of nine studies, TFA from ruminant sources seemed to have less impact on HDL-cholesterol than TFA from industrially-produced sources (Verneque, 2020). However, for total- and LDL-cholesterol, results indicated that TFA from ruminant sources may increase blood concentrations to a greater degree than TFA from industrially-produced sources (Verneque, 2020) albeit there may be differences in the response of men and women. In some clinical studies, amounts of TFA consumed have been high (e.g., 7% of energy) compared to typical intake. Additionally, some studies suggest a greater effect in women, although these sex differences have not been well established.

### Cancer

The association of TFA intake and cancer risk has been investigated for at least 19 types of cancer, with the most studied types of cancer being breast, prostate, and colorectal. One recent meta-analysis of total TFA intake (regardless of dietary source) demonstrated a positive association (significantly higher odds ratio) between TFA consumption and risk for prostate and colorectal cancer. No association was identified for breast, ovarian, or non-Hodgkin lymphoma (Michels, 2021). Data on the association between TFA intake and other cancer sites are very limited. In another recent meta-analysis, no association was found between intake of TFA and breast cancer risk in pre- and post-menopausal women; however, a positive association was found between serum concentration of TFA and breast cancer risk in post-menopausal women (Anjom-Shoae, 2020). There was no association in this meta-analysis between CLA intake and risk for breast cancer (Anjom-Shoae, 2020).

### Insulin sensitivity and diabetes

Some studies suggest that TFA can exacerbate insulin resistance. However, a recent meta-analysis concluded that there was no effect of TFA (ruminant or industrially-produced sources) on fasting glycemia, insulin sensitivity, or insulinemia (Verneque, 2020). In the Nurses' Health Study, high intake of TFA (3% of energy) was associated with an increased risk of type 2 diabetes (Oh, 2005). Results from this study suggest that replacement of 2% of energy from TFA with polyunsaturated fatty acids would result in a 39% increase in risk of type 2 diabetes. However, in two other prospective studies, the Health Professionals Follow-Up Study (van Dam, 2002) and Iowa Women's Health Study (Meyer, 2001), there was no association with TFA intake and risk of diabetes.

### Dietary recommendations, regulations, and dietary intake

Reflecting the growing body of scientific evidence on the adverse effects of industrially-produced TFA, numerous public health recommendations on TFA were issued in the early 2000s. In 2002, the US National Academies of Sciences, Engineering and Medicine recommended that TFA consumption should be as low as possible in a nutritionally adequate diet (Institute of Medicine). In 2003, the World Health Organization (WHO) recommended that TFA intake should be limited to less than 1% of overall energy consumption (World Health Organization). The *Dietary Guidelines for Americans* first included recommendations for TFA in the 2005 edition, with a key recommendation that TFA consumption should be as low as possible (U.S. Department of Health and Human Services). Numerous other national and international organizations have since issued similar recommendations. In a recent scoping review on available guidelines for dietary fat published between 2015 and 2020, most organizations included recommendations for industrially-produced TFA that spanned from complete avoidance to limiting intake to no more than 2% of energy intake (Schwingshackl, 2021).

Denmark became the first country to regulate TFA in the food supply, in 2003, by mandating that only 2% of fats and oils could be TFA (Stender, 2004). Also in 2003, the U.S. Food and Drug Administration (FDA) amended its regulations on food labeling, effective in 2006, to require that *trans* fat be declared on the Nutrition Facts label of foods (U.S. Food and Drug Administration, 2003). New York City took action in 2006 to remove TFA from foods sold in food service establishments, followed by the state of California and several U.S. cities and regions in 2007 and 2008 (e.g., Philadelphia, PA; Baltimore, MD; Boston, MA; and Montgomery County, Maryland). In 2015, the FDA took measures to remove industrially-produced TFA from the US food supply by determining that partially hydrogenated oils (PHOs) are no longer "Generally Recognized as Safe" or GRAS (U.S. Food and Drug Administration, 2015). Consequently, PHOs, which previously were the main source of TFA in the diet, have been largely

removed from foods in the United States. Other countries have also implemented regulations to eliminate PHOs ([Government of Canada, 2018](#)), and in 2018 the WHO called for the global elimination of industrially-produced *trans* fatty acids by 2023 ([Ghebreyesus, 2018](#)). The 2021 WHO report on global *trans* fat elimination summarizes the progress that has been made toward this goal. There are 57 countries that currently have mandatory TFA policies in place, however several countries that have the highest CHD burden attributed to TFA intake have yet to implement mandatory policies ([World Health Organization, 2021a](#)).

Overall, intake of TFA has declined worldwide in the past 25 years as a result of the public health efforts to remove industrially-produced TFA from foods. Consequently, in most countries where data are available, intake of ruminant TFA is now higher than intake of industrially-produced TFA ([Wanders, 2017](#)). Studies evaluating the effectiveness of regulations to limit TFA in the food supply, such as local regulations implemented in New York City, and regulations in other countries, have demonstrated a significant decrease in TFA consumption and disease burden, as reviewed by Li et al. ([Li, 2019](#)). When comparing nationally representative data in the US from 1999 to 2000 versus 2009–2010, which spanned the time period when US labeling requirements for *trans* fat were implemented as well as other actions such as local and state regulations to limit TFA in food-service establishments, plasma TFA concentrations decreased by an average of 61.9% in children and adolescents and by 54% in adults ([Restrepo, 2020](#); [Vesper, 2017](#)). Data are still needed to determine the effectiveness of some of the more recent measures that have been implemented. For example, the data used in analyses of dietary intake and sources of TFA in the US were collected prior to when PHOs were removed from the food supply in the US ([Wanders, 2017](#); [Li, 2021](#)).

Monitoring of TFA intake is a critical tool to not only evaluate the effectiveness of regulations and policies in areas where they have been implemented, but also to demonstrate the need for enacting measures to reduce TFA intake in countries where intake remains high. As previously discussed, although intake has declined in many countries where actions have been taken, intake still remains higher than recommended in countries that have not implemented regulations and policies to reduce TFA. To help reach the goal of elimination of *trans* fat from the global food supply by 2023, the WHO developed the REPLACE action package to help countries eliminate industrially-produced TFA ([World Health Organization, 2021b](#)). This approach highlights several areas where countries can focus their efforts, one of which involves determining and promoting healthier alternatives to industrially-produced TFA.

## **Trans fat alternatives**

*Trans* fats became a prevalent ingredient in food products as a means for replacing saturated fats in the diet, as the adverse effects of saturated fats were well known. It is now understood that the effects of industrially-produced TFA on numerous health outcomes are more deleterious than those of saturated fatty acids. As TFA have been removed or significantly reduced in the food supply, it has led to the question—what alternatives to PHOs should be used as food manufacturers are reformulating products? There are multiple considerations when choosing alternatives for TFA, including taste and texture, as well as cost and availability. Moreover, the potential health effects of the alternative should be considered, so as to avoid introducing a harmful ingredient into the food supply.

One technique that has been utilized to replace industrially-produced TFA is interesterification of fats—a process in which fatty acids are rearranged on a triacylglycerol molecule. This technique is useful because the position of fatty acids on the glycerol molecule is critical in creating a fat with the proper physical properties required for the application. Stearic acid and palmitic acid, both saturated fatty acids, typically are used in interesterification. In a recent systematic review, interesterification with stearic and palmitic fatty acids (increasing their concentration in the *sn*-2 position), compared with low palmitic or stearic fatty acids in the *sn*-2 position, did not affect fasting concentrations of lipids or apolipoproteins ([van Rooijen, 2020](#)). The same authors also conducted a systematic review comparing the effects of stearic acid and palmitic acid and found that replacing palmitic acid with stearic acid lowered LDL-cholesterol ([van Rooijen, 2020](#)). Additional research is needed from both the fasted and post-prandial states to better understand the impact of interesterification on other biomarkers of health, especially cardiometabolic health.

Other TFA alternatives include oils that require little or no hydrogenation, such as tropical oils (palm oil, palm kernel oil, and coconut oil), as well as oils developed by manipulating the fatty acid composition of oil seeds (low-linoleic, midoleic, or high-oleic oils) to create products that exhibit increased oxidative stability during deep-frying and increased shelf-life due to increases in relatively stable fatty acids (i.e., oleic acid) and decreases in relatively unstable fatty acids (i.e., linolenic acid). Tropical oils, however, are high in saturated fatty acids, and are therefore not included in the group of oils that are recommended as part of a healthy dietary pattern ([U.S. Department of Agriculture](#)). When choosing TFA alternatives, an important consideration is whether they provide the functionality needed depending on the food application. For baking applications, where solid or semisolid fats are needed for consistency and feel, alternatives such as interesterified fats, tropical oils, and fully hydrogenated vegetable oil can be used. For frying applications, oils such as soybean, canola, cottonseed, and high-oleic sunflower oil, for example, can be useful. A few dietary intervention studies have demonstrated lipid-lowering effects of high-oleic oils, including high-oleic canola oil ([Gillingham, 2011](#); [Jones, 2014](#)) and high-oleic soybean oil ([Lichtenstein, 2006](#)), when compared to a variety of other oils. In 2018, FDA issued a qualified health claim for edible oils containing  $\geq 70\%$  of oleic acid per serving based on credible evidence that consumption of these oils may reduce the risk of CHD, when substituted for fats and oils that are higher in saturated fat ([U.S. Food and Drug Administration](#)). A more recent study was the first to compare high-oleic oils to alternative oils with similar functionality ([Baer, 2021](#)). In this study, consuming a diet prepared with high-oleic soybean oil, as well as a diet prepared with a blend of high-oleic soybean oil and fully hydrogenated soybean oil, resulted in improved lipid and lipoprotein profiles compared to a diet prepared with a blend of palm oil and palm kernel oil ([Baer, 2021](#)).

Soybean oil and canola oil, which are sources of the essential fatty acids linoleic acid and alpha-linolenic acid, are widely used in the food supply. While modified high-oleic oils have higher amounts of oleic acid than traditional oils, they also have lower amounts of linoleic acid and alpha-linolenic acid. Modeling has been used to estimate the effects of replacing these traditional oils with high-oleic oils on fatty acid intake at population levels. In US adults and children, replacement of soybean oil and canola oil with high-oleic varieties at multiple levels (10%, 25%, and 50% in adults; 20%, 40%, 60%, and 80% in children), were estimated to decrease saturated fatty acid intake, increase monounsaturated fatty acid intake (particularly oleic acid), and decrease polyunsaturated fatty acid intake (particularly linoleic acid and alpha-linolenic acid) (Raatz, 2018; Belury et al., 2022). Further, results suggest that replacement of soybean oil and canola oil with high-oleic soybean oil and high oleic canola oil may lead to inadequate intakes of these essential fatty acids in certain segments of the US adult population and in US children, at levels of replacement of  $\geq 25\%$  and  $\geq 40\%$ , respectively (Raatz, 2018; Belury et al., 2022). In contrast, previous modeling in the US population with different parameters suggests that adequate intake levels of linoleic acid and alpha-linolenic acid are met when estimating the effects of different uses of soybean oil varieties in the food supply (Lefevre, 2012; Crawford, 2011). While additional research is needed on the impact of using different TFA alternatives, these studies demonstrate the importance of using a balanced approach with a variety of different oils and fats in the food supply.

## Conclusions

Overall, data from epidemiologic and clinical studies consistently demonstrate the adverse effects of industrially-produced TFA on CHD risk and lipids and lipoproteins; their effects on other chronic disease risk factors, such as insulin resistance, as well as risk of type 2 diabetes and cancer, are less consistent. Further research is needed to determine the effects of ruminant TFA at amounts typically consumed in the diet. Public health measures have been effective in reducing intake of industrially-produced TFA in countries where they have been implemented. As alternatives to TFA are used in foods, it is important to continue to study their effects on health outcomes. Studies suggest that high-oleic soybean oil, as well as blends of high-oleic soybean oil with fully hydrogenated soybean oil, may be functional alternatives that have beneficial effects on lipid profiles.

## Key points

- The NOVA food classification system has been largely used and it is recognized as a valid tool for public health and nutrition research and policy;
- The most up-to-date evidence suggests that a major contributor of unhealthy dietary patterns and chronic non-communicable diseases is a high intake of ultra-processed foods;
- The article provides the mechanisms underlying the associations between ultra-processed foods and their impact on health;

## Introduction

The food preparation and the techniques used for its cultivation and preservation allowed the evolution and adaptation of the human species (Wrangham, 2013). Historically, food processing has been slowly and gradually consolidated during the history of humanity. However, since the early 1980s, food processing has developed very rapidly and with intense changes through science and technology. Factors such as economic globalization, changes in food production, and consumption patterns have revolutionized the food patterns in most countries by increasing the production, availability, accessibility, and commercialization of processed food products and beverages (Ludwig, 2011; Swinburn et al., 2011). Traditional diets based on fruits and vegetables were replaced by diets with high energy density, rich in sugar and sodium, with increased consumption of fats, especially saturated and trans, refined carbohydrates and animal source foods (WHO, 2003). At the same time, obesity and its related conditions, such as hypertension and diabetes, have risen very rapidly. Such changes in dietary patterns are known as the “nutrition transition” (Popkin, 2004; Popkin et al., 2012), with increased consumption of industrially processed foods as a striking characteristic of these new dietary patterns.

Traditionally, epidemiological studies investigating dietary patterns and their impact on health have used energy and macro and micronutrient intake as the basis for assessing the diet. However, it is well-established that individuals do not ingest isolated nutrients, but meals composed of different foods that provide different nutrients and chemical compounds that interact synergically. Since 1998, the World Health Organization has suggested that food consumption should be assessed based on food rather than nutrients (World Health Organization, 1998), making it possible to measure the dietary pattern more reliably.

The impact of industrial processing and, particularly, techniques and ingredients developed by the food industry on the nature of food and the state of human health is still not widespread. Until recently, food processing was neglected in epidemiological and experimental studies on diet, nutrition, and health.

Recently, in 2010, the NOVA classification system of industrial food processing was developed based on the degree and purpose processing (Monteiro et al., 2010). The NOVA classification precisely defined ultra-processed food (UPF) and is now considered a valid tool for public health and nutrition research and policy. Moreover, there is a growing body of scientific evidence assessing the burden of disease attributable to specific UPF consumption. Therefore, understanding the use of UPF classification and its application is of great importance. The following sections describe the most recent NOVA update and a summary of its uses and the relationship between UPF consumption and nutritional quality and its impact as a risk factor for diseases.

## Defining ultra-processed foods—NOVA classification system

Food processing in itself is not a problem as most foods are processed to some extent, if only to promote longer shelf-life and limit spoilage. Thus, it is essential to highlight that the terms “processing” and “industry” are very general and, therefore, not helpful. NOVA system classifies all foods and food products into four groups based on the extent, nature, and purpose of food processing they undergo. To that extent, the NOVA system considers all physical, biological, and chemical aspects used during the food manufacturing process, including additives (Monteiro et al., 2019b).

Foods may be consumed by themselves (fruits), or as the main item or accompanying items of dishes and meals (such as grains, flours, vegetables, meat, eggs); or as food products for cooking food and creating culinary preparations (such as oils, butter, sugar, salt); or they may be food products ready to consume or heat. NOVA groups are described below. Table 1 presents detailed lists of foods of each of NOVA groups.

### Group 1. Unprocessed or minimally processed foods

Unprocessed and minimally processed foods make up group 1 of NOVA. Unprocessed (or natural) foods are edible parts of plants (seeds, fruits, leaves, stems, roots) or animals (muscle, offal, eggs, milk), and also fungi, algae, and water, after separation from nature. Minimally processed foods are unprocessed foods altered by minimal industrial processes before being purchased and consumed, with the main objective of extending the useful life of the food, allowing its storage for prolonged use.

In this group, industrial processes include removal of inedible or unwanted parts, drying, crushing, grinding, fractioning, roasting, boiling, pasteurization, refrigeration, freezing, placing in containers, vacuum packaging, non-alcoholic fermentation or similar procedures, conserving much of the nutritional properties of the original food and increasing its availability and safety. None of

**Table 1** The NOVA food groups with examples.

(1) Unprocessed or minimally processed foods	(2) Processed culinary ingredients	(3) Processed foods	(4) Ultra-processed foods
<p>Fresh, frozen, or dried fruits or vegetables; grains (rice, corn, oat); legumes (beans, lentils, and chickpeas); starchy roots and tubers (potatoes, sweet potatoes, and cassava); fresh or chilled or frozen meat, poultry, fish and seafood; eggs; fresh or pasteurized milk; 100% pasteurized or fresh fruit juice; no-added-sugar plain yogurt; nuts and seeds without added sugar or salt; spices and dried herbs; tea, coffee, and drinking water.</p> <p>It also includes foods made up from two or more items in this group but contain no added ingredients (e.g., mixed dried fruits).</p>	<p>Vegetable oils (olives oil, coconut oil, soy oil); animal fat (butter and lard); vinegar; sugar, honey, and maple syrup; starches extracted from corn and other plants; and salt.</p> <p>It also includes foods consisting of two group 2 items (e.g., salted butter) and group 2 items with added vitamins or minerals, such as iodized salt.</p>	<p>Canned vegetables and legumes; salted or sugared nuts and seeds; canned fish; plain yogurt with added sugar; fruits in syrup (e.g., Jam made of fruit and sugar with or without added anti-oxidants; freshly made unpackaged bread and cheeses.</p> <p>They may contain additives (e.g., anti-oxidants).</p>	<p>Carbonated soft drinks, sweetened juice; juice powder; cookies; ice cream, sweet or savory packaged snacks; chocolate, candies (confectionery); “breakfast cereals”; cereal bars; cookies (biscuits), cakes and cake mixes; microwave popcorn; flavored granola bars with added sugar and preservatives; artificially flavored cheese; baby cereals; margarine, mayonnaise and dressing; sugary milk beverages; flavored and sugared yogurt; “energy drinks”; fish/chicken “nuggets”; fast food burgers, sausages, hot dogs, and other reconstituted meat products; frozen products ready to heat such as pasta dishes, pizzas, hamburgers, pre-prepared pies; powdered and packaged “instant” soups, noodles and desserts; industrially produced bread.</p>

Adapted from Monteiro et al. (2019b).

these processes add salt, sugar, oils or fats, or other food substances to the original food. Group 1 items may infrequently contain additives that prolong product duration, protect original properties, or prevent the proliferation of microorganisms. Finally, in appropriate combinations and quantity, all foods in this group form the basis for healthy diets.

## Group 2. Processed culinary ingredients

Processed culinary ingredients are substances derived from Group 1 foods or from nature by processes that include pressing, refining, grinding, milling, and drying. Examples are oils, butter, sugar and salt. Their use is in the preparation, seasoning, and cooking of group 1 foods. Processed culinary ingredients are not meant to be consumed by themselves but are normally used in combination with unprocessed and minimally processed foods to make meals and dishes. Group 2 items may contain additives used to preserve the product's original properties, prolong duration or prevent the proliferation of microorganisms.

## Group 3. Processed foods

Processed foods are made essentially by adding salt, oil, sugar or other substances from Group 2 to Group 1 foods. Classic examples included bottled vegetables, canned fish, fruits in syrup, cheeses, and freshly made bread. They are relatively simple products—most processed foods have two or three ingredients and are recognizable as modified versions of Group 1 foods. Processes include various cooking or preservation methods, such as canning and bottling, and, in the case of bread and cheese, non-alcoholic fermentation. The purpose of processing in Group 3 is to increase Group 1 foods' durability or modify or enhance their sensory qualities. Processed food products usually maintain the identity and most proprieties of the original food. While some of these foods may contain additives and ingredients like oil, sugar, and salt, they can be part of a healthy diet in moderate amounts. Group 3 items may contain additives that prolong product duration, protect original properties, or prevent the proliferation of microorganisms.

## Group 4. Ultra-processed foods

The fourth NOVA group is of UPF and drink products. These are formulations of ingredients, most of exclusive industrial use, that result from a series of industrial processes. UPF are not modified foods but formulations made mostly or entirely from substances derived from foods and additives and typically including little or no fresh food from Group 1. Processes enabling the manufacture of ultra-processed foods include fractioning whole foods into substances, chemical modifications of these substances, assembly of unmodified and modified food substances using industrial techniques such as extrusion, molding, and pre-frying. Processes end with sophisticated packaging, usually with synthetic materials.

Sugar, oils and fats, and salt are often ingredients used to make UPF, generally in high quantity. However, in terms of ingredients that are characteristics of ultra-processed foods and used only in the manufacture of these products, they can be divided into food substances of no or rare culinary use and classes of additives ("cosmetic additives"). Food substances of no or rare culinary use include high fructose corn syrup, maltodextrin, hydrogenated or interesterified oils, and protein isolates. Classes of additives found only in ultra-processed products include cosmetic additives whose function is to make the final product palatable or often hyper-palatable. These additives include flavors, flavor enhancers, colors, emulsifiers, sweeteners, thickeners, and anti-foaming, bulking, carbonating, foaming, gelling, and glazing agents. Other additives in ultra-processed foods include some also used in processed foods, such as preservatives, antioxidants and stabilizers that prolong product duration, protect original properties or prevent proliferation of microorganisms. Typical examples of UPF are soft drinks, sweet or savory packaged snacks, breakfast cereal, candies, chocolate, "instant" soups and noodles, processed meats, pre-prepared frozen dishes; and many other products.

The main objective of the processes and ingredients used for the manufacture of UPF is to create products ready to eat, drink, or heat, attractive (hyper-palatable), and highly profitable (low-cost ingredients) food products designed to displace all other food groups, especially from Group 1. **Box 1** shows some ways to recognize ultra-processed food.

### Box 1 How to identify an ultra-processed food?

One of the most practical ways to identify if a product is an ultra-processed food is to check its list of ingredients:

- Typically, these foods have a long list of ingredients. A product containing more than five ingredients is likely to be ultra-processed.
- Among these ingredients, at least contains one item characteristic of the ultra-processed foods: Food substances of no or rare culinary use or cosmetic additives, some of them with unrecognizable ingredients.

## Global participation of ultra-processed foods

The global consumption of ultra-processed foods has increased dramatically (Juul and Hemmingsson, 2015; Marrón-Ponce et al., 2018; Monteiro et al., 2011, 2018). In high-income countries such as the United States (Baraldi et al., 2018), United Kingdom (Rauber et al., 2018), and Canada (Moubarac et al., 2017), ultra-processed foods already represent a significant percentage of about 50–60% of the total dietary energy consumed. In low- and middle-income countries, the participation of ultra-processed foods in the diet is lower than in high-income countries such as Brazil, Mexico, and Chile, ranging from 20 to 30 % (Cediel et al., 2018; Louzada et al., 2015b; Marrón-Ponce et al., 2018). In Brazil, trends analysis from Household Budget Surveys evidenced that the caloric share of UPF in household purchases increased from 8.6% in 2002–2003 to 18.4% in 2017–2018. As intake of ultra-processed foods increased, intake of minimally processed foods also decreased.

While UPF contribution is highest in high-income countries, sales of UPF in low- and middle-income countries are rising at a disproportionate rate compared to high-income countries (Vandevijvere et al., 2019). For example, Euromonitor reported a sales growth in UPF by 30% in Brazil from 2000 to 2013, while in the same period, sales dropped in the United States and Canada (–9% and –7.3%, respectively) (PAHO, 2015). These shifts evidence that food supplies are now becoming part of a global food system increasingly dominated by ready-to-consume ultra-processed foods.

As the sale and consumption of ultra-processed foods increase worldwide, children are a vulnerable group of being their leading consumers. The literature describes a high contribution of ultra-processed foods among children, with values ranging from 19.7 to 47% of total energy intake (Karnopp et al., 2017; Leffa et al., 2020; Rauber et al., 2015; Sparrenberger et al., 2015). In fact, the consumption of these foods begins in early life, even before the recommended timing of food introduction for infants. In Brazil, a cross-sectional study revealed that almost one-quarter (23.3%) of infants under six months consumed at least one UPF on the previous day, with high participation of soft drinks and cookies or crackers (Spaniol et al., 2020). The consumption of UPF in childhood is especially alarming given that dietary patterns in this period often track into adulthood (Ventura and Worobey, 2013).

## Impact of ultra-processed foods on diet quality

Since the NOVA food classification system was proposed in 2010, several studies conducted in different countries have assessed the impact of UPF consumption on diet quality, particularly focusing on nutrients associated with non-communicable diseases. The high contribution of UPF in dietary patterns is associated with diets of lower nutritional quality, characterized by an excess intake of energy, free/added sugar, unhealthy fats (saturated and trans), sodium, and a lower intake of proteins and fibers (Cornwell et al., 2018; Louzada et al., 2015b; Martínez Steele et al., 2017; Moubarac et al., 2017; Rauber et al., 2019). A report of the Food and Agriculture Organization of the United Nations (FAO) summarized evidence of UPF intake and the nutrient profile of the overall diet from analyses of nationally representative data sets collected in 15 countries (Monteiro et al., 2019a). Briefly, the findings revealed that regardless of country and its dietary pattern, ultra-processed foods make the diet nutritionally unbalanced.

In particular, there is an increasing concern about the impact of ultra-processed foods on free/added sugar intake. The World Health Organization guidelines recommend limiting free sugars intake to less than 10% of total energy intake to prevent excess body weight and dental caries and less than 5% for additional health benefits (WHO, 2015). In the United States, a study with a nationally representative sample of the population showed that nearly 90% of the calories of added sugars came from ultra-processed foods (Martínez Steele et al., 2016). Moreover, US Americans in the highest quintile of ultra-processed foods intake exceeded three times the recommended limit of 10% energy from added sugars compared to those in the lowest quintile (82.1% and 26.4%, respectively).

Finally, these studies document that ultra-processed foods are clearly associated with an overall deterioration of the nutritional quality of diets. This has a potential risk for increasing non-communicable diseases, highlighting the critical impact of these foods consumption on public health.

## Impact of ultra-processed foods on health

New research had provided convincing evidence supporting a number of mechanisms to quantify the burden of disease attributable to specific UPF consumption. Rigorous studies have shown that the higher consumption of ultra-processed foods is associated with an increased risk of overweight, obesity, metabolic syndrome, and related diseases, in addition to the increased risk of mortality from all causes. The results of the main evidence on this topic are summarized below:

### Obesity

In adults, studies with representative samples of populations from different countries demonstrated a positive and independent association between the greater participation of ultra-processed foods in the diet and obesity (Canhada et al., 2019; Filgueiras et al., 2019; Juul and Hemmingsson, 2015; Louzada et al., 2015a; Machado et al., 2020; Rauber et al., 2020). Juul et al. in a cross-sectional study with a nationally representative sample of US adults found that the highest consumption of ultra-processed foods was associated with 53% and 62% higher odds of being obese and abdominal obesity, respectively (Juul et al., 2018).

The association between UPF exposure and obesity-related outcomes has recently been confirmed in a randomized controlled trial (Hall et al., 2019). Adults received either ultra-processed or unprocessed diets for 2 weeks immediately followed by the alternate diet for 2 weeks. The diets had a similar nutritional profile in calories, energy density, macronutrients, sugar, sodium, and fiber. When exposed to the ultra-processed diet, the results showed that the participants consumed, on average, 500 calories more per day and increased, on average, 0.9 kg of body weight in two weeks. Significant changes were also observed in the hormones involved in regulating hunger and food intake during the study period. This study is an important milestone in the research field of ultra-processed foods as it was the first to determine a potential mechanism behind the relationship between UPF consumption and weight gain.

Finally, a recent systematic review and meta-analysis, including the results of 14 studies and 189,966 participants ranging between 10 and 64 years, reported the association between UPF with overweight and obesity (Askari et al., 2020). In sensitivity analysis, higher UPF intake was associated with an increase risk of 33% (pooled effect size: 1.33; 95% CI: 1.18, 1.49,  $p < 0.001$ ) of being overweight and 73% (pooled effect size: 1.73; 95% CI: 1.36, 2.20,  $p < 0.001$ ) of obesity. Thus, both clinical and epidemiological studies implicate UPF intake with a higher risk of developing obesity.

### Cardiovascular and metabolic diseases

With regards to metabolic diseases, a population-based cohort study in France (NutriNet-Sant ) longitudinally evaluated the effect of ultra-processed foods consumption of more than 100,000 French adults. Over a five-year period, a 10% increase in the consumption of ultra-processed foods diet was associated with a significant increase in the risk of cardiovascular diseases (12%), coronary heart disease (13%), and cerebrovascular disease (11%) (Srou et al., 2019). These findings are consistent with the results of the Framingham Offspring Study (Juul et al., 2021), which followed more than 3000 adults free from cardiovascular diseases at baseline for up to two decades, indicated that for each additional daily serving of ultra-processed the risk of CVD risk increased by a further 7%, and the risk of CVD mortality increased by 9%. Investigating the impact on blood pressure, a large prospective cohort of adults Spanish (SUN project) with a mean follow-up period of 9.1 years evidenced that higher consumption of ultra-processed foods increased by 23% the risk of developing hypertension (Mendon a et al., 2017). Likewise, in 2 cross-sectional studies conducted in Brazil (Scarannide et al., 2021) and Canada (Nardocci et al., 2021), participants with the highest compared with those in the lowest intake of ultra-processed had 23% and 60% higher odds of hypertension, respectively. Other studies indicate an UPF link to metabolic syndrome in US adults (Mart nez Steele et al., 2019) and Brazilian adolescents (Tavares et al., 2012).

Consumption of ultra-processed foods may affect metabolic health even in early life. A longitudinal study of Brazilian children found an association between consumption of UPF at pre-school age and higher levels of total and LDL cholesterol (Rauber et al., 2015) and waist circumference at school age (Costa et al., 2019). Additionally, Leffa et al. in a longitudinal study with 308 Brazilian children from a low-income population, found that higher UPF consumption at age 3 years was associated with increased levels of total serum cholesterol later and triglycerides later at age 6 years (Leffa et al., 2020).

### Diabetes
