<i>Contributors to Volume 1</i>	<i>ix</i>
<i>Editor Biographies</i>	<i>xiii</i>
<i>Preface</i>	<i>xvii</i>

## THE FOUNDATIONS OF HUMAN NUTRITION

Aluminum <i>Robert A Yokel</i>	1
Amino acids: Chemistry and classification <i>Guoyao Wu</i>	10
Amino acids: Metabolism <i>Guoyao Wu</i>	23
Amino acids: Specific functions <i>Guoyao Wu</i>	36
Antioxidants: Intervention studies <i>Rafael A Casuso, Javier González Gallego, and Jesús Rodríguez Huertas</i>	48
Antioxidants: Physiology and dietary sources <i>Jesús R Huertas, S Stanner, and E Weichselbaum</i>	61
Bioavailability <i>L Davidsson and SA Tanumihardjo</i>	76
Biotin <i>Donald M Mock and Luis Fontana</i>	85
Caffeine <i>Rafael Urrialde</i>	96
Calcium <i>V Loria-Kohen, AM López-Sobaler, A Aparicio, and RM Ortega</i>	105
Carbohydrates: Chemistry and classification <i>Chrysanthi Stylianopoulou</i>	114
Carbohydrates: Regulation of metabolism <i>Chrysanthi Stylianopoulou</i>	126

Carbohydrates: Requirements and dietary importance <i>Chrysanthi Stylianopoulou</i>	136
Carotenoids: Chemistry, sources and physiology <i>E Rodríguez-Rodríguez, LM Bermejo, and RM Ortega</i>	144
Carotenoids: Health effects <i>Sherry A Tanumihardjo</i>	154
Choline and phosphatidylcholine <i>Kevin C Klatt</i>	162
Cholesterol: Sources, absorption, function, and metabolism <i>DJ McNamara</i>	175
Chromium <i>John B Vincent</i>	181
Cofactors: Inorganic <i>ED Harris</i>	189
Copper <i>Peter J Aggett</i>	200
Dietary fiber: Classification and physiological role <i>Madeline Timm and Joanne Slavin</i>	209
Energy requirements <i>Susan B Roberts and Rachel E Silver</i>	217
Fatty acids: Omega-3 polyunsaturated <i>AP Simopoulos</i>	223
Fatty acids: Omega-6 polyunsaturated <i>TA Mori and JM Hodgson</i>	232
Fiber intake and resulting health benefits <i>Rebekah Schulz and Joanne Slavin</i>	239
Folate/folic acid <i>Joshua W Miller</i>	247
Homocysteine <i>Joshua W Miller</i>	259
Iodine: Deficiency disorders and prevention programs <i>MB Zimmermann</i>	268
Iodine: Physiology, dietary sources, and requirements <i>Sonja Y Hess and Elizabeth N Pearce</i>	273
Iron: Physiology, dietary sources, and requirements <i>B Lönnerdal and O Hernell</i>	282
Lipids (fats and oils) <i>AH Lichtenstein</i>	291
Lipoproteins <i>JM Ordovas</i>	301

Magnesium <i>LH Allen</i>	309
Manganese <i>CL Keen, JL Ensunsa, B Lönnerdal, and S Zidenberg-Cherr</i>	315
Niacin and pellagra <i>CJ Bates</i>	322
Nucleic acids, purine, and pyrimidine nucleotides and nucleosides: Physiology, toxicology, and dietary sources <i>EA Carrey, D Perrett, and HA Simmonds</i>	330
Pantothenic acid <i>Christopher J Bates and Luis Fontana</i>	340
Phosphorus <i>Olga P García</i>	346
Physical activity: Beneficial effects <i>Peter T Katzmarzyk</i>	352
Potassium <i>LJ Appel</i>	362
Protein deficiency <i>Rajavel Elango</i>	368
Protein digestion and bioavailability <i>Daniel Tomé</i>	375
Proteostasis and turnover <i>DJ Millward</i>	388
Riboflavin <i>Christopher J Bates and Luis Fontana</i>	401
Selenium <i>Anna Patricia Kipp</i>	412
Sodium: Physiology and dietary sources <i>Elena Rho and Harald Seeger</i>	420
Thiamin: Beriberi <i>DI Thurnham</i>	428
Thiamin: Physiology <i>DI Thurnham</i>	440
Ultratrace elements <i>Forrest H Nielsen</i>	448
Vitamin A: Deficiency and interventions <i>Amanda C Palmer and Keith P West, Jr.</i>	460
Vitamin A: Physiology, dietary sources and requirements <i>A Catharine Ross</i>	471
Vitamin B <sub>12</sub> : Physiology, dietary sources, and requirements <i>R Green</i>	482

Vitamin B <sub>6</sub> <i>PB Mills, EJ Footitt, and PT Clayton</i>	489
Vitamin C <i>David A Bender and Luis Fontana</i>	504
Vitamin C: Deficiency states <i>CJ Bates</i>	515
Vitamin D: Physiology, clinical applications, dietary sources, and requirements <i>MF Holick</i>	521
Vitamin D: Role in chronic and acute diseases <i>Ana I Álvarez-Mercado, María Dolores Mesa, and Ángel Gil</i>	535
Vitamin E   metabolism and requirements <i>Maret G Traber</i>	545
Vitamin E physiology and health effects <i>Jean-Marc Zingg</i>	556
Vitamin K <i>MK Shea and SL Booth</i>	569
Zinc: Deficiency disorders and prevention programs <i>SY Hess</i>	577
Zinc: Physiology, dietary sources, and requirements <i>HC Freake and K Sankavaram</i>	584

## EDITOR BIOGRAPHIES

---

### Editor in Chief

#### Professor Benjamin Caballero

*Emeritus Professor, Bloomberg School of Public Health and School of Medicine, Johns Hopkins University, Baltimore, MD, United States.*

Dr. Caballero is Professor Emeritus at the Department of International Health, Bloomberg School of Public Health, with joint appointment at the Department of Pediatrics, School of Medicine, Johns Hopkins University. He obtained his MD from the University of Buenos Aires, Argentina, and his PhD (in neuroendocrine regulation) from MIT, in Cambridge, Massachusetts. He started his academic career at Boston Children's Hospital, Harvard Medical School, and subsequently became the Founding Director of the Center for Human Nutrition at Johns Hopkins University.

Dr. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries.

He is currently a member of the Council of the International Union of Nutritional Sciences. He has served on the Food and Nutrition Board of the US National Academy of Medicine and on a number of expert panels, including the Dietary Reference Intakes Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the U.S. Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration, and of advisory committees of the National Institutes of

Health and the Department of Agriculture. He is a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK), and a member of the Spanish Academy of Nutritional Sciences.

He is the Editor-in-Chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption, and biological effects. He is also Editor-in-Chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. He also co-edited a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

## Section Editors

### Section 1: *The Foundations of Human Nutrition*

#### Professor Angel Gil

Honorary President of the Iberoamerican Nutrition Foundation (FINUT), Emeritus Professor, Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology, Centre of Biomedical Research, University of Granada, Campus de la Salud, Avda. del Conocimiento, 18100 Armilla, Granada, Spain.

**Angel Gil** is an Emeritus Professor at the University of Granada and a Full Professor in the Department of Biochemistry and Molecular Biology. He is Doctor Honoris Causa at the Autonomous University of Nuevo León, Monterrey, México, and a visitant Professor of the University of Chile, Santiago de Chile, and University of San Miguel de Tucumán, Argentina. He got a major degree in Biology (1973) and PhD in Biochemistry and Molecular Biology (1978).

Prof. Gil is an internationally recognized authority in Food and Nutrition: His expertise extends from the study of human milk composition to the molecular effects of food bioactive compounds and probiotics and the design and development of novel products for infant and clinical nutrition. He conducted pioneering and innovative research, leading 7 international, 27 national, and more than 50 projects and 120 contracts; he has taught since 1981, supervising more than 50 PhD students.

Prof. Gil has several areas of interest that include evaluating the role of dietary nucleotides in early life and the development of infant nutrition products. Besides, the isolation, identification, and description of the mechanism of action of probiotics and the metabolic, molecular, and genetic factors involved in obesity and the early onset of metabolic syndrome (MS) in childhood; and the design, development, and evaluation of enteral clinical nutrition products. What describes Prof. Gil best is the variety of fields

and problems he has faced during his professional carrier and his significant ability to combine his knowledge and expertise in Food Science and Human Biochemistry. This has allowed him to design, develop, innovate, and evaluate exclusive products for Human Nutrition, which are demonstrated in his published articles and his patents' impact.

The multi- and interdisciplinary nature of his work is reflected in the variety of international journals in which he has published 546 articles. Also, he has published 28 books and about 180 book chapters. His five volumes *Treatise of Nutrition*, 3rd Edition, Ed. Medica Panamericana, 2017, with more than 3500 pages, is the "bedside" book for the study of Nutritional Sciences in Spain and all Latin American countries.

He has also been the Chairman of the International Union of Nutritional Sciences (IUNS) 21st International Congress of Nutrition (2013) and the Executive Director of the 23rd International Congress of Nutrition (2017) and has been engaged in the organization of other renowned international congresses. He is a member of prestigious international and national nutrition societies and Honorary President of the Iberoamerican Nutrition Foundation (FINUT), a nonprofit organization promoted by the IUNS, in which the main goal is to contribute to the formation of young scientists in Food and Nutrition in the setting of Iberoamerica. He has received 42 National and International Awards for his contribution to Nutrition and Food Science, among them, the Class Fellow 2022 of the American Society of Nutrition; the Sir David Cuthbertson Lecture Award of the European Society of Clinical Nutrition and Metabolism for scientific achievement in clinical nutrition on 2021; the Award "Granada, City of Science and Innovation" 2021 to the Scientific Career; the Gregorio Marañón Award 2018 to the best Spanish Scientist in the field of Food Science and Nutrition; the Institute Danone Spain Award 2017; the Award of the Spanish Federation of Dairy Industries, 2015; the Nutra Excellence Award 2014, Nutra India Summit; the UIB Honorary Award of 2013; and the NAOS Strategy Prize 2012, Special recognition for his extensive professional experience in the field of nutrition and obesity, Spanish Ministry of Health, Social Services and Equality (AESAN).

### Section 2: *Molecular Mechanisms for the Interaction of Nutrients and Health*

#### Dr. Noel W. Solomons

Center for the Studies of Sensory Impairment, Aging, and Metabolism (CeSSIAM), Guatemala City, Guatemala, Guatemala

**Noel W. Solomons** was Assistant and Associate Professor from 1977 to 1984 in the former Department of Nutrition and Food Science of MIT. A resident of Guatemala since 1975, he cofounded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) in 1985, where he has been Scientific Director ever since. He is an Adjunct Professor at Tufts University in both the Friedman School of Nutrition Science and Policy and the Department of Public Health and Community Medicine.

Dr. Solomons received his MD degree from Harvard Medical School and subsequently undertook clinical and research training in infectious diseases and in gastroenterology and clinical nutrition at the Universities of Pennsylvania and University of Chicago, respectively. He was Editor-in-Chief of the *Food and Nutrition Bulletin* from 2016–2020. He has 364 publications indexed on PUBMED. In addition, he has edited 2 books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection. Also, he has supervised doctoral dissertations for 12 PhD candidates from the USA, Canada, Germany, Spain, the UK and the Netherlands through CeSSIAM.

## Section 3: Diet Composition

**Professor Anura Kurpad***Department of Physiology, St John's Medical College, Bengaluru, India*

**Anura Kurpad** works at St. John's Medical College, Bengaluru. He received his MBBS and MD from St. John's, and his PhD from Bangalore University in 1992. He was a Postdoctoral Fellow at the Rowett Research Institute and at Cambridge University, UK, and a visiting Scientist at MIT, Cambridge, United States. He is an elected Fellow of the Royal College of Physicians (London), Fellow of the Indian National Academy of Medical Sciences, Indian Academy of Sciences, and International Union of Nutritional Sciences. His interests are in human, clinical, and public health aspects of nutrition, applied throughout the life cycle. His research focuses on the physiology and clinical aspects of human energy and protein requirements and metabolism, with more recent interests in micronutrient status and metabolism. He is an Associate Editor of *The American Journal of Clinical Nutrition*. He was the President of the Nutrition Society of India from 2012 to 2016 and is the current President of the Asia Pacific Clinical Nutrition Society. He has been, and is, on many national and international advisory bodies, including being the Chair of the Indian Nutrient Requirements Committee.

## Section 4: Disorders Directly Related to Inadequate Nutrient Intake

**Dr. Katherine L. Tucker***Department of Biomedical and Nutritional Sciences, Center for Population Health, University of Massachusetts Lowell, Lowell, MA, United States*

**Katherine L. Tucker**, PhD, is University Distinguished Professor of Nutritional Epidemiology in the Department of Biomedical and Nutritional Sciences, and Director of the Center for Population Health, at the University of Massachusetts Lowell. She holds an adjunct appointment at the University of Massachusetts Medical School. She received her PhD from Cornell University and her undergraduate degree from the University of Connecticut, both in nutritional sciences. Between these degrees, she spent 2 years as a Peace Corps volunteer in the Philippines. Before joining UMass Lowell, she was at the USDA Human Nutrition Research Center on Aging at Tufts University, and McGill University. Dr. Tucker has contributed to more than 450 articles in scientific journals. Her research focuses on dietary intake and risk of chronic disease, including osteoporosis, cognitive decline, obesity, metabolic syndrome, and heart disease, with an emphasis on health disparities. She is the PI of the Boston Puerto Rican Health Study, an ongoing cohort study, to examine the roles of diet, health behaviors, stress, and genetic predisposition in relation to chronic conditions, including heart disease, cognitive decline, and bone health; and is actively involved as a scientific advisor for the NHLBI Jackson Heart Study. She served two terms on the Food and Nutrition Board of the National Academies of Science and Engineering. She is a Fellow of the American Society for Nutrition (ASN), the Gerontological Society of America, and the American Society for Bone Mineral Research and is

currently the Editor-in-Chief of *Advances in Nutrition*, the international review journal of the ASN, and Senior Editor of the forthcoming 12th edition of the textbook, *Modern Nutrition in Health and Disease*.

## Section 5: Nutrition in Disease States

**Dr. Paolo M. Suter***Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital, Zurich, Switzerland.*

**Paolo M. Suter**, MD, MS, is a Professor of Medicine presently affiliated with the Department of Endocrinology, Diabetology and Clinical Nutrition at the University Hospital Zurich (Switzerland). He received his MD at the University of Zurich and an MS in Nutrition at Tufts University (Boston, USA). He specialized in Internal Medicine and was a Faculty Member at the Medical Polyclinic of the University Hospital Zurich, where he was directing the well-known Hypertension and Obesity Outpatient Consultation. His research activities focused on vitamin nutriture in the elderly, alcohol metabolism and obesity, blood pressure and hypertension, as well as nutrition and lifestyle in non-communicable disease prevention. During his clinical work he focused on the ideal combination of pharmacological therapy with nonpharmacological strategies and on the therapy and prevention of diseases especially hypertension and obesity. Besides many research publications and review articles he authored a widely used textbook entitled *Checkliste Ernährung (Checklist Nutrition)*. He served on different national and international boards in the area of his expertise.

**Section 6: Nutrition in the Life Cycle****Professor Lawrence J. Cheskin**

*Department of Nutrition and Food Studies, George Mason University, Fairfax, VA, United States*

*And*

*Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD, United States*

**Lawrence J. Cheskin, MD, FACP, FTOS**, is Professor and Chair of the Department of Nutrition and Food Studies at George Mason University in Fairfax, VA, and an Adjunct Faculty Member of the Department of Medicine at the Johns Hopkins School of Medicine in Baltimore, MD, United States. He received his medical degree from Dartmouth and was a Postdoctoral Fellow in gastroenterology and liver diseases at Yale University-New Haven Hospital. Dr. Cheskin's work is at the intersection of public health nutrition and clinical medicine and has dedicated his career to research, education, and program building in the service of combating obesity, through both treatment and prevention. He founded the Johns Hopkins Weight Management Center, a multidisciplinary clinical research and treatment program. He was also Director of Clinical Research of the Global Obesity Prevention Center at Johns Hopkins and directed its Pilot Studies Core, which evaluated systems-focused proposals worldwide to study such areas as school policies and the built environment in preventing childhood obesity. He is co-PI of the Mason Cohort Study of entering college freshmen and has authored over 240 peer-reviewed journal articles and 8 books. He is committed to mentoring the next generation of public health and clinical scholars dedicated to nutrition and obesity.

**Section 7: Nutrition Epidemiology****Dr. Manuel Franco**

*Associate Professor at the Department of Surgery, Medical and Social Sciences, University of Alcalá, Madrid, Spain, and adjunct faculty at the Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

**Manuel Franco, MD, PhD**, Epidemiologist, is an Associate Faculty at the University of Alcalá and an Adjunct Faculty at the Johns Hopkins Bloomberg School of Public Health.

He is the Principal Investigator of the European Research Council Starting Grant Heart Healthy Hoods (<http://www.hhhproject.es>) studying urban characteristics in relation to eating patterns, physical activity levels, smoking, and alcohol consumption. He is also the PI of the Participatory Project on food in the cities: Photovoice Villaverde (<https://youtu.be/VliFggKzVas>).

Manuel Franco trained in Medicine both in Madrid and Berlin. As a Fulbright Scholar he joined the Johns Hopkins Bloomberg School of Public Health Department of Epidemiology to obtain his PhD and Postdoctoral Fellowship in the fields of social epidemiology and urban health.

His work focuses on the prevention of chronic diseases and their major risk factors as nutrition. He has published 94 international peer-reviewed articles and has led 15 studies as PI raising over 2.9 million € in competitive international research bids. His methodological interests include the measurement of urban characteristics related to chronic diseases and nutrition, the use of mixed methods, and the conduction of participatory action research methods.

**Section 8: Global aspects of Human Nutrition****Professor Daniel J. Hoffman**

*Department of Nutritional Sciences and director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States*

**Daniel J. Hoffman, PhD**, is a Professor in the Department of Nutritional Sciences and Director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States. He graduated from St. John's University, Collegeville, MN, United States, and received his PhD in Human Nutrition from the Tufts University Friedman School of Nutrition Science and Policy, Boston, MA, United States. For his doctoral training, Dr. Hoffman studied the metabolism of children living in the shantytowns of São Paulo, Brazil. He then completed a Postdoctoral Fellowship at Columbia University, New York, NY, United States, before joining the faculty at Rutgers University.

Dr. Hoffman's research focuses on the long-term impact of undernutrition early in life on body composition and metabolism later in life. This work is complemented by research on sustainable methods to improve diet and growth in lower- and middle-income countries, including Brazil, Mexico, Kenya, South Sudan, and Vietnam. He also directs the Center for Childhood Nutrition Research at the New Jersey Institute for Food, Nutrition, and Health where members conduct interdisciplinary research on childhood growth and development. Dr. Hoffman is an Associate Editor of the *Food and Nutrition Bulletin* and a Section Editor for the *Annals of Human Biology*. His other responsibilities include serving on the editorial board of the *Journal of Nutrition*, serving in leadership positions for the American Society for Nutrition, and advising international and national agencies on matters related to childhood nutrition. Aside from his

academic life, Dr. Hoffman is a published documentary photographer whose portfolio includes work on the life of Roma in Europe, urban landscape of São Paulo, Brazil, gentrification of Times Square in New York City, and punk music as the "American Mosaic."

## PREFACE

---

By the middle of last century, the science of nutrition had identified most of the essential nutrients and had provided evidence to propose specific dietary intake recommendations for many diet constituents, with the practical aim of preventing nutrient deficiencies. As chronic, noncommunicable diseases such as cardiovascular disease, cancer, etc., began to emerge as an important causal factor for disability and early death, scientists turned their attention to the potential effects of nutrients and diet patterns on chronic disease risk. Pioneering studies by Burkitt, Keys, Breslow, and others were followed by a large number of studies on the role of dietary patterns and constituents on certain chronic diseases. Many important studies were completed over the second part of the century, providing the evidence to support specific dietary recommendations to reduce disease risk.

The 21st century ushered the next transition in nutrition science, this time centered on the interrelationships between nutrients, dietary patterns, and the human genome. Over the past few decades, advances in our understanding of the human genome and on the molecular tools to explore it have permitted to probe those interactions in increasing detail. In turn, findings from nutrient–gene interaction studies have informed population-wide and clinical and metabolic studies, further advancing our understanding of the effects of diets on human health at the molecular level. This understanding of the links between genotype, phenotype, and nutrient/dietary intake became a key contributor to the emerging area of personalized nutrition/precision medicine.

All those phases of research emphasis, to different degree, continue to exist today and result in a vast, multidisciplinary, ever-expanding amount of information reaching the peer-reviewed literature. This massive amount of information needs to be organized and summarized in a way that makes it accessible to experts, teachers, and, as much as possible, the general public. This has been and continues to be the goal of the *Encyclopedia of Human Nutrition* since its first edition, over 20 years ago.

Such an ambitious task can only be achieved by the collective work of many people. We all have experienced the challenge of writing an article that combines focus and relevance with conciseness, so we are very appreciative of the work of our contributors. Their effort was backed up by an excellent editorial board, which reviewed and provided feedback on every manuscript. Finally, we must acknowledge the outstanding support of the Major Reference Works division at Elsevier. A publication like this *Encyclopedia* has a lot of moving parts, and it is a great privilege to be able to concentrate on the content, knowing that the other parts of the process are in the hands of excellent professionals.

We hope that this book will help satisfy the need for accurate and concise information to the many students and professionals who are committed to use nutrition science as a tool to improve people's quality of life.

## Key points

- Aluminum is ubiquitous in the environment, beverages and foods
- Foods present the major intake source of aluminum for most humans, ~100-fold more than water
- Governmentally-approved food additives are a major source of aluminum in foods
- The average daily intake of aluminum in foods is ~6 mg, but varies greatly depending on beverages and foods consumed
- Beverage and food preparation and storage in aluminum can increase aluminum content, particularly in acidic or alkaline products or media
- The percentage of aluminum that is taken into the body is very low and most is readily excreted in the urine by people with good renal function

## Introduction

Aluminum is a non-essential ubiquitous element, resulting in exposure and some intake into the body from air and many sources humans are exposed to or consume. The major intake source for most people is food. There are many studies quantifying aluminum in various beverages and foods and determining daily intake from them that are summarized herein. This article focuses on the more common exposure sources, their average aluminum level, how the human body handles aluminum exposure and absorbed aluminum, and some adverse effects that have been shown or suggested to result from aluminum exposure and uptake.

## Properties and natural occurrence

Aluminum (Al) is a soft (2.5–3 on the Mohs scale), light (2.7 g cm<sup>-3</sup>, therefore not a heavy metal), ductile, malleable metal. It is the most common metal and the third most common element in the earth's crust (comprising ~8%, primarily with silica), and is ubiquitously distributed throughout the environment. It has only one stable isotope, <sup>27</sup>Al. It is too reactive to occur in nature as the free metal. Aluminum production from ore requires considerable energy (24 kW h/kg). Recycling requires up to 95% less energy than primary aluminum production. It exists as the trivalent ion (Al<sup>3+</sup>), therefore does not engage in oxidation–reduction

chemistry. Exposure to water, oxygen, and other oxidants leads to surface formation of Al oxide that provides a 4 nm thick film that has high resistance to corrosion and is virtually insoluble from pH 4.5 to 8.5. In aqueous solution, in the absence of bound ligands, its chemical form (species) is pH-dependent. The  $\text{Al}^{3+}$  ion with 6 waters of hydration predominates below pH 5.5, as  $\text{Al}(\text{H}_2\text{O})_6^{3+}$ . As the pH increases  $\text{Al}(\text{OH})^{2+}$ ,  $\text{Al}(\text{OH})_2^+$ ,  $\text{Al}(\text{OH})_3$ , and  $\text{Al}(\text{OH})_4^-$  predominate at pH 5.5, 6, 6.2, and above 6.2, respectively (Haris et al., 1996). It is least soluble as  $\text{Al}(\text{OH})_3$  (gel) at pH 6.2. As a Lewis acid (electron pair acceptor, electrophile) it strongly complexes with multidentate carboxylate- and hydroxyl-/keto-containing ligands, for example citrate, through noncovalent interactions, generally involving ionic or electrostatic bonds. Kinetically aluminum ion reactions are slow. The mean residence time of water in  $\text{Al}(\text{H}_2\text{O})_6^{3+}$  is  $\sim 1$  s. Water replacement by citrate has a complexation half-life of  $\sim 1$ – $2$  min. The chemical species of aluminum has a great impact on its kinetics and effects. The  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  ions, having the same valency and similar ionic radii, engage in some of the same chemical and metabolic processes. Aluminum binds particularly strongly to phosphates, giving it the potential to bind with deoxyribonucleic acid, adenosine triphosphate, and many other biomolecules.

In contrast to its abundance in the earth's crust, natural waters contain little dissolved aluminum. Its average concentration in lakes, rivers, ground water, coastal sea water, and open ocean water is  $\sim 150$ ,  $400$ ,  $100$ ,  $1$  to  $7$ , and  $1 \mu\text{g L}^{-1}$ , respectively. This is a result of the low solubility of some aluminum salts and aluminum hydroxide deposition in sediments. Acidification, e.g., by acid rain and mine runoff, can solubilize aluminum and raise its concentrations in acidified lakes and rivers, producing toxicity to aquatic organisms. Airborne aluminum from natural (soil-derived) and anthropogenic sources ranges from  $<1 \text{ ng/m}^3$  in remote sites to  $>1 \mu\text{g/m}^3$  in industrialized locations. The World Health Organization (WHO) has a 'practicable level' in finished (drinking) of  $\leq 0.1$  and  $\leq 0.2 \text{ mg L}^{-1}$  for large and small water treatment facilities (WHO, 2004). The European Union (EU) "Indicator Parameter" directive for aluminum in drinking water is  $0.2 \text{ mg L}^{-1}$  (EU, 2020). The US Environmental Protection Agency has a secondary, non-enforceable standard of  $0.05$ – $0.2 \text{ mg L}^{-1}$ , based on esthetic (taste, sight, and smell) properties (US EPA, 2021). Canada set  $2.9 \text{ mg L}^{-1}$  as the maximum acceptable concentration and  $0.1 \text{ mg L}^{-1}$  as the operational guidance for total aluminum in drinking water (Health Canada, 2019). The Joint Food and Agriculture Organization (FAO) of the United Nations/WHO Committee on Food Additives established a provisional tolerable weekly intake of  $2 \text{ mg}$  per kg body weight for aluminum from all aluminum compounds in food including food additives (FAO/WHO, 2011). The Agency for Toxic Substances and Disease Registry Minimal Risk Level for intermediate (15–364 days) oral aluminum intake was set at  $1 \text{ mg kg}^{-1} \text{ day}^{-1}$  (ATSDR, 2020). A tolerable weekly intake of  $1 \text{ mg kg}^{-1}$  body weight was established by the European Food Safety Authority (Aguilar et al., 2008).

## Nonfood uses

Aluminum and its compounds are widely utilized. They are used in building and construction, transportation, packaging, containers, water purification, sugar refining, brewing, paper production, glass, ceramics, rubber, abrasives, furnace linings, as wood preservatives, to waterproof textiles, and as a flame retardant. In personal care and medical applications aluminum compounds are in antacids (that are also used as phosphate binders); buffered aspirin products; non-spray and spray antiperspirants; lipsticks as lakes (colorants, salts of water-soluble artificial colors adsorbed onto alumina); skin care products; toothpastes as an abrasive and to reduce dental hypersensitivity; dental rinses; products for dermatitis such as athlete's foot as an astringent and antibacterial; topical products as a protectant against diaper dermatitis and in anorectal disorders; antidiarrheal products; vaginal douches; and anorectal preparations as a keratolytic. It is used as an intravesical irrigant to treat urinary bladder hemorrhage and as an adjuvant in vaccines to increase their antigenic properties. Aluminum's mechanism as an adjuvant includes its up-regulation of gene expression related to the innate and adaptive immune response in human monocytes (Vrieling et al., 2020).

## Food uses of aluminum compounds

Some United States Food and Drug Administration (FDA) and EU approved aluminum compounds that may be employed as food additives are listed in Table 1. These contribute to the high concentrations of aluminum in some of the foods in Tables 2 and 3. Other governments also allow the use of aluminum as a food additive.

## Aluminum in beverages and foods

Tables 2 and 3 show average values from studies published since 1985 for which there were multiple reported values for each entry in the tables. The entered values are medians. This measure of central tendency was selected because there is considerable variability of reported results from some beverages and foods. This variation may result from poor analytical techniques, inadequate removal of soil and/or contamination, and differences due to climate and soil growing conditions.

Plants that accumulate aluminum deposit it in their leaves. The tea plant accumulates and concentrates aluminum, producing a higher aluminum concentration than in other plant-derived beverages. Addition of the anticaking agent sodium aluminosilicate to nondairy creamer and salt, particularly single-use packets, accounts for their high aluminum concentration. The higher aluminum content of soy-than milk-based infant formula derives from the high aluminum content of beans, including soybeans, compared to cow milk.

**Table 1** Some FDA- and EU-approved food additives containing aluminum, or aluminum agents that come in contact with foods, and their uses. The US Code of Federal Regulations title, part, and section numbers are cited in round brackets. The EU No. is in square brackets.

- Aluminum calcium silicate (a.k.a.: calcium aluminum silicate)—Anti-caking agent,  $\leq 2\%$  by weight in table salt (21CFR182.2122) [556].
- Sodium calcium aluminosilicate hydrated (a.k.a.: sodium calcium silicoaluminate)—Anti-caking agent,  $\leq 2\%$  (21CFR182.2729).
- Sodium aluminosilicate (a.k.a.: sodium silicoaluminate)—Anti-caking agent,  $\leq 2\%$  in dried whole eggs and egg yolks and grated cheeses (21CFR182.2727) [554].
- Aluminum ammonium sulfate—Buffer and neutralizing agent (21CFR182.1127) [523].
- Aluminum potassium sulfate—Buffer and neutralizing agent (21CFR182.1129) [522].
- Aluminum sodium sulfate—Buffer and neutralizing agent (21CFR182.1131) [521].
- Sodium aluminum phosphate (SALP)—acidic SALP as a leavening agent in self-rising flours and meals, basic SALP as an emulsifying agent in cheeses. Acidic: (21CFR182.1781) [541] Basic: (21CFR182.1781)
- In lakes, on a substratum of alumina (21CFR182.101, 102, 203, 304, 340, 705, 706) [102, 110, 129, 132, 133].
- Aluminum borate as an antistatic and/or antifogging agent in food-packaging materials,  $\leq 2\%$  by weight of polymer film (21CFR178.3130).
- Aluminum-containing clarifying agents for polypropylene and polypropylene copolymers intended for use in contact with food,  $\leq 0.25\%$  by weight of the copolymer (21CFR178.3295).

**Table 2** Aluminum concentrations of beverages and nondairy creamer.

<i>Beverage</i>	<i>Al concentration (median; as mg L<sup>-1</sup>, except for non-dairy creamer)</i>
Beer	0.10
Coffee	0.24
Non-dairy creamer—multiple serving container	26 mg kg <sup>-1</sup>
Non-dairy creamer—single serving packet	170 mg kg <sup>-1</sup>
Apple juice	0.40
Orange juice	0.19
Pineapple juice	0.36
Tomato juice	0.88
Wine	0.81
Distilled spirit	0.42
Cola	0.27
Black tea	2.6
Green tea	2.6
Herbal tea	0.16
Tap water	0.045
Mineral and spring water	0.020
Cow milk	0.094
Human milk	0.030
Cow-based infant formula	0.019
Soy-based infant formula	0.76

Even though soil contains 3–10% aluminum, most plants and plant-eating animals contain little aluminum, due to its low oral bioavailability (see **Bioavailability and biotransformation** below). Most unprocessed foods contain  $<5$  mg kg<sup>-1</sup>. The addition of aluminum as a food additive can greatly increase its food content, illustrated by baking powder, cake and pancake mixes, cakes and pancakes, and cheese containing sodium aluminum phosphate (SALP). Residual dirt may increase the aluminum concentration in lettuce and spinach. Some spices contain considerable aluminum, illustrated by paprika and pepper. Spice aluminum values are expressed based on their dry weight, whereas most other food aluminum concentrations are based on wet weight.

## Aluminum in foods from processing, packaging, and storage

Food preparation and storage in contact with aluminum can increase the food's aluminum content. Some examples follow. Coffee brewed in an aluminum pot had about twice as much aluminum as coffee brewed in stainless steel. Tea prepared in an aluminum container had 3.4-fold more aluminum than prepared in glass. Water and milk boiled/cooked in aluminum cookware had more aluminum than when prepared in porcelain, stainless steel, Teflon, or enamel cookware. In one study multiple vegetables cooked in old or new aluminum vessels had 40% and 80% more aluminum than when cooked in stainless steel. Cooking matooke, potatoes, beans, cabbage, dodo, tomatoes, kadhi, sambar, mutton curry, and chicken curry in aluminum increased their aluminum content. However, studies have not consistently shown higher aluminum in foods prepared in new versus old aluminum vessels, perhaps

**Table 3** Concentrations of aluminum in foods.

<i>Food</i>	<i>Al concentration (median; as mg kg<sup>-1</sup>)</i>
Beef meat	1.2
Pork meat	2.5
Chicken meat	1.0
Bacon	1.0
Ham	1.3
Meat sausages and frankfurters	3.4
Fish	0.18
Cephalopods (octopus, squid, cuttlefish)	3.0
Crustaceans (crabs, lobsters, crayfish, shrimps, prawns)	5.6
Eggs	0.22
Nuts	4.1
Fruits, fresh	1.1
Raisin	10
Tomato	0.5
Corn	1.25
Beans	5.8
Peas	2.0
Mushrooms	4.0
Potato	2.6
Lettuce	5.4
Spinach	24
Wheat flour	5.1
Oats, oatmeal	2.1
Rice	2.1
Baking powder	70
Biscuits	22
Cake mix	445
Cakes (not stated to contain SALP)	6.3
Cakes (that contain SALP)	190
Cookies	8.0
White bread	2.3
Wheat bread	4.6
Breakfast cereal	1.8
Pancakes	179
Pasta	3.7
Cheese, not from sheep or goat milk	2.3
Cheese from goat milk	15
Frozen pizza cheese	415
Restaurant pizza cheese	2.9
Yogurt, not from goat milk	0.30
Yogurt from goat milk	5.0
Soup	1.2
Butter	1.4
Margarine	1.7
Olive oil	0.043
Sugar	1.7
Honey	0.5
Chocolate	9.4
Jellies and jams	4.1
Paprika	92
Pepper	31
Pickles	7.4
Vinegar	0.21
Salt	2.4
Salt—single serving packet	180

due to differences in vessel manufacture and surface coating, extent of use or cleaning before their study, and the studied food. Tomato cooked for 10 min in an aluminum pan had ~60% more aluminum than cooked in a steel pan. Cottage cheese and yoghurt prepared in aluminum containers had more aluminum than when prepared in boron glass or steel containers. Rhubarb boiled for 12 min in a steel pot had 0.8 and in an aluminum pot 13–20 mg L<sup>-1</sup> aluminum. The aluminum concentration of black currant juice boiled for 90 min in an aluminum vessel increased from 0.05 to 24 mg L<sup>-1</sup> when sugar was added before boiling and to 56 mg L<sup>-1</sup> when the sugar was added after it was brought to a boil.

Household aluminum foil is 0.18 mm thick. Beef, mutton, pork, water buffalo, chicken, and turkey baked in aluminum foil had on average a 2.5-fold increase in the aluminum content. Higher temperature (250 vs. 200 vs. 150 °C) contributed more aluminum to beef, mutton, and pork than longer baking time (20 vs. 40 vs. 60 min) whereas longer time, not temperature, increased aluminum in chicken and turkey. Baking and grilling fish in aluminum foil increased its aluminum concentration by five-fold. Potatoes roasted in aluminum foil had 2.5-fold more aluminum than when roasted in stainless steel.

Tap water storage in an aluminum container increased its aluminum concentration. The aluminum concentration of milk stored in an aluminum pan increased ~14-fold. Milk stored in an aluminum-lined container had more aluminum than when stored in plastic or glass. The aluminum concentration in beer stored in aluminum cans was consistently higher (average 60%) than in steel cans or glass bottles, did not increase over time when stored at 5 °C, but increased ~10%/month when stored at room temperature. Wine stored for 2 years in an aluminum can had more aluminum than when stored in a glass bottle or steel can. Frozen salmon commercially marketed in aluminum foil had more aluminum than when prepared without. The aluminum concentration in apple, lemon, and orange (but not tropical fruit) juice stored in aluminum cans increased over time and the aluminum concentration in grapefruit juice stored in aluminum cans increased with increased storage temperature. Soft drinks (colas, Fanta orange, and soda water, but not Pocari Sweat or orange squash) stored in aluminum cans had a higher aluminum content than when stored in plastic or glass. The aluminum concentration of lemon, orange, and cola drinks stored in aluminum cans for 12 months increased ~1-, 2- and 3-fold monthly above the original aluminum concentration, respectively. Tomato paste stored in steel and aluminum cans increased ~25 and 60% over 2.5 years, respectively. Storage of tomato puree and tamarind in an aluminum pan for 72 h increased its aluminum content 31- and 17-fold, respectively. Addition of salt to the tomato and sugar to the tamarind increased their aluminum content an additional ~15 and 9%, respectively. Aluminum mobilization during food preparation and storage in contact with aluminum is greatest for acidic foods (e.g., rhubarb pH ~3.2 and tomato ~4.5), consistent with the chemical species of aluminum as a function of pH; solubility increases below and above pH 6.2.

## Exposure and dietary intake

Dietary intake provides the greatest percentage of aluminum intake for the typical human. Daily average drinking water consumption is estimated to be 1.4 L. Intake of water with a median aluminum concentration of 0.045 mg L<sup>-1</sup> (Table 2) would provide ~0.06 mg Al daily. Ninety studies conducted since 1970 in 30 countries reported dietary aluminum intake based on total diet studies, market basket surveys, dietary records, calculations based on food aluminum levels, and duplicate diets and portions. Median daily aluminum intake of adolescents and adults was 5.1 mg, with 75% of the reported intakes between 2.5 and 13 mg/day. When reported as mg kg<sup>-1</sup>/week the median intake was 0.6. Reported intakes in China were ~2-fold greater than the US which was ~2-fold greater than Europe and Japan. The greater aluminum intake in the US may be due to a higher utilization of SALP and other approved aluminum food additives in processed foods. Aluminum intake in food is ~100-fold greater than from drinking water (5.1 vs. 0.06 mg daily). As tea contains more aluminum than other beverages, its consumption can contribute 50% of the daily aluminum intake in those who consume considerable amounts of this beverage when other sources do not also have large amounts of aluminum.

## Bioavailability and biotransformation

Aluminum bioavailability is low. The main uptake routes are by inhalation, through the gastrointestinal tract, and medical routes such as injections and during dialysis. Absorption from the gastrointestinal tract, lungs, and after underarm (presumably transdermal) application is ~0.1–0.3%, 1.5–2%, and 0.01%, respectively. Aluminum injected in vaccines is slowly absorbed as it dissolves and may ultimately reach 100%. Aluminum absorption from the gastrointestinal tract appears to be primarily in the distal intestine. There is evidence supporting several mechanisms of intestinal aluminum absorption, including paracellular diffusion, an interaction with calcium uptake, and sodium transport processes. Owing to aluminum's ubiquitous presence, which creates measurable levels in all tissues and fluids and potential analytical contamination problems, and its low bioavailability, determination of its pharmacokinetics, including bioavailability, at relevant exposures is very difficult using <sup>27</sup>Al. More precise measurements have been made using <sup>26</sup>Al. Owing to its high cost and very long half-life (717,000 years), its decay rate is too low for practical application as a radioisotopic tracer. Its quantification by accelerator mass spectrometry is exquisitely sensitive. The limit of detection is ~1,000,000 atoms (4 × 10<sup>-17</sup> g), enabling a lower limit of quantitation in blood and urine of ~1 × 10<sup>-16</sup> g mL<sup>-1</sup>. This enables <sup>26</sup>Al administration to human subjects of doses that present no significant radiation risk and the conduct of exposure dose-relevant pharmacokinetic studies. Studies conducted in rats have shown oral bioavailability from water, tea, acidic SALP in a food (biscuit), and basic SALP in cheese to be ~0.3%, 0.4%, 0.1%, and 0.2%, respectively (Yokel and Florence, 2008). Studies

in humans showed absorption from drinking water and aluminum hydroxide to be ~0.2% and 0.1%, respectively. Oral aluminum absorption is increased by citrate, and other carboxylic acids to a lesser extent. Oral aluminum bioavailability has also been shown to be greater for more soluble aluminum species and increased by fluoride; low iron, calcium, or sodium status; and uremia. In contrast, silicon-containing compounds appear to reduce its gastrointestinal absorption and enhance its urinary elimination as hydroxyaluminosilicate species. Some results suggest oral aluminum absorption is increased in Alzheimer's disease (AD) and Down's subjects.

### Aluminum biokinetics in blood

Median plasma aluminum concentration in several normal human studies was  $\sim 3 \mu\text{g L}^{-1}$ . As this is very low and aluminum is ubiquitously present, much attention must be paid to collection, storage, and blood sample handling to avoid contamination. At equilibrium serum and red blood cell aluminum concentrations are approximately equal. Aluminum's volume of distribution is initially equal to the blood volume, consistent with its equal concentration in serum and blood cells. The volume of distribution then increases over time as it distributes and accumulates in tissues. Within blood plasma, ~91% is bound to transferrin, an iron-transport protein, ~7–8% is bound to citrate, and the remainder to phosphate and hydroxide. Formation of the aluminum transferrin- and aluminum citrate-complexes occurs within minutes. The strength of the binding (stability constant) for  $\text{Al}^{3+}$  with ligands is 3–4 orders of magnitude lower compared to  $\text{Fe}^{3+}$ . Consequently, aluminum will not displace iron from transferrin or most other ligands. Transferrin-receptor-mediated endocytosis may mediate aluminum uptake into the brain and other organs. Citrate enhances aluminum distribution out of the blood and into tissues and its renal clearance (by increasing aluminum's filterable fraction), suggesting a mechanism for distribution of aluminum citrate that is different from that mediating aluminum transferrin.

### Aluminum tissue deposition and body retention

Aluminum distributes unequally throughout the body in normal and aluminum-intoxicated humans. Because of its low bioavailability by most routes of exposure and its effective clearance from blood by the kidney (see [Aluminum excretion](#) below), aluminum concentrations in the human are low compared to most exposure sources. The normal human body burden is estimated to be 30–50 mg aluminum. Steady state tissue aluminum concentrations in normal adults are (in  $\text{mg kg}^{-1}$  wet weight unless stated otherwise): lung: 20, bone: 1–3  $\text{mg kg}^{-1}$  dry weight, liver and spleen: 1, kidney: 0.5, heart: 0.45, muscle: 0.4, brain: 0.35, and blood: 0.002. Approximately 50, 25, 11, 10, 3, 1, 0.3, 0.25, and 0.2% of the aluminum body burden is in the skeleton, lung, muscle, skin, liver, brain, heart, kidney, and spleen, respectively. Aluminum localizes at the bone mineralization front and in osteoid. Lung aluminum may be from airborne environmental particles, occupational exposure, and distribution from the blood. Insoluble particles trapped in the lung are very slowly cleared. Blood and tissue concentrations are higher in uremia and higher still in dialysis encephalopathy. Approximately 80% of an intravenous dose of aluminum citrate was excreted within a week by humans, suggesting the remainder was retained within the body, some of which was excreted over a long time. This finding indicates that under conditions of continuous intake, aluminum accumulates in the body, even in subjects with normal renal function. Human brain, bone, other organ, and serum aluminum concentration increase with age. Hair aluminum concentration as an indicator of aluminum body burden has not been validated. Problems include the lack of standardized hair collection procedures.

Aluminum clearance is characterized by multiple half-lives that are estimated in hours, days, and years, suggesting multiple compartments. The initial half-life (distribution from the vascular compartment) is a few hours. The brain, bone, liver, and kidney aluminum half-life in rats was estimated to be 150 to 1635, 520, 430 and 400 days, respectively. Allometric scaling from this animal species with a lifespan of 2 years to the human with an 80-year life span suggests the aluminum half-life in human brain might be decades or even greater than the lifespan. Estimates of the terminal half-life in the human suggest it may be as great as 50 years, attributed to an aluminum depot in bone. The slow release of aluminum from bone, due to the low rate of bone turnover (~10% per year), may account for the prolonged half-life seen in most organs, including the brain, and prolonged elevated urinary aluminum excretion after significant occupational aluminum exposure. Increased bone turnover rates compared to the healthy adult, as seen in children who exhibit high rates of bone growth and turnover or geriatrics, may accelerate bone aluminum release.

Biological monitoring of aluminum exposure can be conducted with urine, which is thought to indicate recent exposure, and plasma or serum, which is thought to better reflect the aluminum body burden and long-term exposure. However, neither indicates the aluminum body burden well, which is better estimated by bone aluminum, the desferrioxamine challenge test, or combined measurement of serum parathyroid hormone and the desferrioxamine test. Desferrioxamine chelates/complexes with aluminum, iron, and other trivalent metals, and increases their urinary elimination.

### Aluminum excretion

Kidneys provide the primary route of aluminum elimination, ~95%, presumably by glomerular filtration of aluminum citrate. Humans who consume the typical daily dietary amount of aluminum would be expected to excrete 4–12 mg daily, producing a urinary aluminum concentration of 2–10  $\text{mg L}^{-1}$ . However, several industrial studies reported higher values in controls (often

20 mg L<sup>-1</sup>) and even higher in exposed workers. Reduced or lack of renal function creates the risk of aluminum accumulation and toxicity. Bile (feces) accounts for most of the remaining excreted aluminum, although aluminum is excreted in saliva, sweat, and semen.

### Diseases related to aluminum intake

There is no good evidence that aluminum is an essential element for the human or any other plant or animal species. Aluminum toxicity has been extensively reviewed by the WHO, for the US Department of Health and Human Services, and most extensively by a multinational group led by Daniel Krewski (see Further reading). Occupational exposure to high aluminum levels has been associated with lung fibrosis from stamped aluminum powder, asthma from aluminum salts and welding fumes, and increased oxidative stress. Contact dermatitis has been reported. It has been suggested that aluminum can contribute to Crohn's disease. Support was provided by the observation that aluminum increased release of lipopolysaccharide and fragilysin (that contribute to inflammation and diarrhea) by a bacterium (*Bacteroides fragilis*) that resides in the intestine (Alexandrov et al., 2020). In contrast, aluminum altered the expression by cultured human colorectal cells of some cellular oxidative stress and xenobiotic metabolism genes but only at concentrations exceeding those exceeding the exposure from daily intake of 5–10 mg aluminum (Sieg et al., 2020). Neurobehavioral toxicity has been seen in aluminum welders with urine aluminum >100 mg L<sup>-1</sup> (Yokel and Sjögren, 2021). When hemodialysis was initially extensively used, some patients developed a progressive encephalopathy that was fatal within 6 months (see [Aluminum-induced encephalopathy](#), below). Exposure to lower levels of aluminum than those that caused aluminum-induced encephalopathy can produce bone disease (see [Aluminum-induced bone disease](#), below) and anemia (see [Aluminum-induced microcytic anemia](#), below). It has been suggested that aluminum, from vaccines, is a contributor to autism spectrum disorder. Meta-analyses and reviews of a relationship between autism spectrum disorders and aluminum in hair, urine, and/or blood and vaccination receipt found either no or inconsistent support. A review by a US Institute of Medicine of the National Academies panel concluded the evidence rejected a causal relationship between the measles, mumps, and rubella vaccine and autism (Yokel and Sjögren, 2021).

Premature infants who are fed intravenously, because they do not tolerate oral feeding, are a high-risk group for aluminum toxicity. Parenteral nutrition feeding solutions given intravenously can contain significant aluminum. This is primarily associated with calcium gluconate and phosphate parenteral nutrition components, which complex aluminum from glass storage containers. Use of plastic contains largely avoids this problem. As this feeding solution is given intravenously, therefore 100% bioavailable, to premature infants whose kidneys are not fully matured and therefore less able to excrete the aluminum, they are at risk of sufficient aluminum accumulation to develop metabolic bone disease, cholestatic hepatitis, and reduction of mental development. To address this concern the US FDA adopted a labeling requirement for aluminum in large and small volume parenterals used to prepare total parenteral nutrition solutions.

Studies in mice, rats, rabbits, and dogs have shown aluminum has the potential to produce neurobehavioral toxicity, affect the male reproductive system, produce embryotoxicity, and affect development. Based on these concerns, the FAO/WHO established the 2 mg kg<sup>-1</sup> body weight as a provisional tolerable weekly intake of all aluminum compounds in food, noted above.

### Aluminum-induced encephalopathy

Encephalopathy has been associated with the use of hemo- and peritoneal-dialysis fluids that contain significant amounts of aluminum, high dose administration of oral aluminum salts to renal-impaired humans to bind phosphate in the gastrointestinal tract as insoluble aluminum phosphate, alum instillation into the urinary bladder to stop hemorrhaging, and neurosurgical implants of aluminum-containing biomaterials. Dialysis (associated) encephalopathy (also known as: dialysis dementia) is associated with elevated brain aluminum and serum aluminum >80 mg L<sup>-1</sup>. Renal dialysis patients are highly susceptible to aluminum accumulation and toxicity from aluminum in dialysis fluids because aluminum can diffuse across the dialysis membrane, it rapidly and very strongly binds to transferrin in the blood, and they lack the primary route of aluminum elimination, renal function. With recognition of the role of aluminum in dialysis-related toxicity, reduction of aluminum exposure guided by the US Association for the Advancement of Medical Instrumentation's recommendation that water used to prepare dialyzate solution contain <10 mg L<sup>-1</sup>, and use of alternatives to aluminum as an oral phosphate binder, occurrences of aluminum-induced encephalopathy in dialysis patients have become unusual.

### Aluminum-induced bone disease

Aluminum-induced low-turnover bone disease is manifest as osteomalacia. Aluminum-induced bone disease in dialysis patients is seen when serum aluminum is > 30 mg L<sup>-1</sup> and when a stain shows aluminum at 30% of the trabecular bone surface. Aluminum interferes with parathyroid hormone synthesis and function. In osteomalacia, aluminum accumulates at the mineralization front of the bone surface, where it disrupts bone mineralization by inhibiting calcium accretion and osteoblast activity, increases bone resorption, and results in an increase of the nonmineralized bone, leading to painful fractures. Children and adults who received

long-term parenteral nutrition with high aluminum content had bone pain and fractures, and lower bone mass, mineral content, and mineral density than controls.

### Aluminum-induced microcytic anemia

A microcytic, hypochromic anemia is associated with elevated plasma aluminum in chronic renal failure patients. Aluminum interferes with the development of hematopoietic progenitor cells and is thought to interfere with heme synthesis. Geophagy contributes to anemia. Up to 5 mg kg<sup>-1</sup> of the chelator desferrioxamine once or twice a week has been shown to be safe and effective for long-term treatment of aluminum overload, and reduction of aluminum-induced encephalopathy, bone disease, and anemia.

### Evidence for a role in Alzheimer's disease

Aluminum has been implicated in the etiology of AD. Hallmark neuropathological signs include neurofibrillary tangles (NFTs), senile plaques (SP), and cerebrovascular amyloid. Early-onset AD usually has a familial link, due to gene mutations which result in increased secretion of neurotoxic amyloid beta (Aβ) protein. No specific gene mutations have been associated with late-onset AD which accounts for ~95% of AD cases. The lack of identified hereditary links for the majority of AD cases suggests environmental factors may interact with other factors to cause this disease. Aluminum is one of the suggested environmental contributors. The genesis of the hypothesis that aluminum plays a role in the etiology of AD was an observation reported in 1965 of neurofibrillary degeneration in rabbit brain after intracerebral aluminum injection, which resembled, but was not identical to, the NFTs of AD. Similarly, the neuropathology in dialysis encephalopathy is different from that seen in AD. The observation of elevated aluminum in post-mortem human AD brain samples reported in 1973 was interpreted as suggesting a role for aluminum in AD. This was followed by many studies, some of which found a few-fold or less increased concentration of aluminum in AD victim brains than in controls, and some which did not. Studies investigating an elevated level of aluminum in AD brain using microprobe techniques which can quantify aluminum within a cell, NFT, or SP, as well as aluminum-selective stains have also produced mixed results. Meta-analysis found significantly elevated levels of aluminum in brain, serum, and cerebrospinal fluid. Elevated brain aluminum in AD does not demonstrate cause and effect. The neuronal degeneration of AD may result in accumulation of metals, such as aluminum. Elevated aluminum may play a role in AD development.

Another approach to address the potential role of aluminum in AD is the epidemiological study of the association between the aluminum concentration in drinking water and AD incidence, comparing geographic regions where drinking water aluminum concentrations differ with AD incidence. The results of many such studies are not consistent. Drinking water is not the major source of aluminum for the general population, as noted in **Exposure and dietary intake**, above. The only published epidemiological study of AD and aluminum consumption from food was too small to draw firm conclusions, although it found a significant odds ratio for higher association of AD with a food category typically high in aluminum (pancakes, waffles, biscuits, muffins cornbread, and corn tortillas).

Aluminum has been shown to produce many effects in the brain that have been suggested as contributors to its neurotoxicant effects, and contributing to AD. These have included promotion of the formation and accumulation of Aβ and aggregation of hyperphosphorylated tau protein, deficits of cortical cholinergic neurotransmission, increased inflammation and oxidative injury, and impaired cognitive function. The controversy of a contributory role of aluminum to AD has not been resolved. As there are many contributing factors to AD, it will be extremely difficult to demonstrate the lack of contribution of any one factor, such as aluminum, to this disease.

### Conclusions

Aluminum exposure and uptake is unavoidable. Choices of the products one uses and beverages and foods one consumes and how they are prepared and stored can impact one's aluminum intake. The main source of aluminum exposure for most people is food. Approved food additives and preparation and storage in aluminum increase aluminum content. People who have good renal function are not at risk of any proven adverse effects from typical aluminum exposure. Introduction of aluminum directly into the blood or brain can produce toxicity, particularly in people with reduced or no renal function.

## Key points

- Amino acids (AAs) are organic molecules containing both amino and acidic groups. They exist in protein and peptides (~97% of total AAs), as well as the free form in humans.
- The configuration of AAs is generally defined in reference to L- and D-glyceraldehyde. The absolute configuration of AAs is also designated according to the R/S system, and includes *cis* and *trans* for those with a ring structure.
- All  $\alpha$ -AAs, except for glycine and aminomalonic acid, can have both L- and D-isomers. Except for glycine, proteinogenic (protein-creating) AAs in human tissues are L-isomers.
- All L-AAs plus glycine are the most abundant physiological isomers and account for > 99.9% of total AAs in humans.
- Glycine is the most abundant peptide-bound AA in humans, followed by proline, glutamate, and arginine. Glutamine and alanine are the most and second most abundant free AA in the human plasma, respectively.
- Human liver, skeletal muscle, brain, and small-intestinal mucosa contain high concentrations of free aspartate plus taurine plus glutamine plus glutamate, free glutamine plus taurine plus glutamate, free glutamate plus glutamine, and free taurine plus glutamate, respectively.
- Meat is an abundant source of taurine, carnosine and anserine but plants lack these substances.  $\beta$ -Alanine and 4-hydroxyproline are abundant in meat but is negligible or low in plant-sourced foods.
- Different AAs have different chemical properties (e.g., solubility, stability, melting points, reactions, taste, and electrical charges).
- AAs are classified as neutral, basic, and acidic AAs based on their net charges at neutral pH.
- AAs are designated as aliphatic, sulfur-containing, hydroxylated, amidated, carboxylated, phosphorylated, guanidino, aromatic, imidazole, seleno, and secondary amino acids.

## Introduction

Amino acids (AAs) are organic substances containing both amino and acid groups. Usage of the term AA in the English language began in 1898. All natural AAs consist of the elements C, H, N, and O. Some of the natural AAs contain the elements S, P, I, and Se. An acid group in a natural AA can be the carboxyl ( $-\text{COOH}$ ; e.g., alanine), sulfonic acid ( $-\text{SO}_3\text{H}$ ; e.g., taurine), phosphoric acid ( $-\text{PO}_4\text{H}_2$ ; e.g., phosphoethanolamine), or phosphonic acid ( $-\text{PO}_3\text{H}_2$ ; e.g., 2-aminoethylphosphonate) group (Wu, 2022). All

proteinogenic (protein-creating) AAs contain an amino group and an  $\alpha$ -carboxyl group, and two of them (aspartate and glutamate) also have a carboxyl group in their side chains (Fig. 1). A 3-letter abbreviation is used to designate an AA, with the first capital letter followed by two lower-case letters (e.g., Leu for leucine). One capital letter denotes an AA in protein sequences (e.g., L for leucine).

The different carbon atoms of AAs are named in sequence according to the Greek alphabet. If the amino group ( $-\text{NH}_2$ ) is linked to the  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -, or  $\epsilon$ -carbon of the hydrocarbon chain, the AA is designated an  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -, or  $\epsilon$ -AA, respectively. Examples of natural  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -, or  $\epsilon$ -AAs are alanine,  $\beta$ -alanine,  $\gamma$ -aminobutyric acid [GABA, a neurotransmitter (He and Wu, 2020)], 5-aminovaleric acid, and 6-aminocaproic acid, respectively. Examples of non-proteinogenic AAs and their metabolites in humans (including those produced by gastrointestinal bacteria) are illustrated in Fig. 2. Imino acids (e.g., proline and 4-hydroxyproline) contain both a secondary  $\alpha$ -amino ( $\alpha$ -imino) group ( $-\text{NH}$ ) and an acid group, and are loosely called AAs in biochemistry and nutrition.

There is a rich history of chemical studies of AAs (Meister, 1965; Wu, 2022). Asparagine was the first natural AA discovered by two French chemists L.N. Vauquelin and P.J. Robiquet in 1806, and glycine was the first AA isolated from a protein (i.e., gelatin) by

**Fig. 1** Chemical structures of proteinogenic amino acids at neutral pH in humans. Except for selenocysteine (a rare, special amino acid in selenoproteins), the 20 canonical proteinogenic amino acids are present in proteins and peptides as well as the free form. Reproduced from Wu (2018) with permission.

**Fig. 2** Chemical structures of non-proteinogenic amino acids (AAs) and their metabolites at neutral pH in humans (including those produced by gastrointestinal bacteria). These substances occur in physiological fluids of animals, and some of them are also present in microorganisms and plants. Taurine is present in humans as a free AA but is absent from bacteria and plants. Reproduced from [Wu \(2018\)](#) with permission.

the French chemist H. Braconnot in 1820. In 1925, threonine was discovered by S.B. Schryver and H.W. Buston as a common proteinogenic AA in oat protein, and R.A. Gortner and W.F. Hoffmann found that this AA was a constituent of teozein. In 1973 and 2002, selenocysteine and pyrrolysine were found to be rare AAs in selenoproteins and the Archaea methylamine methyltransferase, respectively. AAs are present in humans and their foods in both the free and peptide-bound forms. Over 700 AAs occur in nature,

but only 20 of them serve as the precursors of proteins in humans. Because of variations in their side chains (e.g., carbon numbers, structure, and chemical groups), AAs have remarkably different chemical properties and classifications, which are highlighted in this chapter.

L-Pyrrolysine (Pyl, O;  $C_{12}H_{21}N_3O_3$ ; MW = 255.31 Da)

## Nomenclature of AAs

Most AAs have an asymmetric carbon atom (chiral carbon). Thus, their aqueous solutions exhibit an optical activity and rotate plane-polarized light (Greenstein and Winitz, 1961). The configuration of an AA (L- or D-isomers) was first arbitrarily defined by Emil Fischer in 1908 according to that of L- and D-glyceraldehyde (Fig. 3). Because each asymmetric carbon can have two possible configurations, an AA with  $n$  asymmetric carbons has  $2^n$  different possible stereoisomers. Except for glycine, all proteinogenic AAs can have both D- and L-isomers. Although L-AAs are the predominant physiological isomers of AAs in humans, some D-AAs (e.g., D-serine and D-alanine) occur in certain tissues (e.g., the brain) and fulfill physiological functions. A small amount of D-AAs is present in foods (e.g., milk and heat-processed cereal grains). Human proteins consist of only L-AAs and glycine, but certain bacterial peptides contain D-AAs (e.g., D-proline, D-alanine, and D-glutamate). Some non-proteinogenic AAs [e.g., GABA,  $\beta$ -alanine, and taurine (which have important physiological roles in humans), and aminomalonic acid (which is present as a free AA in humans and microbes)] have no D- or L-isomers. The chemical configuration of AAs is not changed in their crystalline form. All L-AAs plus glycine are the most abundant physiological isomers and account for > 99.9% of total AAs in humans.

The nomenclature of an AA with more than one asymmetric carbon includes an allo-form. For example, a synthetic L-threonine (a 4-carbon AA) whose  $\beta$ -carbon has a configuration opposite to that of the  $\alpha$ -carbon is called L-allo-threonine. L-Threonine and L-allo-threonine are called diastereomers, and the relationship between the two AAs is diastereomerism. Likewise, a synthetic L-isoleucine (a 5-carbon AA) whose  $\beta$ -carbon has a configuration opposite to that of the  $\alpha$ -carbon has a diastereomer of L-allo-isoleucine. This also applies to synthetic D-threonine and D-isoleucine.

To better distinguish some AAs (e.g., 4-hydroxyproline and 3-hydroxyproline) with a pyrrolidine ring structure or more than one chirality center (e.g., threonine and isoleucine), the *R/S* nomenclature is also used to name their absolute configurations, where *R* is *rectus* (right) and *S* is *sinister* (left) in Latin (Hu et al., 2021). This nomenclature system does not involve a reference molecule such as glyceraldehyde, but is based on the prioritized spatial arrangement of the four different groups that are attached to the asymmetric carbon. For AAs (e.g., e.g., hydroxyproline) with a pyrrolidine ring structure, *cis-trans* isomerism is often used to distinguish their chemical structure, with *cis* and *trans* denoting that the functional groups are on the same and opposite side of a plane, respectively. In the *R/S* system, naturally occurring AAs are mostly in the *S* configuration for the first chiral center. *Trans*-(2*S*,4*R*)-4-hydroxyproline (i.e., *trans*-4-hydroxy-L-proline) and *trans*-(2*S*,3*S*)-3-hydroxyproline (i.e., *trans*-3-hydroxy-L-proline) (Fig. 4) play important roles in the structure and stability of collagen and elastin, primarily extracellular proteins in the connective tissue of humans. Human collagen consists of 9.01% *trans*-(2*S*,4*R*)-4-hydroxyproline and 0.09% *trans*-(2*S*,3*S*)-3-hydroxyproline on the molar basis. *Trans*-(2*S*,4*R*)-4-hydroxyproline also contribute to the phosphorylation and catalytic activities of some non-collagen protein kinases in mammals.

**Fig. 3** Fisher projections for the chemical configurations of amino acids relative to L- and D-glyceraldehydes. The general structure of an amino acid in its non-ionized form is shown. Note that glycine, taurine,  $\beta$ -alanine,  $\gamma$ -aminobutyrate, and aminomalonic acid have no asymmetric carbon and, therefore, no L- or D-isomer.

**Fig. 4** Chemical structures of 4-hydroxyproline and 3-hydroxyproline in humans, including those produced by gastrointestinal bacteria. Reproduced from Hu et al. (2021) with permission.

### Free AAs and Peptide- (or protein)-bound AAs

Free AAs are those AAs that are not covalently bound in dipeptides, oligopeptides, or polypeptides. Aspartate, glutamate, glutamine, and taurine are among the most predominant free AAs in human tissues (Adibi and Mercer, 1973; Ahlman et al., 1993; Barle et al., 1996; Perry et al., 1971). In healthy humans, glutamine is the most abundant free AA in their plasma and skeletal muscle, and is the second most abundant free AA in their brain and liver (Table 1). Human skeletal muscle, heart, retina, placenta, brain, and small-intestinal mucosa contain 15–20, 28–40, 20–35, 20–35, 1.16, and 8.74 mM taurine, respectively (Wu, 2020). A healthy 70-kg person has approximately 80 g glutamine and 70 g taurine. In the human brain and small-intestinal mucosa, glutamate is the most abundant and second most abundant free AA, respectively. Interestingly, aspartate is the most abundant free AA in the human liver (Table 1). Selenocysteine does not occur as a free AA in humans (Wu, 2022).

Peptide- (or protein)-bound AAs are those AAs that are linked in peptides or proteins via peptide bonds. A healthy 70-kg adult human contains 15.1% protein (or 10.6 kg protein), including 3.72 kg collagen or 35% of the total body protein. Skeletal muscle contains about 20% protein and accounts for ~45% of body mass in non-obese and non-overweight healthy adults. In skeletal muscle proteins, glutamate is the most abundant amino acid, followed by leucine, lysine, and arginine. In the whole body, glycine is the most abundant amino acid, followed by proline, glutamate, and arginine in descending order (Table 1). Note that selenocysteine is present in selenoproteins due to the conversion of serine and selenium into selenocysteine during the mRNA translation process.

Total free AAs represent ~ 3% of total AAs (free plus peptide-bound) in humans, but individual free AAs may contribute more (e.g., free glutamine) or less (e.g., free tryptophan) to the whole-body AA pool. In beef, about 97–98% of total AAs are present in proteins and polypeptides (Table 2). This is also true for most of plant-sourced foods (e.g., wheat flour, soybean, rice, and corn; Table 2). By contrast, free AAs represent 34.4% and 28.5% of total AAs in potatoes and sweet potatoes, respectively (Hou et al., 2019). Interestingly, free asparagine represents 32.3% and 17.5% of total free AAs in potatoes and sweet potatoes, whereas free glutamine constitutes 25.5% of total free AAs in potatoes (Hou et al., 2019). Taurine is abundant in human milk and animal-sourced foods but is absent from plants (Wu, 2022). In addition, meat is an excellent source of  $\beta$ -alanine and 4-hydroxyproline (Wu et al., 2016), but these two AAs are low or negligible in plants (Li and Wu, 2020). Exposure to high temperatures can result in the formation of a relatively small amount of the following AAs: (1) D-AAs from L-AA (Friedman, 1999), (2) lysinoalanine and lanthionine from cystine or cysteine and serine, (3) 3-methyl-lysinoalanine from lysine and threonine, (4) 3-methyl-lanthionine from cysteine and threonine, and (5) a modified AA (e.g., arginine and lysine) with a Schiff base from an AA (e.g., arginine and lysine) in the presence of a carbohydrate (e.g., glucose and starch) (Wu, 2018;; Fig. 5).

Not all AAs in proteins are precursors for the synthesis of the polymers. This is because some AA residues in proteins undergo post-translational modifications to exert biological functions, such as hydroxylation, methylation, acetylation, phosphorylation, nitrosylation, sulfation, glycosylation (O- and N-linkages), deamination, oxidation, deamidation, racemization,  $\gamma$ -carboxylation, biotinylation, and glycation (Wu, 2022). Thus, in humans, some proteins contain modified AA residues, including

**Table 1** Concentrations of free amino acids in the tissues and plasma of adult humans, as well as amino acid composition in the whole human body

Amino acids	Concentrations of free amino acids					Content of amino acids in	
	Plasma <sup>a</sup>	Liver <sup>b</sup>	Skeletal muscle <sup>a</sup>	Brain <sup>c</sup>	Small intestine <sup>d</sup>	Skeletal muscle protein <sup>e</sup>	The whole human body <sup>f</sup>

<sup>a</sup>Adapted from Bergström et al. (1974) for healthy men and women (20 to 36 years of age). Blood and skeletal muscle (quadriceps femoris muscle) samples were obtained from the study participants after an overnight fast.

<sup>b</sup>Adapted from Barle et al. (1996) for metabolically healthy men and women with no known liver disease. Liver samples were obtained from the study participants after a 12–15 h fast. Concentrations of amino acids in the liver were calculated on the basis of its water content (70%).

<sup>c</sup>Adapted from Perry et al. (1971). Concentrations of amino acids in the brain were calculated on the basis of its water content (70%).

<sup>d</sup>Adapted from Adibi and Mercer (1973) for healthy men (19–24 years of age). The study individuals were fasted overnight and then consumed a meal (containing 50 g of bovine serum albumin). One hour after feeding, jejunal mucosal samples were obtained from the individuals at 1 h for amino acid analysis. The concentration of glutamine plus asparagine was 1.31 mM.

<sup>e</sup>Values were calculated on the basis of the molecular weights of intact amino acids.

<sup>f</sup>Adapted from Wu (2022) and Hu et al. (2021). Values were calculated on the basis of the molecular weights of intact amino acids. The content of asparagine plus aspartate and glutamine plus glutamate in the human body was 90 and 130 mg/g protein, respectively.

<sup>g</sup>Total cysteine (cysteine + ½ cystine). "1/2 cystine" denotes that 1 mol cystine is composed of 2 mol cysteine.

<sup>h</sup>Ryan and Carver (1966).

<sup>j</sup>Borgenvik et al. (2012).

<sup>k</sup>Adapted from Ahlman et al. (1993) for the duodenal mucosa of metabolically healthy, well-nourished men and women. Duodenal mucosal samples were obtained from the study participants after an overnight fast.

4-hydroxyproline, 3-hydroxyproline, 5-hydroxylysine, 3-methylhistidine, 1-methylhistidine, methylated lysine, asymmetrical dimethylarginine, symmetrical dimethylarginine, N<sup>G</sup>-monomethylarginine, N<sup>ε</sup>-acetylated lysine, phosphoserine, phosphotyrosine, nitrosylated cysteine, nitrosylated tyrosine, sulfated tyrosine, N-acetylglucosamine-linked serine, N-acetylglucosamine-linked asparagine, citrulline, allysine (in collagen and elastin), hypusine, D-aspartate (in myelin basic protein), γ-carboxylated glutamate (in blood clotting factors), biotin-acylated lysine (in acyl carrier protein), and glucose-glycated hemoglobin (in diabetes). As shown in Fig. 6, the cross-linkage of certain modified AA residues (e.g., allysine) results in the formation of condensed molecules (e.g., desmosine and its isomer isodesmosine) required for normal extracellular matrix structure and strength (Schmelzer et al., 2020).

**Table 2** Content of free amino acids (FAAs) and peptide-bound amino acids (PAAs) in foods

AA	Corn grain		Potato		Soybean		Sweet potato		Wheat flour		White rice		Beef (loin)

<sup>a</sup>Total cysteine (cysteine + ½ cystine). "1/2 cystine" denotes that 1 mol cystine is composed of 2 mol cysteine.

<sup>b</sup>The molecular weights of intact amino acids were used to calculate the amount of peptide-bound amino acids.

<sup>c</sup>The molecular weights of amino acid residues (i.e., the molecular weights of intact amino acids – 18) were used to calculate the amount of peptide-bound amino acids. Total peptide-bound amino acids represent true proteins plus peptides in foods.

Adapted from Hou et al. (2019) and Wu et al. (2016). Values (the means) for free AAs and peptide-bound AAs are expressed as µg/g of dry matter and mg/g of dry matter, respectively.

## Chemical Properties of AAs

### Physical appearance, fluorescence, and melting points of crystalline AAs

AA crystals are generally white. Phenylalanine, tyrosine, and tryptophan are naturally fluorescent substances, but other AAs are not. This presents a technical challenge for their analysis at a low limit of detection without derivatization with appropriate reagents. AAs generally have a high melting points (Table 2).

### Tastes of crystalline AAs

Different AAs confer different tastes (Wu, 2022). Generally speaking, small AAs (e.g., glycine, L-alanine, L-citrulline, L-proline, L-serine and L-threonine) confer sweet taste, whereas some large L-AAs (e.g., L-arginine, L-isoleucine, L-lysine and L-phenylalanine) have bitter tastes. β-Alanine, L-cystine, L-methionine, and L-tyrosine are flat (lacking taste), whereas L-cysteine, L-histidine, L-leucine, L-ornithine, and L-tryptophan have a flat to bitter taste. L-Glutamate (e.g., monosodium glutamate) and glutamic acid have a "meaty" umami taste. By contrast, D-glutamate is almost tasteless, and D-cystine is flat. Unlike most L-AAs as well as D-glutamate and D-cystine, many D-AAs are sweet substances.

Some AAs have complex tastes. For example, L-aspartate has a sour taste with a slight umami flavor, L-valine has a bitter taste after an initial slightly sweet flavor, and L-histidine-HCl has a slightly bitter taste after an initial sour flavor. The taste of basic AAs is altered by their hydrochloride salts, such that L-arginine-HCl, L-lysine-HCl and L-ornithine-HCl have a mild but characteristic taste. Different individuals may have a different tasting response to the same AA.

L-Amino acid (e.g., L-serine)  $\longleftrightarrow$  D-Amino acid (e.g., D-serine) (heating or AA racemase)

**Fig. 5** Formation of D-amino acids (AAs), lanthionine, lysinoalanine, 3-methyl-lanthionine, 3-methyl-lysinoalanine after heating of free AAs. These reactions can also occur in peptide-bound AAs. In addition, AA racemases can catalyze the formation of D-AAs from L-AAs in humans. Reproduced from Wu (2018) with permission.

**Fig. 6** Formation of desmosine and its isomer isodesmosine from lysine residues in human collagen and elastin for intramolecular and intermolecular cross links. Lysyl oxidase [an ascorbate (Asc, vitamin C) and copper-dependent enzyme] catalyzes the oxidative deamination of lysine residue into allysine residue. Condensations between the indicated molecules occur as spontaneous reactions (SRN) to form desmosine and isodesmosine, which consist of 4 lysine residues to form a pyridinium nucleus. Substrates and products, which are residues in collagen and elastin of all the reactions, are shown. In their intact molecules and non-ionized form, the “-HCO-” group is “-HCOOH” and the “-NH-” group should be “-NH<sub>2</sub>”. The molecular formula of intact desmosine and isodesmosine is C<sub>24</sub>H<sub>40</sub>N<sub>5</sub>O<sub>8</sub> (MW = 526.603).

### Solubility of AAs in water and organic solvents

All AAs are soluble in water. Leucine, isoleucine, valine, phenylalanine, tryptophan, methionine, tyrosine, and cysteine are among the most hydrophobic AAs. Proline and cystine are the most and least soluble, respectively (Table 3). The solubility of tyrosine in water is low. By contrast, *N*-acetyl-cysteine and *N*-acetyl-tyrosine are readily soluble in water (Hou et al., 2015a). The solubility of AAs in water generally increases in acidic or alkaline solutions and with elevated temperatures. With the exception of proline and hydroxyproline, AAs are generally insoluble in organic solvents (e.g., absolute ethanol). The hydrochloride salts of AAs (both neutral and basic) are generally more soluble in water than the corresponding free AAs. Most of the AA hydrochlorides are highly soluble in absolute ethanol.

**Table 3** Chemical properties and classification of amino acids

Amino acids	Side chain	Nitrogen content (%)	MP (°C)	Solub <sup>a</sup> in H <sub>2</sub> O	pK <sub>1</sub> <sup>b</sup>	pK <sub>2</sub> <sup>c</sup>	pK <sub>3</sub> <sup>d</sup>	pI

### The Zwitterionic form of AAs

In an aqueous solution, AAs are ionized to have both positive and negative electrical charges, which are known as the zwitterion. The ionizable groups of AAs interact with water through ionic interactions, hydrogen bonds, and van der Waal interactions. Both the carboxyl and amino groups of an AA, as well as a side chain with an ionizable group have their respective dissociation constants ( $pK_a$ ), which is the negative log of the acid dissociation constant ( $K_a$ ). A lower  $pK_a$  value indicates a stronger acid or greater tendency to give up a proton ( $H^+$ ). When the pH of an aqueous solution is equal to  $pK_a$ , the ionizable group is 50% protonated and 50% deprotonated (Wu, 2022). The dissociation constants for the acid, amino, and side-chain groups are termed  $pK_1$  ( $pK_a$  for the carboxyl group),  $pK_2$  ( $pK_a$  for the amino group), and  $pK_3$  ( $pK_a$  for the side-chain functional group), respectively. The pH of an aqueous solution at which an AA has no net electrical charge is called the isoelectric point (pI). When an AA is dissolved in pure water until the solution is saturated, the pH of this solution will approach the pI value of the AA. At pH 7.4 (e.g., in the plasma) and pH 7.0 (e.g., in the cytoplasm), the  $\alpha$ -carboxylic acid and  $\alpha$ -amino groups of  $\alpha$ -AAs are completely ionized to take the zwitterion form. In their ionized states, glutamic acid and aspartic acid are often referred to as glutamate and aspartate, respectively.

### Chemical stability of AAs

The crystalline forms of all AAs are stable at 25°C for at least 25 years. However, AAs should be protected from light and a high humidity environment during storage. Except for cysteine and aminomalonic acid, AAs in water are stable at -20°C for 3 months and stable at -80°C for 6 months. Likewise, except for cysteine, glutamine, and aminomalonic acid, AAs are generally stable in aqueous solution at physiological pH and body temperature. Cysteine undergoes rapid oxidation to cystine in an aqueous solution that contains oxygen gas, glutamine slowly undergoes intramolecular cyclization to form pyroglutamate (a neurotoxic substance at high concentrations) at a rate of < 1%/day for 1 mM glutamine at pH 7.0 and 37°C; and aminomalonic acid is decarboxylated to glycine.

Most AAs are stable in a neutral aqueous solution at 105°C for 24 h. Under these conditions, glutamine is completely decomposed, whereas asparagine, glutamate, and methionine are partially lost.

Under high pressure and high temperature conditions in an autoclave, glutamine and asparagine are almost completely destroyed. In a dipeptide form (e.g., L-alanyl-glutamine and glycyl-glutamine, as well as L-leucyl-asparagine and glycyl-asparagine), glutamine and asparagine are stable under these conditions.

All AAs except for aminomalonic acid are stable in 1.5 M perchloric acid ( $HClO_4$ ) at  $\leq 25^\circ C$  for at least 15 min and stable in 10% trichloroacetic acid at  $\leq 25^\circ C$  for at least 30 min. Under alkaline conditions (e.g., 4 M NaOH or KOH) at  $\leq 25^\circ C$ , tryptophan is stable for at least 24 h, aminomalonic acid is relatively stable, and other AAs are not stable.

Under standard conditions of acid hydrolysis (i.e., 6 M HCl, 110°C, and 24 h under nitrogen gas), most AAs are stable, but all glutamine and asparagine are converted to glutamate and aspartate, respectively, and tryptophan is completely destroyed. Under the conditions of alkaline hydrolysis at a high temperature (e.g., 105°C), most AAs (including arginine, asparagine, glutamine, glycine, histidine, serine, and threonine) are almost completely destroyed, and many AAs (e.g., cysteine, cystine, and methionine) are decomposed to a great extent. By contrast, tryptophan is stable in alkaline solutions [e.g., 4.2 M NaOH and 1% thiodiglycol (an antioxidant)] at 105°C for 20 h.

### Chemical Reactions of AAs

#### Chemical reactions of the amino group in $\alpha$ -AAs

The amino group of an  $\alpha$ -AA participates in many chemical reactions with a variety of substances. The reactions include: acetylation, benzoylation, carbobenzoxylation, condensation, conjugation, deamination, dinitrophenylation, group protection, methylation, oxy-methylation, and transamination, as well as keto-enol tautomerization and amino-imino tautomerization.

#### Chemical reactions of the carboxyl group in $\alpha$ -AAs

The carboxyl group of  $\alpha$ -AAs participates in chemical reactions, such as amidation, decarboxylation, esterification, and reduction. Esterification of an AA can block its  $\alpha$ -carboxyl group from binding to undesirable substrates. Furthermore,  $\alpha$ -AAs can be chemically converted into the corresponding alcohols through reduction with sodium borohydride and iodine in tetrahydrofuran.

#### Chemical reactions of the side chain in $\alpha$ -AAs

The amino or carboxyl group of the side chain of  $\alpha$ -AAs participates in some chemical reactions. For example, the phenolic ring of tyrosine is iodinated under alkaline conditions. In addition, the  $\epsilon$ -amino group of lysine and the guanidino group of arginine contribute to hydrogen bonding, can be methylated, and react with carbohydrates (e.g., glucose and starch). The guanidination of free or protein-bound lysine with methylisourea generates homoarginine. The guanidino group of arginine can also react with diketones, and this chemical property is useful for studying protein structure and function (e.g., the allosteric and active sites of enzymes). Furthermore, the  $\gamma$ -amino group of asparagine in protein form an N-linkage with glucose, and free asparagine can react

with reactive carbonyls at high temperatures to generate acrylamide (a potential carcinogen). Of particular note, the presence of an acid (e.g., 6 M HCl) at an elevated temperature (e.g., 110°C) results in the deamidation of the  $\gamma$ -amino group of asparagine and the  $\epsilon$ -amino group of glutamine. Finally, glutamine residues in proteins undergo deamidation by transglutaminase I (in the presence of polyamines) or transglutaminase II (in the presence of protein-bound lysine) to release  $\text{NH}_3$ .

### Chemical reactions involving both the amino and carboxyl groups of $\alpha$ -AAs

Both amino and carboxyl groups simultaneously participate in some unique chemical reactions, such as chelation, cyclization, racemization, formation of N-carboxy anhydride, oxidative deamination (decarboxylation; e.g., reaction with ninhydrin), condensation (e.g., peptide formation), and esterification (e.g., among L-arginine monohydrochloride, ethanol, and lauroyl chloride in the presence of NaOH). The resulting products include AA-chelates (providing highly bioavailable minerals for humans), azlactone, dike-topiperazine, N-carboxy AA anhydride (NCA), peptide bonds, and aldehyde.

The formation of one peptide bond from two molecules of AAs results in the loss of one molecule of water (Fig. 7). Proteins are large polymers of AAs, with the whole collagen (three cross-linked chains) molecule containing approximately 3,000 AA residues. In the human body, 100 g of protein consist of 100 g of AA residues but not 100 g of intact AAs. The complete hydrolysis of 100 g of protein yields more than 100 g of free, intact AAs. For example, the enzymatic hydrolysis of 100 g of protein in human skeletal muscle or pork meat generates 118 g of intact AAs. This should be kept in mind when analyzing AA composition in proteins (including those in tissues, cells, and foods).

### Chemical analyses of AAs

Many methods have been used to analyze free AAs, including gas, ion-exchange, and liquid chromatographies, as well as mass spectrometry. Most chromatographic procedures involve pre- or post-column derivatization with reagents that give rise to fluorescent or colorimetric AA derivatives for appropriate detection. To date, liquid chromatography is more widely used than gas chromatography for AA analysis. Among liquid chromatography methods, high-performance liquid chromatography involving the pre-column derivatization with *o*-phthalaldehyde (OPA) is most popular for the analysis of free and peptide-bound AAs in foods and biological samples (Dai et al., 2014).

Derivatizing reagents for UV/VIS detection include butylisothiocyanate (BITC), benzylisothiocyanate (BZITC), 4-chloro-3,5-dinitrobenzotrifluoride (CDNBTF), 4-dimethylaminoazobenzene-4-sulfonyl chloride (DABSYL-Cl), diethyl ethoxymethylenemalonate (DEEMM), 2,4-dinitrofluorobenzene (Sanger's reagent; DNFB), 1-fluoro-2,4-dinitrobenzene (FDNB), *N,N*-diethyl-2,4-dinitro-5-fluoroaniline (FDNDEA), 1-fluoro-2-4-dinitrophenyl-5-L-alanine amide (Marfey's reagent; FDNPA), 2,2-dihydroxyindane-1,3-dione (ninhydrin), 1,2-Naphthoquinone-4-sulfonate (NQS), 4-Nitrophenylisothiocyanate (NPITC), and phenylisothiocyanate (PITC). Derivatizing reagents for fluorescence detection include 3-(4-Carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA), fluorescein-5-isothiocyanate (FITC), 9-fluorenylmethyl chloroformate (FMOC-Cl), fluorescamine (FRA), 4-chloro-7-nitrobenzofurazan [CNBF; Also known as 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl)], 4-fluoro-7-nitro-2,1,3-benzoxadiazole (NBD-F), naphthalene-2,3-dialdehyde [NDA; also known as naphthalene-2,3-dicarboxaldehyde (NDB)], OPA, 4,7-phenanthroline-5,6-dione (PAD; also known as phanquinone), and styrene-divinylbenzene (SBD-P). Derivatizing reagents for either UV/VIS or fluorescence detection include 6-aminoquinolyl-N-hydroxysuccinimidyl carbamate (AQC), 4-chloro-7-nitrobenzofurazan (CNBF), and 1-dimethylaminonaphthalene-5-sulphonyl chloride (Dansyl-Cl). The use of a derivatizing reagent depends on the availability of laboratory equipment and sample type.

To analyze AAs in proteins and peptides, the polymers must first be completely hydrolyzed by appropriate acid, alkaline, or enzymatic methods. The standard method for the acid hydrolysis of proteins involves 6 M HCl at 110°C for 24 h (Dai et al., 2014). The major disadvantage of this procedure is the complete conversion of glutamine and asparagine into glutamate and aspartate, respectively, and the complete destruction of tryptophan, as noted previously. To overcome this problem, a mixture of proteases and peptidases (e.g., pronase E, prolidase, pyroglutamate aminopeptidase, carboxypeptidase A, and aminopeptidase M) is used to analyze glutamate, glutamine, aspartate and asparagine in proteins (Li et al., 2021), whereas the analysis of peptide-bound

**Fig. 7** Synthesis of a dipeptide from two amino acids (AAs). R1 and R2 represent the side chains of the two AAs. With the loss of one  $\text{H}_2\text{O}$  molecule (one "H" atom from the  $\alpha$ -amino group of an AA and the "OH" from the carboxyl group of the other AA), a peptide bond ( $-\text{CONH}-$ ) is formed. This reaction is used to produce peptides through chemical manufacturing, and is catalyzed by enzymes in human cells. Peptides are generally stable in an aqueous solution.

tryptophan involves the hydrolysis of proteins in the presence of an alkaline solution (e.g., 4.2 M NaOH) at 105 °C for 20 h and 1% thioglycol (an antioxidant).

## Classification of AAs

AAs can be classified as neutral (e.g., alanine and glycine), basic (arginine and lysine), and acidic (aspartate and glutamate) AAs, based on their net charges (e.g., 0, +1, and −1) at neutral pH (Table 2). At neutral pH, the side-chain  $\text{-NH}_2$  group in asparagine, glutamine and citrulline is not ionized and, therefore, has no electric charge. Thus, in contrast to statements in some books and papers, these three AAs are not basic AAs at pH 7.0 or 7.4. Note that the net charges of AAs at acidic pH (e.g., pH 1.5 to 3.5 in the luminal fluid of the stomach of humans) are different from those at neutral pH. The net electrical charges of AAs have important implications for their intestinal absorption, transport by cells, and inter-organ metabolism in the body, as well as dietary supplementation with AAs. For example, the addition of an acidic or basic AA to a solution with a weak buffering capacity will substantially decrease or increase the pH of the solution, respectively. Likewise, arginine-HCl, but not arginine base, is used for intravenous infusion to humans to prevent acid-base imbalance.

Based on the side chain, AAs are classified as aliphatic AAs (e.g., branched-chain AAs); AAs with a hydroxylic ( $\text{-OH}$ ) group (e.g., serine and threonine); AAs containing at least one sulfur atom (e.g., cysteine and methionine); AAs with an acidic group (e.g., aspartate and glutamate); AAs containing amide groups (e.g., asparagine and glutamine); AAs with a basic group (e.g., lysine and ornithine); AAs containing an aromatic group (e.g., phenylalanine and tryptophan); AAs with guanidino groups (e.g., arginine and homoarginine); AAs with imidazole groups (e.g., histidine and 3-methylhistidine); AAs with AAs with a seleno group (e.g., selenocysteine); AAs with an imino group (e.g., proline and 4-hydroxyproline); and phosphorylated AAs (e.g., phosphoserine and phosphotyrosine). Some AAs (e.g., desmosine, isodesmosine, and cystine) contain two or more amino groups and acidic groups. The side-chain of AAs affects their chemical properties and reactions (either spontaneous or enzyme-catalyzed).

Since 1912, AAs have long been classified as nutritionally essential or nonessential for humans (see Hou et al., 2015b for review). AAs that are not synthesized *de novo* by human tissues, which are known as nutritionally essential AAs (EAAs), must be provided in diets for maintenance, survival, and growth (Hou and Wu, 2018). Over the past three decades, a growing number of studies have revealed that endogenous syntheses of AAs are inadequate for the maximum growth or the optimum lactation, reproduction, and health of mammals (Hou et al., 2016). Thus, the term “nutritionally nonessential AAs” (NEAAs) has now been recognized as a misnomer in nutritional sciences (Hou and Wu, 2017). There is no compelling evidence that infants, adolescents and adults can synthesize *de novo* sufficient NEAAs (Hou et al., 2015b; Wu et al., 2013). Rather, results of recent clinical studies have shown that humans are not capable of forming sufficient amounts of all proteinogenic NEAAs and all nonproteinogenic NEAAs (Wu, 2022). For example, infants, particularly preterm neonates, have a limited ability to synthesize taurine, and suffer from severe cardiac and retinal damage when not fed a taurine-containing diet (Wright et al., 1986). In addition, adults fed solely plant-based diets do not produce sufficient taurine to meet optimum physiological needs, particularly under stress or diseased conditions (Wu, 2020). Furthermore, adults consuming little or no arginine exhibit metabolic defects, such as an inadequate synthesis of nitric oxide in the vasculature, reduced blood flow, and impaired fertility (Wu et al., 2021).

## Conclusion and outlook

AAs (organic molecules containing both amino and acidic groups) are major molecules in humans and foods. The configuration of AAs is generally defined in reference to L- and D-glyceraldehyde. The absolute configuration of AAs is designated according to the R/S system, and includes *cis* and *trans* for those with a ring structure. AAs exist in both free and peptide-bound forms. All  $\alpha$ -AAs, except for glycine and aminomalonic acid, can have both L- and D-isomers. Except for glycine, proteinogenic (protein-creating) AAs in human tissues are L-isomers. All L-AAs plus glycine are the most abundant physiological isomers and account for > 99.9% of total AAs in humans, but some D-AAs have important functions particularly in the neurological and immune systems. AAs in proteins plus peptides and free AAs account for approximately 97% and 3% of the total AAs in animals, respectively. Glycine is the most abundant peptide-bound AA in humans, followed by proline, glutamate, and arginine. Glutamine and alanine are the most and second most abundant free AA in the human plasma, respectively. Human liver, skeletal muscle, brain, and small-intestinal mucosa contain high concentrations of free aspartate plus taurine plus glutamine plus glutamate, free glutamine plus taurine plus glutamate, free glutamate plus glutamine, and free taurine plus glutamate, respectively. In some plant-sourced foods, select AAs (e.g., glutamine and asparagine) are highly abundant in the free form, with free AAs representing 34.4% and 28.5% of the total AAs in potatoes and sweet potatoes, respectively. Animal-sourced foods generally contain high amounts and proper ratios of all proteinogenic AAs. Of note, meat is an abundant source of taurine,  $\beta$ -alanine and 4-hydroxyproline, as well as carnosine ( $\beta$ -alanyl-L-histidine) and anserine ( $\beta$ -alanyl-L-1-methylhistidine), whereas plants lack taurine, carnosine and anserine and contain only a small or negligible amount of  $\beta$ -alanine and 4-hydroxyproline (Wu, 2020). Different AAs have different chemical properties (e.g., solubility, stability, melting points, reactions, taste, and electrical charges). Depending on the availability of laboratory instruments, many methods are available for the analysis of free and peptide-bound AAs, with the precolumn derivatization with OPA being the most widely used. AAs can be classified as neutral, basic, and acidic AAs based on their net charges at neutral pH, or as aliphatic, sulfur-containing, hydroxylated, amidated, carboxylated, phosphorylated, guanidino, aromatic, imidazole, seleno, and

secondary amino acids. Much needs to be done about the content of AAs (particularly glutamate, glutamine, aspartate, asparagine, proline, hydroxyprolines, cysteine, and tryptophan) in foods. Knowledge of AA chemistry and classification is essential for the understanding of human nutrition and health.

## Key points

- Humans can synthesize *de novo* the following nine proteinogenic AAs (alanine, arginine, aspartate, asparagine, glutamate, glutamine, glycine, proline, and serine), as well as non-proteinogenic AAs (e.g., citrulline, ornithine, and taurine) in a cell- and tissue-specific manner.
- Humans can convert methionine into cysteine in the liver; phenylalanine into tyrosine mainly in the liver and kidneys; and serine plus selenium into selenocysteine as a component of selenoproteins in cells during the mRNA translation.
- Humans can degrade all proteinogenic AAs and physiological non-proteinogenic AAs via compartmentalized metabolic pathways and inter-organ cooperation.
- In the mucosa of the human small intestine, dietary glutamate, glutamine, and aspartate are the major metabolic fuels after feeding, whereas glutamine is the primary energy substrate in the post-absorptive state.
- Microbes in the small and large intestines actively degrade dietary and endogenous AAs.
- Products of AA catabolism and conjugation include CO<sub>2</sub>, water, ammonia, urea, nitric oxide (NO), carbon monoxide (CO), hydrogen sulfide (H<sub>2</sub>S), γ-aminobutyrate (GABA), heme, serotonin, melanin, melatonin, histamine, polyamines, glutathione, creatine, phospholipids, and nucleic acids.
- Based on their metabolic fates, AAs can be classified as ketogenic, glucogenic, and ketogenic plus glucogenic.
- The mechanistic target of rapamycin (MTOR) cell signaling pathway integrates anabolic factors to promote protein synthesis in cells, whereas ATP and ubiquitin-dependent proteasomes as well as autophagy and lysosomal proteases are responsible for the bulk of intracellular proteolysis.

- Elevated concentrations of ammonia in the plasma are highly toxic to the central nervous system, and this metabolite must be removed as urea primarily via the periportal hepatocytes of the liver and, to a much lesser extent, the enterocytes of the small intestine.
- In adults, adequate intakes of dietary protein and AAs are essential to mitigate muscle loss during aging and under catabolic conditions.

## Introduction

In healthy adult humans, concentrations of total amino acids (AAs) in their plasma are increased after the oral consumption of a diet [e.g., soy or milk; providing 0.41 g protein/kg body weight (BW)] to peak values at approximately 1 h post-feeding, maintained at plateau until 3 h post-feeding, decreased thereafter gradually to baseline levels at 6 h post-feeding, and then maintained constant until 8 h post-feeding (Bos et al., 2003). The post-prandial changes in the plasma concentrations of total branched-chain AAs (BCAAs) and total glucogenic AAs (alanine, glutamate, glutamine, glycine, proline, serine, and threonine) followed the same pattern as those for the total AAs. In healthy term neonates (5–7 days of age), concentrations of total AAs and many AAs (including BCAAs, arginine, ornithine, and proline) in their plasma are increased after the oral consumption of human milk and cow's milk formula (providing 0.20 and 0.4–0.8 g protein/kg BW, respectively) to peak values at approximately 0.5 and 1 h post-feeding, respectively, and decreased thereafter gradually until 3 h post-feeding (Tikanoja, 1982; Tikanoja et al., 1982a). Similar phenomena occur in preterm infants (4–12 days of postnatal age; gestational days of 34–37 weeks) fed under the same conditions (Tikanoja et al., 1982b). In both adults and neonates, the patterns of AAs in the plasma differ remarkably from those in diets as a result of tissue-specific AA metabolism (Sarkar et al., 2021; Wu, 2022). The maintenance of AA homeostasis in the body is regulated by many metabolic processes, including gastrointestinal protein digestion and the intestinal absorption of its products (AAs and small peptides), the inter-organ transport of AAs, intracellular protein turnover (protein synthesis and degradation), post-translational protein modifications, and the cell-specific synthesis and catabolism of AAs (Phang, 2019; Tsikas, 2021; Wu, 2022). These aspects of AA metabolism are highlighted in this article.

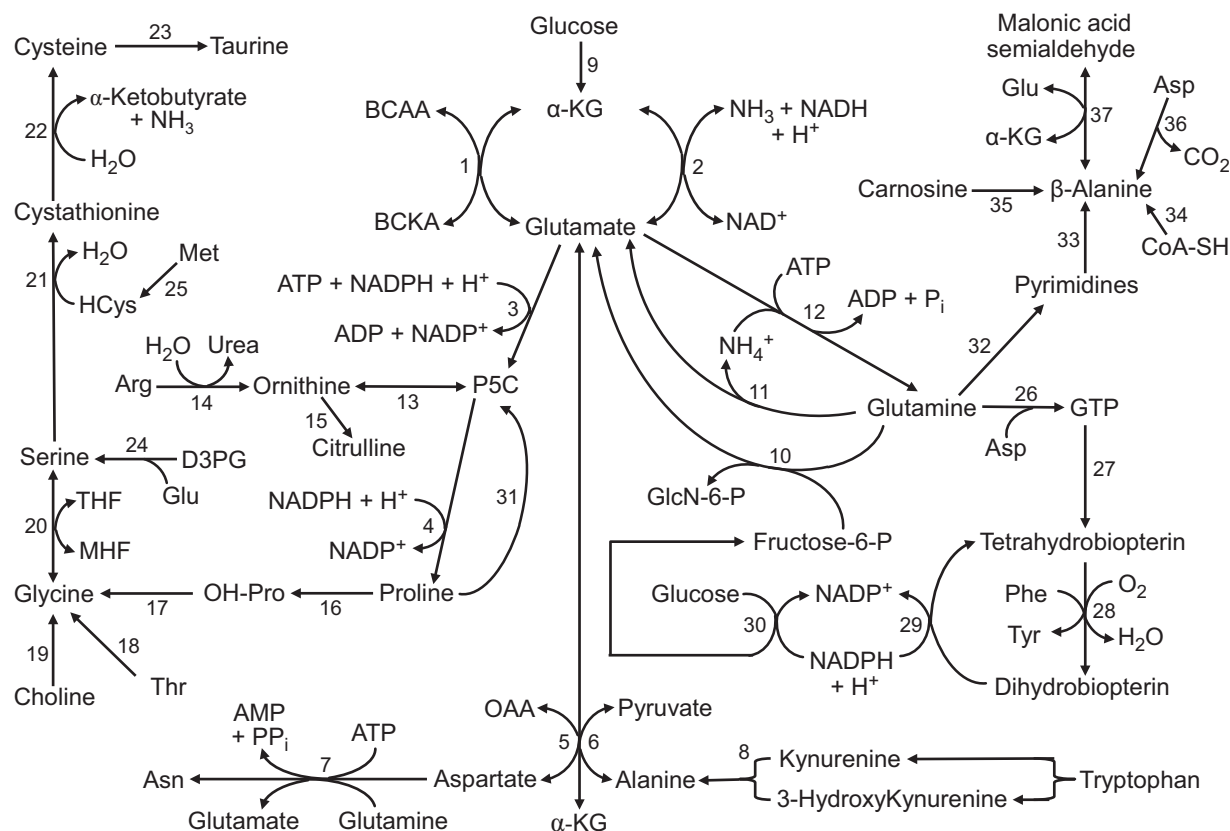

## Synthesis of AAs in humans

### Overall view of AA synthesis in humans

Human and cow milk-based formulas contain relatively low concentrations of arginine and glycine and, therefore, do not provide an adequate amount of both AAs to infants (Davis et al., 1994; Wu, 2022). Likewise, individuals consuming plant-based foods (which are all deficient in glycine and proline, Hou et al., 2019; Li and Wu, 2020) do not ingest a sufficient quantity of these two nutrients. Furthermore, because taurine [a physiologically essential AA (Wu, 2020a)] is absent from plants, vegetarians have little or no intake of this AA from their diets. Thus, humans must be able to synthesize certain AAs for survival, growth, and development. In support of this view, the optimal production of collagen (the most abundant protein in the body) requires the endogenous formation of glycine and proline *de novo* from other AAs under both healthy and diseased (e.g., burning and infection) conditions (Hamanaka and Mutlu, 2021; Meléndez-Hevia et al., 2009). Finally, most of dietary aspartate, glutamate, and glutamine are degraded by the small intestine during their first pass into the portal vein, and, therefore, these AAs (which are among the most abundant AAs in the body) must be produced from other AAs in humans (Wu, 1998). AA syntheses require energy and the so-called nutritionally essential AAs (EAAs), and these processes are energetically inefficient and also produce ammonia (a toxic substance at elevated concentrations). Under normal feeding conditions, AAs that are synthesizable *de novo* in animal cells (AASAs) play important roles in mammalian nutrition, metabolism and redox signaling, but the amounts are insufficient for the maximum growth and optimum health of humans (Wu, 2022). AAs that are not synthesized *de novo* in human tissues, which are known as nutritionally essential AAs, must be provided in diets to ensure survival, growth, development, and health (Wu, 2022). The century-old notion of “nonessential AAs” has now been recognized as a misnomer (Hou and Wu, 2017). Likewise, the long-standing nutritional concept of “ideal protein” ignores all AASAs and should no longer be used in research or feeding practices.

### Cell- and tissue-specific synthesis of AAs in humans

Humans can synthesize *de novo* the following nine proteinogenic AAs (alanine, arginine, aspartate, asparagine, glutamate, glutamine, glycine, proline, and serine), as well as non-proteinogenic AAs (e.g., citrulline, ornithine, taurine, and GABA) in a cell- and tissue-specific manner (Wu, 2022). In addition, humans can form (a) citrulline from glutamate, glutamine and proline in the small intestine; (b) taurine from cysteine in the liver; (c) tyrosine from phenylalanine in the liver, kidneys, and skin; (d) phosphoethanolamine from serine; and (e) certain L-AAs (e.g., L-serine and L-aspartate) into D-AAs (e.g., D-serine and D-aspartate); and some D-AAs (e.g., D-methionine and D-phenylalanine) into L-AAs (e.g., L-methionine and L-phenylalanine). The overall metabolic pathways are illustrated in Fig. 1, and the amounts of AAs synthesized in the whole-body of humans are summarized in

**Fig. 1** Synthesis of amino acids in humans in a cell- and tissue-dependent manner. The enzymes catalyzing the indicated reactions are: (1) BCAA transaminase; (2) glutamate dehydrogenase; (3) P5C synthase; (4) P5C reductase; (5) aspartate transaminase; (6) alanine transaminase; (7) asparagine synthetase; (8) enzymes for tryptophan catabolism; (9) enzymes for converting glucose into  $\alpha$ -KG; (10) glutamine:fructose-6-phosphate transaminase; (11) phosphate-activated glutaminase; (12) glutamine synthetase; (13) ornithine aminotransferase; (14) arginase; (15) ornithine carbamoyltransferase; (16) enzymes for protein synthesis, hydroxylation of peptide-bound proline, and protein degradation; (17) enzymes for converting 4-hydroxyproline into glycine; (18) enzymes for converting threonine into glycine; (19) enzymes for converting choline into glycine; (20) serine hydroxymethyltransferase; (21) cystathionine  $\beta$ -synthase; (22) cystathionine  $\gamma$ -lyase; (23) enzymes for converting cysteine into taurine; (24) enzymes for converting D-3-phosphoglycerate and glutamate into serine; (25) enzymes for methionine catabolism; (26) enzymes for GTP synthesis; (27) enzymes for tetrahydrobiopterin synthesis; (28) phenylalanine hydroxylase; (29) dihydrobiopterin reductase; (30) enzymes of the pentose cycle; (31) proline oxidase; (32) enzymes for pyrimidine synthesis; (33) enzymes for pyrimidine catabolism; (34) enzymes for coenzyme A (CoA-SH) catabolism; (35) carnosinase; (36) aspartate decarboxylase; (37)  $\beta$ -alanine- $\alpha$ -KG transaminase, with malonic acid semialdehyde being produced from propionyl-CoA and malonyl-CoA semialdehyde. BCAA, branched-chain amino acid; BCKA, branched-chain  $\alpha$ -ketoacid; D3PG, D-3-phosphoglycerate; GlcN-6-P, glucosamine-6-phosphate; HCys, homocysteine; MTH,  $N^5$ -methylene tetrahydrofolate; OH-Pro, 4-hydroxyproline; OAA, oxaloacetate; P5C,  $\Delta^1$ -Pyrroline-5-carboxylate; THF, tetrahydrofolate. Reproduced from Wu (2013) with permission.

**Table 1.** Much evidence shows that endogenous AA production is altered during development and in diseased states (Wu, 2022) (Fig. 2).

Microbes in the small intestine have a net consumption of dietary AAs (Dai et al., 2011, 2015). Although microbes in the large intestine can convert free AAs and small peptides into proteins, the microbial proteins are not absorbed into the blood circulation and, therefore, have no nutritive value (Wu, 2013). In the fed and post-absorptive states, only a small or nutritionally insignificant amount of free AAs is absorbed from the lumen of the large intestine into the blood circulation of humans (Bergen and Wu, 2009).

**Liver**

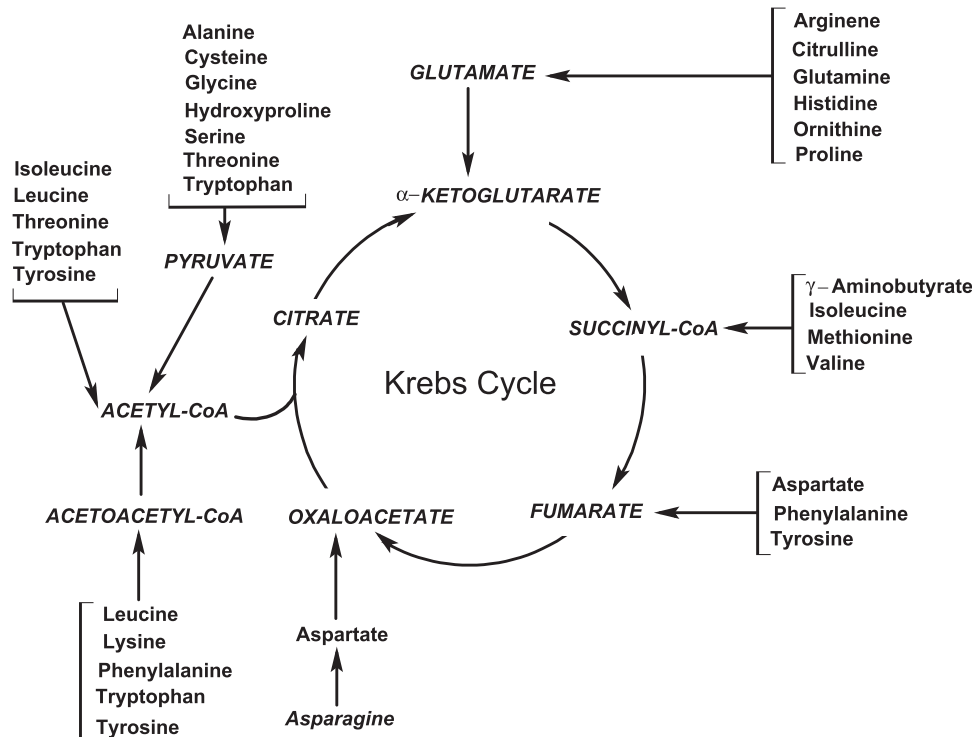

The liver is an active organ in mammalian AA metabolism (Hou et al., 2020). Under physiological conditions, there is no net synthesis of citrulline or arginine in the human liver. This is because ornithine-derived citrulline is immediately converted into arginine via argininosuccinate synthase and lyase, and the arginine formed via the urea cycle is rapidly hydrolyzed to urea plus ornithine by arginase in hepatocytes. The liver cannot synthesize proline from glutamine or glutamate due to its lack of pyrroline-5-carboxylate (P5C) synthase. By contrast, the human liver can form proline from arginine via arginase, ornithine aminotransferase (OAT), and P5C reductase (Wu and Morris, 1998). The human liver can form (a) aspartate, asparagine, glutamate, glutamine, glycine, and serine from other AAs; (b) cysteine from methionine, taurine from cysteine, and cholytaurine from taurine plus bile acid; (c) tyrosine from phenylalanine (via phenylalanine hydroxylase); and (d) phenylacetylglutamine from phenylalanine,

**Table 1** Rates of the syntheses of amino acids (AAs) in humans.

AA	Species	Nutritional state	Flux in arterial plasma ( $\mu\text{mol/kg}$ of body weight/h)	Endogenous synthesis ( $\mu\text{mol/kg}$ of body weight/h)
Arginine	Human infants	TPN	209	15
	Preterm infants	Fed (enterally)	461	42 (from proline)
	Adult humans	Fed (enterally)	73	5.2
Glutamine	Preterm human infants	Fasted	755	655
	Preterm human infants	Fed (enterally)	644	529
	AGA infants	Fasted	545	472
		Fed (enterally)	494	423
		Fasted	791	679
	SGA infants	Fed (enterally)	677	569
Glutamate	Adult humans	Post-absorptive	348	245
	Human infants	Fed (enterally)	607 (423–791)	482
	Adult humans	Post-absorptive	83	67
Glycine	Adult humans	Fed (enterally)	458	72
Proline	Adult humans	Fed (enterally)	128	39
Serine	Adult humans	Overnight fasted	150	110

**Fig. 2** An overall view of amino acid catabolism in humans. Different metabolic pathways for the catabolism of amino acids converge to common intermediates ( $\alpha$ -KG, oxaloacetate, and pyruvate) that feed into the Krebs cycle in tissues. Different amino acids have different metabolic fates in the body. Reproduced from Wu (2013) with permission.

acetyl-CoA, and glutamine. This organ has a limited ability to convert BCAAs into other AAs due to the near absence of BCAA transaminase activity under physiological conditions (Harper et al., 1984). Note that in the human liver, glutamine synthase is expressed primarily in perivenous hepatocytes to convert the ammonia that escapes periportal hepatocytes plus glutamate into glutamine to maximize the removal of ammonia from the blood. In contrast to adults and term infants, preterm humans have a limited ability to synthesize taurine from cysteine in the liver.

#### Skeletal muscle, heart, brain, lungs, and white adipose tissue

In humans, alanine, aspartate, and glutamate can be synthesized from BCAAs (the donors of the amino group) and glucose-derived carbon skeletons in the skeletal muscle, heart, brain, lungs, and white adipose tissue (Brosnan and Brosnan, 2006). These reactions

require BCAA transaminase, glutamine synthetase, glutamate transaminase, and alanine transaminase. A small amount of aspartate can be further converted into asparagine via asparagine synthetase in these tissues. In fasting individuals, alanine and glutamine account for approximately 50% of total AAs released by their skeletal muscle (Marliss et al., 1971). Because of its large mass (45% and 40% of BW in adults and neonates, respectively), skeletal muscle is the major source of both alanine and glutamine in post-absorptive humans (Ryan et al., 2021). The synthesis of glutamine from  $\text{NH}_3$  and glutamate plays a major role in removing ammonia from the blood. Furthermore, the skeletal muscle, heart, brain, lungs, and white adipose tissue of humans can interconvert serine and glycine.

### **The small intestine**

The small intestine is the terminal site for the digestion of dietary proteins and the absorption of its products (small peptides and free AAs). In addition, as for many other mammals, the small intestine of humans can form alanine, arginine, aspartate, asparagine, citrulline, ornithine, and proline from glutamate and glutamine; glutamate from BCAAs plus glucose, glutamine, and proline; glycine from serine; tyrosine from phenylalanine; and methionine from homocysteine (Wu, 2022). The gut releases alanine, arginine, citrulline, ornithine, and proline in the post-absorptive state. The mammalian small intestine has a limited ability to synthesize glutamine due to a low activity of glutamine synthetase. Citrulline bypasses the liver and only about 10% of arginine in the portal vein is taken up by this organ so as to maximize the bioavailability of diet- and gut-derived citrulline and arginine to the extrahepatic tissues. Because of the complex compartmentation of AA metabolism involving both the mitochondrion and cytoplasm, extracellular ornithine is poorly utilized for citrulline or arginine synthesis in enterocytes. These reactions occur in both enterocytes and bacteria. Microorganisms in the lumen of the gastrointestinal tract can synthesize all AAs from ammonia, carbohydrates, and sulfur (Dai et al., 2011).

### **Kidneys**

In humans, the kidneys can synthesize alanine, aspartate, and glutamate from BCAAs, glutamine, and 4-hydroxyproline, while interconverting phenylalanine into tyrosine, serine into glycine, and proline into ornithine (Hu et al., 2022; Li et al., 2020). In contrast to many other mammals (e.g., rats and rabbits), human kidneys lack glutamine synthetase (Wu, 2022). Alanine transaminase activity is present in the kidneys of humans. The kidneys contain argininosuccinate synthase and argininosuccinate lyase for converting citrulline into arginine. These two enzymes are strategically localized within the proximal convoluted tubules which express little arginase activity. In adults, approximately 60% of net arginine synthesis from citrulline occurs in the kidneys.

### **Endothelial cells, smooth muscle cells, macrophages, and lymphocytes**

These cells can synthesize alanine, aspartate, and glutamate from BCAAs and glutamine, and convert citrulline into arginine to conserve arginine for the production of nitric oxide (NO) at the expense of aspartate (Wu, 2022). This is commonly referred to as the arginine–citrulline cycle. By contrast, all these cells do not synthesize: (1) citrulline from glutamine, glutamate and proline; (2) tyrosine from phenylalanine; or (3) taurine from cysteine.

### **Sense organs**

In humans, sense organs (the eyes, ears, nose, tongue, and skin) can synthesize alanine, aspartate, glutamate, and 4-hydroxyproline, while converting citrulline into arginine, phenylalanine into tyrosine, serine into glycine, arginine into ornithine, and ornithine into proline (Wu, 2020b). The eyes and skin also produce asparagine, glutamine and glycine from BCAAs, glutamate, and 4-hydroxyproline, but little is known about these reactions in other sense organs. In addition, retinal cells in the eyes can decarboxylate glutamate to generate GABA. All the sense organs do not convert: (1) methionine into cysteine; or (2) glutamine, glutamate and proline into citrulline.

### **Placentae, mammary glands, ovaries, testes, and pancreas**

In humans, these organs can synthesize glutamate, glutamine, alanine, aspartate, and asparagine from BCAAs, form ornithine and proline from arginine, interconvert serine into glycine, and produce 4-hydroxyproline from proline (via collagen synthesis) (Wu, 2022). During lactation, the mammary glands contribute to a large amount of glutamate, glutamine, aspartate, and proline for milk synthesis. The human placenta, ovaries, and testes lack both phenylalanine hydroxylase activity and P5C synthase, whereas P5C synthase is also absent from the pancreas. By contrast, both the mammary glands and the pancreas can form tyrosine from phenylalanine.

## **Degradation of AAs in humans**

### **Overall view of AA degradation in humans**

Degradation of AAs occurs in humans regardless of their nutritional states but at higher rates immediately after feeding than during fasting (Jungas et al., 1992). Because physiological concentrations of free AAs are readily soluble in water but their accumulation in the body can increase the extracellular and intracellular osmolarity, most of the excessive AAs are degraded in a cell- and tissue-specific manner. The major products of AA catabolism are  $\text{CO}_2$ , water, ammonia, urea, uric acid, pyruvate, and acetyl-CoA, with the metabolic fates of pyruvate (e.g., glucose or fatty acid synthesis) and acetyl-CoA (oxidation to  $\text{CO}_2$  or fatty acid synthesis),

depending on nutritional, physiological, and pathological states (Wu, 2022). Reactions for initiating AA degradation include transamination, amidotransferase, cleavage, condensation, deaminated oxidation (FAD-dependent), deamination, decarboxylation, dehydration, dehydrogenation [ $\text{NAD(P)}^+$ -dependent], dioxygenation, hydrolysis (via amidinohydrolysis or deamidation), hydroxylation, one-carbon unit transfer, oxidation (FAD-dependent), oxidative deamination, and reduction. AA metabolism generates bioactive metabolites (e.g., NO, taurine, creatine, polyamines, dopamine, serotonin, and  $\text{H}_2\text{S}$ ) with enormous physiological importance. Thus, in humans consuming a normal meal with protein, carbohydrate and lipids, the catabolism of any excess AAs takes precedence over the degradation of carbohydrates and fatty acids. Aspartate, glutamate and glutamine are major metabolic fuels for the human small intestine as noted previously and help to regulate the homeostasis of these AAs in plasma (Bertolo and Burrin, 2008; Rhoads and Wu, 2009). However, the use of AAs for ATP production in the whole body is energetically inefficient in mammals (e.g., 47% for glutamate, 49% for threonine, and 24% for methionine; Wu, 2022).

### Cell- and tissue-specific degradation of AAs in humans

In humans, most AAs are degraded in a tissue-, cell-, and concentration-dependent manner, but some pathways (e.g., NO synthesis, the hydrolysis of arginine by arginase, the oxidation of proline to P5C by proline oxidase, and the decarboxylation of ornithine to putrescine) occur in nearly all cell types. There are also diurnal changes in the catabolism of some AAs independent of food intake, such as the conversion of tryptophan to melatonin during the dark period of the light–dark cycle (Armstrong, 1999). Transport into cells via specific and multiple systems is the first step for the utilization of AAs (Bröer and Bröer, 2017; Closs et al., 2000). The complete catabolic pathways for most AAs may involve both the cytosol and mitochondria (Curthoys and Watford, 1995; Morris, 2009). Because of the complex compartmentation of AA metabolism, extracellularly- and intracellularly-derived AAs may have very different metabolic fates. The cooperation of multiple organs is required for the complete oxidation of AAs to  $\text{CO}_2$ ,  $\text{NH}_3$  (a gas) and water. In an aqueous solution, free ammonia ( $\text{NH}_3$ ) is at equilibrium with ammonium ion ( $\text{NH}_4^+$ ;  $\text{pK}_a = 9.2$ ). At pH 7.4 and 37 °C, approximately 1.6% and 98.4% of ammonia exists as free  $\text{NH}_3$  and ammonium ion, respectively (Wu, 2022). In this article, free  $\text{NH}_3$  and  $\text{NH}_4^+$  are collectively referred to as ammonia.  $\text{NH}_3$  is further oxidized primarily to urea in humans and, to a lesser extent, uric acid. Note that AA transaminases and AA decarboxylases require vitamin  $\text{B}_6$  as an essential cofactor for their catalytic activities. Other vitamin  $\text{B}_6$ -dependent enzymes include threonine aldolase, some D-AA racemases, cystathionase, cystathionine synthase, the glycine cleavage system, kynureninase (kynurenine hydrolase), kynurenine transaminase, methionine synthetase, and serine hydroxymethyl transferase. Another unique feature of AA degradation is that tetrahydrobiopterin is essential for the hydroxylation of arginine, phenylalanine, tyrosine, and tryptophan by NO synthase, phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase, respectively. The physiological half-lives of plasma AAs in healthy adult humans are relatively short; for example, L-arginine, L-citrulline, and L-glutamine:  $\sim 1.0$  h; L-glutamate: 0.5 h; glycine: 1.05 h; and L-leucine: 0.57–1.0 (Wu, 2022). The rates of whole-body catabolism of some AAs in humans are summarized in Table 2, and are altered during development and in diseased states. For example, both acidosis and cancer stimulate the whole-body catabolism of glutamine and BCAAs in humans to regulate pH and energy homeostasis (Curthoys and Watford, 1995). Available evidence shows that infants, children, and adults can tolerate dietary intakes of at least 4.7, 5.1, and 3.5 g protein/kg BW/day (Wu, 2016), as well as high intakes of various AAs (Blachier et al., 2021; McNeal et al., 2018).

**Table 2** Rates of the catabolism of amino acids (AAs) in humans.

AA	Species	Nutritional state	Endogenous flux ( $\mu\text{mol/kg}$ of body weight/h)	Degradation ( $\mu\text{mol/kg}$ of body weight/h)
Arginine	Human infants	Total parenteral nutrition	173	34
	Preterm infants	Fed (enterally)	461	29
	Adult humans	Fed (enterally)	58	20
Cysteine	Adult humans	Fasted for 12 h	36–47	5.3

### Liver

In humans, the liver actively degrades most AAs (including lysine and methionine), but neither BCAAs due to the near absence of BCAA transaminases nor extracellular citrulline because of no uptake. Thus, concentrations of aromatic AAs (tyrosine, phenylalanine, and tryptophan) in the plasma of individuals with liver failure are usually increased due to a limited inability of the liver to degrade these AAs. Of particular note, there is metabolic zonation for hepatic AA catabolism. For example, glutamate and aspartate in the arterial and portal venous blood escape periportal hepatocytes and enter perivenous hepatocytes for glutamine synthesis ([Brosnan and Brosnan, 2013](#)). AA-derived ammonia is detoxified primarily as urea in hepatocytes via the urea cycle (see the section below). This organ is the only site for the complete catabolism of all  $\alpha$ -ketoacids of AAs [including branched-chain  $\alpha$ -ketoacids (BCKAs) of BCAAs] released from extrahepatic tissues. The liver produces glucose from alanine and other glucogenic AAs, constituting the glucose-alanine cycle between this organ and other tissues (primarily skeletal muscle). The  $\alpha$ -ketoacids of AAs can be converted into glucose, ketone bodies, or fatty acids in the human liver ([Table 3](#)), depending on nutritional, physiological and pathological states.

### Skeletal muscle, heart, brain, lungs, and white adipose tissue

In humans, these tissues actively transaminate BCAAs and  $\alpha$ -KG to form BCKAs and glutamate ([Chen et al., 2020](#); [Huston et al., 2005](#); [He and Wu, 2020](#)). Glutamate then undergoes transamination with pyruvate and oxaloacetate to generate alanine and aspartate, respectively, or amidated with  $\text{NH}_4^+$  to yield glutamine. All of these tissues contain glutaminase (a mitochondrial enzyme) to hydrolyze glutamine into glutamate and  $\text{NH}_4^+$ , and, therefore, the intracellular glutamine-glutamate cycle, as originally proposed for rat and avian skeletal muscle ([Wu et al., 1991](#)). The balance of this metabolic cycle is the major determinant of glutamine release from the tissues in response to nutritional and physiological needs as well as pathological alterations. Interestingly, concentrations

**Table 3** Ketogenic, glucogenic, and ketogenic plus glucogenic amino acids in humans.

Group	Amino acids (AAs)
Ketogenic AAs <sup>a</sup>	Leucine, lysine, and taurine
Glucogenic AAs <sup>b</sup>	Alanine, $\gamma$ -aminobutyrate, arginine, asparagine, aspartate, citrulline, cysteine, glutamate, glutamine, glycine, histidine, 4-hydroxyproline, 3-hydroxyproline, methionine, ornithine, phosphoarginine, proline, serine, and valine
Ketogenic plus glucogenic AAs <sup>c</sup>	Isoleucine, phenylalanine, threonine, tryptophan, and tyrosine

<sup>a</sup>Forming only acetyl-CoA.

<sup>b</sup>Forming pyruvate and 4–5 carbon unit metabolites (e.g., oxaloacetate and  $\alpha$ -KG).

<sup>c</sup>Forming acetyl-CoA, pyruvate, and 4–5 carbon metabolites.

of the three branched-chain AAs (leucine, isoleucine, and valine) in the plasma of patients with liver failure are usually decreased possibly due to increased catabolism of these AAs in skeletal muscle and other extrahepatic tissues, as well as reduced food intake (Hou et al., 2020).

### **The small intestine**

Enterocytes actively degrade most of proteinogenic AAs present in the lumen of the small intestine. Intestinal microbes are also capable of degrading dietary AAs (Dai et al., 2011, 2015). Thus, in healthy adult humans, the small intestine actively sequesters many diet-derived AAs during their first pass into the portal circulation (expressed as the % of AAs present in the lumen of the small intestine) mainly via catabolism: arginine, 40%; BCAAs, 20–30%; glutamate, 96%; glutamine, 64%; lysine, 19%; phenylalanine, 27%; and threonine, 18% (Chapman et al., 2013; Haisch et al., 2000; Matthews et al., 1993; Wu, 1998). Likewise, in preterm infants, the small intestine utilizes 73% of dietary glutamine (van der Schoor et al., 2010) and 77% of dietary aspartate (Corpeleijn et al., 2010) primarily for oxidation to CO<sub>2</sub>. In addition to the mucosa of the small intestine, its microbes degrade all proteinogenic AAs and some nonproteinogenic AAs (Dai et al., 2015; Davila et al., 2013). Because all dietary AAs but taurine are degraded by the small intestine during their entry into the portal circulation, the pattern of AAs in the plasma differs substantially from that in the diet. Interestingly, among all AAs in the arterial blood, only glutamine is taken up by the small intestine in the post-absorptive state.

### **Kidneys**

In humans, the kidneys play an important role in the regulation of acid-base balance through hydrolyzing glutamine to glutamate and NH<sub>3</sub> (which takes up H<sup>+</sup> to form NH<sub>4</sub><sup>+</sup>), as well as converting glutamate to α-KG and NH<sub>3</sub> (Li et al., 2020). α-KG can be used for renal gluconeogenesis or oxidation to CO<sub>2</sub>, depending on nutritional and physiological states. The human kidneys also form tyrosine from phenylalanine, arginine from citrulline, ornithine from arginine, alanine/aspartate from glutamate, glycine from 4-hydroxyproline, and S-adenosylmethionine from methionine, while interconverting glycine into serine, proline into ornithine, proline and 4-hydroxyproline (via collagen synthesis and degradation), and serine and glutamate/glucose (via D-3-phosphoglycerate dehydrogenase and phosphatase pathways) (Wu, 2022). Furthermore, in humans, the kidneys convert arginine and glycine into ornithine and guanidinoacetate, with the latter being taken up primarily by the liver for conversion into creatine in the presence of S-adenosylmethionine as the methyl group donor.

### **Endothelial cells, smooth muscle cells, macrophages, and lymphocytes**

These cells oxidize arginine to NO and citrulline for the endothelium-dependent vasodilation, innate immunity, and cell signaling, while generating a small amount of H<sub>2</sub>S (a vasodilator and an oxidant) from cysteine (Wu, 2022). All these cells can also convert citrulline into arginine in the presence of aspartate; degrade BCAAs for the formation of glutamate; oxidize glutamine, glutamate, and aspartate as metabolic fuels; and convert glutamine to glutamate and glucosamine-6-phosphate via glutamine:fructose-6-phosphate transaminase for the synthesis of glycoproteins. Of particular note, glutamine is a major energy substrate in macrophages and lymphocytes, particularly under the conditions of immunological challenges (Li et al., 2007).

### **Sense organs**

In humans, sense organs (the eyes, ears, nose, tongue, and skin) can degrade alanine, arginine, aspartate, glutamate, and BCAAs (Wu, 2020b). In addition, both the eyes and the skin can degrade asparagine, glutamine, glycine, serine, and tryptophan. There is evidence that the skin catabolize histidine, lysine, methionine, phenylalanine, proline, 4-hydroxyproline, and tyrosine. All these tissues can hydrolyze arginine to ornithine plus urea, while oxidizing arginine to NO and citrulline.

### **Placentae, mammary glands, ovaries, testes, and pancreas**

In humans, these organs can extensively degrade BCAAs to form glutamate, glutamine, alanine, and aspartate, while hydrolyzing arginine to ornithine plus urea (Wu, 2022). All these tissues can oxidize arginine to NO plus citrulline and recycle citrulline to arginine in the presence of aspartate; interconvert ornithine and P5C into proline; and catabolize alanine, aspartate, glutamate, glutamine, glycine, 4-hydroxyproline, methionine, serine, tryptophan, and tyrosine. Furthermore, placentae, ovaries, testes, and pancreas oxidize proline to P5C by proline oxidase, whereas both mammary glands and pancreas can hydrolyze phenylalanine to tyrosine. Finally, the pancreas can convert guanidinoacetate into creatine, while degrading cysteine, GABA, histidine, and threonine (Wu, 2022). By contrast, mammary glands may have no or limited ability to degrade proline, and may also lack phosphate-activated glutaminase for hydrolyzing glutamine to glutamate plus ammonia.

## **Ammonia detoxification via ureagenesis in the liver and small intestine of humans**

### **Production and toxicity of ammonia in humans**

In humans, ammonia is produced from AA catabolism by tissues and cells, as well as the microorganisms of the gastrointestinal tract. The central nervous system is particularly sensitive to adverse effects of ammonia. Because multiple metabolic pathways remove ammonia from the blood, the concentrations of ammonia (NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>) in the plasma of healthy children and adults are usually ≤35 and ≤30 μM, respectively (Wu, 2022). Hyperammonemia, which is generally defined as a concentration of ammonia (NH<sub>3</sub> + NH<sub>4</sub><sup>+</sup>) in plasma being ≥50 μM in infants, children and adolescents (Raina et al., 2020) or >30 μM in adults

(Sakusic et al., 2018), frequently occur under various nutritional and pathological conditions. This condition causes multiple organ dysfunctions, vomiting, nausea, seizures, and death in humans, particularly preterm infants maintained on a total parenteral nutrition (TPN) solution. The underlying biochemical mechanisms include reductions in NO bioavailability, blood flow to the brain, and tissue oxygenation; depletion of  $\alpha$ -KG in the Krebs cycle; and oxidative stress. Major factors responsible for hyperammonemia include arginine deficiency, liver failure, inherited metabolic disease (a defect in a urea-cycle enzyme or fatty acid oxidation), excessive AA load, AA imbalances, and AA antagonism (Wu, 2022).

### The urea cycle in the liver and small intestine

In humans, the urea cycle is the major metabolic pathway for ammonia detoxification (Fig. 3), with the net reaction of  $2\text{NH}_3 + \text{HCO}_3^- \longrightarrow \text{H}_2\text{N-CO-NH}_2$  (urea) and the net consumption of 4 mol ATP/mol urea. This metabolic process occurs primarily in the liver (Meijer et al., 1990) and, to a much lesser extent, the small-intestinal mucosa (Wu, 2022). The urea cycle spans both the mitochondria and the cytoplasm in periportal hepatocytes and enterocytes.  $\text{NH}_3$  and  $\text{HCO}_3^-$  are formed from the

**Fig. 3** The urea cycle in mammals. The synthesis of urea from ammonia and bicarbonate involves both the mitochondrion and the cytoplasm. Citrulline exits the mitochondrion into the cytoplasm where it is converted into arginine, which is rapidly hydrolyzed by arginase into urea plus ornithine. Ornithine is then re-used for another turnover of the cycle. ASL, argininosuccinate lyase; ASS, argininosuccinate synthase; CPS-I, carbamoylphosphate synthetase-I; NAG, N-acetylglutamate. Reproduced from Wu (2013) with permission.

catabolism of AAs (including glutamate, glutamine, and glycine) in these cell types, and can also be derived from the blood. Glutamate dehydrogenase and glutaminase are major enzymes for generating ammonia in the liver and intestine, respectively. After carbamoylphosphate synthetase I (CPS-I) converts  $\text{NH}_3$  plus  $\text{HCO}_3^-$  into carbamoyl phosphate, the latter combines with ornithine (an AA from the diet, blood, or cytosolic arginase) to form citrulline by ornithine carbamoyltransferase (OCT). The cytosolic ornithine is transported by ORNT1 (mitochondrial ornithine transporter 1, an antiporter) to the mitochondrial matrix in exchange for the exit of mitochondrial citrulline to the cytosol, where citrulline is rapidly metabolized to arginine in the presence of aspartate and then to urea plus ornithine via a series of three enzymes: argininosuccinate synthase, argininosuccinate lyase, and arginase-I (Meijer et al., 1990). A major source of the cytosolic aspartate is the mitochondrial aspartate, which is exchanged with the cytosolic glutamate through the action of Citrin (a transporter in the mitochondrial membrane). Thus, the urea cycle is characterized by metabolic compartmentation and channeling to facilitate the immediate transfer of intermediates between enzymes and helps maintain a relatively high concentration of substrates in catalytic sites (Watford, 2020). This ensures the rapid and efficient formation of urea from ammonia. In adult humans, about 20%–25% of the urea newly synthesized in the liver is taken up by the small and large intestines, where urea is hydrolyzed into ammonia and  $\text{CO}_2$ . Some of the ammonia (e.g., 75% in the upper part of the gut) enters the portal vein for ureagenesis in the liver (Bergen and Wu, 2009).

### Protein turnover in humans

AAs are constantly used for protein synthesis primarily in the endoplasmic reticulum and, to a much lesser extent, the mitochondria of cells, whereas intracellular proteins undergo continuous degradation to AAs by proteases and peptidases in lysosomes and non-lysosomal compartments of cells. These two processes are collectively referred to as intracellular protein turnover. The nonlysosomal pathway (including proteasomes) is responsible for the degradation of 70–80% of cellular proteins (Wu, 2022). In addition, extracellular proteins (e.g., proteins in the extracellular matrix and plasma) are degraded by proteases in the interstitial space of tissues and in the blood. In growing humans, the rate of protein synthesis is greater than the rate of protein degradation to result in protein accretion. The opposite is true in a catabolic state. In healthy adults gaining no protein, the rate of protein synthesis is equal to the rate of protein degradation, with the value being about 300 g per day in a 70 kg person (Waterlow, 1995). The incorporation of 1 mol AA into protein requires 5 mol ATP, and the hydrolysis of protein to release 1 mol AA consumes 2 mol ATP. In fed adults, 14.5% of dietary energy is utilized for the synthesis of 300 g protein/day, and protein turnover accounts for about 20% of whole-body energy expenditure (Wu, 2022). Over the past decades, there has been active debate regarding quantitative aspects of human requirements for dietary AAs.

Protein turnover is subjected to nutritional and hormonal regulation. Anabolic hormones (e.g., insulin, growth hormone, insulin-like growth factors, and testosterone), AAs (e.g., arginine, glutamine, glycine, and leucine), and muscle contraction stimulate protein synthesis in skeletal muscle. In adults with minimal physical activity, adequate intakes of high-quality dietary protein (e.g., 1.0–1.2 g/kg BW/day) such as an appropriate mixture of highly digestible animal and plant proteins are essential to mitigate muscle loss, and this beneficial effect may be attributed to a group of functional AAs but not all AAs. By contrast, catabolic hormones (e.g., cortisol), starvation, acidosis, heat stress, infections, and diseases reduce muscle protein synthesis. Muscle proteolysis is inhibited by insulin, insulin-like growth factors, testosterone, and AAs, but is promoted under catabolic conditions. The mechanistic target of rapamycin (mTOR) cell signaling pathway integrates anabolic factors to promote protein synthesis in cells (Paudel et al., 2021), whereas ATP and ubiquitin-dependent proteasomes as well as autophagy and lysosomal proteases are responsible for the bulk of intracellular proteolysis (Shen et al., 2021). Provision of dietary AAs in sufficient amounts and proper ratios is crucial for maximum protein synthesis in tissues (Wu, 2022). For example, either a deficiency or an excess of dietary threonine reduces protein synthesis in the jejunum and skeletal muscle of young mammals (Wang et al., 2007). Various metallo-proteases and peptidases catalyze the extracellular degradation of collagens and elastin in tissues to form free AAs (including 4-hydroxyproline), as well as small peptides containing high proportions of glycine, proline, and hydroxyproline residues (Phang et al., 2010). Many functional AAs (e.g., arginine, branched-chain AAs, glutamine, and glycine) inhibit proteolysis in skeletal muscle, small intestine, mammary glands, and many other tissues (Wu, 2022).

### Metabolites of AAs in humans

Cell- and tissue-specific catabolism and conjugation of AAs generate hundreds of nitrogen-, sulfur-, and oxygen-containing metabolites in humans, including urea, ammonia, creatine, creatinine, catecholamines (e.g., dopamine, epinephrine, and norepinephrine), amino sugars, glucose, ketone bodies, fatty acids, NO, carbon monoxide (CO), hydrogen sulfide ( $\text{H}_2\text{S}$ ), nitrite, nitrate, sulfate, polyamines (putrescine, spermidine, and spermine), homoarginine, serotonin, taurine, GABA, homocysteine, dimethylarginines, formate, and thyroid hormones (Table 4). Some of them are end products for excretion in the urine and feces (e.g., creatinine and urea), most of them (e.g., NO and creatine) at physiological concentrations are essential to life, and some of them (e.g., homocysteine and ammonia) are toxic at elevated concentrations (Bazer et al., 2021; Beaumont and Blachier, 2020; Stipanuk, 2004; Tsikas and Wu, 2015). In addition, the enzyme-catalyzed condensation of AAs form di-, tri-, and other oligo-peptides, such as carnosine, glutathione, and oxytocin. Furthermore, some AAs (e.g., taurine and glycine) can form conjugates with lipids (e.g., bile

**Table 4** Products of amino acid metabolism in humans.

Amino acid	Metabolites
Amino acids	CO <sub>2</sub> , water, ammonia, urea, uric acid, nitrite, nitrate, peptides, xenobiotic conjugates, glucose, fatty acids, and ketone bodies
Alanine	Pyruvate, aspartate, and glutamate
β-Alanine	Coenzyme A, pantothenic acid, carnosine (β-alanyl-L-histidine), and carcine (β-alanyl-histamine)
Arginine	Nitric oxide, agmatine, and ornithine
Asparagine	Aspartate and <i>N</i> -acetylglucosamine-linked conjugate (N-linkage)
Aspartate	Purine, pyrimidine, asparagine, arginine, D-aspartate, and <i>N</i> -acetylaspartate
Citrulline	Arginine
Cysteine	Taurine, H <sub>2</sub> S, sulfate, and homocysteine
Glutamate	Glutamine, citrulline, arginine, ornithine, proline, γ-aminobutyrate, and <i>N</i> -acetylglutamate
Glutamine	Purine, pyrimidine, ornithine, citrulline, arginine, proline, glutamate, aspartate, asparagine, and glucosamine-6-phosphate
Glycine	Bile salts, heme, bilirubin, purines, and serine
Histidine	Dipeptides, histamine, imidazoleacetate, and urocanate
Isoleucine	Glutamate, glutamine, alanine, and aspartate
Leucine	Glutamate, glutamine, alanine, aspartate, and β-hydroxy-β-methylbutyrate
Lysine	Trimethyllysine in calmodulin, desmosine and isodesmosine in collagen and elastin, and 5-hydroxylysine in collagen
Methionine	Homocysteine, betaine, cysteine, <i>S</i> -adenosylmethionine, taurine, and phospholipids
Phenylalanine	Tyrosine and phenylacetylglutamine
Proline	H <sub>2</sub> O <sub>2</sub> , pyrroline-5-carboxylate, ornithine, arginine, and 4-hydroxyproline
Serine	Cysteine, purine, pyrimidine, ceramide, phosphatidylserine, glucose, glycine, D-Serine, N <sup>5</sup> -N <sup>10</sup> -methylene-tetrahydrofolate, and <i>N</i> -acetylglucosamine-linked conjugate (O-linkage)
Threonine	Glycine and glucose
Tryptophan	Serotonin, <i>N</i> -acetylserotonin, melatonin, anthranilic acid, niacin, indoles, and kynurenate
Tyrosine	Dopamine, epinephrine, norepinephrine, melanin, triiodothyronine, and thyroxine
Valine	Glutamate, glutamine, alanine, and aspartate
Arg & Met	Polyamines (putrescine, spermidine, and spermine)
Arg, Met & Gly	Creatine
Cys, Glu & Gly	Glutathione
Gln, Asp & Gly	Nucleic acids and uric acid
Lys, Met & Ser	Carnitine
Ser & Met	Choline

acids) via covalent bonds. Finally, intestinal bacteria produce many methylated, acetylated, hydroxylated, phosphorylated, and conjugated metabolites (Liu et al., 2019).

## Summary and outlook

Dietary AAs are metabolized in humans via both synthetic and catabolic pathways in a cell- and tissue-specific manner, as well as intracellular protein turnover (protein synthesis and degradation) and extracellular proteolysis. Humans cannot synthesize *de novo* histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. By contrast, humans can form alanine, arginine, aspartate, asparagine, glutamate, glutamine, glycine, proline, and serine *de novo*, while converting methionine into cysteine, phenylalanine into tyrosine, and serine plus selenium into selenocysteine. AA syntheses require energy, substrates, and also cofactors /substrates (e.g., NADH, NADPH, FAD, pyruvate, oxaloacetate, and α-KG). Growing evidence shows that endogenous AA syntheses are crucial for human growth, development, and health and that humans have dietary requirements for not only EAAs but also AASAs. As for other mammals, humans can degrade all proteinogenic AAs and physiological non-proteinogenic AAs at various rates via compartmentalized metabolic pathways and inter-organ cooperation, with products including CO<sub>2</sub>, water, ammonia, pyruvate, acetyl-CoA, NO, SO<sub>4</sub><sup>2-</sup>, glutathione, creatine, serotonin, and polyamines. Based on their metabolic fates, AAs can be classified as ketogenic, glucogenic, and ketogenic plus glucogenic. The complete oxidation of most AAs involves the formation of acetyl-CoA, which is oxidized to CO<sub>2</sub>, NADH, and FADH<sub>2</sub> via the Krebs cycle. NAD(P)H and FADH<sub>2</sub> are oxidized into water via the mitochondrial electron transport system for the production of ATP from ADP plus Pi. Microbes in the small and large intestines degrade AAs via multiple pathways to form CO<sub>2</sub>, ammonia, H<sub>2</sub>S, and polyamines, as well as methylated, acetylated, hydroxylated, phosphorylated, and conjugated metabolites. Degradation of dietary AAs by the small intestine during their first-pass into the portal vein modifies the patterns of AAs in the plasma and reduces the efficiency of the utilization of dietary protein and free AAs for homeostasis and growth in the body. In healthy adults gaining no protein, active protein turnover occurs (i.e., 300 g protein/70 kg person per day) to account for about 20% of whole-body energy expenditure. Because elevated concentrations of ammonia in the plasma are highly

toxic to the brain, this metabolite must be removed as urea via the urea cycle primarily in the liver (periportal hepatocytes) and, to a much lesser extent, the enterocytes of the small intestine. The coordination of AA metabolism via multiple pathways is essential for the growth, development, and health of humans. Much needs to be determined about the optimum requirements of infants, children, and adults for dietary AAs (particularly AASAs). Finally, systematic research is warranted to identify important roles of functional AAs in stimulating muscle protein synthesis and alleviating muscle loss during aging and under catabolic conditions (e.g., heat stress, cancers, and viral infections) in humans.

### Key points

- Amino acids (AAs) fulfill structural, metabolic, physiological, and immunological needs in humans.
- Some AAs (e.g., aspartate, glutamate, and glycine) and metabolites (e.g.,  $\gamma$ -aminobutyrate, serotonin, nitric oxide, carbon monoxide, and hydrogen sulfide) are neurotransmitters.
- Some AAs (e.g., arginine, glutamine, glycine, leucine, tryptophan, and valine) activate the mechanistic target of rapamycin cell signaling pathway to stimulate protein synthesis and inhibit autophagy-mediated proteolysis.
- Some AAs (e.g., alanine, glutamine, and leucine) inhibit autophagy and lysosomal proteolysis.
- Most physiological metabolites (e.g., creatine, heme, formate, purines, pyrimidines, and polyamines) are essential for biochemical processes (e.g., ATP production, energy storage, oxygen delivery, and cell growth).
- AAs regulate gene expression, cell signaling pathways, food intake, chemical sensing, the digestion and absorption of dietary nutrients, neurological development and behavior, and the metabolism of energy and nutrients.
- AAs are also crucial for immunity, reproduction, hormone secretion, anti-oxidative and anti-inflammatory responses, the detoxification of endogenous and exogenous substances, acid-base and mineral balances, and osmolality.
- Dietary supplementation with functional AAs (e.g., L-arginine, L-glutamate, and glycine) can enhance immunity, anti-oxidative responses, fertility, wound healing, ammonia detoxification, and lean tissue mass; ameliorate metabolic syndromes (including dyslipidemia, obesity, diabetes, and hypertension); and treat individuals with erectile dysfunction, sickle cell disease, muscular dystrophy, and pre-eclampsia in humans.

## Introduction

Amino acids (AAs) are the building blocks of proteins, which fulfill structural, metabolic, and regulatory functions in humans. A healthy adult with a normal body mass index contains 15.1% protein, i.e., 10.6 kg protein/70 kg person (Wang et al., 2003), including 3.72 kg collagen (Meléndez-Hevia et al., 2009). Collagen (the most abundant protein humans) consists of approximately 1/3 glycine and 1/3 proline plus 4-hydroxyproline on the molar basis, and comprises about 30% and 35% of body proteins in newborns and adults, respectively (Wu, 2022). Thus, large amounts of AAs, particularly glycine and proline, are required for protein synthesis and, therefore, the survival, health, growth, and development of humans. In addition, AAs serve as essential substrates for the syntheses of small peptides, low-molecular-weight substances [e.g., nitric oxide (NO), carbon monoxide (CO), hydrogen sulfide (H<sub>2</sub>S), glutathione, creatine, polyamines, carnitine, choline, and homoarginine], and non-protein large molecules [e.g., bradykinin (MW 1060.2 Da) and oxytocin (MW 1007.2 Da)] (Bazer et al., 2021; Beaumont and Blachier, 2020; Calder et al., 2002; Closs et al., 2000; Dai et al., 2013; Li et al., 2009; Suryawan and Davis, 2011; Wu, 2022). Furthermore, AAs are signaling molecules to regulate food intake, gene expression, post-translational protein modifications, metabolism, immune and anti-oxidative responses, cell-to-cell communication, and whole-body homeostasis (Brosnan and Brosnan, 2013; Li et al., 2022; Moffett, 2003; Phang, 2019; Rhoads and Wu, 2009; Tsikas, 2021; Wetzel et al., 2019; Wu, 2009). These specific functions of AAs beyond protein synthesis are highlighted in this article.

## Physiological functions of AAs

In humans, different AAs have different physiological functions beyond protein synthesis (Table 1). The overall functions of AAs include their roles in the regulation of gene expression (including epigenetics), cell signaling pathways, food intake, chemical sensing, digestion and absorption of dietary nutrients, neurological development and behavior, energy and nutrient metabolism, immune responses, female and male reproduction, endocrine status, anti-oxidative and anti-inflammatory responses, the detoxification of endogenous and exogenous substances, acid-base and mineral balances, osmolarity, whole-body homeostasis, and health and well-being (Bieffer et al., 2017; Brasse-Lagnel et al., 2010; Calder et al., 2002; Chen et al., 2020; Curthoys and Watford, 1995; Fernstrom, 2013; Field et al., 2002; Gietzen and Aja, 2012; He and Wu, 2020; Li et al., 2022; Paudel et al., 2021; Wu, 2009). For example, some AAs (e.g., aspartate, glutamate and glycine) are neurotransmitters in the brain and spinal cord (Fig. 1), whereas some AAs (e.g., BCAAs, glutamine and alanine) participate in the inter-organ transport and metabolism of nitrogen and carbon (Hou et al., 2020; Li et al., 2020; Watford, 2008). In addition, arginine, glutamine, glycine, leucine, tryptophan, and valine activate the mechanistic target of rapamycin (mTOR) cell signaling pathway to stimulate protein synthesis and inhibit autophagy-mediated proteolysis (Bröer and Bröer, 2017; Wu, 2022). Many AAs (e.g., alanine, glutamine, leucine, and tyrosine) directly inhibit autophagy in cells such as hepatocytes (Mortimore and Khurana, 1990; Shen et al., 2021). Thus, dietary supplementation with AAs (e.g., L-arginine, glycine, and branched-chain AAs) can enhance immunity, anti-oxidative responses, fertility, wound healing, ammonia detoxification, lean tissue mass, and lactation; ameliorate metabolic syndromes (including dyslipidemia, obesity, diabetes, and hypertension); and treat individuals with erectile dysfunction, sickle cell disease, muscular dystrophy, and preeclampsia in humans (Cynober, 2004; Durante, 2020; Holeček, 2018; Jiang et al., 1993; Le Floc'h et al., 2011; Lei et al., 2012; Li et al., 2007; McNeal et al., 2018; Newsholme et al., 1999; Popovic et al., 2007; Posey et al., 2021; Ryan et al., 2021; Tomé, 2018; Wu et al., 2021; Ziegler et al., 1998). Furthermore, the catabolism, racemization, and conjugation of AAs results in the formation of non-gaseous products (e.g., heme, D-serine, D-aspartate, glutathione, creatine, bile salts, and homoarginine) with enormous versatility and physiological importance (see below). In addition, the human host, dietary AAs may also alter the population, metabolism, and function of its gastrointestinal microbes (Dai et al., 2011, 2015; Davila et al., 2013). Adequate consumption of balanced AAs in the form of protein and supplements is essential for the optimum human nutrition (Wu, 2016). Note that animal-sourced foods generally contain much more proteins than plant-sourced foods (Davis et al., 1994; Hou et al., 2019; Li and Wu, 2020; Li et al., 2021).

Based on recent advances in AA biochemistry and physiology, Wu (2010) proposed a new nutritional concept of functional AAs, which are defined as AAs that regulate key metabolic pathways to improve the growth, development, reproduction, lactation, physical performance, immunity, and health of humans. These AAs include arginine, cysteine, glutamate, glutamine, glycine, leucine, methionine, proline, and tryptophan. The concept of functional AAs is now transforming human protein nutrition research and feeding practice (Hou and Wu, 2017; Posey et al., 2021; Ryan et al., 2021). Humans have dietary requirements for all proteinogenic AAs plus some nonproteinogenic AAs (e.g., taurine and  $\beta$ -alanine) for optimum growth, development, physical strength, health, and well-being (Hou et al., 2015; Wu et al., 2013). Thus, it is counter-intuitive to classify biosynthesizable AAs as nutritionally nonessential (dispensable) in human nutrition.

## Physiological functions of AA metabolites

### Functions of oligopeptides

AAs are used to synthesize oligopeptides, including antibiotics produced by bacteria and the intestinal mucosa, as well as many other oligopeptides consisting of 9 or 10 AA residues (Wu, 2022). Examples of the physiologically important oligopeptides include:

**Table 1** Major physiological functions of amino acids and their metabolites in humans.<sup>a</sup>

<i>Amino acid</i>	<i>Metabolites or direct action</i>	<i>Major functions</i>
Amino acids	Directly	Osmolarity, inhibition of autophagy, cell signaling, and protein function
	Proteins	Structural components of the body; cell growth, development, and function;
	Peptides	Hormones, antibiotics, metabolic regulation, and antioxidants
	Ammonia	Syntheses of glutamate, glutamine, carbamoyl phosphate, and urea
Alanine	Directly	Inhibition of pyruvate kinase and hepatic autophagy, gluconeogenesis, the glucose-alanine cycle, and therapy of muscular glycogen depletion
	Asp and glu	Major metabolic fuels for the small intestine, the malate shuttle for the transfer of NADH from the cytosol to mitochondria, and the interorgan metabolism and transport of both carbon and nitrogen
β-Alanine	Directly	A component of coenzyme A and pantothenic acid
	Dipeptides	Carnosine (β-alanyl-L-histidine), carbinine (β-alanyl-histamine), (β-alanyl-1-methyl-L-histidine), and balenine (β-alanyl-3-methyl-histidine)
Arginine	Directly	Activation of mTOR and AMPK signaling pathways
	Nitric oxide	Vasodilator, signaling molecule, immune response, regulator of metabolism
	Agmatine	Ligand for α <sub>2</sub> -adrenergic and imidazoline receptors, and NOS inhibitor
	Ornithine	Ammonia detoxification; syntheses of proline, glutamate and polyamines
	Proline	Collagen synthesis, wound healing, and many other functions (see below)
	Methylarginines	Competitive inhibition of NOS
Asparagine	Directly	Regulation of gene expression, immunity, immune function, and the survival of leukemic cells
Aspartate	Directly	Syntheses of purine, pyrimidine, and arginine; activation of NMDA receptors
	D-Aspartate	Activation of NMDA receptors in the brain
Citrulline	Directly	Antioxidant; arginine synthesis, osmoregulation, and ammonia detoxification
Cysteine	Directly	Disulfide linkage in protein, and the interorgan transport of sulfur
	Taurine	Antioxidant, and the regulation of cellular redox state
	H <sub>2</sub> S	Neurotransmission, vasodilation, killing of pathogens, and cell metabolism
Glutamate	Directly	Syntheses of glutamine and arginine, metabolism via multiple pathways, flavor enhancer for increasing food intake, the activation of NMDA receptors, and a precursor of <i>N</i> -acetylglutamate in hepatocytes and enterocytes
	γ-Aminobutyrate	Inhibitory or excitatory neurotransmitter, depending on age, type of receptor, and the region of brain; regulation of neuronal excitability
Glutamine	Directly	Regulation of protein turnover, cell volume, gene expression, and immune responses; syntheses of purine, pyrimidine, citrulline, arginine, and NAD(P)
	Glu and asp	Excitatory neurotransmitters, components of the malate shuttle, cell metabolism, ammonia detoxification, and major fuels for enterocytes
	Alanine	Interorgan metabolism of nitrogen and carbon; also see above.
	Glucosamine-6-P	Synthesis of aminosugars, anti-inflammation, angiogenesis, and cell growth
	Ammonia	Renal regulation of acid-base balance, glutamate and carbamoyl-P syntheses
Glycine	Directly	Activation of a glycine-gated channel; syntheses of purine, serine, porphyrins, glutathione, and heme; an inhibitory neurotransmitter in the brain; antioxidant; one-carbon metabolism; conjugation with bile acids
	Heme	A component of hemoproteins, carbon monoxide production, iron storage
	Bilirubin	Natural ligand of aryl hydrocarbon receptor in the cytoplasm
Histidine	Directly	Hemoglobin structure, antioxidative dipeptides, and one-carbon metabolism
	Histamine	Allergic reaction, vasodilator, a neurotransmitter, the stimulation of gastrointestinal secretions, and the regulation of immunocyte metabolism
	Imidazoleacetate	Analgesic and narcotic actions
	Urocanate	Immune responses in the skin, and protecting the skin against UV radiation
Isoleucine	Directly	Synthesis of glutamine and alanine
Leucine	Directly	Regulation of protein turnover, activator of glutamate dehydrogenase
	Gln and Ala	Many metabolic functions (see above)
	HMB	Regulation of immune response and skeletal-muscle protein synthesis
Lysine	Directly	Regulation of nitric oxide synthesis; and O-linked glycosylation
	5-Hydroxylysine	Structure and function of collagen
	Desmosine	Structure and function of collagen and elastin
Methionine	Homocysteine	Oxidant; independent risk factor for cardiovascular disease
	Betaine	Methylation of homocysteine to methionine, and one-carbon metabolism
	Cysteine	Cellular metabolism and nutrition
	SAM	Methylation of proteins and DNA; methyl group donor in biosynthesis
	Phospholipids	Synthesis of lecithin and phosphatidylcholine; and cell signaling

**Table 1** Major physiological functions of amino acids and their metabolites in humans.<sup>a</sup>—cont'd

Amino acid	Metabolites or direct action	Major functions
Phenylalanine	Directly	Activation of tetrahydrobiopterin (a cofactor for NOS) synthesis, syntheses of tyrosine and phenylacetylglutamine, and neurological function
Proline	Directly	Collagen structure and function, neurological function, and an antioxidant
	H <sub>2</sub> O <sub>2</sub>	Killing pathogens, intestinal integrity, a signaling molecule, and immunity
	P5C	Cellular redox state, arginine synthesis, gene expression, and stress response
	4-hydroxyproline	Structure and function of collagen, glycine synthesis, and cell signaling
Serine	Directly	Methionine catabolism; one-carbon metabolism; syntheses of cysteine, purine, pyrimidine, ceramide and phosphatidylserine
	Glycine	Many metabolic and regulatory functions (see above)
	D-serine <sup>b</sup>	Activation of NMDA receptors in brain
Threonine	Directly	Syntheses of mucins and glycine, immunity, O-linked glycosylation, and the therapy of spastic syndromes
Tryptophan	Serotonin	Neurotransmitter; regulation of food intake, mood, sleep, and behavior; stimulation of gut motility
	N-acetylserotonin	Antioxidant, and anti-inflammatory responses
	Melatonin	Antioxidant, anti-inflammatory responses, and circadian rhythms
	Anthranilic acid	Inhibiting production of proinflammatory T-helper-1 cytokines
	Niacin	A component of NAD and NADP, and modifications of proteins
	Indoles <sup>c</sup>	Natural ligands of aryl hydrocarbon receptor in the cytoplasm, and immunity
	Quinolinic acid	An agonist of the NMDA receptor
	Kynurenic acid	A nonselective NMDA receptor antagonist and therefore a blocker of AA- modulated excitation of the brain, neuromodulatory activity, as well as anti-excitotoxic and anti-convulsant effects
Tyrosine	Directly	Protein phosphorylation, nitrosation, and sulfation
	Dopamine	Neurotransmitter (neurological development, brain reward, pleasure, motivation, motor control, emotion, and executive function); and enhancement of immunity
	EPN & NEPN	Neurotransmitters in the brain; the most important neurotransmitters in the sympathetic nervous system; the regulation of cell metabolism; increasing blood pressure and heart rate, and alertness; and decreasing intestinal motility
	Melanin	Antioxidant, sexual activity, and pigmentation of the skin and hair
	T3 and T4	Regulation of energy and protein metabolism, growth, and development
Valine	Directly	Synthesis of glutamine and alanine
A group of AAs <sup>d</sup>	Directly	Activation of the mTOR cell signaling
Arg & Met	Polyamines	DNA and protein synthesis, ion channel function, and mTOR activation
Arg, Met & Gly	Creatine	Antioxidant; energy metabolism in the heart, skeletal muscle and brain
Cys, Glu & Gly	Glutathione	Antioxidant, cell metabolism, cellular redox, immunity, and gene expression
Gln, Asp & Gly	Nucleic acids	Gene expression; cell growth, and syntheses of protein and uric acid
	Uric acid	Antioxidant, and the major metabolite of purines (adenosine and guanosine)
Lys, Met & Ser	Carnitine	Transport of long-chain fatty acids into mitochondria for oxidation
Ser & Met	Choline	A component of acetylcholine (a neurotransmitter) and phosphatidylcholine (a structural lipid); syntheses of betaine, sarcosine and glycine

Note: BCAAs, branched-chain amino acids; SAM, S-adenosylmethionine; EPN, epinephrine; HMB, β-hydroxy-β-methylbutyrate; mTOR, mechanistic target of rapamycin; NEPN, norepinephrine; NOS, nitric oxide synthase; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine.

<sup>a</sup>Adapted from Wu, (2022). Unless indicated, amino acids (except for glycine, taurine, β-alanine, and γ-aminobutyrate) are L-isomers.

<sup>b</sup>Synthesized from L-serine by serine racemase.

<sup>c</sup>Including indole acetic acid, kynurenine, and tryptamine.

<sup>d</sup>Arginine, glutamine, glycine, leucine, tryptophan, and valine.

angiotensin II [10 AAs; Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu (NH<sub>2</sub>)], bradykinin [(9 AAs); Arg-Pro-Gly-Phe-Ser-Pro-Phe-Arg (NH<sub>2</sub>)], oxytocin [(9 AAs); Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly (NH<sub>2</sub>)], and arginine vasopressin [9 AAs; Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly (NH<sub>2</sub>)] (Forbes and Krishnamurthy, 2020). Through actions including vasoconstriction and the stimulation of the sympathetic nervous system, angiotensin II can raise blood pressure and, therefore, is used to treat hypotension resulting from septic shock. Bradykinin causes arterioles to dilate and augment vascular permeability by increasing the release of prostacyclin, NO, and endothelium-derived hyperpolarizing factor from blood vessels. Oxytocin (a peptide hormone and neuropeptide) strengthens the contractions of the uterus during labor and induces the let-down of milk from the lactating mammary glands. Arginine vasopressins (also known as antidiuretic hormone) increases blood pressure in humans by stimulating the renal reabsorption of water into the blood circulation and constricts arterioles and, therefore, is used to treat individuals with vasodilatory shock.

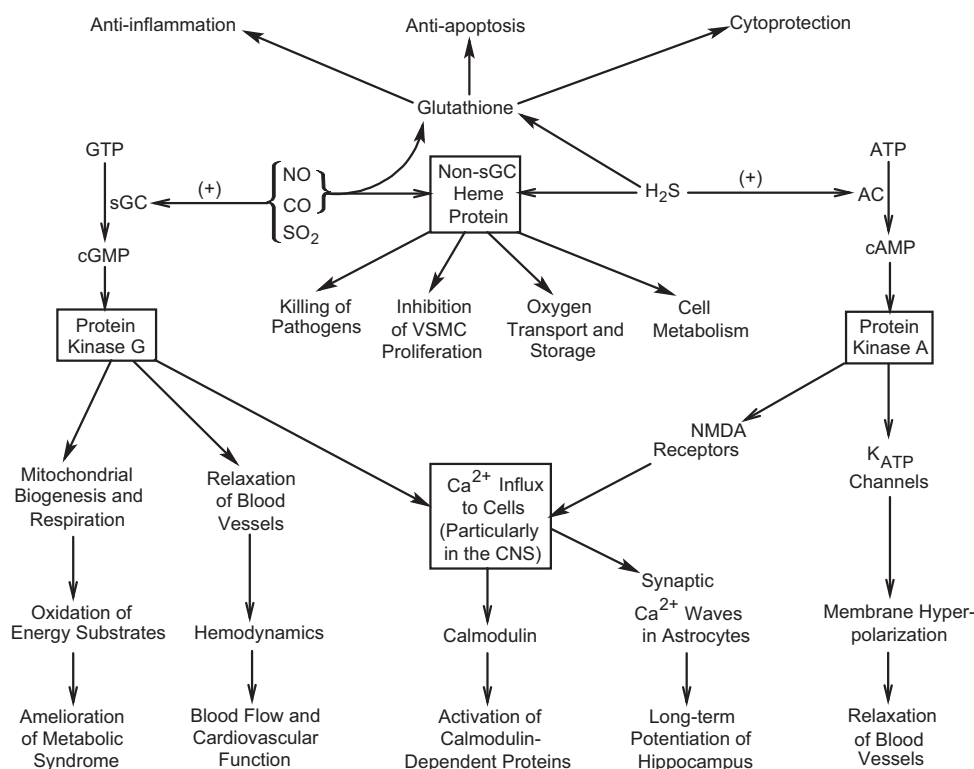

**Fig. 1** Structure of the various parts of the brain and the spinal cord for the production and actions of neurotransmitters. GABAergic neurons are located in the hippocampus, thalamus, basal ganglia, hypothalamus, and brainstem;  $\gamma$ -Aminobutyrate (GABA) is a major inhibitory transmitter in the mature brain but is primarily excitatory in the developing brain. Heme oxygenase is localized in many regions of the brain, including the hypothalamus and olfactory bulb. Cholinergic neurons are found in the striatum. Dopaminergic neurons extend from the midbrain (e.g., the substantia nigra pars compacta, the ventral tegmental area, the arcuate nucleus, and the retrorubral area) through the forebrain (e.g., the olfactory bulb). Epinephrine is produced in the medulla oblongata of the brainstem.  $H_2S$  is produced by cystathionine  $\beta$ -synthase (CBS), cystathionine  $\gamma$ -lyase (CSE), and 3-mercaptopyruvate sulfurtransferase (3MST); CBS is highly expressed in the astrocytes and microglial cells of the hippocampus and cerebellum; CSE is mainly expressed in the cardiovascular system but is also present in microglial cells, spinal cord, and cerebellar granule neurons; and 3MST occurs in the neurons and astrocytes of the brain. Histaminergic neurons are confined to the tuberomammillary nucleus of the posterior hypothalamus. Neuronal nitric oxide synthase (nNOS) is expressed in neurons and pineal gland of the brain and in the spinal cord; in the juvenile and mature hippocampus and neocortex, nNOS is primarily expressed in subpopulations of GABAergic interneurons. Norepinephrine is produced primarily by neurons of the locus coeruleus and to a lesser extent in the lateral tegmental field of the brain. Serotonergic neurons are predominantly located in the brainstem raphe complex, a midline complex closely associated with the reticular formation within the midbrain, pons, and medulla. Thal, thalamus; Str, striatum. Reproduced from a freely available article by Nieto-Alamilla et al. (2016) at <https://molpharm.aspetjournals.org/content/molpharm/90/5/649.full.pdf>.

### Functions of NO, CO, and $H_2S$

NO, CO, and  $H_2S$  are produced from L-arginine, heme (formed from glycine), and L-cysteine, respectively. NO synthase and heme oxygenase are wide-spread in human tissues. By contrast,  $H_2S$  is synthesized by cystathionase in the liver, kidneys, enterocytes, and vascular smooth muscle cells, by cystathionine- $\beta$ -synthase in the brain, and by 3-mercaptopyruvate sulfurtransferase in cardiac tissues (Kamat et al., 2015). These gases readily penetrate cell membranes to exert their physiological effects (Fig. 2). At the molecular level, NO, CO and  $H_2S$  activate guanylyl cyclase to convert GTP into cGMP, whereas  $H_2S$  stimulates adenylyl cyclase to convert ATP into cAMP and also increases cGMP availability in cells (Beltowski, 2015; Li et al., 2009; Nakahira et al., 2006; Otterbein et al., 2000). As oxidants, NO and  $H_2S$  can kill pathogenic microbes. In this regard, it is noteworthy that NO can kill coronaviruses, including severe acute respiratory syndrome coronavirus (SARS-CoV; Åkerström et al., 2005) and SARS-CoV-2 [the virus causing the coronavirus disease-2019 (Covid-19); Akaberi et al., 2020]. Physiological concentrations of NO are essential for the endothelium-dependent relaxation of blood vessels, blood flow, angiogenesis, embryogenesis, mitochondrial biogenesis, neuro-transmission, immunity, ovulation in females, spermatogenesis in males, and wound healing (Wu et al., 2021). Physiological concentrations of CO relax blood vessels, act as a retrograde messenger at synapses, stimulate long-term potentiation in the hippocampus, have potent cytoprotective effects in cells (particularly neurons), modulate immune responses, and stimulate the oxidation of glucose and fatty acids in tissues (e.g., white adipose tissue and skeletal muscle; Li et al., 2009). Physiological concentrations of  $H_2S$  play an important role in the body through modulating the endothelial arginine-NO pathway, stimulating ATP-sensitive  $K^+$  channels and membrane hyperpolarization, protecting cells from oxidant (e.g., homocysteine)-induced injury, facilitating the induction of hippocampal long-term potentiation, and reducing oxidative metabolism (Li et al., 2009).

### Functions of polyamines

Polyamines (putrescine, spermidine, and spermine) are synthesized from arginine- and proline-derived ornithine via ornithine decarboxylase, spermidine synthase, and spermine synthase in humans (Wu, 2022). Methionine is required for the production of spermidine and spermine via the formation of S-adenosylmethionine as the methyl group donor. Polyamines are essential for DNA and protein syntheses, angiogenesis, spermatogenesis, and wound healing (Agostinelli, 2020; Pegg, 2016). Polyamines also participate in the posttranslational modifications of some proteins, such as eIF5A by deoxyhypusine synthase to form the hypusine residue that is critical for eukaryotic translation (Park and Wolff, 2018). Furthermore, polyamines are substrates for some transglutaminases that catalyze the formation of an isopeptide bond (an amide bond) between a primary amine or the  $\gamma$ - $NH_2$  group of a glutamine residue in a polypeptide chain and the  $\epsilon$ - $NH_2$  of a lysine residue of another polypeptide chain. In humans, mutations in the spermine synthase gene decrease spermine concentrations, resulting in Snyder-Robinson syndrome, an X-linked recessive condition characterized by mental retardation, skeletal defects, hypotonia, and movement disorders (Becerra-Solano et al., 2009).

**Fig. 2** Gaseous signaling in cells via cGMP and cAMP-dependent and independent pathways in humans. Physiological levels of both NO and CO activate guanylate (guanylyl) cyclase to generate cGMP, which stimulates cGMP-dependent protein kinase. H<sub>2</sub>S activates adenylate cyclase activity to yield cAMP, which stimulates cAMP-dependent protein kinase. NO, CO, and H<sub>2</sub>S enhance glutathione synthesis to protect cells from oxidative stress. These gases also play important roles in innate and cell-mediated immunities, including cytoprotection for immunocytes, the modulation of inflammatory responses, reductions in the production of proinflammatory cytokines, and increases in the production of anti-inflammatory cytokines. AC, adenylate cyclase; CNS, central nervous system; and sGC, soluble guanylate cyclase. Reproduced from Li et al. (2009) with permission.

### Functions of creatine

Creatine is synthesized from arginine, glycine and methionine via inter-organ cooperation (Brosnan and Brosnan, 2007). Creatine kinase converts creatine and ATP into phosphocreatine and ADP as a mechanism for energy storage. The phosphocreatine/creatine kinase system is characterized by cell- and tissue-specific isoforms of creatine kinase, which are differentially localized in the cytoplasm and mitochondria to fulfill metabolic needs (Wallimann et al., 2011). This enzyme is present in many tissues (including skeletal muscle, brain, heart, kidneys, testes, and ovaries), but is absent from the liver (Wyss and Kaddurah-Daou, 2000). Creatine plays an important role in cellular energy metabolism and anti-oxidative reactions, particularly in the nervous, muscular, and reproductive systems and under hypoxic conditions. Therefore, oral administration of creatine can improve the health and exercise performance of humans (Posey et al., 2021). Conversely, defects in creatine synthesis result in neurological and muscular dysfunction and possibly reproductive failure (Philip et al., 2020).

### Functions of glutathione

Glutathione (GSH) is synthesized from glycine, cysteine, and glutamate. GSH directly and effectively scavenges free radicals and other reactive oxygen species, while reacting with various electrophiles, physiological metabolites (e.g., estrogen, melanins, prostaglandins and leukotrienes), and xenobiotics (e.g., bromobenzene and acetaminophen) to form mercapturates for excretion (Meister and Anderson, 1983; Sies, 1999). In addition, GSH serves as a cofactor for the conversion of prostaglandin H<sub>2</sub> into prostaglandins D<sub>2</sub> and E<sub>2</sub> by endoperoxide isomerase. Furthermore, GSH contributes to the glutathionylation of proteins (e.g., thioredoxin, ubiquitin-conjugating enzyme, and cytochrome *c* oxidase). Finally, GSH maintains cellular redox state, confers anti-infectious effects (Diotallevi et al., 2017), and reduces the susceptibility of humans to SARS (Wu et al., 2004) and COVID-19 (Polonikov, 2020; Silvagno et al., 2020).

### Functions of purine and pyrimidine nucleotides

Purines are synthesized from aspartate, glutamine, glycine, bicarbonate, and formate, whereas pyrimidines from aspartate, glutamine, and bicarbonate in cells (Wu, 2022). Purine and pyrimidine nucleotides form DNA and RNA. DNA stores genetic information and directs the syntheses of RNA (including mRNA, tRNA, rRNA, sRNA, miRNA, and siRNA) and protein. In addition, ATP and other nucleoside triphosphates (i.e., GTP and CTP) store biological energy and drive endergonic reactions in nutrient transport and metabolic pathways. The nucleoside triphosphates also participate in reactions that generate the phosphorylated metabolites (e.g., glucose-6-phosphate and fructose-6-phosphate) and phosphorylated proteins. Furthermore, cGMP and cAMP are second messengers in cell signaling. Finally, nucleotides are components of FAD, FMN, NAD, NADP, CoA, and SAM, which participate in many reactions, including oxidation, dehydrogenation, and methylation (Wu, 2018).

### Functions of taurine

Taurine is synthesized from cysteine in the liver and is transported into extrahepatic cells. A 70 kg adult person has ~70 g taurine (Huxtable, 1992). This AA is highly abundant in the liver, intestine, eyes, skeletal muscle, heart, brain, and many of other tissues, as well as bile and milk. In humans, taurine, along with glycine, conjugates with bile acids to form bile salts, which facilitate the intestinal digestion and absorption of dietary lipids (including lipid-soluble vitamins) and eliminate cholesterol (Wu, 2020a). In addition, taurine is a major antioxidant, anti-inflammatory, and anti-apoptotic factor; a regulator of intracellular osmoregulation and retinal photoreceptor activity; and a key component of nerve and muscle conduction networks (Wright et al., 1986). Furthermore, taurine stimulates neurological development, and serves as an inhibitory neurotransmitter in the brain. Finally, taurine reacts with HOCl and HOBr in activated granulocytes and neutrophils to produce taurine chloramine (N-chlorotaurine) and taurine bromamine (N-bromotaurine), which can kill bacteria, fungi, parasites, and viruses (Marcinkiewicz and Kontny, 2014).

### Functions of histamine

Histamine results from the decarboxylation of histidine in activated mast cells, and act on immunocytes (e.g., monocytes, T cells, macrophages, neutrophils, eosinophils, B cells, and dendritic cells) and other cell types (including smooth muscle cells). This amine mediates allergic reactions in humans (Thangam et al., 2018) by serving as the endogenous ligand of histamine receptors H1R–H4R (a class of G protein-coupled receptors) present in different tissues. For example, H1R is found in many cells (including mast cells, the smooth muscle cells of blood vessels and bronchi, neurons, respiratory epithelium, and endothelial cells); H2R in the gastric mucosa, B cells, T cells, dendritic cells, smooth muscle cells, the brain, and heart; H3R exclusively in neurons; and H4R in immunocytes, intestinal epithelia, lungs, synovial tissue, and brain. In addition, histamine has a vasodilatory effect to increase permeability and lower blood pressure in humans. Furthermore, histamine regulates acetylcholine secretion by the central nervous system, while stimulating gastric acid secretion as well as the contraction of the heart and the smooth muscle cells of the lungs, uterus, and stomach. H1R and H2R antagonists have been used to treat allergy and inhibit gastric acid secretion (e.g., individuals with peptic ulcer disease and acid reflux esophagitis) in humans, respectively.

### Functions of melanin

In the skin of humans, melanin (a metabolite of tyrosine) is a color pigment in melanocytes in the basal layer of the epidermis (Wu, 2022). Pigmentation by melanin has important biological, cosmetic and social significance. Eumelanin (black or brown) and pheomelanin (red or yellow in the skin and hair) are the known forms of melanin in the body. There are two types of eumelanin based on their colors: black or brown. Dark-skinned persons have more melanin than light-skinned individuals. Melanin protects the skin from ultraviolet light, and can affect stress response, immunity, sexual activity, and anti-oxidative responses (Lambert et al., 2019).

### Functions of melatonin

Melatonin (a metabolite of tryptophan) is produced by the pineal gland and retina (Cipolla-Neto and Amaral, 2018). This hormone activates melatonin receptors (G protein-coupled receptors) on the plasma membrane to induce cell signaling. Concentrations of melatonin in the blood are altered during a daily cycle to regulate the circadian rhythms and sleep-wake pattern of humans. Physiological concentrations of melatonin confer anti-oxidant effects, modulate neurological function (e.g., memory and mood), aging, and immunity in humans (Strasser et al., 2016). Oral administration of melatonin can be used to alleviate sleep disorders due to circadian rhythm abnormalities and travel-related jet lag.

### Functions of carnosine

Carnosine (a dipeptide consisting of  $\beta$ -alanine and histidine) is highly abundant in the human skeletal muscle (approximately 25 mM in women and 30 mM in men). This substance quenches reactive oxygen, nitrogen and carbonyl species, and other oxidants (Boldyrev et al., 2013). In addition, carnosine acts on histamine H1 or H3 receptors and on the hypothalamic suprachiasmatic nucleus (a master regulator of the circadian clock) in humans. Furthermore, carnosine activates the signaling cascades involving mitogen-activated protein kinase and cGMP-dependent protein kinase, while inhibiting proapoptotic signaling. Due to its histidine moiety, carnosine also plays a role in pH buffering, which is of physiological importance in the contraction of skeletal muscle during intense exercise (Derave et al., 2019).

### Functions of 4-hydroxyproline

4-Hydroxyproline is formed post-translationally from some proline residues in collagen, elastin, and certain regulatory proteins. This AA has structural, physiological, and nutritional significance in humans (Hu et al., 2021). For example, 4-hydroxyproline, along with proline, permits the sharp twisting of the collagen helix to establish the rigid structure of the collagen molecule in connective tissues. In addition, the presence of 4-hydroxyproline in the Gly-X-Y collagen peptides inhibits chemotaxis and apoptosis in neutrophils. Furthermore, 4-hydroxy-L-proline is a major substrate for glycine synthesis in human tissues and can scavenge reactive oxygen species. Finally, the formation of 4-hydroxyproline residues in protein kinases A and B, eukaryotic elongation factor 2 activity, and hypoxia-inducible transcription factor plays an important role in regulating their phosphorylation and catalytic activation, as well as metabolic signaling in cells (Hu et al., 2021).

### Functions of glucosamine

Glucosamine (formed from glutamine and fructose-6-phosphate) inhibits constitutive NO synthesis in endothelial cells by reducing pentose cycle activity and, therefore, the intracellular levels of NADPH (Wu et al., 2001). This amino sugar also decreases inducible NO synthesis in immunologically activated macrophages and other cell types by suppressing the expression of the iNOS protein (Meininger et al., 2000). Furthermore, N-acetylglucosamine-6-phosphate is used to form all glycoproteins in cells. Thus, oral administration of glucosamine alleviates osteoarthritis in humans (Salazar et al., 2014).

### Functions of dopamine

Dopamine (4-(2-aminoethyl)benzene-1,2-diol) is synthesized from tyrosine in dopaminergic neurons of the brain (Kopin, 1985). Tyrosine hydroxylase, a (6R)-5,6,7,8-tetrahydro-L-biopterin (BH4)-dependent enzyme, catalyzes the initial reaction of this metabolic pathway. Dopamine is a neurotransmitter in the central nervous system to modulate neurological development, learning, motor control, behavior, reward, emotion, and executive function in humans and to reduce their food intake (Liu et al., 2021). The physiological importance of dopamine is epitomized by the finding that the disruption of dopaminergic neurons in the basal ganglia results in Parkinson's disease in humans. In addition, immune cells, specifically T lymphocytes and dendritic cells, can convert tyrosine into dopamine, thereby modulating immune responses in mammals (Matt and Gaskill, 2020). Mental retardation and neurodegenerative disorders occur in individuals with little or no dopamine in the brain due to a deficiency of BH4 or phenylalanine hydroxylase and in patients with Parkinson's disease. L-3,4-Dihydroxyphenylalanine (L-DOPA), the most immediate precursor of dopamine, has beneficial effects in treating Parkinson's disease.

### Functions of serotonin

The catabolism of tryptophan via the hydroxylation and decarboxylation pathway in endocrine cells of the gastrointestinal tract and in neurons of the brain generates serotonin (5-hydroxytryptamine), with 80–90% of the whole-body serotonin being present in the gastrointestinal tract (Sanger, 2008). In the small intestine of humans, this neurotransmitter stimulates gastrointestinal secretion, motility, and food intake. In the brain, serotonin modulates neuropsychological processes and neural activity to improve mood, cognition, behavior, and nocturnal sleep in humans, while reducing aggressive behavior. Thus, drugs that selectively inhibit the reuptake of serotonin from the synaptic cleft (a space between two neurons) into the presynaptic cell to increase its extracellular concentrations are usually used to treat depression, anxiety disorders, and other psychological conditions (Preskorn et al., 2004). In both the gut and the brain, serotonin and its metabolite N-acetylserotonin inhibit the production of inflammatory cytokines and superoxide, scavenge free radicals, and enhance host immunity (Schiavone et al., 2013). Furthermore, N-acetylserotonin is an inhibitor of sepiapterin reductase, an enzyme for the synthesis of BH4 (an essential cofactor for NO synthase), thereby decreasing NO synthesis by inducible NO synthase under inflammatory conditions. Furthermore, taste cells in the digestive tract may synthesize and release serotonin (Uneyama et al., 2006), which transmits electrical impulses from the vagal nerve to the forebrain to amplify taste signal transduction. Thus, low concentrations of tryptophan in plasma may contribute to mood, behavioral, bowel and neurological disorders. Note that branched-chain AAs (leucine, isoleucine, and valine) compete with tryptophan for uptake by the brain and, therefore, have been used to alleviate tryptophan-induced cognitive impairment and chronic fatigue disorders in humans, particularly those with hepatic encephalopathy (Holeček, 2018).

### Functions of quinolinic acid and kynurenic acid

Quinolinic acid and kynurenic acid are two of the metabolites of tryptophan catabolism via the kynurenine pathway in the brain of humans (Wu, 2022). Interestingly, these two substances have opposite effects, as quinolinic acid and kynurenic acid are an agonist and a nonselective antagonist of the NMDA receptor (Schwarcz and Stone, 2017). Because quinolinic acid can activate but kynurenic acid can block AA-modulated excitation of the brain, their imbalance can result in an excitotoxic neuronal cell death. This may be a pathogenesis of some neurological diseases, including Huntington's chorea and epilepsy.

### Functions of AAs and metabolites as activators of the aryl hydrocarbon receptor

Tryptophan and its metabolites (e.g., indole acetic acid, kynurenine, and tryptamine), as well as bilirubin (a metabolite of heme), are natural ligands and activators of the aryl hydrocarbon receptor (AhR; Bessedé et al., 2014). Upon ligand binding, AhR undergoes a conformational change and translocates from the cytosol to the nucleus, resulting in the expression of target genes (e.g., cytochrome P450s) to catalyze the monooxygenation of various endogenous and exogenous substrates for excretion in the urine and feces. Furthermore, AhR confers anti-oxidative and anti-inflammatory effects in cells (Rothhammer and Quintana, 2019).

### Functions of heme

Heme is synthesized from glycine and succinyl-CoA by virtually all cell types in humans, with approximately 85% and 15% of heme being formed in immature red blood cells of the bone marrow and the liver (mainly hepatocytes), respectively (Ajioka et al., 2006). Heme accounts for 95% of iron in the human body and about two-thirds of dietary iron intake by humans in developed nations. Heme is an essential component of hemoglobin, myoglobin, and other heme-containing proteins (including enzymes), with hemoglobin accounting for 85% of the total heme in humans (Ferreira, 2013). These proteins are essential for oxygen transport in the blood, oxygen storage in tissues (particularly skeletal muscle and heart), proteins in the mitochondrial electron transport system (e.g., cytochromes), and heme enzymes (Wu, 2018). The latter include catalyze, guanylyl cyclase, indoleamine 2,3-dioxygenase, myeloperoxidase, peroxidase, prostaglandin endoperoxide synthase, and tryptophan 2,3-dioxygenase. In addition, intestinal bacteria express heme-containing nitrite reductase to convert nitrite into NO. Anemia, stunting, physical weakness, and metabolic defects occur in individuals with a deficiency of heme synthesis.

### Functions of AAs in sensing

AAs are crucial for the functions of sense organs, including the eyes, ears, nose, tongue, and skin that provide senses of sight, hearing, smell, taste, and touch, respectively to aid the survival, development, learning, and adaptation of humans. The chemosensory transduction is the biochemical basis of sensing responses, which help humans to avoid foods with strong bitter tastes, sour tastes, or unusual (e.g., bad or strong) smell, and to protect the organisms against consuming toxic substances or toxic foods (San Gabriel and Uneyama, 2013; Wu, 2020b). For example, taste cells express different taste receptors (transmembrane proteins) for different tastants. The gene *Tas1R* encodes for sweet and umami receptor proteins, which bind sweet AAs and glutamate, respectively. By contrast, the gene *Tas2R* encodes for bitter receptor proteins, which bind bitter AAs. Sour and salty taste receptors are transmembrane  $H^+$  and  $Na^+$  channels, respectively.

### Functions of D-AAs

AA racemases can convert certain L-AAs into D-AAs in humans and their intestinal microbes, including D-aspartate, D-serine, D-alanine, and D-glutamate (Friedman and Levin, 2012; Guercio and Panizzutti, 2018; Lee et al., 2020). High concentrations of D-aspartate, D-serine, and D-alanine occur in the endocrine glands and brain to regulate hormone secretion, as well as neurological growth, development and function (Errico et al., 2012; Flynn et al., 2020). For example, D-alanine is an agonist of the glycine site on the NMDA subtype glutamate receptor, thereby possibly affecting memory function and synaptic plasticity (Baccari et al., 2020). In addition, D-aspartate is the precursor for NMDA (Baccari et al., 2020; D'Aniello, 2007) and also binds NMDA receptors to affect long-term potentiation and spatial memory. Likewise, D-serine is an endogenous ligand for the glycine site of the NMDA receptor and functions as a novel neurotransmitter (McKay et al., 2019). Of note, both glycine and D-serine have been proposed as adjuvant therapy to the standard psychopharmacological treatment of individuals with schizophrenia. In the small and large intestines, some peptides that contain D-AAs are potent antimicrobials (Wu, 2018).

### Summary and outlook

AAs are substrates for the syntheses of not only proteins and peptides but also other nitrogen-sulfur-, and oxygen-containing substances with enormous versatility and physiological significance. Some AAs (e.g., aspartate, glutamate, and glycine) and metabolites (e.g., GABA, NO, CO, and  $H_2S$ ) are neurotransmitters. Some AAs (e.g., arginine, glutamine, glycine, leucine, tryptophan, and valine) activate the mTOR cell signaling pathway to stimulate protein synthesis and inhibit autophagy-mediated proteolysis. Some

AAs fulfill structural (e.g., proline, 4-hydroxyproline, and 5-hydroxylysine), metabolic (e.g., alanine, leucine, and glutamate), physiological (e.g., D-aspartate, D-serine, and taurine), and immunological (e.g., arginine, tryptophan, and glycine) needs of humans. Most physiological metabolites (e.g., creatine, heme, formate, purines, pyrimidines, and polyamines) are essential for biochemical processes (e.g., ATP production, energy provision, oxygen delivery, and cell growth). Thus, through direct and indirect actions, specific functions of AAs in humans include their roles in regulating gene expression, cell signaling pathways, food intake, chemical sensing, the digestion and absorption of dietary nutrients, neurological development and behavior, the metabolism of energy and nutrients, immunity, reproduction, hormone secretion, anti-oxidative and anti-inflammatory responses, the detoxification of endogenous and exogenous substances, acid-base and mineral balances, osmolarity, whole-body homeostasis, health and well-being (Bröer and Bröer, 2017; Li and Wu, 2022; Wu, 2021). Therefore, dietary supplementation with functional AAs (e.g., L-arginine, L-glutamate, and glycine) can improve the integrity and health of tissues and cells (e.g., the small intestine, brain, liver, skeletal muscle, heart, blood vessels, testes, ovaries, and immunocytes), enhance immunity, anti-oxidative responses, fertility, wound healing, ammonia detoxification, and lean tissue mass; ameliorate metabolic syndromes (including dyslipidemia, obesity, diabetes, and hypertension); and treat individuals with erectile dysfunction, sickle cell disease, muscular dystrophy, and pre-eclampsia in humans. Like any other nutrients, excessive AA intakes beyond upper safe levels can disturb whole-body homeostasis and must be avoided (Wu, 2022). Further research on dietary requirements (particularly functional AAs) is warranted to optimize human protein nutrition research and feeding practice.

### Key points

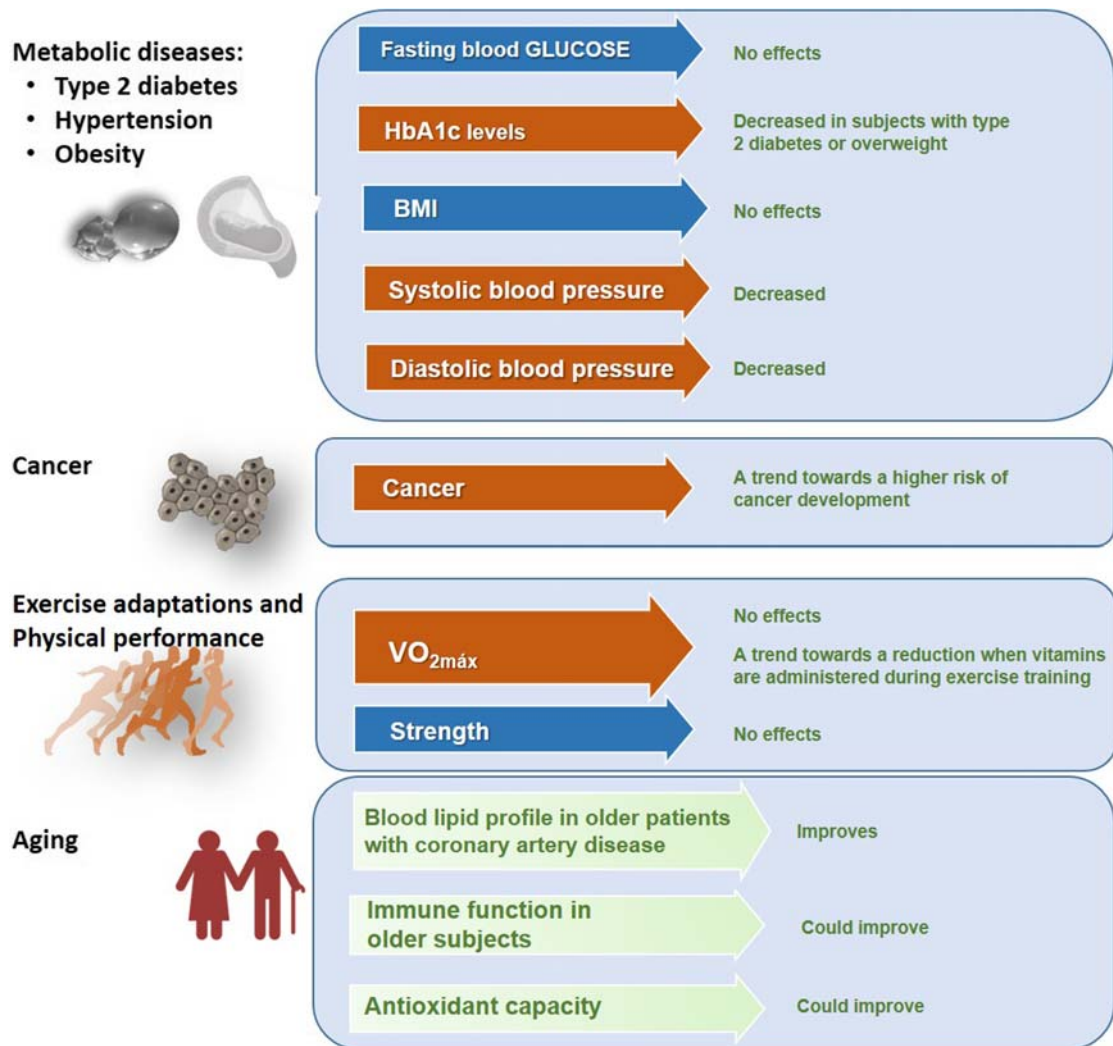

We summarize and discuss findings from intervention trials with antioxidants (vitamin C and vitamin E) supplementation (Fig. 1). Information available for, at least, these two vitamins make possible to shed light on the issue of its usefulness in patients suffering from conditions associated with oxidative stress: diabetes, metabolic syndrome, obesity, hypertension, cancer, other pathologies associated to aging as well as the role of physical performance as a tool to strong the health and prevented these diseases.

- Vitamin C and E supplementation may reduce fasting blood glucose and HbA<sub>1c</sub> levels in subjects metabolically compromised but this reduction is unlikely to have a clinically meaningful effect.
- Vitamin supplementation concomitant to exercise training could prevent the gain of ~1 mL/kg/min induced by training.
- An analysis of large cohort studies revealed a trend toward higher cancer risk among subjects supplemented with antioxidants.
- In certain situations, loading the cell with high doses of antioxidants leads to a blunting of the positive effects of a balanced diet and/or exercise training and interferes with important ROS-mediated physiological processes.
- We recommend that an adequate intake of antioxidants through a varied and balanced diet remains the best approach to maintain the optimal antioxidant status in individuals.

### Introduction

The oxygen molecule was introduced into the earth's atmosphere several billion years ago due to the appearance of photosynthetic oxygen-releasing organisms. Oxygen played a key role in the evolutionary process of erobic organisms, due to its ability to act as a final electron acceptor in the mitochondrial transport chain. Oxidative metabolism has the advantage to generate a large amount of energy through the complete combustion of glucose. However, the process requires a sequence of reactions mediated by enzymatic systems that generate the superoxide anion, which in turn initiates a cascade of production of reactive oxygen species (ROS), such as hydrogen peroxide, the hydroxyl radical or the oxygen singlet. The oxygen molecule can also generate nitric oxide, and this in turn reacts with the superoxide anion to produce peroxynitrite, a highly reactive and deleterious molecule.

ROS play relevant physiological roles; reduced levels of these molecules are required for cell signaling and modulation of processes such as growth and differentiation, immune function, mitochondrial biogenesis, apoptosis, angiogenesis or muscle hypertrophy. From this point of view, molecules such as superoxide anion or nitric oxide are essential for the body. However, when production is excessive and/or the levels of antioxidant defenses are reduced, oxidative/nitrosative stress and cell damage occur, with alterations in macromolecules such as lipid proteins or nucleic acids. Moreover, evidence accumulated in recent years suggests that increased oxidative stress unaccompanied by antioxidant adaptations is the trigger for the pathophysiology of inflammation, through activation of the transcription factor NF-kappaB and other pathways, such as those involving mitogen-activated

**Fig. 1** Graphical abstract of the intervention studies.

protein kinases (MAPK). As a result, a loss of physiological regulatory capacity can occur in various systems, such as cardiovascular, respiratory, or neuromuscular. Furthermore, ROS-mediated damage can contribute to the development of chronic diseases, such as cardiovascular and neurodegenerative diseases, as well as a higher incidence of tumors.

The cell is able to maintain a balance in the redox state when low and moderate levels of these molecules are generated, thanks to the antioxidant systems. The body uses enzymatic and non-enzymatic antioxidant systems to protect membranes and macromolecules from ROS-induced damage. Non-enzymatic antioxidants include dietary vitamins and provitamins (vitamins C, E, and beta-carotene), polyphenols (especially flavonoids), thiols (such as reduced glutathione), and various low-molecular weight protein compounds, such as ubiquinone, uric acid, and others. In contrast to other vertebrates, the human organism is not capable of synthesizing antioxidant vitamins, which means that the plasma and tissue levels of non-enzymatic antioxidants depend on the quality and quantity of the food eaten.

A large number of in vitro and animal research has shown beneficial effects of antioxidants in different conditions associated with oxidative/inflammatory damage, and results from observational studies suggest that lack of dietary antioxidants is casually related to chronic diseases risk. However, data obtained with those approaches do not allow for drawing conclusions regarding causality, and a number of intervention trials have been (and are being) carried out to shed light on this issue. The existing evidence shows potential positive-health effects, but the diversity of findings (including negative effects), the design variation between intervention trials, the small number of patients recruited, or the different characteristics of patients, make difficult to reach valid conclusions for most dietary antioxidants.

In this article we summarize and discuss findings from intervention trials with vitamin C and vitamin E supplementation. Information available for, at least, these two vitamins makes possible to shed light on its usefulness in patients suffering from conditions associated with oxidative stress. First, we performed a systematic review with the aim of summarizing the relationship between

antioxidant intake and a variety of aging markers. We next performed an in-deep search aiming to quantify through meta-analytic procedures the effects of antioxidant supplementation on health markers related to obesity and diabetes as well as hypertension. We also analyzed long-term antioxidant supplementation in healthy older subjects on the risk of cancer development during follow-up (3–10 years). Finally, as exercise exerts powerful protection against these metabolic diseases, we explored the effect of antioxidant supplementation on exercise adaptations.

## Effects of antioxidant supplementation on aging

There are numerous and very diverse alterations derived from aging or that have an impact on it. Sufficient homogeneous variables have not been found to perform a meta-analysis about vitamin C and/or vitamin E supplementation and its impact on aging. The physiological parameters related to aging that are measured in clinical trials are very diverse: mortality, antioxidant capacity, various markers indicating genetic damage, blood lipid profile, blood pressure, immune function, eye disease and cognitive impairment. Since the variables were so heterogeneous, it was not possible to perform a meta-analysis, so a systematic review was performed (Table 1).

A search was performed in the Web of Science database, using the following keywords: (“aging”) and (“vitamin\*” or “vitamin C” or “ascorbic acid” or “vitamin E” or “tocopherol”). The filter “Clinical Trial” was used, obtaining 802 results. The following were established as inclusion criteria: trials that only used vitamin C and/or E supplements, without including other vitamins and antioxidant substances; trials that measured physiological parameters that have an impact on or are a cause of aging; and trials published in journals ranked Q1 in JCR.

Clinical trials using cocktails of antioxidant substances, such as multivitamins, fatty acids, zinc, etc., and those published in lower impact journals were excluded. Finally, 21 clinical trials were analyzed, consisting of very diverse methodologies, finding significant variations in the age range of the participating subjects, in the habits or underlying diseases of the subjects, and in the physiological parameters evaluated.

The effects of vitamin E supplementation on mortality depend on the dietary intake of vitamin C and the age of the subjects (Hemilä and Kaprio, 2009, 2011). In supplemented subjects consuming higher dietary amounts of vitamin C, from 66 years of age onwards, mortality decreases (Hemilä and Kaprio, 2009, 2011); whereas mortality increases in supplemented subjects younger than 65 years of age (Hemilä and Kaprio, 2009). Regarding antioxidant capacity, significant positive effects have been seen in subjects supplemented with vitamin C, vitamin E or both (Lara-Padilla et al., 2007; Naeini et al., 2014). However, a higher antioxidant capacity does not influence the cognitive function of patients (Naeini et al., 2014; Cetin et al., 2010). On the other hand, there are contradictory results on the effects of both vitamins on genetic damage, and these effects could be influenced by the age of the subjects (Sacheck et al., 2003; Huang et al., 2000). Immune function seems to be favored by vitamin E supplementation, but there are no significant differences vs. placebo (Meydani et al., 1990; Meydani, 1995; Pallast et al., 1999). Vascular parameters are not affected by vitamin C supplementation (Singh et al., 2002). In older subjects with coronary artery disease, vitamin E supplementation significantly improves the lipid profile vs. placebo (Paolisso et al., 1995). Alzheimer’s disease alters telomeric profiles, and vitamin E supplementation shows no effect on these profiles (Guan et al., 2012). It also had no effect on cognitive performance in a trial conducted in patients with Down syndrome (Sano et al., 2016). Age-related eye diseases, such as maculopathy and cataracts, were also unaffected by vitamin C and E supplementation (Christen et al., 1999, 2008, 2010a,b, 2015; Teikari et al., 1997; McNeil et al., 2004).

In conclusion, vitamin E supplementation seems to improve the blood lipid profile in older patients with coronary artery disease, and could improve immune function in older subjects. Moreover, simultaneous supplementation with vitamins C and E could improve antioxidant capacity. However, the evidence currently available reflects more uncertainty than certainty, so further research and new clinical trials, perhaps with a better-defined methodology, are needed.

## Effects of antioxidant supplementation on diabetes, metabolic syndrome, obesity and hypertension

### Inclusion criteria and search strategy for meta-analysis

We considered any randomized clinical trial comparing vitamin C and/or vitamin E with placebo. Only original articles written in English were included. Exclusion criteria included intravenous vitamin administration, lack of placebo group (i.e. a control group receiving no pill or supplement), pregnant women or performed in children or adolescent. If vitamin supplementation included another component (i.e. other antioxidants, minerals or drugs), the study was only included if there was a group receiving only this component with which it was compared. In addition, we included several large studies assessing the risk of cancer development when vitamin C and/or E are supplemented. Note that the last section assessed the effects of vitamins on aging related parameters but due to the impossibility to normalize the data only a qualitative analysis was provided.

A systematic search of the literature was conducted on Medline, Scopus, CINAHL and Embase, current to October 2021. A combination of terms related to vitamin C, vitamin E, diabetes, metabolic syndrome, obesity, exercise performance, hypertension and cancer was used.

**Table 1** Antioxidants and healthy aging.

Author	Treatment	Duration	Dose (per day)	Age	Physiological parameter	Effect	Observations
(Hemilä and Kaprio, 2009)	Vit E	5–8 y	50 mg	50–62	Mortality	↑ <sup>b</sup>	Male smokers (high vitamin C intake)

ACP = antioxidant capacity of plasma; TAC = total antioxidant capacity; GSH = glutathione; MDA = malondialdehyde; PBMC = peripheral blood mononuclear cells;

DTH = delayed-type hypersensitivity.

<sup>a</sup>Significant within the same group.

<sup>b</sup>Significant vs. placebo.

### Data extraction and synthesis

The relevant variables extracted included HbA<sub>1c</sub>, fasting blood glucose, body mass index, blood arterial pressure, maximal oxygen consumption, maximal strength, risk of cancer development as well as study length. The change in mean ( $\Delta$ Mean) and  $\Delta$ SD was calculated for each treatment (i.e. placebo and vitamin) and outcome. When  $\Delta$ SD was not reported we calculated it assuming a correlation coefficient of 0.7 as suggested by the Cochrane Handbook for Systematic Reviews of Interventions (Higgins and Green, 2011) as follows:

$$\Delta\text{SD} = \sqrt{(\text{SD}_{\text{pre}}^2 + \text{SD}_{\text{post}}^2 - 2 \times \text{corr} \times \text{SD}_{\text{pre}} \times \text{SD}_{\text{post}})}.$$

The assumption of a 0.7 correlation coefficient was also recently validated for a similar paper, showing no substantial differences when varying it from 0.5 to 0.7 (Mason et al., 2021). Crossover trials followed the same treatment as parallel trials. When several doses of vitamin were studied the higher dose was used for calculations. Similarly, when several time-points were analyzed the last one was used.

### Meta-analysis

A random-effects meta-analysis with DerSimonian-Laird methods was performed using R software on the change of each outcome (i.e. vitamin vs. placebo). Effects sizes are presented as standardized mean differences (SMD), mean differences (MD) or risk ratio (RR) with means  $\pm$  SD and 95% CIs. Heterogeneity was assessed by  $\chi^2$  and  $I^2$  and significance was set at  $p < 0.05$ . Additionally, subgroup analysis (i.e. vitamin E vs. vitamin C, or trained vs. untrained) and meta-regression (length of the study) were performed.

### Fasting glucose, HbA<sub>1c</sub> % and body mass index

We analyzed 35 clinical trials including more than 1700 type 2 diabetic and/or overweight to obese subjects (Economides et al., 2005; El-Aal et al., 2018; Paolisso et al., 1993; Ward et al., 2007; Ceriello et al., 1991; Reaven et al., 1995; Fuller et al., 1996; Gazis et al., 1999; Duffy et al., 2001; Botham et al., 2005; Ble-Castillo et al., 2005; Winterbone et al., 2007; Manning et al., 2013; Stonehouse et al., 2016; Rafraf et al., 2016; Farajbakhsh et al., 2019; Mazloom et al., 2011; Bishop et al., 1985; Ragheb et al., 2020; Kunsongkei et al., 2019; Devanandan et al., 2020; Siavash and Amini, 2014; Sanguanwong et al., 2016; Tousoulis et al., 2007; Gillani et al., 2017; Dakhale et al., 2011; Mason et al., 2016; Paolisso et al., 1995; Gokce et al., 1999; Lu et al., 2005; Chen et al., 2006; Mason et al., 2019; Naylor et al., 1985). When both vitamin C and E are analyzed together there was a trend  $p = 0.09$  toward decreasing fasting blood glucose in 1762 subjects from 32 studies (SMD -0.17 [95% CI -0.38%, 0.03%]) (Fig. 2). However, the analysis showed a high heterogeneity among studies  $I^2 = 74.7\%$ ,  $p < 0.01$ . As this could be due to differences in the response to vitamin C and E, we next analyzed and compared both subgroups. We found that neither vitamin C ( $n = 1114$ , in 17 studies) nor vitamin E ( $n = 648$ , in 15 studies) decreased fasting blood glucose and no difference was detected between subgroups. It should, however, be noted that heterogeneity was higher among vitamin C studies ( $I^2 = 82.1\%$ ) than in vitamin E studies ( $I^2 = 40.6\%$ ). We also explored whether the length of the interventions could be a source of heterogeneity, however, this was not the case ( $Q_m = 2.5$ ,  $df = 1$ ,  $p = 0.109$ ).

Regarding HbA<sub>1c</sub>, we analyzed 1404 subjects from 23 studies (Fig. 3). The analysis shows that vitamin supplementation decreased HbA<sub>1c</sub> in subjects with type 2 diabetes or overweight (SMD -0.33 [95% CI -0.58%, -0.09%]). Here, again, we observed a high heterogeneity among studies ( $I^2 = 79.9\%$ ,  $p < 0.01$ ). We therefore tested the hypothesis of subgroup differences, however, no differences were observed between vitamin C and vitamin E treatments ( $p = 0.42$ ). Furthermore, and similar to the analysis of fasting blood glucose, we observed that an important source of heterogeneity comes from vitamin C studies ( $I^2 = 80\%$ ,  $p < 0.01$ ) rather than from vitamin E studies ( $I^2 = 7.1\%$ ,  $p = 0.2$ ). Notably, we further observed that the length of the intervention is also an important source of heterogeneity when addressing HbA<sub>1c</sub> ( $Q_M = 7.65$ ,  $df = 1$ ,  $p = 0.01$ ). In fact, under our analysis, our data suggest that each week of treatment would add 0.0198 to the estimate in favor to vitamin supplement. Note that this analysis is true when both vitamin E and vitamin C studies are analyzed together (Fig. 3).

**Fig. 2** Forest plot of the results from a random-effects meta-analysis shown as standardized mean difference with 95% CIs on fasting blood glucose. The rhombi represent the weighted vitamin E, vitamin C and total group's standardized mean difference.

**Fig. 3** Forest plot of the results from a random-effects meta-analysis shown as standardized mean difference with 95% CIs on % HbA<sub>1c</sub>. The rhombi represent the weighted vitamin E, vitamin C and total group's standardized mean difference.

**Fig. 4** Forest plot of the results from a random-effects meta-analysis shown as mean difference with 95% CIs on Body Mass Index<sub>c</sub>. The rhombi represent the weighted vitamin E, vitamin C and total group's mean difference.

Surprisingly, only 9 studied ( $n = 657$ ) body mass index as an outcome (Fig. 4). Therefore, although no effects of vitamin C and E has been observed in our analysis (SMD  $-0.10$  [95% CI  $-0.25, 0.06$ ]) this result may be limited to the low number of studies included.

### Blood pressure

We found that 30 clinical trials ( $n = 1555$ ) studied the effects of vitamin administration on blood pressure (Figs. 5 and 6) (Rodrigo et al., 2014, 2008; Farvid et al., 2004, 2006; Huang et al., 2000; Palumbo et al., 2000; Chappell et al., 1999; Izadi et al., 2019; Farajbakhsh et al., 2019; Aryaeian et al., 2008; Studinger et al., 2004; Jessup et al., 2003; Rasool et al., 2003, 2006, 2008; Boshtam et al., 2002; Paolisso et al., 1995; Mason et al., 2019; Oliveira et al., 2015; Goldstein et al., 2012; Darko et al., 2002; Singh et al., 2002; Duffy et al., 2001; Fotherby et al., 2000; Gokce et al., 1999; Ghosh et al., 1994). Overall, it seems that systolic blood pressure (MD  $-5.0$  [95% CI  $-8.49, -1.53$ ];  $p < 0.001$ ) is greatly decreased by vitamin treatment. Which is also observed when vitamin C and E are consumed together ( $p = 0.007$ ) and when vitamin C ( $p = 0.006$ ) and vitamin E ( $p = 0.03$ ) are consumed alone. However, there was a high heterogeneity among the studies analyzed (overall:  $I^2 = 93\%$ ). Which can be mainly attributed to vitamin E trials ( $I^2 = 96\%$ ) as no significant heterogeneity effect was observed in vitamin C trials. In fact, one particular vitamin E trial (Boshtam et al., 2002) which reported a huge hypotensive effect.

Regarding diastolic blood pressure (Fig. 6) we found a similar overall hypotensive effect induced by vitamin treatment (MD  $-2.06$  [95% CI  $-3.29, -0.83$ ;  $p = 0.001$ ] in 30 clinical trials ( $n = 1537$ ). However, when analyzing each supplementation on its own, no effects were observed for vitamin C ( $p = 0.06$ ), vitamin E ( $p = 0.05$ ) and vitamin E + C ( $p = 0.05$ ). It is important to note that the length of the supplementation was not a source of heterogeneity neither for systolic nor for diastolic blood pressure as showed by the meta-regression model.

### Effects of antioxidant supplementation on cancer development risk

We haven't found any clinical trial analyzing the effects of antioxidant supplementation on cancer patient. Instead, several trials have addressed the long term effect of antioxidant supplementation in healthy women (Lee et al., 2005), subjects at risk of cancer development due to is lifestyle (i.e. smokers) (Albanes et al., 1996; Varis et al., 1998; Rautalahti et al., 1999; Virtamo et al., 2000; Wright et al., 2007), subjects at risk of prostate cancer (high baseline prostate-specific antigen but normal rectal exploration) (Klein et al., 2011) and subjects at risk of cardiovascular disease (Lin et al., 2009). The outcome was cancer development during the follow-up (5–12 years).

We identified 8 trials which studied 116,882 subjects, and cancer development was registered during a period of 5–10 years where there were supplemented with vitamins or placebo (Fig. 7). Only one of these trials was performed with vitamin C, while 7 were performed with vitamin E. Risk ratio analysis showed that there was a trend ( $p = 0.09$ ) toward a higher risk of cancer development in those subjects consuming vitamins (RR  $-0.07$  [95% CI  $-0.15, 0.01$ ]). Notably, this analysis showed a really low heterogeneity.

**Fig. 5** Forest plot of the results from a random-effects meta-analysis shown as mean difference with 95% CIs on systolic blood pressure. The rhombi represent the weighted vitamin E, vitamin C and total group's mean difference.

**Fig. 6** Forest plot of the results from a random-effects meta-analysis shown as mean difference with 95% CIs on diastolic blood pressure. The rhombi represent the weighted vitamin E, vitamin C and total group's mean difference.

**Fig. 7** Forest plot of the results from a random-effects meta-analysis shown as risk ratio with 95% CIs on cancer development. The rhombi represent the weighted vitamin E, vitamin C and total group's risk ratio.

### Effects of antioxidant supplementation on exercise adaptations and physical performance

Exercise can improve cardiovascular health, glucose homeostasis as well as lower the risk of cancer development (Handschin and Spiegelman, 2008). Therefore, it is important to know whether antioxidant can prevent exercise-related adaptations.

We next analyzed whether vitamin supplementation could alter physical performance. We found that 14 trials analyzed maximal oxygen consumption during exercise ( $n = 341$  subjects) (Gomez-Cabrera et al., 2008; Zychowska et al., 2021; Itoh et al., 2000; Roberts et al., 2011; Morrison et al., 2015; Jessup et al., 2003; Oberbach et al., 2010; Collins et al., 2003; Margaritis et al., 2020; Cobley and Marrin, 2012; Paschalis et al., 2016; Gaeini et al., 2006; Patil et al., 2009). Of them, 5 trials were performed with vitamin C, 7 with vitamin E and 2 with both vitamin C and E (Fig. 8). Notably, 7 trials included concomitant training while the other 7 trials did not. Therefore, a two-subgroup analysis was performed including those with concomitant training vs. those with no training.

Overall, vitamin supplementation did not alter maximal oxygen consumption; but, similarly to previous analysis, there was a high heterogeneity among studies ( $I^2 = 75\%$ ) (Fig. 8). Which was not due to the length of the intervention as suggested by the moderator test. However, the heterogeneity was higher among those studies which did not include concomitant training ( $I^2 = 90\%$ ) than in those who included a trained period ( $I^2 = 39\%$ ). It should be noted that although there was not a difference between subgroups, there was a trend ( $p = 0.1$ ) toward a reduction in  $VO_{2max}$  when vitamins are administered during exercise training. In absolute terms, this analysis suggests that vitamin supplementation during exercise would prevent the gain of 0.82 mL/kg/min induced by training [95% CI -0.52, 2.17 mL/kg/min]. Finally, we found 5 studies engaging 6 strength outcomes ( $n = 142$ ) (Barker et al., 2015; Beaton et al., 2002; Bjørnsen et al., 2016; Close et al., 2006; Dutra et al., 2018). The analysis suggests that vitamin supplementation does not alter strength ( $p = 0.3$ ) (Fig. 9).

### Conclusions

Here we show that vitamin C and E supplementation may reduce fasting blood glucose and HbA<sub>1c</sub> levels in subjects metabolically compromised. However, and similar to a previous meta-analysis on the effects of vitamin C (Mason et al., 2021) this reduction is unlikely to have a clinically meaningful effect. In contrast, previous data reported that vitamin C supplementation shows a hypotensive effect (Mason et al., 2021). Here, we show that this effect can be extrapolated to vitamin E and vitamin C + E supplementation. It should however be noted that we found a large heterogeneity among all the studies and most of the variables. Therefore, future work should further investigate the source of this heterogeneity as antioxidant supplementation may not be safe for all people in all conditions.

**Fig. 8** Forest plot of the results from a random-effects meta-analysis shown as standardized mean difference with 95% CIs on maximal oxygen uptake ( $VO_{2max}$ ). The rhombi represent the weighted vitamin E, vitamin C and total group's standardized mean difference.

**Fig. 9** Forest plot of the results from a random-effects meta-analysis shown as standardized mean difference with 95% CIs on maximal strength. The rhombi represent the weighted vitamin E, vitamin C and total group's standardized mean difference.

For instance, we found that vitamin supplementation concomitant to exercise training could prevent the gain of  $\sim 1$  mL/kg/min induced by training. More importantly, an analysis of large cohort studies revealed a trend toward higher cancer risk among subjects supplemented with antioxidants. Therefore, antioxidant supplementation must be avoided in subjects at risk to develop cancer.

The main findings of these studies are that, in certain situations, loading the cell with high doses of antioxidants leads to a blunting of the positive effects of a balanced diet and/or exercise training and interferes with important ROS-mediated physiological processes, such as vasodilation and insulin signaling. Moreover, an analysis of large cohort studies revealed a trend toward higher cancer risk among; however, samples from these studies were heterogeneous, including healthy subjects, and people at risk of develop cancer (smokers) and at cardiovascular risk. Therefore, more research is needed to produce evidence-based guidelines regarding the use of antioxidant supplementation. We recommend that an adequate intake of antioxidants through a varied and balanced diet remains the best approach to maintain the optimal antioxidant status in individuals.

### Key points

- Free radicals, including reactive oxygen and nitrogen species (ROS/NOS), are formed in the human body as a result of oxidative metabolism.
- Free radicals are capable of modifying important molecules such as DNA, lipids, and proteins, and therefore affecting their ability to function or causing them to function abnormally.
- The body's antioxidant system is complex and prevent formation of ROS and terminate chains of ROS-initiated peroxidation of biological substrates.
- Antioxidants present in the diet include vitamin C, vitamin E, carotenoids, polyphenols, chlorophylls, metals and minerals such as zinc or selenium, etc.
- Diets rich in plant foods (particularly fruit and vegetables) convey health benefits, as do high plasma levels of several antioxidant nutrients found in these foods, a causal link between lack of antioxidants and disease occurrence or between antioxidant administration and disease prevention remains to be established.
- Many antioxidants can also act as pro-oxidants in certain conditions, such as the presence of transition metals or at high concentrations.
- Vitamin E and other nutrients that are classified as antioxidants have also been shown to modulate pathways of cell signaling and gene expression.
- Intervention studies demonstrating higher risk of cancer in smokers with β-carotene supplementation have, for example, attributed this finding to its pro-oxidant effect.
- Further evidence is required regarding the efficacy, safety, and appropriate dosage of anti-oxidants in relation to chronic disease.
- Currently, the most prudent public health advice continues to be to consume a variety of plant foods.

## Introduction

Free radicals, including reactive oxygen and nitrogen species (ROS/NOS), are formed in the human body as a result of oxidative metabolism, i.e., as a result of the many chemical reactions and metabolic processes that occur in the body and also have numerous beneficial functions (Fig. 1). Free radicals are capable of modifying important molecules such as DNA, lipids, and proteins, and therefore affecting their ability to function or causing them to function abnormally. These processes are often referred to as oxidative damage. Antioxidants have the ability to scavenge and neutralize free radicals, or are necessary to enable other molecules to perform such a function. The body's antioxidant system is complex and consists of various intracellular and extracellular, endogenous and exogenous, and aqueous and lipid-soluble components that act in concert to prevent formation of ROS and terminate chains of ROS-initiated peroxidation of biological substrates. Antioxidants present in the diet include vitamin C, vitamin E, carotenoids and polyphenols. Metals and minerals that are key components of antioxidant enzymes, such as zinc or selenium, are also referred to as antioxidants. Many antioxidants can also act as pro-oxidants in certain conditions, such as the presence of transition metals or at high concentrations. Intervention studies demonstrating higher risk of cancer in smokers with  $\beta$ -carotene supplementation have, for example, attributed this finding to its pro-oxidant effect (see section on  $\beta$ -Carotene).

Oxidant or oxidative stress is a pro-oxidant shift in the oxidant–antioxidant balance caused by a relative or absolute deficiency of antioxidants. A pro-oxidant shift promotes damaging oxidative changes to important cellular constituents, and this may in turn lead to cellular dysfunction and, ultimately, to aging, disability, and disease. Long-term oxidative stress has therefore been linked with a number of chronic diseases including coronary heart disease (CHD), cancer, cataract, dementia, and stroke (Fig. 2).

Currently, it is known that ROS act as key signaling molecules for the maintenance of the metabolism. Therefore, maintaining ROS production at physiological levels is critical for achieving a correct metabolic function. A deregulation of ROS production, mostly an up-regulation, occurs in most metabolic diseases. Therefore, it could be suggested that the supplementation with antioxidants in these diseases can attenuate the disease. However, the blocking of ROS production through the use of antioxidants could prevent the correct function of molecular signaling and, therefore, it could be counterproductive (Fig. 2).

Other plant components, including polyphenols, have also been shown to possess antioxidant potential. To date, most of the evidence on antioxidant potential of polyphenols comes from *in vitro* studies, many possessing higher antioxidant potential *in vitro* than vitamins and carotenoids. However, although polyphenols show strong antioxidant properties *in vitro*, there has been much discussion about whether they are present in sufficient quantities *in vivo* to influence antioxidant activities. Studies have shown that polyphenols do not appear to be circulating in the blood at high enough concentrations to contribute significantly to the body's total antioxidant capacity. Further, it has been estimated that, after ingestion, around 90–95% of polyphenols undergo molecular changes. These changes to the structure of polyphenols can moderately or even radically change the “biological activities” of polyphenols found in *in vitro* studies. However, it has been suggested that polyphenols may exert an indirect antioxidant effect, by protecting endogenous antioxidant enzymes in the human body.

Recently, a new study provides a first level of evidence on the *in vivo* health benefits of olive oil triterpenes (oleanolic and maslinic acids) in healthy humans, decreasing DNA oxidation and plasma inflammatory biomarkers.

Owing to a lack of concise evidence of the potential antioxidant properties of polyphenols in the human body, these will not be discussed in this article.

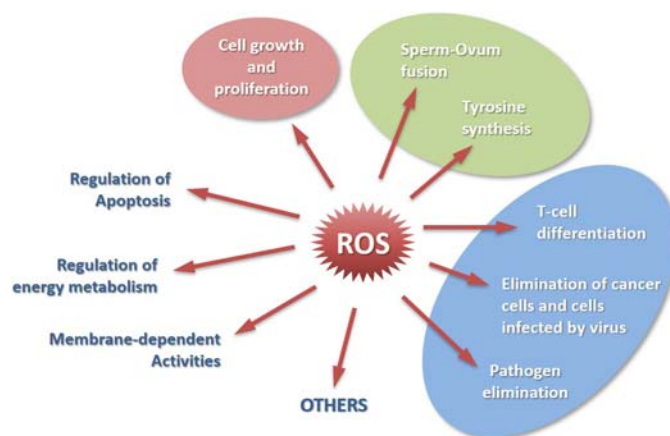

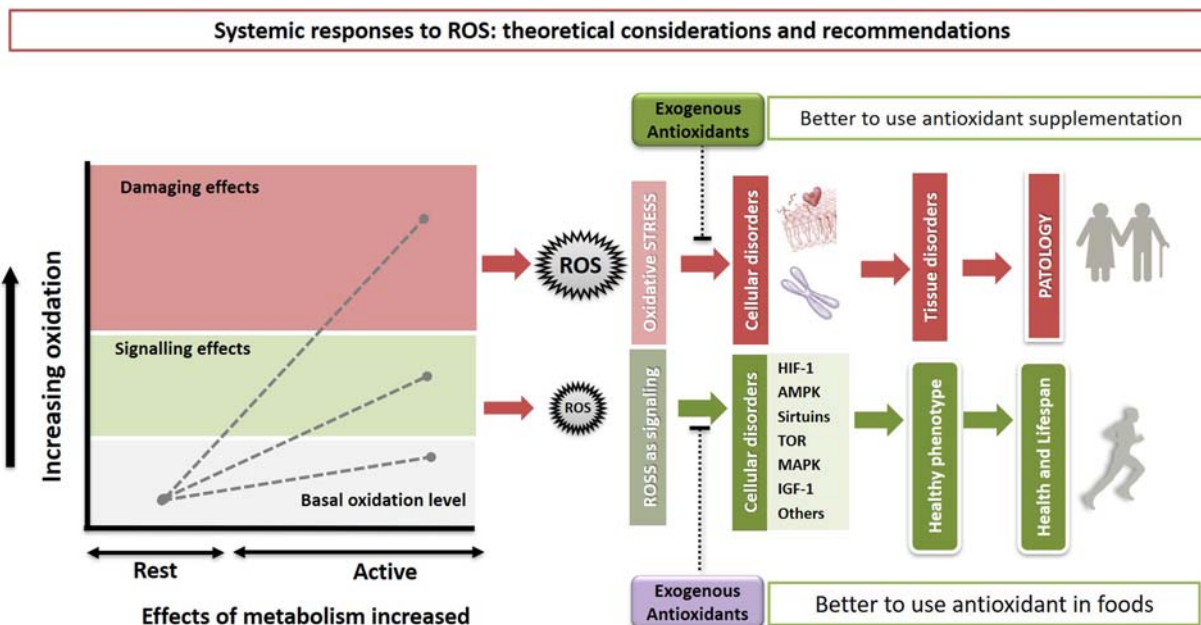

Fig. 1 Relevant actions and physiological functions of ROS. Adapted from Casuso and Huertas (2018).

**Fig. 2** Hypothetical model depicting body responses to increasing oxidation of redox-sensitive components due to increased ROS exposure. ROS are required in very small amounts as mediators of expression of critical genes for establishing an active and healthy phenotype. Low levels of ROS change the cellular redox state to increase the redox-sensitive signaling pathways and supplementation with antioxidants will be negative. High levels generate damaging effects. IGF-1, insulin-like growth factor-1; HIF-1, hypoxia-inducible factor-1; AMPK, AMP-activated protein kinase; FoxOs, forkhead box O proteins.

## Definition of antioxidant

Word such “antioxidant” is difficult to define. Considering its function we could coin numerous definitions, but probably the most complete is the provided by B. Halliwell and Gutteridge in 1992: “an antioxidant is any substance that when present at low concentrations compared to those of an oxidizable substrate delays or prevents oxidation of that substrate.” Mechanisms of antioxidant action can include: removal of O<sub>2</sub>, scavenging reactive oxygen/nitrogen species or their inhibiting ROS/RNS formation, binding metal ions needed for catalysis of ROS generation, repair mechanisms and up regulation of endogenous antioxidant defenses.

Sics in 1996 defined antioxidants as the substances that neutralize free radicals or their actions. Ternay and Sorokin in 1997 defined antioxidant as any substance that hinders a free radical reaction. Azzi and Davies in 2004 defined antioxidant as the substances which counteract free radicals and prevent the damage caused by them.

## Antioxidants sources

Antioxidants are molecules widely distributed in foods, especially those of plant origin. The concentration and nature of antioxidants depends on the type of food (plants or fruits), its seasonality and especially on the processing to which these foods have been subjected.

In **Tables 1** and **2** we include foods and spices, ordered from the highest to the lowest antioxidant content (mg/100 g) and by their content in typical cooking portions (mg/portion). In addition to the numerical value, we incorporate a color range for quick visual reference.

## Normal plasma concentration of the most common antioxidants

At present there are no consensus plasma normal values for antioxidants, probably due to their wide variety and nature. In **Table 3** we make a proposal based on our data (Barranco-Ruiz et al., 2017) and on values obtained from numerous investigations and clinical trials in humans, published in the most relevant journals. One of the problems for the elaboration of this proposal is that plasma values usually present a multimodal distribution due to the intake of foods more or less rich in antioxidants or to the consumption or not of supplements. For example, as shown in **Fig. 3A**, the plasma tocopherol values of 100 healthy subjects show several peaks. Eighty percent of the sample (n = 75) presented  $\alpha$ -tocopherol values < 80 nmol/mL, which are considered physiologically normal levels from a balanced diet, whereas the remaining 20% (n = 19) presented significantly elevated levels (>80 nmol/mL), suggesting vitamin E supplementation (**Fig. 3A**). In addition, a detailed analysis of the plasmatic  $\alpha$ -tocopherol concentrations distribution in the normal levels group showed two peaks (**Fig. 3B**). The second peak corresponded to only five

participants with values between 46 and 80 nmol/mL, surpassing the average of the group without antioxidant supplementation evidence. These values correspond to subjects with a high antioxidant foods in their diet.

### Antioxidants as signaling

In the last years the physiological role of the ROS have evolving and today playing important functions as keys in signaling mechanisms (Casuso and Huertas, 2018). In fact, it is necessary the maintenance of a physiological amount of ROS for maintaining the biologic function (Fig. 2). It is harmful having high levels of ROS as those produced in metabolic disease as well as having ROS levels below the physiological minimum. This hormetic response has been tested under different circumstances, among them it should be highlighted the study of supplementation with antioxidants during exercise. As described above, a large amount of ROS is produced during exercise through several independent pathways. Therefore, for years it has been tested if the intake of antioxidants could prevent certain processes related to the oxidative damage such as inflammation and the associated sarcomere damage. It was found that the intake of antioxidants before a strenuous test can, in fact, prevent muscle damage associated with ROS production. These findings affected the society becoming the supplementation with antioxidants extended to athletes. However, the chronic effect of the combination of exercise and supplementation with antioxidants was not considered. It was not until well into the 2000s when a series of researchers used animal and human models to test how the intake of antioxidant supplements interfere in chronic adaptations to training. Among the observed effects there was a performance decrease which was associated with a decrease in mitochondrial function and biogenesis by preventing the expression of PGC-1 $\alpha$ . Therefore, the concept of “mitohormesis” was extended, where a minimum of mitochondrial oxidative stress is key for adaptations, whereas the total suppression of ROS as well as a sustained increase of ROS is harmful. There is still much to elucidate and to research with this regard, e.g., the discovery of antioxidants blocking particular pathways of ROS production could help to individualize pharmacological treatments in particular diseases. Indeed, diseases such as type 2 diabetes, cardiovascular diseases, cancer and alzheimer have been associated with an overproduction of ROS. In almost all these diseases the exercise seems to produce a beneficial effect, among other mechanisms by controlling this production of ROS. Nevertheless, the intake of antioxidants seems to prevent these improvements, this is very evident in subjects with risk of developing type 2 diabetes. In these subjects, the supplementation with antioxidants prevented the beneficial effects of exercise on insulin signaling.

### New physiological antioxidants

The enzymatic antioxidant systems are synthesized in the body and it has been shown that they can be induced in response to the presence of ROS produced by exercise. This response depends on factors such as exercise duration and intensity. Several studies have shown that training can induce increased levels of antioxidant enzymes in human and laboratory animals muscle tissue, leading to reduced susceptibility of muscle to oxidative stress.

Recently, it has been shown that some of the antioxidant effects of exercise may be explained by an antioxidant mechanism at the mitochondrial level (Huertas et al., 2017). Complex I of the mitochondrial electron transport chain is a site of ROS production during exercise. Data accumulated over the past few years suggest that the distribution of mitochondrial electron transport chain complexes can change in response to cellular stimuli such as oxidative or energetic stress and that they can assemble into

supramolecular structures called mitochondrial supercomplexes. The main function attributed to these structures is an increased efficiency of mitochondrial respiration, which among other effects would prevent an excessive production of ROS. A very recent study has shown that exercise can limit ROS production by increasing the amount of complex I assembled in mitochondrial supercomplexes. The mechanism that leads to lower ROS production by complex I when it is in a supercomplex is not clear, although it has been suggested that these structures stabilize complex I. It has been confirmed that in metabolic diseases the levels of supercomplex assembly are lower, which has been related to oxidative damage. Therefore, research into strategies to improve the assembly of mitochondrial supercomplexes will be important over the next few years. In any case, exercise appears to be a potent stimulus that can decrease oxidative damage and associated metabolic diseases through changes in mitochondrial morphology.

### The antioxidant hypothesis

A predominantly plant-based diet, high in fruit and vegetables, reduces the risk of developing several chronic diseases, including cancer and cardiovascular disease (CVD). It is often assumed that antioxidants, including vitamin C, Vitamin E, and carotenoids, contribute to this protection by interfering passively with oxidative damage to DNA, lipids, and proteins. This hypothesis is supported by numerous *in vitro* studies in animals and humans. A large number of descriptive, case-control, and cohort studies have also demonstrated an inverse association between high intakes or plasma levels of anti-oxidants and risk of CVD and cancer at numerous sites, as well as other conditions associated with oxidative damage, such as age-related macular degeneration, cataracts, and chronic obstructive pulmonary disease (COPD).

These findings provided a strong incentive for the initiation of intervention studies to investigate whether a lack of dietary antioxidants is causally related to chronic disease risk and if providing antioxidant supplements confers benefits for the prevention and treatment of these conditions. This article summarizes the findings of the largest primary and secondary trials published to date and considers their implications for future research and current dietary advice.

**Fig. 3** (A) Multimodal distribution of Alpha-tocopherol concentrations after analysis with high-performance liquid chromatography. (B) Alpha-Tocopherol distribution for normal subjects without supplementations.

## Cardiovascular disease

Of all the diseases in which excess oxidative stress has been implicated, CVD has the strongest supporting evidence. Oxidation of low-density lipoprotein (LDL) cholesterol appears to be a key step in the development of atherosclerosis, a known risk factor in the development of CVD. Small studies have demonstrated reductions in LDL oxidation (mostly *in vitro*) following supplementation with dietary antioxidants (particularly vitamin E, which is primarily carried in LDL-cholesterol), suggesting that they may provide protection against the development of heart disease. A number of large intervention trials using disease outcomes (rather than biomarkers such as LDL oxidation) have also been conducted to try to demonstrate a protective effect of vitamin E,  $\beta$ -carotene, and, to a lesser extent, vitamin C supplements on CVD. Most have been carried out in high-risk groups (e.g., smokers) or those with established heart disease (i.e., people with angina or who have already suffered a heart attack).

### Primary prevention

The results of most primary prevention trials have not been encouraging (Table 4). For example, in the Finnish Alpha-Tocopherol Beta-Carotene Cancer prevention (ATBC) study, approximately 30,000 male smokers received vitamin E ( $50 \text{ mg d}^{-1}$  of  $\alpha$ -tocopherol),  $\beta$ -carotene ( $20 \text{ mg d}^{-1}$ ), both, or an inactive substance (placebo) for approximately 6 years. There was no reduction in risk of major coronary events with any of the treatments despite a 50% increase in blood vitamin E concentrations and a 17-fold increase in  $\beta$ -carotene levels. Moreover, with vitamin E supplementation, there was an un-expected increase in risk of death from hemorrhagic stroke and a small but significant increase in mortality from all causes with  $\beta$ -carotene supplementation (relative risk (RR), 1.08; 95% confidence interval (CI), 1.01–1.16). In the Physicians' Health Study (PHS) II, looking at the effect of 400 IU  $\alpha$ -tocopherol supplementation on alternate days in approximately 14,000 male physicians, the risk of hemorrhagic stroke almost doubled with vitamin E supplementation during 8 years of follow-up (hazard ratio (HR) 1.99, 95% CI, 1.13–3.52). An increase in CVD deaths was also observed in the Beta-Carotene and Retinol Efficacy Trial (CARET), which tested the effects of combined treatment with  $\beta$ -carotene ( $30 \text{ mg d}^{-1}$ ) and retinyl palmitate ( $25,000 \text{ IU d}^{-1}$ ) in 18,000 men and women with a history of cigarette smoking or occupational exposure to asbestos compared to the placebo group (RR, 1.26; 95% CI, 0.99–1.61). However, during 6-year follow-up after stopping supplements no effect of supplementation was found. In contrast, in the Women's Health Study (WHS), which looked at the effect of 600 IU  $\alpha$ -tocopherol (alternate days) in approximately 40,000 female nurses over a period of 10 years, a significant reduction in cardio-vascular deaths (RR, 0.76; 95% CI, 0.59–0.98), largely attributable to fewer sudden deaths, was observed.

### Secondary prevention

The most positive results from secondary prevention trials came from the Cambridge Heart Antioxidant Study (CHAOS), a controlled trial on 2002 heart disease patients with angiographically proven coronary atherosclerosis randomly assigned to receive a high dose of vitamin E (400 or 800 IU  $\text{d}^{-1}$ ) or placebo (Table 5). Those receiving the supplements were 77% less likely to suffer from nonfatal heart disease over the 1<sup>st</sup>-year trial period than those who did not receive vitamin E (RR, 0.23; 95% CI, 0.11–0.47), although there was no reduction in CVD deaths. However, other large secondary prevention trials with longer follow-up have been less encouraging. For example, in a further analysis of the ATBC study, the  $\beta$ -carotene supplementation was associated with an increased risk of CHD deaths among men who had a previous heart attack and were thus at high risk of subsequent coronary events. There were significantly more deaths from fatal CHD in the  $\beta$ -carotene group (RR, 1.75; 95% CI, 1.16–2.64) and in the combined  $\beta$ -carotene and vitamin E group (RR, 1.58; 95% CI, 1.05–2.40) compared to the placebo group. The Heart Outcomes Prevention Evaluation (HOPE) study observed no benefit from vitamin E supplementation (400 IU  $\text{d}^{-1}$ ) on CVD or all-cause mortality. The Heart Protection Study (HPS) in the UK examined the effect of 5 years of supplementation with a cocktail of anti-oxidant vitamins (600 mg vitamin E, 250 mg vitamin C, and 20 mg  $\beta$ -carotene) alone or in combination with the lipid-lowering drug Simvastatin or placebo in more than 20,000 adults with CHD, other occlusive arterial disease, or diabetes mellitus. Although blood levels of antioxidant vitamins were substantially increased, no significant reduction in the 5-year mortality from vascular disease or any other major outcome was noted. In the Italian GISSI-Prevenzione Trial dietary fish oils reduced the risk of fatal or nonfatal CVD in men and women who had recently suffered from a heart attack but vitamin E supplementation (300 mg daily for 3<sup>rd</sup> years) did not provide any benefit. In these three trials, no significant adverse effects of vitamin E were observed. The PSH II study was designed as a primary prevention study including more than 14,000 male physicians, 754 of which had prevalent CVD. Analysis of this subsample showed that there was a nonsignificant decrease of total CVD (HR 0.82, 95% CI, 0.63–1.09), myocardial infarction (MI) (HR 0.88, 95% CI, 0.50–1.55), stroke (HR 0.74, 95% CI, 0.47–1.16) and cardiovascular mortality risk (HR 0.91, 95% CI, 0.70–1.17) with vitamin E supplementation, and of MI (HR 0.57, 0.32–1.02) with vitamin C supplementation. In the Women's Antioxidant Cardiovascular Study (WACS) in over 8000 post-menopausal women with a history of CVD or at least cardiac risk factors, supplementation with Vitamin E,  $\beta$ -carotene nor vitamin C showed any effect on total cardio-vascular events, MI, stroke, or deaths.

Systematic reviews and meta-analyses of the clinical trials to date have therefore concluded that supplementation with any single antioxidant nutrient or combination of nutrients has not demonstrated any consistent benefit for the treatment or prevention of CVD.

**Table 4** Summary of large intervention trials (>1000 subjects) investigating the role of antioxidants and CVD in primary prevention.

<i>Trial</i>	<i>Characteristics of subjects</i>	<i>Sex</i>	<i>Length of follow-up (years)</i>	<i>Treatment</i>	<i>Effect of antioxidant supplementation</i>
ATBC	29,133 smokers, Finland	Male	6	50 mg $\alpha$ -tocopherol or 20 mg $\beta$ -carotene	No significant effect on fatal or nonfatal CHD or total strokes with either supplement increase in deaths from hemorrhagic stroke in vitamin E group increase in hemorrhagic stroke (+62%) and total mortality (+8%) in b-carotene group
CARET	14,254 smokers, 4060 asbestos workers, USA	Male and female	3	30 mg $\beta$ -carotene and 25,000 IU retinol	Increase in deaths from CVD (+26%) (terminated early)
LCPS	29,584 poorly nourished, China	Male and female	4	15 mg $\beta$ -carotene, 30 mg $\alpha$ -tocopherol, and 50 mg selenium	Small decline in total mortality (−9%)
NPCT	1004 subjects with nonmelanoma skin cancer but without CVD, USA	Male and female	7.6	200 mg selenium daily	No effect on total CVD events, MI, stroke, or CVD mortality reduction in deaths from stroke in men (−55%) but not women
PHS	22,071 physicians, USA	Male	12	50 mg $\beta$ -carotene or aspirin (alternate days)	No effect on fatal or nonfatal MI or stroke
PHS II	13,887 physicians, USA	Male	8	400 IU $\alpha$ -tocopherol (alternate days) or 500 mg ascorbic acid (daily) or placebo	No effect of vitamin E or vitamin C on CV events, MI, stroke, or CV mortality. Significantly increased risk of hemorrhagic stroke (+99%) with vitamin E
POPADAD	1276 adults with type 1 or type 2 diabetes and asymptomatic peripheral arterial disease, UK	Male and female	6.7	Antioxidant capsule (200 mg $\alpha$ -tocopherol, 100 mg ascorbic acid, 25 mg pyridoxine hydrochloride, 10 mg zinc sulfate, 10 mg nicotinamide, 0.4 mg lecithin, 0.8 mg sodium selenite) or 100 mg aspirin or placebo daily	No effect of antioxidant on CVD deaths or events
PPP	4495 with one or more CVD risk factors, Italy	Male and female	3 $\frac{1}{2}$	Low-dose aspirin or 300 mg $\alpha$ -tocopherol	No effect on CVD deaths or events (but inadequate power due to premature interruption of trial)
SCPS	1720 with recent nonmelanoma skin cancer, Australia	Male and female	8	50 mg $\beta$ -carotene	No effect on CVD mortality
SUVIMAX	13,017, France	Male and female	7.5	Combination of 120 mg ascorbic acid, 30 mg vitamin E, 6 mg of $\beta$ -carotene, 100 mg selenium, 20 mg zinc, daily	No effect on incidence of ischemic CVD
VACP II	1204 former asbestos workers, Australia	Male and female	5	30 mg $\beta$ -carotene or 25,000 IU retinol (no placebo group)	No effect of b-carotene on CHD deaths
WHS	39,876, United States	Female	2 10	50 mg $\beta$ -carotene (alternate days) 600 IU $\alpha$ -tocopherol (alternate days)	No effect on fatal or nonfatal CVD No effect on total CV events, MI or stroke significant 24% reduction in CV deaths (largely attributable to fewer sudden deaths)

<sup>a</sup>Secondary prevention is defined as including patients with known or documented vascular disease.

## Cancer

The oxidative hypothesis of carcinogenesis asserts that carcinogens generate ROS that damage RNA and DNA in cells, predisposing these cells to malignant changes and enhanced cancer risk. Most, but not all, damage is corrected by internal surveillance and repair systems involving dietary antioxidants, as well as endogenous antioxidant mechanisms. Antioxidants are therefore proposed to prevent cell damage by neutralizing free radicals and oxidants, thus preventing subsequent development of cancer.

### $\beta$ -carotene

Many of the randomized controlled trials (RCTs) investigating a protective role for antioxidant nutrients in cancer prevention (Table 6) have focused on  $\beta$ -carotene. A study in Linxian, China, of a rural population with poor nutritional status found that supplementation with a combination of  $\beta$ -carotene, selenium, and vitamin E for 5 years provided a 21% reduction in stomach cancer mortality and a 13% reduction in all cancer deaths. Although interesting, the population studied was likely to have very low intakes of a number of micro-nutrients and this study does not contribute to knowledge about the effects of individual antioxidants or offer any insight into their effects on populations with good nutritional status. The findings of a number of large double-blind RCTs in well-fed subjects using high-dose  $\beta$ -carotene supplements (either alone or in combination with other agents) have generally been unsupportive of any protective effect, although most have only focused on high-risk groups (e.g., smokers, asbestos workers, and older age groups), although newer studies provide data from the general population or subjects with a health issue not related to cancer risk (e.g., established CVD or CVD risk factors). In the ATBC Cancer Prevention Trial, in which 29,000 male smokers were randomly assigned to receive  $\beta$ -carotene,  $\alpha$ -tocopherol or placebo each day,  $\beta$ -carotene showed no protective effect on the incidence of any type of cancer after approximately 6 years. In fact, concern was raised following the publication of the findings of this trial because those randomized to receive  $\beta$ -carotene had an 18% higher risk of lung cancer (RR, 1.18; 95% CI, 3–36) as well as an 8% higher total mortality than nonrecipients. Subgroup analyses suggested that the adverse effect of  $\beta$ -carotene on lung cancer risk was restricted to heavy smokers and that the risk appeared to be transient, being lost at follow-up 4–6 years after cessation of supplementation.

The CARET was also terminated early because of similar findings; subjects receiving a combination of supplements (30 mg  $\beta$ -carotene and vitamin A daily) experienced a 28% increased risk of lung cancer incidence compared with the placebo group (RR, 1.28; 95% CI, 1.04–1.57). Subgroup analyses also suggested that the effect was found in current, but not former, smokers. In contrast, in the PHS, supplementation of male physicians with 50 mg  $\beta$ -carotene on alternate days had no effect on cancer incidence (men who were smokers did not experience any benefit or harm). The HPS also demonstrated no effect on 5-year cancer incidence or mortality from supplementation with 20 mg  $\beta$ -carotene in combination with vitamins E and C in individuals at high risk of CVD, despite increases in blood concentrations of these nutrients (plasma  $\beta$ -carotene concentrations increased 4-fold). They did not,

**Table 6** Summary of large intervention trials (>1000 subjects) investigating the role of antioxidants and cancer in primary prevention.

<i>Trial</i>	<i>Characteristics of subjects</i>	<i>Sex</i>	<i>Length of follow-up (years)</i>	<i>Treatment</i>	<i>Effect of antioxidant supplementation</i>
ATBC	29,133 smokers, Finland	Male	5–8	50 mg $\alpha$ -tocopherol or 20 mg $\beta$ -carotene	18% increase in lung cancer in $\beta$ -carotene group (no effect in vitamin E group) 34% reduction in incidence of prostate cancer in vitamin E group No effect of either vitamin on colorectal, pancreatic, or urinary tract cancer, or cancer of the oral cavity/pharynx, esophagus and larynx
CARET	14,254 smokers, 4060 asbestos workers, USA	Male and female	4	30 mg $\beta$ -carotene and 25,000 IU retinol	Lung cancer increased by 28%
HPS	20,536 at high CVD risk, UK	Male and female	>5	20 mg $\beta$ -carotene, 600 mg $\alpha$ -tocopherol, and 250 mg vitamin C	No effect on cancer incidence or mortality
LCPS	29,584 poorly nourished, China	Male and female	5	15 mg $\beta$ -carotene, 30 mg $\alpha$ -tocopherol, and 50 mg selenium	Cancer deaths declined by 13% Stomach cancer declined by 21%
NSCPT	1621 (73% without skin cancer at baseline), Australia	Male and female	4 1/2	30 mg $\beta$ -carotene with or without sunscreen application	No effect on basal cell or squamous cell carcinoma
PHS	22,071 physicians, United States	Male	12	50 mg $\beta$ -carotene or aspirin (alternate days)	No effect on incidence of malignant neoplasms or nonmelanoma skin cancer
SELECT	35,533, USA, Canada, and Puerto Rico	Male	5.5	200 mg selenium or 400 IU vitamin E or both	No effect of either treatment on prostate cancer incidence No effect on lung, colorectal and all other cancers, and cancer deaths
SUVIMAX	13,017, France	Male and female	7.5	Combination of 120 mg ascorbic acid, 30 mg vitamin E, 6 mg of $\beta$ -carotene, 100 mg selenium, 20 mg zinc, daily See above	No effect on overall cancer incidence in whole cohort, but significant reduction (–31%) of overall cancer incidence in men No effect on overall skin cancer incidence in total sample; but increased incidence in women taking antioxidants, not in men No effect on nonmelanoma skin cancer No effect on overall prostate cancer incidence Significant reduction (–48%) of prostate cancer in those with baseline PSA levels $<3 \mu\text{gL}^{-1}$
	5141 men, France	Male	8.5–9		
VACP II	1204 former asbestos workers, Australia	Male and female	5	30 mg $\beta$ -carotene or 25,000 IU retinol (no placebo group)	No effect of $\beta$ -carotene on cancer mortality
WHS	39,876, USA	Female	2 10	50 mg $\beta$ -carotene (alternate days) 600 IU $\alpha$ -tocopherol (alternate days)	No effect on cancer incidence No effect on overall cancer incidence and death, no effect on site-specific cancers (breast, lung, colon, rectum, and stomach)
WACS	7627 postmenopausal women with history of CVD or at least 3 cardiac risk factors, USA	Female	9.4	600 IU $\alpha$ -tocopherol or 50 g $\beta$ -carotene (both every other day) or 500 g vitamin C (daily)	No effect of any antioxidant on total cancer incidence and mortality. Higher lung cancer rates in vitamin C group (+84%)

LCPS, Linxian Cancer Prevention Study; NSCPT, Nambour Skin Cancer Prevention Trial; SELECT, Selenium and Vitamin E Cancer Prevention Trial; SUVIMAX, Supplementation en Vitamines et Minéraux Antioxydants (Vitamin and Mineral Antioxidant Supplementation Study); VACP, Vitamin A and Cancer Prevention; PSA, prostate-specific antigen.

however, find any harmful effects from these vitamins. The WACS in approximately 7600 postmenopausal women having established CVD or CVD risk factors showed no effect of supplementation with  $\beta$ -carotene (in combination with vitamin E or vitamin C or placebo) on total cancer incidence and mortality. Interestingly, the Vitamin and Mineral Antioxidant Supplementation Study (SUVIMAX) found a significant 31% reduction of total cancer incidence in men (RR 0.69, 95% CI, 0.53–0.91) taking a low-dose supplement containing  $\beta$ -carotene along with vitamin C, vitamin E, selenium, and zinc, but found no effect in women (RR 1.04, 95% CI, 0.85–1.29). The authors suggested that the difference in men and women may be explained by differences in nutrient

status at baseline, but that lower baseline status alone could not entirely explain the observed differences. In men, supplementation with this mixture of low-dose micronutrients showed no effect on overall prostate cancer incidence, but showed a significant reduction of prostate cancer (HR 0.52, 95% CI, 0.29–0.92) in those with baseline prostate-specific antigen (PSA) levels  $>3 \text{ mg L}^{-1}$  (high PSA levels can be an indicator for higher risk of prostate cancer or existing prostate cancer).

A number of trials have attempted to investigate the effect of  $\beta$ -carotene supplementation on nonmelanoma skin cancer, the most common forms of which are basal cell and squamous cell carcinomas (these types of cells are both found in the top layer of the skin). However, none have shown any significant effect on skin cancer prevention. For example, the PHS found no effect after 12 years of  $\beta$ -carotene supplementation on the development of a first nonmelanoma skin cancer. The Nambour Skin Cancer Prevention Trial (NSCPT) of 1621 men and women followed for nearly 5 years (most of whom had no history of skin cancer at baseline) showed that those supplemented with 30 mg  $\beta$ -carotene did not experience any reduction in risk of basal cell or squamous cell carcinoma or the occurrence of solar keratoses (precancerous skin growths that are a strong determinant of squamous cell carcinoma). The SUVIMAX found no effect of low-dose  $\beta$ -carotene along with vitamin C, vitamin E, selenium, and zinc on risk of skin cancer in the total sample, but found an increased frequency of skin cancer in the female group (1.3% vs. 0.7%,  $p = 0.02$ ). A 5-year trial of 1805 men and women with recent nonmelanoma skin cancer (the Skin Cancer Prevention Study) also found that supplementation with 50 mg of  $\beta$ -carotene gave no protection against either type of skin cancer, although this may have been because these cancers have a long latency period of approximately 12 years (Table 7).

Together, these trials suggest that  $\beta$ -carotene supplements offer no protection against cancer prevention in healthy individuals and, among smokers, may actually increase the risk of lung cancer. Investigators have sought to explain these findings by proposing that components of cigarette smoke may promote oxidation of  $\beta$ -carotene in the lungs, causing it to exert a pro-oxidant (rather than antioxidant) effect and act as a tumor promoter.

### Vitamin C

Only one RCT has investigated the effect of vitamin C alone in primary prevention of cancer. In the WACS trial 500 g of vitamin C per day for an average of 9.5 years had no effect on total cancer incidence and mortality in postmenopausal women with history of CVD or cardiac risk factors, but was associated with higher lung cancer rates in vitamin C group (RR 1.84, 95% CI 1.14–2.97). Data from a small number of trials of vitamin C in combination with other nutrients have not provided any support for a role for high-dose vitamin C supplementation in cancer prevention (Table 6). The Linxian trial found no significant effect of supplementing Chinese men and women with 120 mg vitamin C and 30 mg molybdenum daily for 5 years on the risk of cancers of the esophagus or stomach. The polyp prevention study, a trial of 864 patients with previous adenoma, found no effect of either  $\beta$ -carotene or a combination of vitamins E and C (1000 mg) on the incidence of subsequent colorectal adenomas. The HPS also found no beneficial effects of supplementation with these three vitamins on cancer mortality. However, trials have generally been carried out on those with diets containing sufficient amounts of vitamin C and there is a need for further studies in people with low intakes. As mentioned above, in the SUVIMAX study a low-dose supplement containing vitamin C along with  $\beta$ -carotene, vitamin E, selenium, and zinc found a significant reduction in total cancer incidence in men (RR 0.69, 95% CI, 0.53–0.91) but not in women.

### Vitamin E

The ATBC trial showed no significant effect of  $\alpha$ -tocopherol supplementation ( $50 \text{ mg d}^{-1}$ ) on risk of lung, pancreatic, colorectal, or urinary tract cancers among heavy smokers (Table 6). However, in a post hoc subgroup analysis a 34% reduction in the risk of prostate cancer was seen in men who received this supplement. Although interesting, prostate cancer was not a primary endpoint of this

**Table 7** Summary of large intervention trials ( $>1000$  subjects) investigating the role of antioxidants and cancer in secondary prevention<sup>a</sup>.

Trial	Characteristics of subjects	Sex	Length of follow-up (years)	Treatment	Effect of antioxidant supplementation
NPCT	1312 with history of basal or squamous cell carcinoma, United States	Male and female	4 1/2	200 mg selenium	No effect on incidence of skin cancer overall increased risk of squamous cell carcinoma (+25%) and of total nonmelanoma skin cancer (+17%) reduced cancer mortality (–50%), cancer incidence (–37%), prostate cancer (–63%), colorectal cancer (–58%), and lung cancer (–46%)
SCPS	1805 with recent nonmelanoma skin cancer, USA	Male and female	5	50 mg $\beta$ -carotene	No effect on occurrence of new nonmelanoma skin cancer

NPCT, Nutritional Prevention of Cancer Trial; SCPS: Skin Cancer Prevention Study.

<sup>a</sup>Secondary prevention defined as subjects with documented cancer including nonmelanoma skin cancer (although some of the primary prevention trials did not exclude those with nonmelanoma skin cancer at baseline).

study. In the Selenium and Vitamin E Cancer Prevention Trial (SELECT) study, where prostate cancer was the primary outcome, no effect of vitamin E supplementation over a period of 5.5 years in around 35,000 men was found. In this study, no effect on any other cancer site was observed, including lung, colorectal and all other cancer sites, and there was no effect on cancer death rates. The WHS and WACS trials, both carried out in women, also found no effect of vitamin E supplementation on overall cancer incidence or deaths. The HPS found no effect of vitamin E in combination with vitamin C and  $\beta$ -carotene on cancer incidence or mortality, and the SUVIMAX study found a reduction of total cancer incidence in men but not women with low dose vitamin E along with vitamin C,  $\beta$ -carotene, selenium, and zinc. Two smaller, short-term intervention studies found no effect of  $\alpha$ -tocopherol supplementation on mammary dysplasia or benign breast disease. Several trials have also been unable to demonstrate a protective effect of vitamin E supplementation on the risk or recurrence of colorectal adenomatous polyps.

### Selenium

A few trials have suggested that selenium supplementation may have a protective effect on liver cancer in high-risk groups living in low-selenium areas. For example, the provision of selenium-fortified salt to a town in Qidong, China, with high rates of primary liver cancer, reduced the incidence of this cancer by 35% compared with towns that did not receive this intervention. Some trials have also demonstrated the incidence of liver cancer to be significantly reduced in subjects with hepatitis B and among members of families with a history of liver cancer receiving a daily supplement of 200 mg of selenium for 4 and 2 years, respectively. The Nutritional Prevention of Cancer Trial (NPCT) in the US also supported a possible protective role of selenium in 1312 patients (mostly men) with a previous history of skin cancer who were supplemented with 200 mg selenium per day for 4<sup>1</sup> years (Table 7). Those receiving selenium demonstrated significant reductions in the risk of total cancer incidence (37%) and mortality (50%) compared to those receiving placebo. The selenium-treated group also had substantial reductions in the incidence of lung, colorectal, and prostate cancers of 46, 58, and 63%, respectively. However, recurrent squamous cell carcinoma was increased by 25% and total non-melanoma skin cancer by 17%. Further analysis showed the protective effect on prostate cancer to be confined to those with lower baseline PSA and plasma selenium levels. However, the SELECT study, one of the largest human cancer prevention trials ever undertaken in 45,533 healthy males from the US, Puerto Rico, and Canada, found no effect of 200 mg of selenium on prostate cancer, lung cancer, colorectal cancer and all other cancers, or on cancer deaths. Comparison of this study to other clinical trials involving selenium and to animal studies suggests that the source of the selenium supplement, L-selenomethionine, and the relatively high initial levels of selenium in the enrolled men may have contributed to this outcome.

## Other diseases associated with oxidative damage

### Type 2 diabetes

Type 2 diabetes is associated with elevated oxidative stress (especially lipid peroxidation) and declines in antioxidant defense. This is thought to be due in part to elevated blood glucose levels (hyperglycemia), but severe oxidative stress may also precede and accelerate the development of type 2 diabetes and then of diabetic complications (CVD and microvascular complications such as retinopathy, neuropathy, and nephropathy).

Some of the trials looking at antioxidants and CVD and cancer have also reported on the association of the examined antioxidants and the risk of diabetes. In the WACS women with a history of CVD or at least 3 CVD risk factors but free of diabetes at baseline ( $n = 6574$ ) received 500 mg vitamin C daily, or 600 IU  $\alpha$ -tocopherol every other day, or 50 mg  $\beta$ -carotene every other day. During a median follow-up of 9.2 years no significant effect of any of the treatments could be found: RR in vitamin C group was 0.89 (95% CI, 0.78–1.02), RR in vitamin E group 1.13 (95% CI, 0.99–1.29) and RR in  $\beta$ -carotene group 0.97 (95% CI, 0.85–1.11). Analysis of data from the ATBC study in 27,379 smokers free of diabetes at baseline showed that neither supplementation with  $\alpha$ -tocopherol (50 mg d<sup>-1</sup>) nor with  $\beta$ -carotene (20 mg d<sup>-1</sup>) for 5–8 years had an effect on diabetes risk over a median follow-up of 12.5 years. Data from the WHS from almost 39,000 healthy women free of diabetes, cancer, and CVD at baseline and receiving either 600 IU of  $\alpha$ -tocopherol or placebo on alternate days showed no effect of study treatment on diabetes risk over a median follow-up period of 10 years. In a smaller study, the NPCT, in 1202 participants with a history of non-melanoma skin cancer but no baseline diabetes treatment with 200 mg d<sup>-1</sup> selenium was associated with an increased risk of developing diabetes (HR 1.55, 95% CI, 1.03–2.33) after an average follow-up of 7.7 years.

Small-scale human trials have shown administration of high doses of vitamin E to reduce oxidative stress and improve some CVD risk factors, such as blood glycated hemoglobin, insulin, and triglyceride levels, in people with diabetes. Such trials have also indicated benefit from vitamin E in improving endothelial function, retinal blood flow, and renal dysfunction. However, the findings of large clinical trials investigating the role of individual or a combination of antioxidant nutrients in reducing the risk of CVD and microvascular complications in people with diabetes have generally been disappointing. For example, the HOPE trial investigated the effects of vitamin E and the drug Ramipril in patients at high risk for CVD events and included a large number of middle-aged and elderly people with diabetes (more than 3600). An average of 4<sup>1</sup> years of supplementation with 400 IU of vitamin E per day was found to exert no beneficial or harmful effect on CVD outcomes or on nephropathy. The Primary Prevention Project (PPP) trial found no effect of vitamin E (300 mg d<sup>-1</sup>) supplementation for 3 or 4 years in diabetic subjects, and the HPS, which included a number of people with diabetes, also reported no benefit of a combination of antioxidant vitamins on mortality or incidence of vascular disease. In the ATBC study, no effect of supplementation with  $\alpha$ -tocopherol (50 mg d<sup>-1</sup>) nor

$\beta$ -carotene ( $20 \text{ mg d}^{-1}$ ) was found during the intervention period (median 6.1 years) on the risk of macro-vascular complication or total mortality in 1700 men with type 2 diabetes at baseline. No essential changes were found in these effects when the follow-up was extended up to 19 years. In another study, the Prevention of Progression of Arterial Disease and Diabetes (POPADAD) study, no effect of an antioxidant capsule (containing 200 mg  $\alpha$ -tocopherol, 100 mg vitamin C, 25 mg pyridoxine hydrochloride, 10 mg zinc sulfate, 10 mg nicotinamide, 9.4 mg lecithin, and 0.8 mg sodium selenite) was found on CVD risk in 1276 adults with type 1 or type 2 diabetes and an ankle brachial pressure index of 0.99 or less but no symptomatic CVD at baseline over a median follow-period of 6.7 years. However, a meta-analysis of two studies reporting by diabetes subtype, the Haptoglobin (Hp) 2-2 genotype which is characterized by a markedly increased risk of CVD compared to other types, found that patients with Hp 2-2 diabetes taking vitamin E supplements reduced the risk of cardiovascular events (combined odds ratio (OR) 0.58, 95% CI 0.40–0.86).

### Asthma and chronic obstructive pulmonary disease (COPD)

Asthma is a chronic inflammatory disease resulting in reversible airways bronchoconstriction which affects a large number of children and adults. Epidemiological studies suggest that intake and status of antioxidant nutrients are inversely associated with the risk of asthma and wheezing. A number of studies have also demonstrated a beneficial effect of fruit and vegetable intake on lung function. For example, regular consumption of fresh fruit rich in vitamin C (citrus fruits and kiwi) has been found to have a beneficial effect on reducing wheezing and coughs in children.

In COPD patients, many of the pathophysiological changes associated with the disease are produced through the generation of oxygen free radicals by activated inflammatory cells. Antioxidant nutrients have therefore been suggested to play a role in the prevention and treatment of these conditions. Common examples of COPD are emphysema and chronic bronchitis. COPD mainly affects smokers or people with a smoking history.

Vitamin C is the major antioxidant present in extracellular fluid lining of the lung, and intake in the general population has been inversely correlated with the incidence of asthma, bronchitis, and wheezing and with pulmonary problems. Although some trials have shown high-dose supplementation ( $1\text{--}2 \text{ g d}^{-1}$ ) to improve symptoms of asthma in adults and protect against airway responsiveness to viral infections, allergens, and irritants, this effect has been attributed to the antihistaminic action of the vitamin rather than to any anti-oxidant effect. The results of these trials have also been inconsistent, and a Cochrane review of nine RCTs concluded that there is insufficient evidence to recommend a specific role for vitamin C in the treatment of asthma. However, a need for further trials to address the question of the effectiveness of vitamin C in asthmatic children was highlighted.

Other dietary antioxidants have been positively associated with lung function in cohort studies but the findings of clinical trials have been mixed. In a study of 158 children with moderate to severe asthma, supplementation with vitamin E ( $50 \text{ mg d}^{-1}$ ) and vitamin C ( $250 \text{ mg d}^{-1}$ ) led to some improvement in lung function following ozone exposure. A study in 72 adults with asthma receiving 500 mg vitamin E daily for 6 weeks did not show any effect on bronchial re-activity to methacholine, lung function, morning peak flow, or any other outcome measures. A Cochrane review looking at selenium and asthma only identified one study meeting their pre-defined criteria. The study in 24 patients suffering from chronic asthma found that  $100 \text{ mg d}^{-1}$  of selenium for 14 days was associated with significant improvements in subjective asthma symptoms but this improvement could not be validated by significant changes in the separate clinical parameters of lung function and airway hyperresponsiveness. A subsequent RCT in 197 participants found no effect of 100 mg daily for 24 weeks on asthma-related quality of life, lung function, asthma symptom scores, or any other outcome measures. The ATBC trial found no benefit from supplementation with  $\alpha$ -tocopherol ( $50 \text{ mg d}^{-1}$ ) and  $\beta$ -carotene ( $20 \text{ mg d}^{-1}$ ) on symptoms of COPD, despite the fact that those with high dietary intakes and blood levels of these vitamins at baseline had a lower prevalence of chronic bronchitis and dyspnea.

### Macular degeneration and cataracts

The eye is at particular risk of oxidative damage due to high oxygen concentrations, large amounts of oxidizable fatty acids in the retina, and exposure to ultraviolet rays. In Western countries, age-related macular degeneration (AMD) is the leading cause of blindness among older people. Cataracts are also widespread among the elderly and occur when the lens is unable to function properly due to the formation of opacities within the lens. These develop when proteins in the eye are damaged by photooxidation; these damaged proteins build up, clump, and precipitate. It has been proposed that antioxidants may prevent cellular damage in the eye by reacting with free radicals produced during the process of light absorption.

The results of intervention trials in this area have also been mixed. The age-related eye disease study in the US investigating the effects of combined antioxidant vitamins C (500 mg), E (400 IU), and  $\beta$ -carotene (15 mg) with and without 80 mg zinc daily for 6 years showed some protective effect (a reduction in risk of approximately 25%) on the progression of moderately advanced AMD but no benefit on the incidence or progression or early AMD or cataracts. Further analysis of the data showed that an individual's response could be related to a specific genotype. The lutein antioxidant supplementation trial, a 12-month study of 90 patients with AMD, found significant improvements in visual function with  $10 \text{ mg d}^{-1}$  lutein (one of the major carotenoids found in the pigment of a normal retina) alone or in combination with a number of other antioxidant nutrients. The Roche European Cataract Trial, providing a combined daily supplement of  $\beta$ -carotene, vitamin C, and vitamin E among adults with early signs of age-related cataract, showed a small deceleration in the progression of cataract after 3 years.

However, the Linxian trial found no influence of vitamin supplementation on risk of cataract; the ATBC trial found no reduction in the prevalence of cataracts with vitamin E,  $\beta$ -carotene, or both among male smokers; and the PHS of more than 22,000 men

showed no benefit from 12 years of supplementation with  $\beta$ -carotene (50 mg on alternate days) on age-related maculopathy or cataract incidence. In fact, current smokers at the beginning of this trial who received the supplement experienced an increased risk of cataract (by approximately 25%) compared to the placebo group. The Vitamin E, Cataract, and Age-Related Maculopathy Trial also reported no effect of supplementation with vitamin E for 4 years (500 IU d<sup>-1</sup>) on the incidence or progression of cataracts or AMD.

### **Immune function—common cold**

Antioxidants, vitamins, and minerals have also been linked with immune function. Deficiency of these nutrients, including vitamin C, vitamin E, vitamin A, selenium, and zinc, has been associated with compromised immune function. A Cochrane systematic review looked at the effects of the use of vitamin C supplements on the incidence of colds in the normal population. Based on 30 trials including almost 12,000 study participants on the use of vitamin C supplements (doses from 200 mg or higher), the reviewers concluded that supplements did not reduce the incidence of colds in the normal population. Vitamin C supplementation taken for prophylaxis reduced the duration of common cold symptoms by 8% in adults and by 13.6% in children, but no effect was found when vitamin C was taken therapeutically (i.e., after the onset of the common cold). Despite the lack of effectiveness in reducing the risk of a common cold infection in the normal population, vitamin C supplementation could reduce the risk of a common cold by half in study participants exposed to short periods of extreme physical or cold stress, or both (including marathon runners and skiers). In the ATBC study long-term vitamin E and  $\beta$ -carotene supplementation had no overall effect on common cold incidence. Among subjects aged 65 years or older, the incidence of colds was slightly lower in the vitamin E group compared with the control (unsupplemented) group (RR ¼ 0.95; 95% CI ¼ 0.90–1.00); this reduction was greatest among older city dwellers who smoked fewer than 15 cigarettes per day (RR ¼ 0.72; 95% CI ¼ 0.62–0.83). A Cochrane review on the use of zinc for common cold treatment based on seven studies including around 800 study participants concluded that, overall, treatment with zinc lozenges did not reduce the duration of cold symptoms.

### **Possible explanations for the disagreement between the findings of observational studies and clinical trials**

Various explanations have been given for the different findings of observational studies and intervention trials. Clearly, non-randomized studies are unable to exclude the possibility that antioxidants are simply acting as a surrogate measure of a healthy diet or lifestyle and that the protective effect of certain dietary patterns, which has been presumed to be associated with dietary antioxidants, may in fact be due to other compounds in plant foods, substitution of these foods for others, or a reflection of other health behaviors common to people who have a high fruit and vegetable intake. However, although intervention studies provide a more rigorous source of evidence than observational studies, they are not without weaknesses from a nutritional perspective. Many of the trials to date have been criticized for their use of high-risk populations and high doses of single supplements, insufficient duration of treatment, and follow-up and lack of consideration of the impact of genetic variability. More recent trials that have attempted to answer some of these criticisms. For example, SUVIMAX was designed to assess the efficacy of supplementation among more than 12,000 healthy men and women over a 7.5-year period with a cocktail of antioxidant vitamins and minerals at doses achievable by diet (approximately one to three times the daily recommended dietary allowances) on premature death from CVD and cancer. This low-dose anti-oxidant supplementation had no effect on vascular disease incidence but lowered total cancer incidence in men, but not in women. This suggests that the contradictory results of observational and interventional studies may be due to differences in the effects of antioxidants in relation to supplement doses (nutritional vs. pharmacological), baseline antioxidant status (different between gender or nutritional status), and health status of subjects (healthy vs. cancer high-risk subjects). This study concluded that antioxidant supplementation may have a beneficial effect on cancer incidence only in healthy subjects who are not exposed to cancer risk, and with a particularly low baseline status. In contrast, high doses of anti-oxidant supplements may be deleterious in high-risk subjects without any clinical symptoms in whom the initial phase of cancer development has already started. Studies are also now attempting to look at genetic variation by studying the effects of antioxidants in individuals with specific genotypes. For example, in a meta-analysis of two trials (Hope and ICARE), vitamin E supplementation was associated with reduced risk of CVD in individuals with diabetes mellitus and the haptoglobin 2-2 genotype, both of which are associated with increased risk of the disease.

### **Conclusion**

Although there is a substantial body of evidence that diets rich in plant foods (particularly fruit and vegetables) convey health benefits, as do high plasma levels of several antioxidant nutrients found in these foods, a causal link between lack of antioxidants and disease occurrence or between antioxidant administration and disease prevention remains to be established. There is a lack of understanding of the mechanisms underpinning the apparent protective effect of plant foods and, as yet, no clear picture of which components are effective and hence no way of predicting whether all or just some plant foods are important in this respect.

If future trials do demonstrate a reduction in chronic disease risk with antioxidant supplementation, this cannot be definitively attributed to the antioxidant effect of these nutrients because other biological functions may also play a role. For example, in

addition to retarding LDL oxidation, vitamin E may help to protect against CVD *via* its action on platelet aggregation and adhesion or by inhibition of the proliferation of smooth muscle cells. Vitamin E and other nutrients that are classified as antioxidants have also been shown to modulate pathways of cell signaling and gene expression. Furthermore, although vitamin C, vitamin E, and selenium have been shown to decrease the concentration of some of the biomarkers associated with oxidative stress, the relationship between many of these biomarkers and chronic disease remains to be elucidated.

The intervention studies highlight the lack of information on the safety of sustained intakes of moderate to high doses of micro-nutrient supplements and long-term harm cannot be ruled out, particularly in smokers. Further evidence is required regarding the efficacy, safety, and appropriate dosage of anti-oxidants in relation to chronic disease. Currently, the most prudent public health advice continues to be to consume a variety of plant foods.

## Glossary

**Bioavailability** The fraction of absorbed and utilized micronutrient.

**Bioconversion** The rate at which absorbed provitamin A is cleaved to vitamin A in the intestine.

**Bioefficacy** Combines absorption and bioconversion and is the efficiency with which ingested dietary provitamin A carotenoids are absorbed and converted to vitamin A.

**Biofortification** Agronomically improving stable crops by enhancing micronutrient levels through traditional breeding or genetic modification.

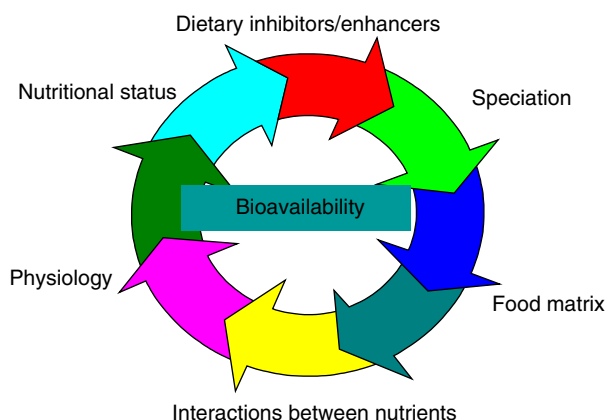

**Stable isotope** Nonradioactive isotope.

## Introduction

Bioavailability refers to the fraction of absorbed and utilized micronutrient. This concept is particularly important for some micronutrients, e.g., nonheme iron, zinc, provitamin A carotenoids, folate, and vitamin B<sub>12</sub> as bioavailability varies widely depending on a number of factors. These factors include nutritional status, physiological factors such as gastric acid secretion, food matrix, and interactions between nutrients in addition to the presence of enhancers and inhibitors in the diet (**Figure 1**). Stable (nonradioactive) isotope techniques to assess micronutrient bioavailability have been developed over the last 20 years or so and the application of these techniques has contributed significantly to our understanding of the importance of bioavailability in micronutrient nutrition. As stable isotope techniques do not expose the study population, or the investigators, to any potential health hazard related to ionizing radiation, studies in vulnerable population groups at high risk of developing micronutrient deficiencies are feasible. Consequently, over the last 10–15 years, crucial new information, for example, about dietary enhancers and inhibitors of nonheme iron absorption in infants and children has been made available, and important data have been generated on nonheme iron bioavailability from iron compounds used in food fortification programs. In vitamin A nutrition, the development of stable isotope techniques to estimate body pool sizes of vitamin A has provided new important information on the bioefficacy of provitamin A carotenoids and the influence of dietary composition, as well as the nutritional status of the consumer, on provitamin A bioavailability.

## Nonheme Iron Bioavailability

Fractional absorption of nonheme iron varies widely in individuals, from less than 1% to 100%, depending on the nutritional status and physiological factors of the individual as well as the composition of the test meal (see **Figure 1**). From a methodological point of view, the rapid incorporation of newly absorbed iron into a target tissue, which can be sampled relatively easily, i.e., erythrocytes,

**Figure 1** Factors influencing bioavailability of nonheme iron and provitamin A carotenoids.

is a major advantage, and a stable isotope technique to evaluate iron bioavailability has been developed based on the incorporation of stable iron isotopes into red blood cells 14 days after administration of labeled test meals. This methodology was originally developed by investigators using radioactive isotopes of iron, and the development of stable isotope technique has benefited greatly from this original work related to the development of the study protocol (defining the appropriate times for blood sampling, collecting data on incorporation rates etc.). Usually, the incorporation rate of newly absorbed iron into erythrocytes is assumed to be relatively constant, approximately 80–90% (see [Figure 2](#)). However, when the incorporation rate cannot be assumed to remain stable, for example, during pregnancy or in individuals infected with malaria, incorporation of a stable isotope administered intravenously can be used to correct for changes in incorporation rate.

Considerable interindividual variation in iron bioavailability has been demonstrated, largely due to differences in iron status among individuals, and paired comparisons are therefore essential when evaluating iron bioavailability from different foods or food fortificants. Using a double isotope technique, i.e., administration of two stable isotopes of iron (usually  $^{57}\text{Fe}$  and  $^{58}\text{Fe}$ ) – on consecutive days – information about iron bioavailability from two different test meals can be obtained simultaneously ([Figures 3 and 4](#)). When evaluating bioavailability from iron compounds used for food fortification, ferrous sulfate is typically used as the reference compound and relative bioavailability is reported, i.e., bioavailability from ferrous sulfate is set at 100% and bioavailability of other compounds are compared to this value ([Table 1](#)). Blood samples drawn at baseline and 14 days after administration are analyzed for  $^{57}\text{Fe}$ - and  $^{58}\text{Fe}$ -enrichment by Thermal Ionization Mass Spectrometry (TIMS) or High Resolution Inductively Coupled Plasma Mass Spectrometry. Although the number of suitable mass spectrometers dedicated to nutrition remains limited worldwide, the application of this technique has been used in a wide range of settings, based on close North–South collaboration. The recently installed TIMS in Bangalore, India, will hopefully increase the application of this technique in Asia. Successful implementation of stable isotope studies depend on joint efforts made by a group of people, including analytical chemists, nutritionists, and relevant health professionals such as pediatricians, nurses, and health workers. As many different steps are crucial – both during the preparation for the study, i.e., development of study protocols, preparation of test meals, preparation of stable isotope doses, administration of labeled test meals – as well as in the final analysis of enriched blood samples – a multi-disciplinary team is clearly needed to plan and implement this kind of study.

Over the last 10–15 years, stable isotope technique has been used to generate new data on iron bioavailability from iron compounds used in food fortification programs and information about dietary enhancers and inhibitors of iron absorption in

**Figure 2** Newly absorbed iron is rapidly incorporated into red blood cells (RBC) at a relatively constant, high rate.

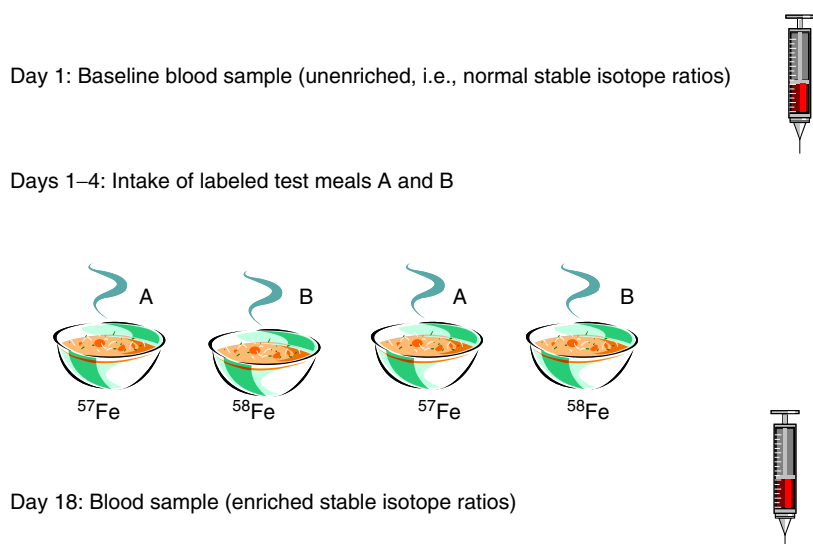

**Figure 3** Basic principles of the double stable isotope technique to evaluate iron bioavailability based on incorporation into red blood cells (RBC).

vulnerable population groups. More information about the importance of bioavailability of nonheme iron in the development of food-based strategies to combat iron deficiency, i.e., food fortification and dietary diversification, is provided below.

### Bioavailability as an Important Component in the Development of Food-Based Strategies to Combat Iron Deficiency: Food Diversification

A number of dietary factors influencing nonheme iron bioavailability were identified during the earlier studies using radioactive isotopes of iron, as well as more recent data based on stable isotope technique. Inhibitors include phytic acid, polyphenols, and calcium, as well as some proteins, whereas ascorbic acid and muscle tissue (the ‘meat factor’) enhance nonheme iron absorption. More recently, the importance of host factors such as nutritional deficiencies, infection/inflammation, and genetic disorders has received more attention, and there is clearly a need to further investigate the importance of these factors in different population groups. The identification of hepcidin as a key regulator of iron homeostasis highlights the need for future studies to investigate the role of this peptide and its increased expression during chronic inflammation and obesity on iron absorption. In addition, in spite of numerous studies, including studies to evaluate the potential influence of vitamin A on nonheme iron bioavailability in healthy Western adults and African children with subclinical vitamin A deficiency, the influence of vitamin A and provitamin A carotenoids on nonheme iron absorption still remains largely unknown.

The importance of optimizing nonheme iron bioavailability from the diet can be assumed to be crucial for individuals with high requirements and consuming inhibitory diets, in particular, infants and young children in developing countries. The positive effect of adding meat to a vegetable-based complementary food on nonheme iron bioavailability has been demonstrated in European infants and the inclusion of meat into the diet of young children would thus be beneficial by providing highly bioavailable heme iron as well as by enhancing the bioavailability of nonheme iron. However, meat is often not available or affordable and,

**Figure 4** Study design to evaluate iron bioavailability from test meals A and B.

**Table 1** Examples of data on relative iron bioavailability in adult humans

Compound	Relative iron bioavailability (%)
Ferrous sulfate	100
Sodium iron EDTA	>100
Ferrous fumarate	100
Ferric pyrophosphate	21–74
Elemental iron; electrolytic	75

[http://www.who.int/nutrition/publications/guide\\_food\\_fortification\\_micronutrients.pdf](http://www.who.int/nutrition/publications/guide_food_fortification_micronutrients.pdf)

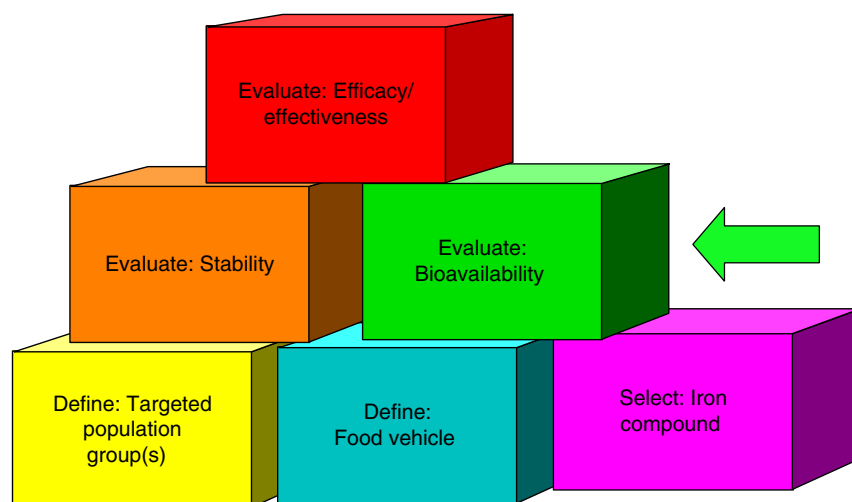

thus, infants and young children living in resource poor communities where monotonous, cereal-based diets are consumed are of special concern.

Stable isotope technique has been used to demonstrate the potent inhibitory effect of phytic acid as well as the strong enhancing effect of ascorbic acid on nonheme iron bioavailability in infants. Dephytinization of cereals and legumes can be made by the addition of exogenous phytase or by the use of whole-grain cereals as a source of phytase, and ascorbic acid can be included into the diet by consumption of fruits, in particular citrus fruits rich in vitamin C. However, inclusion of fruits into the young child's diet can be limited by availability, affordability, and tradition. An alternative source of ascorbic acid in the diet of African infants and young children was identified – human milk – and subsequently tested for its effect on nonheme iron bioavailability from a traditional complementary food in Bangladesh, using stable isotope technique. Although human milk contributed considerable amounts of ascorbic acid, no significant effect on iron bioavailability was observed, indicating that components in human milk modify the influence of ascorbic acid. A more recent study confirmed the potent enhancing effect of ascorbic acid on nonheme iron bioavailability in Pakistani infants and clearly demonstrated that breastfeeding immediately after intake of a complementary food with added ascorbic acid does not blunt the enhancing effect of the vitamin when evaluated by stable isotope technique.

### Bioavailability as an Important Component in the Development of Food-Based Strategies to Combat Iron Deficiency: Food Fortification

Food fortification is currently implemented as a public health strategy to combat iron deficiency in many countries, either by fortification of staple foods such as milled cereal flours to reach a large proportion of the population or by targeted approaches based on fortification of products consumed by vulnerable population groups, e.g., fortified commercial infant foods. More recently, other approaches have been developed to reach individuals, in particular, infants and young children, who do not have access to centrally produced foods by providing micronutrients in sachets, crushable tablets, and spreads for 'in-home fortification'.

The concept of bioavailability is central to the development of food fortification strategies as the overall impact of a food fortification program on the consumers' iron status will be influenced by the bioavailability of the iron compound used as well as the presence of inhibitors and enhancers of iron absorption in the diet. Information about bioavailability of iron compounds represents an integral part of the development of food fortification strategies, together with careful selection of the food vehicle and testing of changes to the organoleptic properties of the fortified food (Figure 5). These findings include important information on significant

**Figure 5** Components of an iron fortification program.

**Figure 6** Examples of iron compounds with different solubility, ranging from freely soluble in water to poorly soluble in dilute acid.

differences in iron bioavailability between iron compounds, with different physicochemical properties such as solubility in water and dilute acid (**Figure 6**). For example, stable isotope technique has been used to demonstrate a three-fold difference in iron bioavailability from iron compounds with different solubility properties used to fortify infant cereals in different parts of the world, i.e., ferrous fumarate and ferric pyrophosphate, in infants. In addition, substantially lower relative bioavailability of ferrous fumarate versus ferrous sulfate has been noted in preschool children in Bangladesh (approximately 30%) as compared to that in Western adult women (100%). These observations clearly highlight the importance of studies in appropriate population groups as opposed to extrapolating data from other groups, e.g., healthy adults in the North to infants and young children in the South, who are less well-nourished and have lower gastric acid output. Furthermore, stable isotope technique has been applied to demonstrate the usefulness of NaFeEDTA for fortification of high extraction rate cereal flours and condiments such as fish sauce and soy sauce. This technique has also been used to evaluate different strategies to optimize iron bioavailability from fortified foods consumed by children, for example, by the addition of enhancers such as ascorbic acid or NaEDTA.

The World Health Organization (WHO) and the Food and Agriculture Organization of the United Nations (FAO) have developed guidelines to assist in the development and evaluation of food fortification programs. The importance of bioavailability data to optimize the impact of food fortification by selecting iron compounds with high relative bioavailability as well as by modifying the composition of the diet to increase iron absorption, is highlighted in these guidelines. In particular, the potent enhancing effect of ascorbic acid and the strong inhibitory effect of phytic acid are emphasized. Briefly, these recommendations provide a list of iron fortificants (based on relative bioavailability data) in the following order of preference: (1) ferrous sulfate, (2) ferrous fumarate, (3) encapsulated ferrous sulfate or fumarate, (4) electrolytic iron, and (5) ferric pyrophosphate. To compensate for low relative bioavailability from electrolytic iron and ferric pyrophosphate, it is recommended to add twice the amount. In addition, it is recommended to add ascorbic acid at a 2:1 molar ratio; for foods high in phytic acid, the molar ratio should be increased to 4:1 to counteract the inhibitory effect of phytic acid. NaFeEDTA is recommended for fortification of cereal flours high in phytic acid and for certain condiments such as fish sauce and soy sauce.

## Bioavailability of Provitamin A Carotenoids

### Carotenoids

Carotenoids are responsible for the colors of many fruits and vegetables. Bioavailability of carotenoids from food sources is an active area of research because of purported health benefits. For example, a diet high in fruit and vegetables, which are high in carotenoids, is related to a reduced risk of various types of cancer. Many factors are known to impact the bioavailability of these fat-soluble compounds from food. Evidence exists that the structure of the carotenoid impacts its ability to become part of the lipid complex (i.e., micelle) that makes it easily absorbed by the human body. The hydroxyl-group containing carotenoids tend to be more bioavailable than the hydrocarbon carotenoids. Cooking enhances carotenoid bioavailability by disrupting the vegetable matrix, but prolonged heat destroys them or changes the structural configuration. The isomeric form of  $\beta$ -carotene impacts its bioavailability and the forms that are 'bent' or in the *cis* configuration are less bioavailable than the 'straight' or all-*trans* forms.

Provitamin A carotenoids number approximately 50 in nature, but only three of these are common in the human diet, namely,  $\alpha$ -carotene,  $\beta$ -carotene, and  $\beta$ -cryptoxanthin (**Figure 7**).  $\alpha$ -Carotene is found predominantly in carrots and some squashes,  $\beta$ -carotene in orange vegetables and green leafy vegetables, and  $\beta$ -cryptoxanthin in citrus fruits and yellow maize.

### Bioconversion of Carotenoids to Vitamin A

The process of producing vitamin A from provitamin A carotenoids is termed bioconversion. The nutritional status of the person impacts whether or not the provitamin A carotenoids are converted to vitamin A. For example, if a person is vitamin A deficient they

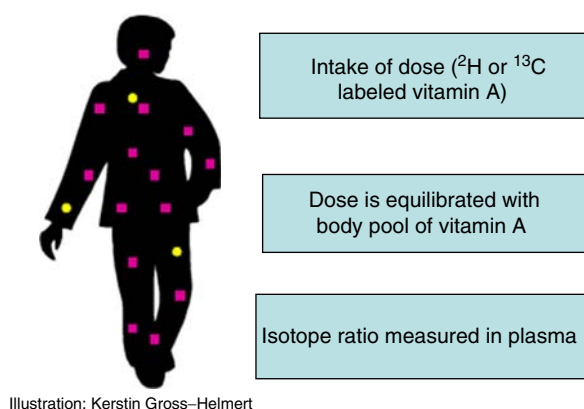

**Figure 7** Chemical structures of provitamin A carotenoids in comparison to retinol.  $\beta$ -Carotene is able to supply two molecules of retinol, whereas  $\alpha$ -carotene and  $\beta$ -cryptoxanthin supply one.

will convert more of the absorbed provitamin A carotenoids to vitamin A. However, if the person is zinc deficient, less provitamin A will be converted to vitamin A because the enzyme that cleaves the provitamin A carotenoids to vitamin A is zinc dependent.

### Bioavailability of Carotenoids

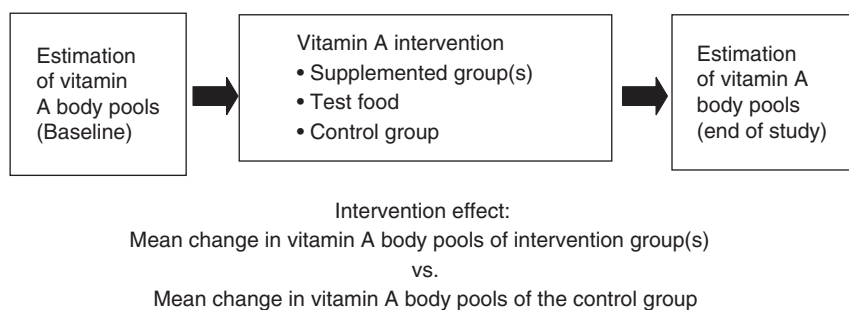

Bioavailability is often measured by looking at differences in serum carotenoid concentrations. However, this only determines relative differences between two comparisons. Stable isotope techniques to evaluate vitamin A status were developed to use in vulnerable populations. The method involves administering a dose of isotopically labeled tracer and waiting for the dose to equilibrate with body pools of vitamin A, usually two to three weeks (Figure 8). Basically, the method is an indirect measure of liver reserves of vitamin A, and the test does require blood samples. Typically a blood sample is taken at baseline and then after equilibration to measure the change in enrichment caused by the administered isotope. The application of stable isotope techniques to evaluate changes in vitamin A body pools has contributed significantly to the evaluation of interventions based on provitamin A carotenoids. The principles of the study design used for these applications are described in Figure 9. In practice, two stable isotopes have been used including the heavy isotope of hydrogen, deuterium, and the heavy isotope of carbon, carbon 13. Usually, deuterated retinol esterified to acetate with four or eight deuterium atoms is administered, followed by analysis of deuterium enrichment in serum or plasma samples by gas chromatography-mass spectrometry (GCMS), the so-called 'paired-stable isotope dilution technique'. The study design used in 'paired-stable isotope dilution technique' studies is presented in Figure 10. In particular, the paired-stable isotope dilution technique has been used to generate new data on provitamin A conversion factors to retinol.

**Figure 9** Principle of study design based on vitamin A body pool size.

**Figure 10** Design for studies based on vitamin A body pool assessment using the paired-isotope dilution technique.

### Conversion Factors

Conversion factors are a way to define how much of an ingested provitamin A carotenoid is converted to 1 µg retinol. This is also known as bioefficacy. The Institute of Medicine uses the factors of 12 µg β-carotene:1 µg retinol and 24 µg α-carotene or β-cryptoxanthin:1 µg retinol (Table 2). This equivalency is referred to as retinol activity equivalents (RAE) to distinguish it from the conversion factors still used by the Food and Agriculture Organization, which is 6 µg β-carotene:1 µg retinol and referred to as retinol equivalents or RE. This estimate of vitamin A formation from provitamin A assumes that the person is healthy and eating a mixed diet. In comparison to these generalized conversion factors, a mean conversion factor of 26.7 µg β-carotene:1 µg retinol was reported for green and yellow vegetables consumed by Chinese school-aged children and 13.4 µg β-carotene:1 µg retinol for sweet potato, 9.5:1 for Indian spinach (*Basella alba*), and 6.3:1 for pure β-carotene in oil were obtained in Bangladeshi men. These studies were able to determine conversion factors by applying the paired-stable isotope dilution technique to evaluate the changes in total body vitamin A pools in response to the intervention with the test food.

**Table 2** The commonly used bioconversion factors of provitamin A carotenoids to yield 1 µg retinol include those published by the Institute of Medicine and the Food and Agriculture Organization of the United Nations (FAO)

<i>Institute of medicine</i>	<i>FAO</i>
2 µg β-Carotene in oil supplement	2 µg β-Carotene in oil supplement
12 µg β-Carotene	6 µg β-Carotene
24 µg β-Cryptoxanthin	12 µg β-Cryptoxanthin
24 µg α-Carotene	12 µg α-Carotene

Other isotopic methods have also been developed to evaluate bioconversion factors. Using a different approach other than the paired-stable isotope dilution technique, intrinsically deuterium-labeled vegetables were prepared by growing carrots and spinach hydroponically in deuterated water. Humans were fed the labeled vegetables and a reference dose of  $^{13}\text{C}_8$ -retinyl acetate was administered for comparison. Intake of vegetables resulted in conversion of 20.9  $\mu\text{g}$   $\beta$ -carotene:1  $\mu\text{g}$  retinol and 14.8:1 for spinach and carrots, respectively. More recently, the intrinsic labeling technique was used to evaluate bioconversion of provitamin A carotenoids in rice that was genetically modified to contain  $\beta$ -carotene. The process of enhancing micronutrients in staple crops, such as rice, is called biofortification. This rice is called 'Golden Rice' due to its deep yellow hue exclusively due to  $\beta$ -carotene. In comparison to a reference dose, the  $\beta$ -carotene from Golden Rice resulted in a mean conversion factor of 3.8  $\mu\text{g}$   $\beta$ -carotene to 1  $\mu\text{g}$  of retinol for five adults. These data highlight the potential usefulness of biofortification to impact vitamin A status. In general, animal and human studies that have tested stable crops biofortified with provitamin A have shown very good conversion rates of provitamin A to retinol demonstrating the feasibility of this agronomic technique. At this time, plant sources of provitamin A are often overlooked in infant feeding strategies in developing countries. However, a simulation based on intake of 100 g orange-fleshed sweet potato each day using the Institute of Medicine's 12:1 conversion factor resulted in a significant increase of vitamin A liver stores in infants. Furthermore, feeding sweet potato to children in South Africa and Mozambique improved vitamin A status demonstrating sweet potato  $\beta$ -carotene is bioavailable and converted to vitamin A.

Finally, extrinsic reference methods using stable isotopically labeled  $\beta$ -carotene and retinyl ester have been used to determine bioconversion factors from supplements and foods. These methods have been compared to traditional oral–fecal balance studies and seem to be better suited to supplement studies than mixed diets.

### Effectors of Bioavailability

Dietary fat is needed for absorption of carotenoids in order to facilitate the formation of micelles in the small intestine. However, fat does not seem to be a strong limiting factor in human diets when vegetables are consumed as part of a composite meal. For example, studies in Filipino schoolchildren, based on the paired-isotope dilution test, found no difference between three levels of fat (7, 15, or 29 g fat day<sup>-1</sup>) when fed with 4.2 mg provitamin A carotenoids in the form of carotenoid-rich vegetables. Studies in animals, however, did see enhancement of bioefficacy when high levels of fat were fed with orange-fleshed sweet potato. Some forms of fiber also interfere with the bioavailability of carotenoids, although the addition of dry matter in the form of white sweet potato to orange-fleshed sweet potato did not seem to affect the bioefficacy.

### Influence of Vitamin A Status

From a methodological point of view, it is important to recognize that the retinol response to provitamin A carotenoids in humans and animals varies inversely with vitamin A status. Clearly, there is an urgent need for additional, well-designed studies to evaluate the bioavailability of provitamin A carotenoids consumed in settings where vitamin A deficiency remains a public health problem among infants, children, and women of child-bearing age. The WHO continues to advocate high-dose vitamin A supplements, which are oil-based, to preschool children in part due to the lack of consistent high provitamin A sources in the diets of the poor and the questionable bioavailability of the provitamin A carotenoids.

### Conclusion

Stable isotope techniques provide excellent tools to assess bioavailability of nonheme iron and provitamin A carotenoids and thus contribute important information to be used in the development of nutrition interventions.

## Key points

- To obtain an overview of the role of biotin in intermediary metabolism.
- To understand the relationship between the chemical structure of this vitamin and its biological function.
- To know the processes of absorption, transport, excretion and metabolism of this vitamin.
- To have information about the dietary intakes of this vitamin.
- To know the metabolic disorders related to biotin.
- To know the most important dietary sources and the requirements of this vitamin.

## Introduction

Biotin is known as vitamin B<sub>7</sub> (Combs and McClung, 2016; Rodwell et al., 2018). As other vitamins of the B complex, it is water-soluble and widely distributed in food, is not particularly stored in the organism and does not usually produce toxicity due to

overdosage. Together with thiamine, riboflavin, niacin, pantothenic acid and pyridoxine, biotin shares the participation as coenzymes in the metabolism of macronutrients (Stipanuk and Caudill, 2018).

This article will consider the metabolic functions, the main food sources, the requirements, the deficiencies, the processes of absorption, transport, excretion and metabolism, and the assessment of the nutritional status of biotin.

## Biotin is a vitamin

Biotin (also known as Vitamin B<sub>7</sub>, Vitamin H, and Coenzyme R) is a water-soluble vitamin that is generally classified in the B complex group. Mammals (including humans) cannot synthesize biotin and depend on biotin synthesized by microbes and plants (Combs and McClung, 2016; Rodwell et al., 2018). Biotin was discovered in nutritional experiments that demonstrated a factor in many foodstuffs capable of curing the scaly dermatitis, hair loss, and neurologic signs induced in rats fed dried egg white.

Avidin, a glycoprotein found in egg white, binds biotin very specifically and tightly. From an evolutionary standpoint, avidin probably serves as a bacteriostat in egg white; consistent with this hypothesis is the observation that avidin is resistant to a broad range of bacterial proteases in both the free and biotin-bound form. Because avidin is also resistant to pancreatic proteases, ingested avidin binds to dietary biotin (and probably any biotin from intestinal microbes) and prevents absorption, carrying the biotin on through the GI tract. Cooking denatures avidin, rendering avidin susceptible to digestion and unable to interfere with absorption of biotin (Bistas et al., 2021).

## Digestion of protein-bound biotin

The content of free biotin and protein-bound biotin in foods is variable, but the majority of biotin in meats and cereals appears to be protein-bound via an amide bond between biotin and lysine. The determinants of biotin bioavailability have been not clearly delineated. Biotin release from covalent protein binding is likely mediated by a specific biotin-amide hydrolase, biotinidase (EC 3.5.1.12). Biotinidase mRNA is present in pancreas and intestinal mucosa. Biotinidase also similarly plays a critical role in intracellular recycling of biotin by releasing biotin from intracellular proteins during protein turnover.

## Intestinal absorption

At physiologic pH, the carboxylate group of biotin is negatively charged. Thus, biotin is at least modestly water-soluble and requires a transporter to cross cell membranes. Biotin transport must occur across two structurally and functionally different membrane domains of human intestinal epithelial cells: the brush border (apical) membrane that faces the intestinal lumen and the basolateral membrane that faces the interstitium in contact with blood that perfuses the intestine.

A biotin transporter is present in each of the membrane domains. In the brush border membrane, transport occurs via a Na<sup>+</sup>-dependent, electroneutral, carrier-mediated mechanism that saturates at the micromolar range, accounting for the overall limitation in nondiffusion transport. In the presence of a Na<sup>+</sup> gradient, biotin transport occurs against a concentration gradient. This biotin transporter can also transport pantothenic acid and lipoic acid and hence has been named Sodium-dependent MultiVitamin Transporter (SMVT). Human SMVT is the product of the *SLC5A6* gene, which is located on chromosome 2p23 and consists of 17 exons. SMVT is exclusively targeted to the brush border membrane (Sabui et al., 2016).

Biotin transport across the basolateral membrane is also a carrier-mediated mechanism. However, this carrier is Na<sup>+</sup>-independent, electrogenic, and cannot accumulate biotin against a concentration gradient.

The intestinal biotin transport upregulates in response to biotin deficiency. Upregulation likely is accomplished primarily by induction of SMVT mRNA synthesis and, hence, an increased number of SMVT transporters per cell. The increase in SMVT is likely mediated by an induction in the activity of P1, which is one of the two promoter regions upstream from the SMVT gene.

Based on a study in which biotin was administered orally in pharmacologic amounts, bioavailability of biotin is approximately 100%. Thus, both physiologic intakes and the pharmacologic doses of biotin given to treat biotin-dependent inborn errors of metabolism are likely to be well absorbed.

## The contribution of microbial biotin to absorbed biotin

The contribution of microbial biotin to absorbed biotin, if any, remains unknown. Biotin is synthesized by many intestinal microbes. Based on rat studies, carrier-mediated transport of biotin is most active in the proximal small bowel, where microbes are the least numerous. However, biotin absorption from the proximal colon where microbes are the most numerous is still significant, supporting the potential nutritional significance of biotin synthesized and released by enteric flora.

## Transport from the intestine to peripheral tissues

Biotin concentrations in plasma are small relative to other water-soluble vitamins. Most biotin in plasma is free and dissolved in the aqueous phase of plasma. However, approximately 7% is reversibly bound to plasma protein, and approximately 12% is covalently bound to plasma protein. Binding to human serum albumin likely accounts for reversible binding. Biotinidase has been proposed as a biotin-binding protein or biotin-carrier protein for transport into cells. A biotin-binding plasma glycoprotein has been observed in pregnant rats. Although the importance of protein binding in the transport of biotin from the intestine to the peripheral tissues is not yet clear, the immunoneutralization of this protein led to decreased transport of biotin to a fetus and early death of the embryo.

## Biotin uptake by liver and most peripheral tissues

SMVT is widely expressed in human tissues. Studies by Said and coworkers provide strong evidence that biotin uptake by liver (and likely many other somatic tissues) occurs via SMVT. Metabolic trapping, (e.g., biotin bound covalently to intracellular proteins) is also important.

Studies by Zemleni and coworkers provide evidence in favor of monocarboxylate transporter 1 (MCT1) as the lymphocyte biotin transporter. MCT1 may also be responsible for biotin transport in keratinocytes.

A child with biotin-responsive neurologic problems and a pattern of organic aciduria consistent with multiple carboxylase deficiency has been reported. An autosomal recessive defect in lymphocyte biotin transport was identified. SMVT gene sequence was normal. These investigators speculated that lymphocyte biotin transporter is expressed in other tissues and mediates some critical aspect of tissue biotin homeostasis.

## Biotin transport

### Transport of biotin into the central nervous system

Biotin is transported across the blood–brain barrier. The transporter is saturable and structurally specific for the free carboxylate group on the valeric acid side chain. Transport into the neuron also appears to involve a specific transport system with subsequent trapping of biotin by covalent binding to brain proteins, presumably carboxylases.

Ozand and collaborators have described several patients in Saudi Arabia with biotin-responsive basal ganglia disease. Symptoms include confusion, lethargy, vomiting, seizures, dystonia, dysarthria, dysphagia, seventh nerve paralysis, quadriparesis, ataxia, hypertension, chorea, and coma. Gusella and coworkers provided evidence of a genetic defect in SLC19A3 and speculated that this might be a biotin transporter. However, Said and coworkers conclusively proved that SLC19A3 codes for THTR2, a thiamine transporter located in the apical membrane of intestinal, renal tubule, and hepatic cells. THTR2 does not transport biotin, leaving the biotin responsiveness of these patients unexplained.

### Placental transport of biotin

Biotin concentrations are 3–17-fold greater in plasma from human fetuses compared to their mothers in the second trimester, consistent with active placental transport. SMVT is likely responsible for placental biotin transport based on the observations that SMVT is expressed in normal human placenta and that the microvillus membrane of the placenta contains a biotin transport system that is saturable, Na<sup>+</sup>-dependent and actively accumulates biotin. However, in the isolated, perfused single cotyledon from placenta, transport of biotin across the placenta is relatively weak, potentially allowing greater fetal deficiency than maternal deficiency. Indeed, in mice, the degree of fetal biotin deficiency is substantially greater than maternal biotin deficiency.

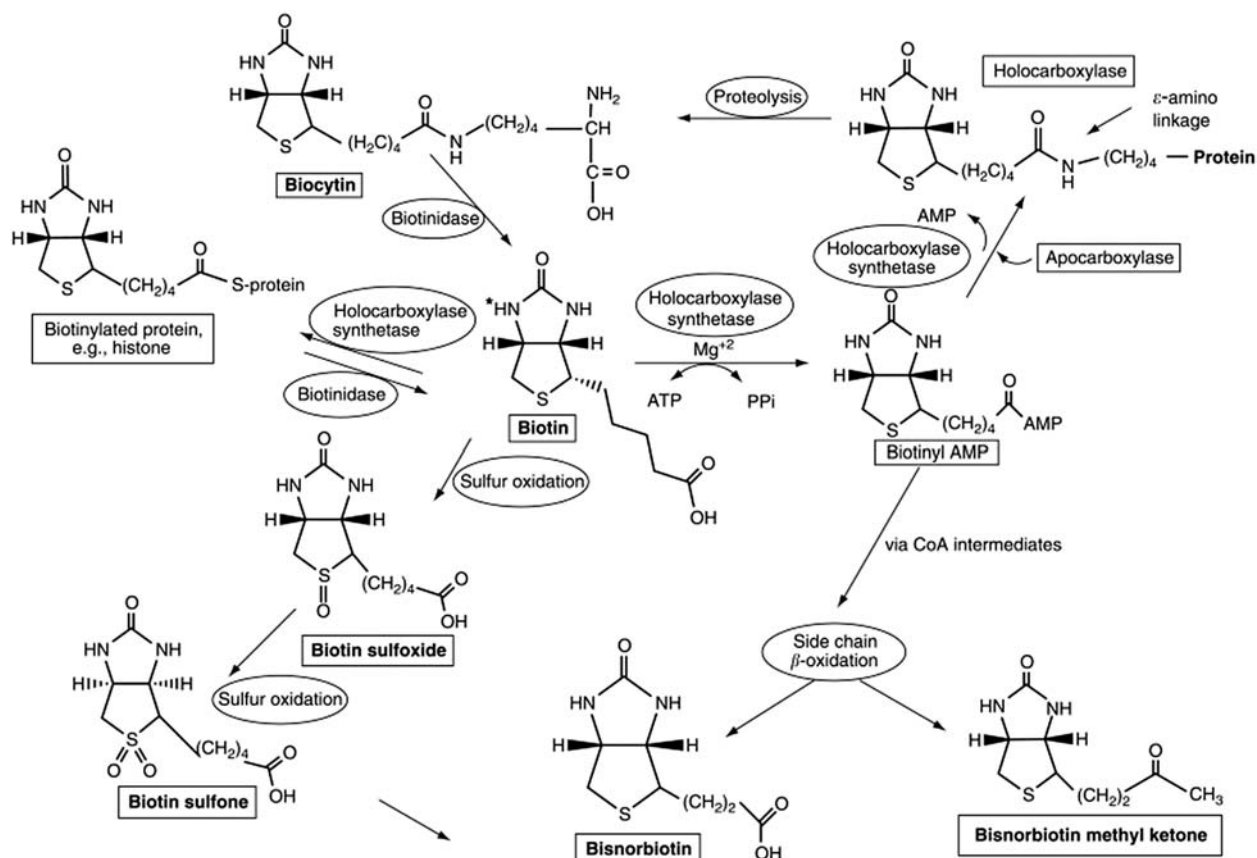

### Transport of biotin into human milk

More than 95% of the biotin in human milk is free in the skim fraction. The concentration of biotin varies substantially in some women and exceeds the concentration in serum by 1–2 orders of magnitude, suggesting that there is a system for transport into milk. Metabolites account for more than half of the total biotin plus metabolites in early and transitional human milk. With post-partum maturation, the biotin concentration increases. No soluble biotin-binding protein has been detected in human milk.

## Metabolism and urinary excretion of biotin and metabolites

Biotin is a bicyclic compound (Fig. 1). One of the rings contains an ureido group (–N–CO–N–). The tetrahydrothiophene ring contains sulfur and has a valeric acid side chain. A significant proportion of biotin undergoes catabolism before excretion (Fig. 1). Two principal pathways of biotin catabolism have been identified in mammals. In the first pathway, the valeric acid side chain of biotin is degraded by  $\beta$ -oxidation.  $\beta$ -Oxidation of biotin leads to the formation of bisnorbiotin, tetranorbiotin, and related intermediates that are known to result from  $\beta$ -oxidation of fatty acids. The cellular site of this  $\beta$ -oxidation of biotin

**Fig. 1** Biotin metabolism and degradation. Ovals denote enzymes or enzyme systems; rectangles denote biotin, intermediates and metabolites. AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PPI, pyrophosphate; and \*, site of attachment of carboxyl moiety.

is uncertain. Spontaneous (nonenzymatic) decarboxylation of the unstable  $\beta$ -ketoacids ( $\beta$ -ketobiotin and  $\beta$ -ketobisnorbiotin) leads to formation of bisnorbiotin methylketone and tetranorbiotin methylketone; these catabolites appear in urine.

In the second pathway, the sulfur in the thiophane ring of biotin is oxidized leading to the formation of biotin l-sulfoxide, biotin d-sulfoxide, and biotin sulfone. Sulfur oxidation may be catalyzed by an NADPH-dependent process in the smooth endoplasmic reticulum. Combined oxidation of the ring sulfur and  $\beta$ -oxidation of the side chain lead to metabolites such as bisnorbiotin sulfone. In mammals, degradation of the biotin ring to release carbon dioxide and urea is quantitatively minor.

On a molar basis, biotin accounts for approximately half of the total avidin-binding substances in human serum and urine (Table 1). Biocytin, bisnorbiotin, bisnorbiotin methylketone, biotin-d,l-sulfoxide, and biotin sulfone account for most of the balance. Biotin catabolism to these inactive forms is accelerated by anticonvulsant therapy, by cigarette smoking, and during pregnancy, thereby increasing the ratio of biotin metabolites to biotin in urine and potentially contributing to an increased requirement.

Because biotin and its metabolites are small molecules ( $\leq 244$  Da) and mainly free in plasma, most of the biotin will pass into the glomerular filtrate. Thus, specific systems for the reabsorption of biotin from the glomerular filtrate are important to avoid substantial losses in urine. Based on work by Said and coworkers, SMVT is the principal transporter responsible for biotin reabsorption. Biotin uptake by SMVT is adaptively regulated by biotin deficiency, consistent with previous studies demonstrating reduced biotin excretion in marginal biotin deficiency induced experimentally in human subjects.

Subsequent egress of biotin from the tubular cells occurs via a basolateral membrane transport system that is not dependent on  $\text{Na}^+$ . Studies in patients with biotinidase deficiency suggest that there may be a role for biotinidase in the renal handling of biotin.

**Table 1** Normal range of urinary excretion of biotin and major metabolites.

Biotin	Bisnorbiotin	Biotin sulfoxide
18–77	11–39	8–19

Results are expressed in nmol/24 h.

## Biliary excretion of biotin and metabolites

Biliary excretion of biotin and metabolites is quantitatively negligible compared to urine based on a study in rats. Although the concentrations of biotin, bisnorbiotin, and biotin-d,l-sulfoxide were approximately 10-fold greater in bile than serum of pigs, the bile to serum ratio for biotin is still more than 10-fold less than the bile to serum ratio for bilirubin, which is actively excreted in bile.

## Metabolic functions

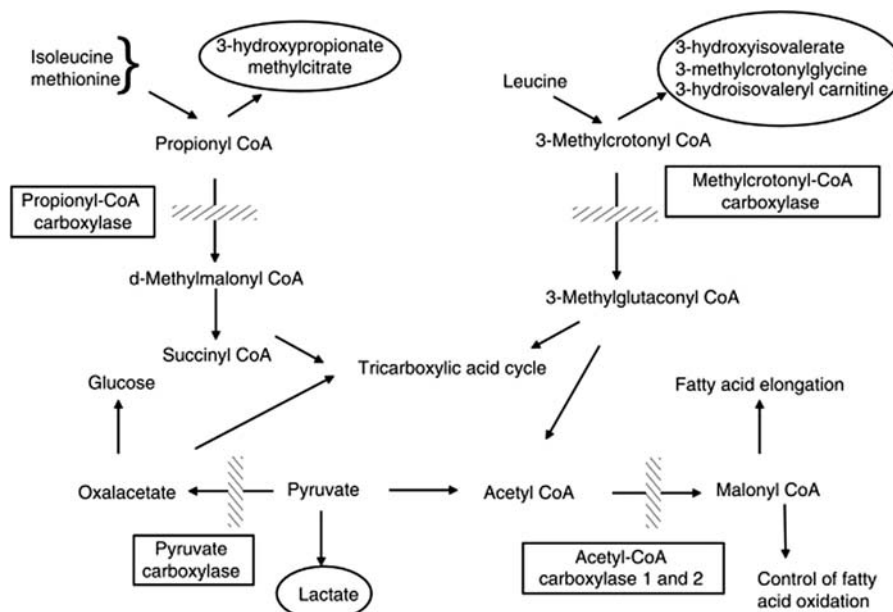

In mammals, biotin serves as an essential cofactor for five carboxylases, each of which catalyzes a critical step in intermediary metabolism (Mock, 2014). All five of the mammalian carboxylases catalyze the incorporation of bicarbonate as a carboxyl group into a substrate. All five employ a similar catalytic mechanism.

Biotin is attached to the apocarboxylase by a condensation reaction catalyzed by holocarboxylase synthetase (HCS) (Fig. 1). An amide bond is formed between the carboxyl group of the valeric acid side chain of biotin and the  $\epsilon$ -amino group of a specific lysyl residue in the apocarboxylase; these regions contain sequences of amino acids that are highly conserved for the individual carboxylases both within and between species.

In the carboxylase reaction, the carboxyl moiety is first attached to biotin at the ureido nitrogen opposite the side chain; then the carboxyl group is transferred to the substrate. Because the valeric acid side chain of biotin is coupled to the side chain of lysine in each holocarboxylase, this  $\text{CO}_2$  is at the end of a long, flexible chain, allowing the biotinyl coenzyme to be carboxylated at one site and used as a  $\text{CO}_2$  donor at a second site. The reaction is driven by the hydrolysis of ATP to ADP and inorganic phosphate. Subsequent reactions in the pathways of the mammalian carboxylases release carbon dioxide from the product of the carboxylase reaction. Thus, these reaction sequences rearrange the substrates into more useful intermediates but do not violate the classic observation that mammalian metabolism does not result in the net fixation of carbon dioxide.

The five biotin-dependent mammalian carboxylases (Fig. 2) are acetyl-CoA carboxylase (EC 6.4.1.2) isoforms ACC-1 and ACC-2 (formerly known as  $\alpha$  ACC and  $\beta$  ACC), pyruvate carboxylase (EC 6.4.1.1, PC), methylcrotonyl-CoA carboxylase (EC 6.4.1.4, MCC), and propionyl-CoA carboxylase (EC 6.4.1.3, PCC).

Both ACC-1 and ACC-2 catalyze the incorporation of bicarbonate into acetyl CoA to form malonyl CoA (Fig. 2), but ACC-1 and ACC-2 are thought to have two very different roles in cellular metabolism; one controls fatty acid synthesis, and the other controls fatty acid oxidation. ACC-1 is located in the cytosol and produces malonyl CoA, because availability of malonyl CoA is rate limiting, activity of ACC-1 controls fatty acid synthesis (elongation) and is tightly regulated in a sophisticated fashion. Cytosolic ACC-1 exists as a very large polymer with a molecular mass in the millions of Daltons and is inactivated by dissociation into its protomer units. Citrate activates ACC-1 by increasing polymerization. CoA itself activates ACC-1 by lowering the  $K_m$  for acetyl CoA. ACC-1 is inhibited by the products of fatty acid synthesis, the long-chain acyl CoAs, which also act to depolymerize the enzyme. In addition,

**Fig. 2** Interrelationship of pathways catalyzed by biotin-dependent enzymes (shown in boxes). Organic acids and odd-chain fatty acids accumulate because biotin deficiency causes reduced activity of biotin-dependent enzymes. Hatched bars denote metabolic blocks at deficient carboxylases; ovals denote accumulation of products from alternative pathways.

ACC-1 activity is regulated by covalent modification (phosphorylation) in response to the hormones insulin and glucagon. A high insulin-to-glucagon ratio typical of the immediate postprandial state with increased blood glucose level favors dephosphorylation of ACC-1 to an active form, whereas a low insulin-to-glucagon ratio (typical of fasting) favors phosphorylation to the inactive form. The amount of ACC-1 protein also responds to changes in dietary and hormonal conditions.

ACC-2 is located on the outer mitochondrial membrane and regulates the availability of fatty acids for oxidation through the inhibition of carnitine palmitoyltransferase I by malonyl CoA. Carnitine palmitoyltransferase I catalyzes the rate-limiting transfer of the fatty acid from CoA to carnitine; the fatty acyl carnitine is transported into the mitochondrial matrix converted back to the CoA derivative and oxidized.

The three remaining carboxylases are mitochondrial. PC catalyzes the incorporation of bicarbonate into pyruvate to form oxaloacetate, an intermediate in the Krebs tricarboxylic acid cycle (Fig. 2). Thus, PC catalyzes an anaplerotic reaction. In gluconeogenic tissues (that is, liver and kidney), the oxaloacetate can be converted to glucose. Deficiency of PC is probably the cause of the lactic acidemia, central nervous system lactic acidosis and abnormalities in glucose regulation observed in biotin deficiency and in genetic biotinidase deficiency and HCS deficiency. PC also plays a role in the formation of the protective myelin sheath that surrounds certain nerve cells and the production of neurotransmitters, both of which may contribute to the phenotype of inherited PC deficiency.

In the "A" form of inherited PC deficiency, affected infants present in the first few months of life with mild or moderate lactic acidemia and psychomotor retardation. Lactic acidemia can lead to vomiting, abdominal pain, fatigue, muscle weakness, and difficulty breathing. Most children die within the first few years, and survivors have severe mental retardation.

In the more severe "B" form of PC deficiency, the initial presentation usually occurs shortly after birth with hypotonia, seizures, coma, severe lactic acidemia, and signs of liver failure such as elevated blood ammonia concentrations. Death usually occurs before 3 months of age.

MCC catalyzes an essential step in the degradation of the branched-chain amino acid leucine (Fig. 2). MCC is composed of two non identical subunits: a biotinylated  $\alpha$  subunit that is encoded by the gene MCCC1 and a nonbiotinylated  $\beta$  subunit, which is encoded by the gene MCCC2. MCC is not regulated by small molecules or by dietary or hormonal factors. Deficient activity of MCC leads to metabolism of 3-methylcrotonyl CoA to 3-hydroxyisovaleric acid, 3-hydroxyisovaleryl carnitine and 3-methylcrotonylglycine by an alternate pathway. Thus, increased urinary excretion of these abnormal metabolites reflects deficient activity of MCC. The inherited deficiency of MCC characteristically presents with recurrent episodes of vomiting, diarrhea, lethargy, hypotonia, severe metabolic acidosis, hypoglycemia, and carnitine depletion. Moderate restriction of dietary protein to limit leucine intake and carnitine supplementation to correct or prevent carnitine deficiency generally result in normal development. Some cases respond to biotin supplementation. Newborn screening of acyl carnitines has identified a much higher incidence of asymptomatic MCC deficiency than expected from the number of patients ascertained by clinical symptoms; this observation suggests that many patients may have a benign clinical course.

PCC catalyzes the incorporation of bicarbonate into propionyl CoA to form methylmalonyl CoA; methylmalonyl CoA undergoes an isomerization to succinyl CoA catalyzed by the  $B_{12}$ -dependent enzyme methylmalonyl-CoA mutase and enters the tricarboxylic acid cycle (Fig. 2). In a fashion analogous to MCC deficiency, deficiency of PCC leads to increased urinary excretion of 3-hydroxypropionic acid and 3-methylcitric acid. Sources of propionyl CoA include catabolism of the amino acids valine, isoleucine, threonine, and methionine;  $\beta$ -oxidation of odd-numbered or branched-chain fatty acids; byproducts of bile acid synthesis from cholesterol; and intestinal microflora. PCC is not rate limiting in the metabolism of propionyl CoA, and the enzyme activity is not sensitively regulated by allosteric effectors or by dietary or hormonal changes. PCC is composed of two nonidentical subunits: a biotinylated  $\alpha$  subunit that is encoded by the gene PCCA and a nonbiotinylated  $\beta$  subunit, which is encoded by the gene PCCB.

Propionic acidemia is the disease caused by an inherited deficiency of PCC. Affected individuals have repeated, life-threatening episodes of severe ketosis and metabolic acidosis that often begin in infancy. Findings include vomiting, dehydration, and lethargy, which can progress to coma and death if not treated. Frequent neurological complications include developmental delay, seizures, and cerebral atrophy. The concentration of propionyl CoA increases proximal to the metabolic block caused by decreased PCC activity and results in increased urinary excretion of a constellation of propionate metabolites that are diagnostic of propionic acidemia. These include 3-hydroxypropionate, propionylglycine, propionylcarnitine, and methylcitrate.

The most important treatment for propionic acidemia is restriction of dietary protein, thereby limiting the amino acid precursors of propionate. Use of special formulas that have very low levels of isoleucine, valine, methionine, and threonine has the same goal. The minimum requirement for these essential amino acids is met by the addition of other proteins after calculation of the content of each amino acid. Loss of propionylcarnitine can lead to a secondary deficiency of carnitine. Therapy includes dietary carnitine to prevent carnitine deficiency; this promotes the conversion of propionyl CoA to propionylcarnitine, which helps restore free CoA concentrations and facilitates excretion of propionate.

## Biotin deficiency diseases

### HCS deficiency

Genetic deficiencies of HCS and biotinidase cause the two types of multiple carboxylase deficiency that were previously designated the neonatal and juvenile forms. The inherited deficiency of HCS activity results in decreased activities of all five of the biotin-dependent carboxylases. In turn, these multiple carboxylase deficiencies result in clinical findings arising from the roles of all

five carboxylases in metabolism. In patients with a severe HCS deficiency, illness often occurs in the neonatal period and includes severe ketoacidosis, seizures, and lethargy, if not recognized and treated, coma and death can ensue. In patients who have a milder form of HCS deficiency, hair loss (alopecia), and an erythematous skin rash typical of biotin deficiency can appear at several months of age. Elevated urinary excretions of the metabolites characteristic of deficiency of several of the biotin-dependent carboxylases deficiencies are seen (Saleem and Soos, 2021).

Treatment with large oral doses of biotin (e.g., 10–60 mg/day), usually gives dramatic improvement of the biochemical abnormalities, skin rash, alopecia, and neurological findings, provided irreversible neurological damage has not occurred. A variety of mutations of the HCS gene have been reported. When studied, the concentration of biotin needed to attain half of the maximal reaction rate (the  $K_m$ ) generally was found to be increased far above biotin levels found in normal cells. On the contrary, the maximal enzyme activity ( $V_{max}$ ) usually was importantly greater than zero and approached normal. These observations explain why treatment with very large doses of biotin that increased tissue levels of biotin far above normal can result in enough active of HCS to convert enough apocarboxylases to active holocarboxylases, correcting the multiple carboxylase deficiencies. A complete absence of HCS activity, which would mean no activity of any of the five carboxylases, would probably be fatal *in utero*.

### Biotinidase deficiency

In the normal turnover of cellular proteins, holocarboxylases are degraded to biocytin or biotin linked to an oligopeptide containing at most a few amino acid residues (Fig. 1). Biotinidase similarly plays a critical role by releasing biotin for recycling from intracellular proteins such as carboxylases and histones during protein turnover. Consistent with this global role, biotinidase is found in many tissues including heart, brain, liver, lung, skeletal muscle, kidney, plasma, and placenta in addition to pancreas and intestine. The liver is thought to be the source of serum biotinidase.

Individuals with less than 10% of normal activity in serum exhibit seizures, hypotonia, skin rash, and alopecia, usually presenting in infancy. Many children have ataxia, developmental delay, conjunctivitis, hearing loss, and visual problems, including optic atrophy as well as a characteristic organic aciduria. If untreated, some progress to coma or death. Some only manifest one or two features, or present later in life with motor limb weakness, spastic paresis, and eye problems, such as loss of visual acuity and scotomata. Once hearing loss, optic atrophy, and moderate or severe developmental delay appear, they are often irreversible despite treatment with biotin. If treatment is begun before onset of clinical findings, signs and symptoms appear to be preventable (Saleem and Simpson, 2021).

Thus, the clinical findings and biochemical abnormalities of biotinidase deficiency resemble those of biotin deficiency (dermatitis, alopecia, conjunctivitis, ataxia, and developmental delay) suggesting that they are caused by biotin deficiency. However, the signs and symptoms of biotin deficiency and biotinidase deficiency are not identical. Seizures, irreversible neurosensory hearing loss, and optic atrophy have been observed in biotinidase deficiency, but not in biotin deficiency. A knockout mouse model has recently been reported that recapitulates many of these findings.

### Role of biotin in gene expression

Hymes and Wolf suggested that the posttranslational biotinylation of histones might play a role as a covalent modifier in the epigenetic code that regulates DNA transcription. However, subsequent work showed that <0.001% of human histones (primarily H3 and H4) are biotinylated, suggesting that the abundance is too low to elicit biological effects *in vivo*. However, HCS is located prominently in the nucleus, and the knockout of HCS in *Drosophila* as well as in human and other mammalian cells in culture produces distinct phenotypes, including the derepression of long terminal repeats and chromosomal instability; aspects of this HCS knockout phenotype have been attributed to the effects on gene expression rather than reduced activities of the biotin-dependent carboxylases.

Zempleni and colleagues have proposed that the biological effects of biotin on gene expression are caused by a multiprotein complex, including proteins involved in DNA methylation, histone methylation, and histone deacetylation. They proposed that the docking of HCS in chromatin causes an occasional biotinylation of histones ("marks") near the various HCS binding sites. Their studies provide evidence that HLCS enters the nuclear compartment and is recruited to chromatin through physical interactions with DNA methyltransferase 1 and methyl CpG-binding protein 2. Chromatin-bound HCS has been shown to recruit the eukaryotic histone H3 methyltransferase euchromatic histone lysine N-methyltransferase 1, which creates abundant Lys9-methylated histone H3 gene repression marks. In addition, HLCS interacts with nuclear receptor corepressor, a protein known to facilitate the binding of histone deacetylases (HDACs) in chromatin. HDACs remove histone acetylation marks and thus play a critical role in gene repression. Overall, emerging data suggest histone biotinylation marks are a side effect of HCS being in close physical proximity to histones and play no direct role in gene repression, despite contributing toward chromatin condensation.

Biotin status affects gene expression (León-Del-Río, 2018). The participation of biotin in gene expression was derived from two different observations. First, biotin deprivation in different experimental models was shown to affect the transcription or enzymatic activity of hepatic enzymes including glucokinase, pyruvate kinase, 6-phosphofructokinase, and ornithine transcarbamylase. Second, in cells in culture and rat tissues biotin was shown to have a nitric oxide (NO)-like function capable of increasing the intracellular concentration of the second messenger cGMP through the activation of the soluble form of the enzyme guanylate cyclase

(sGC). In human hepatocytes, biotin was found to regulate the expression of the asialoglycoprotein receptor (ASGR) through the activation of sGC and the cGMP-dependent protein kinase (PKG).

The sGC-PKG signal transduction pathway was found to regulate the transcription of genes encoding PC, PCC, ACC1, SMVT, and HCS in human hepatocytes. Interestingly, fibroblasts from a patient carrying a homozygous mutation in HCS, R508W, which increases the  $K_m$  of the enzyme for biotin 370-fold, required a 100-fold increase in biotin concentration, compared to normal fibroblasts, to increase HCS mRNA levels to within normal values.

These results demonstrated that biotinyl-AMP, the product of HCS, is the transcriptionally active form of biotin and indicates that the HCS-sGC-PKG pathway regulates transcription of the biotin-cycle enzymes.

The study of biotin-deficient rats showed that the mRNA levels of enzymes of the biotin cycle are down-regulated during biotin deficiency in the liver and kidney, but remain constitutively expressed in the brain.

## Assessment of biotin status

### Measurement of biotin

For measuring biotin at physiological concentrations (that is, from  $100 \text{ pmol L}^{-1}$  to  $100 \text{ nmol L}^{-1}$ ), most recent studies have used an avidin-binding assay to evaluate biotin status. Avidin-binding assays generally detect all avidin-binding substances after chromatographic separation of biotin analogs. This method appears to be both sensitive and chemically specific.

### Laboratory findings of biotin deficiency

In humans, laboratory indicators of biotin deficiency have been validated in studies in which progressive, but asymptomatic biotin deficiency was induced experimentally by feeding diets high in egg white. The urinary excretion of biotin declines dramatically, reaching frankly abnormal values in approximately 90% of subjects after 3 weeks. Urinary excretion of 3-hydroxyisovaleric acid and plasma and urinary 3-hydroxyisovalerylcarnitine increase to greater than the normal range in approximately 90% of subjects after 2 weeks of egg-white feeding, providing evidence that biotin depletion decreases the activity of MCC. The most sensitive indicator of biotin status appears to be activity of PCC in lymphocytes isolated from venous blood samples. Unfortunately, this assay is technically demanding, and the blood samples require special handling and storage.

Serum concentrations of free biotin decrease to abnormal values in less than half of the subjects. This observation is consistent with the impression of many investigators in this field that blood biotin concentration is not an early or sensitive indicator of impaired biotin status.

### Requirements

Data providing an accurate estimate of the dietary and parenteral biotin requirements for infants, children, and adults are lacking. However, recommendations for biotin intakes have been formulated by both the European Food Safety Authority (EFSA) and the Institute of Medicine (USA) for preterm infants, term infants, children, and adults (Tables 2 and 3).

The EFSA considers that the available data are insufficient to derive Adequate Requirements (ARs) and Population Reference Intakes (PRIs) for biotin, and therefore proposes to set an Adequate Intake (AI) for all population groups (European Food Safety Authority, 2017). The setting of an AI for biotin is based on observed biotin intakes with a mixed diet and the apparent absence of signs of deficiency in the EU, suggesting that current intake levels are adequate. There is no indication that the AI should differ according to sex. The AI for adults also applies to pregnant women. For lactating women, an increment in the adult AI is proposed, in order to compensate for biotin losses through secretion of breast milk. An AI is also proposed for infants aged 7–11 months based on extrapolation from the estimated intake of infants aged 0–6 months using allometric scaling, and for children and adolescents based on observed intakes in the EU (Table 2).

**Table 2** Adequate Intakes (AIs) for biotin.

Age	AI ( $\mu\text{g/day}$ )
7–11 months	6
1–3 years	20
4–10 years	25
11–17 years	35
$\geq 18$ years <sup>a</sup>	40
Lactation	45

<sup>a</sup>Including pregnancy.

**Table 3** Adequate Intakes (AIs) for biotin by life stage group.

Age	AI ( $\mu\text{g/day}$ )
<b>Life stage group<sup>a</sup></b>	
0–6 months	5
7–12 months	6
1–3 years	8
4–8 years	12
9–13 years	20
14–18 years	25
19–30 years	30
31–50 years	30
51–70 years	30
>70 years	30
<b>Pregnancy</b>	
≤18 years	30
19–50 years	30
<b>Lactation</b>	
≤18 years	35
19–50 years	35

<sup>a</sup>All groups except pregnancy and lactation represent males and females.  
Taken from [Institute of Medicine \(2006\)](#).

The Institute of Medicine also provides AIs, in this case based on extrapolation from the amount of biotin in human milk ([Table 3](#)) ([Institute of Medicine, 2006](#)).

## Dietary sources, deficiency, and high intakes

### Dietary sources

There is no published evidence that biotin can be synthesized by mammals; thus, the higher animals must derive biotin from other sources. The ultimate source of biotin appears to be *de novo* synthesis by bacteria, primitive eukaryotic organisms such as yeast, molds, and algae, and some plant species.

The great majority of measurements of biotin content of foods have used bioassays. Recent publications provide evidence that the values are likely to contain substantial errors. However, some worthwhile generalizations can be made. Biotin is widely distributed in natural foodstuffs so requirements are easily met with a balanced diet, but the absolute content of even the richest sources is low when compared to the content of most other water-soluble vitamins.

Foods that contain the most biotin include organ meats, eggs, fish, meat, seeds, nuts, and certain vegetables (such as sweet potatoes). The biotin content of food can vary; for example, plant variety and season can affect the biotin content of cereal grains, and certain processing techniques (e.g., canning) can reduce the biotin content of foods.

### Circumstances leading to deficiency

That normal humans have a requirement for biotin has been clearly documented in three situations: prolonged consumption of raw egg white, parenteral nutrition without biotin supplementation in patients with short bowel syndrome, and infant feeding with an elemental formula devoid of biotin. Because biotin could not legally be added as a supplement to infant formulas in Japan until 2003, all reports related to infant formula have come from Japan. Often feeding of an elemental formula was required to treat intractable, chronic diarrhea. The infants typically developed both the classic cutaneous manifestations of biotin deficiency and the characteristic pattern of organic aciduria.

Based on lymphocyte carboxylase activities and plasma biotin levels, some children with severe protein-energy malnutrition are biotin deficient. Investigators have speculated that the effects of biotin deficiency may be responsible for part of the clinical syndrome of protein-energy malnutrition.

Long-term anticonvulsant therapy in adults can lead to biotin depletion severe enough to interfere with leucine metabolism and cause increased urinary excretion of 3-hydroxyisovaleric acid. The mechanism of biotin depletion during anticonvulsant therapy is not known, but may involve accelerated biotin catabolism, impaired biotin absorption, impaired biotin transport in plasma, impaired renal reclamation biotin, or a combination of these.

Recent studies of biotin status during pregnancy and of biotin supplementation during pregnancy provide evidence that a marginal degree of biotin deficiency develops in at least one-third of women during normal pregnancy. Although the degree of biotin deficiency is not severe enough to produce overt manifestations of biotin deficiency, the deficiency is severe enough to

produce metabolic derangements. A similar marginal degree of biotin deficiency causes high rates of fetal malformations in some mammals. Moreover, data from a multivitamin supplementation study provide significant, albeit indirect, evidence that the marginal degree of biotin deficiency that occurs spontaneously in normal human gestation is teratogenic.

Biotin deficiency has also been reported or inferred in several other clinical circumstances including Leiner's disease, sudden infant death syndrome, renal dialysis, gastrointestinal diseases, and alcoholism.

### Clinical findings of frank deficiency

The clinical findings of frank biotin deficiency in adults, older children and infants are similar. Typically, the findings appear gradually after weeks to several years of egg-white feeding or parenteral nutrition. Thinning of hair and progression to loss of all hair including eyebrows and lashes has been reported. A scaly (seborrheic), red (eczematous) skin rash was present in the majority; in several, the rash was distributed around the eyes, nose, mouth, and perineal orifices. These cutaneous manifestations, in conjunction with an unusual distribution of facial fat, have been dubbed "biotin deficiency facies." Depression, lethargy, hallucinations, and paresthesia of the extremities were prominent neurologic symptoms in the majority of adults. The most striking neurologic findings in infants were hypotonia, lethargy, and developmental delay.

The clinical response to administration of biotin has been dramatic in all well-documented cases of biotin deficiency. Healing of the rash was striking within a few weeks, and growth of healthy hair was generally present by 1–2 months. Hypotonia, lethargy, and depression generally resolved within 1–2 weeks, followed by accelerated mental and motor development in infants. Pharmacological doses of biotin (e.g., 1–10 mg) have been used to treat most patients.

### Pharmacology

Mounting reports of biotin deficiency in commercial animals and humans have led to several studies of plasma levels, pharmacokinetics, and bioavailability after acute or chronic oral, intramuscular, or intravenous administration of biotin in cattle, swine, fish, and humans (Mock, 2017). High doses (e.g., 1200 mg) result in high biotin concentrations in blood and the urinary excretion of a large proportion as the unchanged biotin. Increased blood concentrations of bisnorbiotin and biotin sulfoxide and increased urinary excretion of bisnorbiotin and biotin sulfoxide are also reported, providing evidence that the biotin metabolites originate from human tissues rather than enteric bacteria.

Daily doses up to 200 mg orally and up to 20 mg intravenously have been given to treat biotin-responsive inborn errors of metabolism and acquired biotin deficiency. Toxicity has not been reported.

In recent years, dietary intervention using vitamins has been proposed as an alternative therapeutic approach for progressive multiple sclerosis (MS), including biotin. However, in 2017 the use of biotin to treat MS patients received a major setback, when the Committee for Medicinal Products for Human Use of the European Medicines Agency, after reviewing the available evidence, considered that the data were not robust enough and concluded that the observed benefits of high-dose biotin (HDB) did not outweigh its potential risks. A very recent systematic review and meta-analysis of randomized controlled trials evaluated the administration of HDB (at least 300 mg/day administered orally and for at least 3 months) to multiple sclerosis patients. According to this study, a moderate certainty of evidence suggests a potential benefit in favor of HDB administered for 12–15 months in terms of 25-foot walk time (ITW25) in patients with progressive multiple sclerosis. However, an important trade-off of this benefit is the high certainty of evidence suggesting an increased incidence of laboratory test interference when HDB is taken (Espiritu and Remalante-Rayco, 2021).

### Conclusions

Among all the vitamins with coenzymatic functions in metabolism, biotin is the only one that behaves as a coenzyme without the need for structural modifications. Bound by covalent bonds to enzymatic proteins, it is always involved in carboxylation reactions that affect the functioning of the Krebs cycle, lipogenesis and the degradation of some amino acids. Nutritional deficiencies in biotin are very rare, because it is found in most foods and is synthesized by the intestinal microbiota.

## Introduction

Caffeine (1, 3, 7-trimethylxanthine) in food and beverages, an adenosine antagonist, is the most widely used mood-altering drug in the world. Caffeine is rapidly absorbed and distributed throughout the body with peak plasma concentrations typically reached 30–45 min after ingestion. The average half-life of caffeine is 4–6 h. Genetics account for some of the variability in responses to caffeine and individual differences in caffeine pharmacokinetics.

Many people around the world consume it every day to increase wakefulness, alleviate fatigue including to have a good physical activity, and improve concentration and focus for having an optimal cognitive performance.

It is also important to say caffeine is a drug, and with any drug, the withdrawals are hard. Food Drug Administration approve a statement in 2018 warning companies to stop selling dangerous and illegal pure and highly concentrated caffeine products.

## General concepts

Caffeine is the most widely used psychoactive drug in the world. In the US, an estimated 87% of the population regularly consume beverages containing caffeine. Mean caffeine consumption among all users is 193 mg per day, with the highest intake among men aged 35–54 who consume an average of 336 mg of caffeine per day.

Caffeine is a natural constituent of more than 60 species of plants, including coffee, tea, cola nut, cacao, yerba maté, and guarana. Caffeine (1,3,7-trimethylxanthine) is a member of the methylxanthine class of alkaloids that include theobromine and theophylline. In its free base form, caffeine is a bitter white powder that is moderately soluble in water (21.7 mg mL<sup>-1</sup>). World-wide, caffeine is most commonly consumed as coffee and tea. Consumption of beverages with added caffeine (i.e., soft drinks) has markedly increased over the past half century, with consumption volume of soft drinks now being approximately twice that for coffee in the US. A notable recent trend has been the increasing popularity of “energy drinks” which vary considerably in the amount of caffeine (from 30 mg to over 75 mg of caffeine per 100 mL). Hundreds of such products are now marketed in the US (Table 1).

**Table 1** Update caffeine content of some beverages.

<i>Substance</i>	<i>Typical serving size (volume)</i>	<i>Typical caffeine content (mg)</i>	<i>Caffeine content range (mg)</i>
<b>Coffee</b>			
Brewed/drip	12 oz <sup>a</sup>	200	108–420
Starbucks hot brewed coffee	16 oz	330	
Espresso	1 oz	70	60–95
Starbucks espresso (solo)	1 oz	75	
Instant	6 oz	70	20–130
Decaffeinated	12 oz	8	0–10
<b>Tea</b>			
Brewed	6 oz	40	30–90
Instant	6 oz	30	10–35
Can or bottle (typical)	12 oz	20	8–32

<sup>a</sup>Historically, a “typical” serving size of coffee has been considered to be 6 oz. However, standard servings of coffee tend to be much larger than this. The smallest serving size offered at many fast food restaurants and coffee houses (e.g., Starbucks) is 12 oz.

<sup>b</sup>Specified range does not include energy shot products, which can contain as much as 500 mg caffeine per 1 oz serving.

## Caffeine pharmacokinetics

Caffeine is rapidly and completely absorbed from the gastrointestinal tract after oral administration. Caffeine is readily distributed throughout the body and is found in all body fluids. Peak plasma concentrations are typically reached 30–45 min following oral ingestion. The fraction of caffeine bound to plasma protein is 10–35%.

More than 25 caffeine metabolites have been identified in humans. The primary metabolic pathways involve the cytochrome P-450 liver enzyme system which produces three demethylated active metabolites: paraxanthine, theobromine, and theophylline, accounting for 80%, 10%, and 4% of caffeine metabolism, respectively. The average half-life of caffeine is 4–6 h, with elimination rates varying by more than 10-fold across individuals. Caffeine half-life is prolonged in individuals with liver disease and during the end of pregnancy. Caffeine metabolism is inhibited by numerous compounds including oral contraceptive steroids, cimetidine, some quinoline antibiotics, fluvoxamine, mexiletine, and high doses of caffeine itself. Neonates have a markedly increased caffeine half-life (80–100 h) due to immature liver enzyme systems which are fully developed at approximately 6 months of age. Tobacco smoking increases caffeine metabolism by stimulating the cytochrome P-450 1A2 enzyme (CYP1A2), with smokers metabolizing caffeine about twice as fast as nonsmokers. Genetic variations in CYP1A2 activity are a significant determinant of caffeine metabolism. For more information on individual differences in genetics, see the Section on [Caffeine genetics](#).

## Mechanisms of action

The primary cellular site of action of caffeine is the adenosine receptor. Among the adenosine receptor subtypes that have been identified, A<sub>1</sub> and A<sub>2A</sub> receptors are the preferential targets of caffeine. A<sub>1</sub> receptors are widely expressed throughout the brain, whereas A<sub>2A</sub> receptors are concentrated in dopaminergic-rich areas, such as the striatum. Adenosine is an endogenous purine nucleoside that generally exerts inhibitory effects throughout the central and peripheral nervous system (e.g., excitatory neurotransmitter inhibition,

suppression of motor activity, and inhibition of gastric secretion). Caffeine is a nonselective competitive  $A_1$  and  $A_{2A}$  receptor antagonist. Thus, caffeine produces a variety of central and peripheral effects that are opposite to the effects of adenosine.

Of most relevance to caffeine's central nervous system (CNS) stimulating effects, caffeine enhances dopamine activity indirectly by competitive antagonism of adenosine receptors that are co-localized and functionally interact with dopamine. Adenosine receptors can form functional receptor heteromers with dopamine receptors (i.e.,  $A_1$ - $D_1$  and  $A_{2A}$ - $D_2$ ). There is some evidence that the motor stimulant and reinforcing effects of caffeine are mediated by dopamine. Preclinical studies demonstrate that caffeine produces behavioral effects similar to the dopamine-mediated effects of classic stimulants, such as cocaine and amphetamine. Moreover, dopamine depletion or blockade of dopamine receptors significantly impairs the motor stimulant and discriminative stimulus effects of caffeine.

Although caffeine can inhibit phosphodiesterase and increase intracellular calcium concentration, typical dietary doses of caffeine are believed to be too low to be significantly influenced by these nonadenosine mechanisms. Thus, caffeine's effects appear to be primarily mediated by direct antagonism of adenosine and indirect enhancement of brain dopamine activity. For more information on ergogenic mechanisms of action, see the Section on Caffeine and Exercise.

## Physiological and health effects of caffeine

Caffeine modestly increases blood pressure but appears to have no effects on or to reduce heart rate. Hypertensive and hypertensive-prone caffeine users appear to be particularly sensitive to the pressor effects of caffeine. Caffeine produces increases in gastric acid secretion, colonic stimulation, diuresis (30% or more increased volume), respiratory stimulation, and bronchodilation. Caffeine also increases plasma epinephrine, norepinephrine, adrenocorticotrophic hormone, cortisol, renin, and free fatty acids. Acute caffeine administration produces increased cerebral blood flow velocity and electroencephalography (EEG) beta power activity. In addition, caffeine has prominent sleep-disrupting effects. For more information on the sleep disrupting effects of caffeine see the Section on Caffeine-Induced Sleep Disorder.

Although studies of the association between caffeine consumption and coronary heart disease have yielded inconsistent findings, one recent investigation demonstrated an association between slow caffeine metabolism and the incidence of coronary heart disease in moderate and heavy caffeine consumers. For more information on caffeine genetics, see the Section on Caffeine Genetics. Several studies have found that moderate coffee intake is associated with decreased risk for coronary heart disease, possibly because of protective effects of antioxidant and other protective compounds in coffee.

Over the last few decades, studies have yielded inconsistent findings regarding the effects of caffeine on reproductive and perinatal outcomes. Although some investigations have not found evidence of a significant association between caffeine exposure and adverse birth outcomes, several recent studies did show a relationship. Although equivocal findings preclude definitive conclusions regarding the effects of caffeine on pregnancy, some governmental health agencies have taken a prudent stance and issued health warnings to limit the use of caffeine during pregnancy. Health Canada recommends that women of reproductive age consume no more than 300 mg of caffeine per day. The Food Standards Agency of the UK advises that pregnant women keep their daily intake of caffeine below 200 mg. European Food Safety Authority approved on May 2015 a scientific opinion on the safety of caffeine, saying: "single doses of caffeine up to 200 mg (about 3 mg/kg bw for a 70 kg adult) do not give rise to safety concerns. The same amount does not give rise to safety concerns when consumed <2 h prior to intense physical exercise under normal. Habitual caffeine consumption up to 200 mg per day by pregnant women does not give rise to safety concerns for the fetus. Single doses of caffeine and habitual caffeine intakes up to 200 mg consumed by lactating women do not give rise to safety concerns for breastfed infants. For children and adolescents, the information available is insufficient to derive a safe caffeine intake. The Panel considers that caffeine intakes of no concern derived for acute caffeine consumption by adults (3 mg/kg bw per day) may serve as a basis to derive single doses of caffeine and daily caffeine intakes of no concern for these population subgroups" (EFSA, 2015).

## Caffeine and cognitive performance

Numerous investigations have examined the effects of caffeine on human cognitive performance. The most consistent finding to emerge is that caffeine restores cognitive performance that has been degraded by sleep deprivation, fatigue, or prolonged vigilance. At normal dietary doses, caffeine may improve tapping speed, reaction time, and sustained attention (vigilance), although results have been variable, and sizes of the effects are often modest. A large number of experimental studies have examined the effects of caffeine on memory, but evidence is insufficient to conclude that caffeine produces acute improvements in memory.

A significant limitation of the majority of studies that have found cognitive performance-enhancing effects of caffeine is that subjects in these studies have been regular caffeine users who were required to abstain from caffeine before testing (e.g., overnight abstinence). Thus, the observed cognitive performance-enhancing effects of caffeine in these studies may reflect restoration of deficits that are produced by caffeine withdrawal. For more information on the caffeine withdrawal syndrome, see the Section on Caffeine Withdrawal. It is important to note, however, that a few studies have found cognitive performance-enhancing effects of caffeine in nondependent caffeine users and nonusers. Some studies conclude that low doses of caffeine (32 mg), equivalent to those found in commonly consumed beverages and foods, can significantly improve performance on auditory and visual tasks, without having negative effects on mood profiles such as anxiety (Peeling and Dawson, 2007). In support of these outcomes, Smith

et al. in 1999 showed that a number of common drink choices (water, tea, coffee, or cola) supplemented with an additional low dose (40 mg) of caffeine could significantly enhance performance of a choice reaction time test, a semantic memory task, and a delayed recognition memory task compared with a decaffeinated placebo drink.

A few studies have also demonstrated cognitive performance increases in caffeine users who were not required to abstain from usual caffeine use, suggesting that complete tolerance to the cognitive performance-enhancing effects of caffeine does not occur at usual dietary doses. However, in high-dose caffeine consumers, cognitive performance-enhancement beyond withdrawal reversal is likely to be modest.

## Caffeine and physical exercise

A large body of research has examined the effects of caffeine on exercise performance. Numerous well-controlled studies have found that relative to placebo, caffeine enhances performance during endurance physical exercise. Studies have also generally found that caffeine reduces ratings of perceived exhaustion or effort during physical exercise. Ergogenic effects of caffeine are typically demonstrated at doses of 3–6 mg kg<sup>-1</sup>; higher doses of caffeine (e.g., 9 mg kg<sup>-1</sup>) appear to exert little or no additional benefit on endurance physical exercise. There is some evidence that caffeine produces greater endurance physical exercise benefits in caffeine nonusers and in athletes who abstained from caffeine for several days before dosing. Findings from studies examining the effects of caffeine on short-term, high-intensity physical exercise performance have generally been equivocal, however a recent review suggested that caffeine can improve performance in team-sports physical exercise and power-based sports, with this effect more common in elite athletes who do not regularly consume caffeine. Supplementation with caffeine has been shown to acutely enhance many aspects of exercise, including prolonged aerobic-type activities and brief duration, high intensity exercise. Caffeine is ergogenic when consumed in doses of 3–6 mg/kg body mass. The most commonly used timing of caffeine supplementation is 60 min pre-exercise (Guest et al., 2021). Although not rigorously studied, findings are suggestive that tolerance occurs to the ergogenic effects of caffeine. Several non-independent mechanisms have been proposed for caffeine's effects on exercise physical performance, including increased fatty acid oxidation, increased availability of muscle glycogen, mobilization of intracellular calcium, increased muscle contractile force, and direct CNS effects via adenosine antagonism. Caffeine may improve cognitive and physical performance in some individuals under conditions of sleep deprivation. Caffeine at the recommended doses does not appear significantly influence hydration, and the use of caffeine in conjunction with exercise in the heat and at altitude is also well supported (Guest et al., 2021).

## Caffeine genetics

Much of the variability in caffeine consumption and individual differences in response to caffeine can be accounted for by genetic factors. Findings from twin studies indicate that there may be common genetic factors underlying the use of caffeine, nicotine, and alcohol. Moreover, twins studies indicate that genetic factors may influence total caffeine consumption, heavy caffeine consumption, caffeine tolerance, caffeine withdrawal, caffeine intoxication, and caffeine-related sleep disturbances.

The CYP1A2 gene codes for the isoenzyme P-450 1A2, which is responsible for the demethylation of caffeine to paraxanthine, theobromine, and theophylline. For more information on caffeine metabolism, see the Section on Caffeine Pharmacokinetics. More than 150 CYP1A2 single-nucleotide polymorphisms have been identified. Individual variability in the pharmacokinetics of caffeine can be in large part accounted for by variations in CYP1A2 activity. Recent evidence suggests that individuals homozygous for the allele associated with slow metabolism (CYP1A2\*1F) are at increased risk for nonfatal myocardial infarction associated with caffeinated coffee intake. Thus, caffeine consumption may increase risk for myocardial infarction in individuals with slow caffeine metabolism.

Genetic differences in adenosine A2A receptors have been implicated in individual differences in human caffeine responses. Variations in A2A receptor polymorphisms have been associated with caffeine sensitivity, caffeine-induced anxiety, caffeine-related sleep impairment, and caffeine consumption. One study reported evidence that a polymorphism in dopamine DRD2 receptors is associated with caffeine-induced anxiety.

## Caffeine subjective effects

The qualitative subjective effects of caffeine depend on caffeine dose, individual differences in sensitivity, and degree of tolerance to caffeine. Low to moderate doses of caffeine typically produce positive subjective effects, including increased well-being, arousal, energy, alertness, concentration, motivation to work, and sociability, and decreased feelings of sleepiness or tiredness. Positive subjective effects are more likely to be reported in individuals who have undergone overnight caffeine abstinence.

At higher acute doses of caffeine (e.g., 400–800 mg), negative subjective effects of caffeine typically emerge. Negative subjective effects include increased anxiety, nervousness, jitteriness, tense negative mood, and upset stomach. Anxiogenic subjective effects are more likely to be reported in individuals with panic disorder or generalized anxiety disorder, and in nonclinical populations who

endorse high levels of anxiety sensitivity (i.e., fear of anxiety). For more information about high dose caffeine effects, see the Section on [Caffeine intoxication](#).

## Caffeine reinforcement

The efficacy of a substance in establishing or maintaining self-administration behavior reflects the reinforcing effects of the substance. The circumstantial evidence indicating that caffeine functions as a reinforcer is compelling. Caffeine is the most widely used mood-altering drug in the world. Regular daily consumption of pharmacologically active doses occurs in widely varying cultural and social contexts. Historically, efforts to restrict or eliminate consumption of caffeine-containing foods and beverages have been unsuccessful. Caffeine consumption occurs in a wide variety of vehicles (e.g., coffee, tea, maté soft drinks, energy drinks; chewing kola nuts). Finally, caffeine-containing beverages tend to be more popular than their caffeine-free counterparts. As an example, in 2009, in the US, the top six selling carbonated soft drink brands, and eight of the top 10 selling brands, contained added caffeine.

Numerous well-controlled experimental studies have demonstrated caffeine reinforcement in various subject populations. Across studies, approximately 40% of normal caffeine users demonstrate caffeine reinforcement. Higher rates of reinforcement have been observed among individuals with high levels of caffeine consumption or a history of drug or alcohol abuse. Caffeine can function as a reinforcer at very low doses (i.e., 25 mg per cup of coffee), but may produce avoidance at higher doses (e.g., 400 or 600 mg).

In habitual caffeine consumers, avoidance of caffeine withdrawal plays an important role in the reinforcing effects of caffeine. This relationship has been shown in retrospective questionnaire studies and in experimental studies that have used direct behavioral measures of reinforcement. For example, in one experimental study, moderate caffeine consumers who reported withdrawal symptoms (i.e., headaches and drowsiness) were more than twice as likely to show caffeine reinforcement. Other studies that have prospectively manipulated caffeine physical dependence have demonstrated that subjects were more than twice as likely to exhibit caffeine reinforcement when they were caffeine physically dependent (and thus prone to experiencing withdrawal symptoms when they abstain).

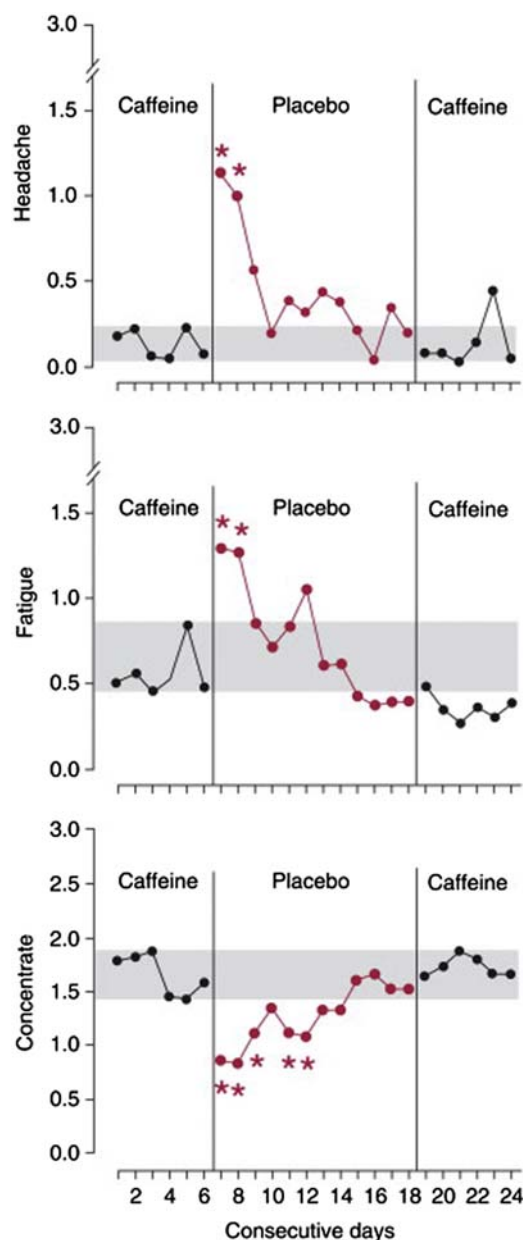

Studies using a conditioned flavor preference paradigm have provided indirect evidence of caffeine reinforcement. In these studies, caffeine abstinent subjects develop a liking and preference for caffeine-paired flavored beverages, relative to beverages paired with placebo. Further studies showed that, in subjects who were repeatedly exposed to a caffeine-paired flavored beverage, the development of liking and preference for the beverage was determined by alleviation of withdrawal symptoms. These studies suggest that conditioned flavor preferences (driven at least in part by alleviation of unpleasant withdrawal symptoms) likely play an important role in consumer preferences for caffeine-containing beverages.

## Caffeine withdrawal

Cessation or reduction of daily caffeine consumption results in withdrawal symptoms in many caffeine users. Caffeine withdrawal has been well characterized in numerous rigorous experimental studies and in survey studies. Caffeine withdrawal headache, which is the hallmark feature of the caffeine withdrawal syndrome, has been the most frequently assessed withdrawal symptom. Approximately half of regular caffeine users report headache when abstaining from caffeine. The caffeine withdrawal headache, which develops gradually, is described as diffuse, throbbing, severe, and phenomenologically distinct from migraine headache. In addition to headache, other withdrawal symptoms that have been reliably observed across experimental and survey studies include: fatigue, decreased energy/activeness, decreased alertness, drowsiness, decreased contentedness, depressed mood, difficulty concentrating, irritability, foggy/not clearheaded, nausea/vomiting, and muscle stiffness/pain. Based on these observed symptoms, five primary clusters of withdrawal symptoms have been proposed: (1) headache, (2) fatigue and drowsiness, (3) dysphoric mood, depressed mood, or irritability, (4) difficulty concentrating, and (5) flu-like somatic symptoms, nausea, vomiting, or muscle pain/stiffness.

Onset of withdrawal typically occurs 12–24 h after abrupt caffeine cessation, although onset has been observed as early as 6 h and as late as 43 h after abstinence in some individuals. Typically, peak intensity of symptoms occurs 1–2 days after abstinence. The duration of caffeine withdrawal symptoms is generally 2–9 days. Re-administration of caffeine (usually within 30–60 min of onset) rapidly and often completely reverses caffeine withdrawal. [Fig. 1](#) shows the time-course of caffeine withdrawal from an illustrative double-blind experimental study.

The severity of caffeine withdrawal symptoms can range from mild to extreme and depends on several factors. Some caffeine users report clinically significant functional impairment associated with caffeine withdrawal (e.g., interference with work or child care activities). Studies show that clinically significant distress occurs in approximately 13% of caffeine users. A much higher rate (73%) of withdrawal-related clinically significant distress occurs in individuals meeting criteria for caffeine dependence. Severity of caffeine withdrawal is positively associated with increases in caffeine maintenance dose, such that greater withdrawal is experienced following cessation of higher maintenance doses. Caffeine withdrawal can occur after daily doses of caffeine as low as 100 mg day<sup>-1</sup>. Caffeine withdrawal may also occur when lower doses of caffeine are substituted for the maintained caffeine dose. As the substituted dose of caffeine decreases, withdrawal severity increases. Nevertheless, even a small amount of substituted caffeine (e.g., 25 mg) can mitigate severity of caffeine withdrawal symptoms.

**Fig. 1** Time course of caffeine withdrawal symptoms in four volunteers. Under double-blind conditions volunteers received either 100 mg day<sup>-1</sup> of caffeine or placebo. Assessments included subjective ratings of headache (top), feelings of lethargy/fatigue/tired/sluggish (middle), and ability to concentrate (bottom). Ratings ranged from 0 (not at all) to 3 (very much). Shaded areas indicate the range of means from the initial 6-day caffeine period. Mean ratings are presented in black for caffeine days and red for placebo days. Asterisks indicate placebo days that are significantly different from the initial caffeine period ( $p \leq 0.05$ ). Reproduced from Griffiths, R.R., Evans, S.M., Heishman, S.J., Preston, K.L., Sannerud, C.A., Wolf, B., Woodson, P.P., 1990. Low-dose caffeine physical dependence in humans. *J. Pharmacol. Exp. Therapeut.* 255: 1123–1132, with permission from ASPET.

## Caffeine tolerance

Caffeine tolerance may occur in response to daily caffeine consumption. Tolerance can occur to the subjective, sleep disrupting, and physiological effects of caffeine. The degree of caffeine tolerance depends on several factors including the challenge and maintenance doses, frequency of administration and individual differences in elimination rate. The prevalence of self-reported tolerance among current caffeine users varies from 8% to 50%. Rates as high as 92% have been reported among caffeine-dependent individuals.

Regular caffeine users may acquire complete tolerance (i.e., no difference between placebo and caffeine after prolonged exposure to caffeine) to some, but not all, of the subjective effects of caffeine. For example, experimental studies showed that volunteers who

received moderate to high doses of caffeine (400 mg–900 mg day<sup>-1</sup>) for at least two weeks developed complete tolerance to ratings of subjective stimulant effects. Other studies indicate that complete tolerance to caffeine subjective effects does not occur at lower caffeine doses and over shorter periods of dosing.

Tolerance development may differ across different outcome measures. One study showed that tolerance or complete tolerance developed to subjective ratings but not to measures of cerebral blood flow or EEG in volunteers receiving 400 mg day<sup>-1</sup>.

With regard to other physiological effects, tolerance may develop to the effects of caffeine on diuresis, parotid gland salivation, metabolic rate, plasma norepinephrine and epinephrine levels, and plasma renin activity. Findings suggest that regular caffeine users develop partial, but not complete tolerance to the effects of caffeine on cerebral blood flow and EEG measures. Two studies, which tested a small number of volunteers demonstrated the development of complete tolerance to the pressor effects of high doses of caffeine (e.g., 600–850 mg day<sup>-1</sup>). However, several more recent studies examining a larger number of volunteers showed that tolerance to the pressor effects of caffeine is variable across individuals, with some subjects showing complete tolerance, whereas others show only incomplete tolerance.

## Caffeine intoxication

Caffeine intoxication, which is a DSM-IV-TR recognized disorder, is defined by the development of symptoms and clinical features in response to acute caffeine consumption that cause clinically significant distress or impairment. Although the DSM-IV-TR definition specifies that the diagnosis depends on recent consumption of at least 250 mg of caffeine, symptoms typically emerge at doses greater than 500 mg. Symptoms of caffeine intoxication include restlessness, nervousness, insomnia, flushed face, diuresis, gastrointestinal disturbance, muscle twitching, rambling flow of thought and speech, tachycardia or cardiac arrhythmia, periods of inexcitability, and psychomotor agitation. Although children and caffeine-intolerant individuals may be particularly sensitive to the acute adverse effects of caffeine, habitual caffeine users may also experience episodes of caffeine intoxication. Several case reports and experimental studies suggest that caffeine consumption may produce hallucinations in some individuals, particularly under conditions of stress. Intoxications with caffeine are rare, however can be fatal. In general, caffeine use seems not harmful within typical doses of intake. Gahr concluded in 2020 that caffeine features several, however, not all characteristics of potentially addictive drugs; withdrawal after termination of a longer period of use and tolerance are known. In the DSM-5 “caffeine use disorder” is categorized as a possible future disorder that currently needs further study. The pattern of caffeine use of patients should be considered in the medical practice.

## Caffeine-induced sleep disorder

Caffeine reduces total sleep time and limits latency to sleep onset, most probably by blocking the sleep promoting effects of adenosine. In addition, caffeine decreases stage 3–4 sleep and suppresses EEG slow wave activity during sleep. The sleep-disrupting effects of caffeine are well documented even at low doses (e.g., one cup of coffee). Surveys have found associations between daily dietary caffeine intake and sleep problems in both adults and adolescents. Eid et al. concluded in 2021 that the risk factors for objective sleep impairment included parenting young children and watching television at night, whereas better sleep outcomes were associated with greater engagement with physical activity.

Some caffeine users may develop caffeine-induced sleep disorder, which is a DSM-IV-TR recognized disorder typically characterized by insomnia. Some caffeine users may present with caffeine-induced hypersomnia with daytime sleepiness due to withdrawal symptoms. Sleep disturbances secondary to caffeine may increase in severity as caffeine dose increases and proximity to caffeine administration at bedtime decreases. Individuals who are not regular caffeine users and are not tolerant, or have only partial tolerance to the sleep-disrupting effects of caffeine are more likely to experience caffeine-related sleep disruption. Lunsford-Avery et al. concluded 2021 that for experimental factors, past studies often lacked a baseline control for diet and sleep and none discussed the possible reversal of withdrawal effect due to pre-experimental fasting.

## Caffeine-induced anxiety disorder

In addition to the symptom of anxiety that can be a component of caffeine intoxication, caffeine can also produce caffeine-induced anxiety disorder, a DSM-IV-TR disorder. Presentation of a caffeine-induced anxiety disorder may include symptoms of generalized anxiety, panic attacks, obsessive–compulsive disorder, or phobic disorder. Individuals who have an existing anxiety disorder, or who endorse symptoms of anxiety sensitivity, are at increased risk of experiencing anxiety symptoms in response to caffeine.

## Caffeine dependence

Substance dependence is characterized by a cluster of cognitive, behavioral, and physiological symptoms indicating that an individual is continuing to use a substance despite experiencing clinically significant substance-related problems. Caffeine dependence

is recognized as a diagnosis in ICD-10, the official diagnostic system of the World Health Organization. In contrast, the DSM-IV-TR currently excludes caffeine from a diagnosis of substance dependence despite using very similar diagnostic criteria to ICD-10. A growing literature from experimental studies, clinical interviews, and survey studies indicates that some caffeine users manifest a pattern of symptoms consistent with a DSM-IV-TR diagnosis of substance dependence as applied to caffeine.

One population-based survey study of 162 randomly-selected caffeine users found that 9% of the sample endorsed three or more of four DSM-IV-TR substance dependence criteria that are thought to be most relevant of a meaningful diagnosis of caffeine dependence. The criteria and past-year incidence were: (1) Persistent desire or unsuccessful efforts to cut down or control use (56%); (2) Characteristic withdrawal syndrome or substance taken or relieve or avoid withdrawal (18%); (3) Use is continued despite a physical or psychological problem likely caused or exacerbated by the substance (14%); and (4) Tolerance defined by either a need for markedly increased amounts to achieve desired effect or markedly diminished effect with continued use of the same amount (8%).

Individuals meeting criteria for caffeine dependence vary considerably in the amount of caffeine consumed per day and in the types of caffeine-containing products that they regularly consume (e.g., coffee, soft drinks, tea). Importantly, the problems associated with caffeine dependence are not trivial. These include, but are not limited to anxiety, insomnia, stomach problems, and cardiovascular problems. One survey found that 13% of caffeine users had been advised by a physician or counselor to reduce or cut down caffeine in the last year. Fifteen percent of caffeine consumers were particularly resistant to modifying their use, indicating that they would not change when or how much caffeine they used, no matter what they were doing or where they were.

## Caffeine and food

In addition to being consumed in its natural plant forms (e.g., coffee and tea), caffeine is also frequently consumed as an added ingredient with or without added sugars for both kind of beverages in many popular sugar-sweetened soft drinks and energy drinks. The bitter taste profile of caffeine is often masked or obscured by the addition of sugar, fat, and other flavors in caffeine-containing foods and beverages. Beverage manufacturers have made the claim that caffeine is added to beverages in order to enhance flavor, but most individuals are unable to detect flavor differences between sugar-sweetened soft drinks with and without caffeine at the caffeine concentration found in most soft drink beverages. It is likely that caffeine-containing beverages are widely consumed because caffeine can function as a reinforcer, increase flavor preferences for caffeine-containing beverages, and produce physical dependence, which results in a substance dependence syndrome.

As described above, caffeine-dependent users may be unable to cut down or control caffeine use despite a persistent desire to do so and may also continue to use caffeine despite medical problems associated with caffeine consumption. Thus, caffeine dependence may exacerbate adverse health outcomes associated with the consumption of caffeine-containing sugar-sweetened beverages. Sugary drinks have been associated with weight gain, obesity, and type-2 diabetes even after controlling for other factors. Of particular concern is that sugar-sweetened beverages together other food containing added sugars consumption may be associated with weight gain and obesity in children and may displace milk and other important nutrients in the diets of children and adolescents.

Caffeine is an added ingredient in many over-the-counter weight loss medications. Experimental studies have generally found that acute caffeine consumption is associated with increased energy expenditure, decreased food intake, and reduced ratings of hunger. There is also some evidence that caffeine increases fat oxidation. It is not clear whether any or all of these effects are due to acute caffeine effects *per se* versus reversal of caffeine withdrawal (e.g., the observed increased energy expenditure may be due to the reversal of suppressed energy expenditure in the caffeine-deprived comparison condition). Prospective longitudinal studies have shown that caffeine consumption is negatively associated with weight gain, but few well-controlled studies have examined the long-term efficacy of caffeine alone as an intervention for weight loss and weight loss maintenance.

Experimental studies have shown that the co-ingestion of caffeine and catechins enhances energy expenditure and fat oxidation more than an equivalent amount of caffeine without added catechins. Numerous investigations have examined the combined effects of caffeine and catechins, most commonly co-ingested in green tea, on weight loss outcomes. A recent meta-analysis of studies comparing a caffeine/catechin condition with either a placebo condition or a low-dose caffeine/catechin condition found that the caffeine-catechin combination had small positive effects on weight loss and maintenance of weight loss after a period of negative energy balance. There is some evidence that effects are attenuated in habitual caffeine consumers with high daily caffeine intake (e.g.,  $>300$  mg day<sup>-1</sup>). This effect may be mediated through caffeine tolerance. Several studies have found that caffeine in combination with ephedrine is efficacious for weight loss. However, ephedrine alkaloid supplements have been associated with adverse events and have been banned by the Food and Drug Administration (FDA) in the US.

## Conclusion

Caffeine can function as a reinforcer and produces a wide range of physiological, behavioral, and subjective effects, including anxiety, insomnia, diuresis, alertness, and enhancement in some types of performance. Regular caffeine consumption can produce tolerance, withdrawal, and a substance dependence syndrome.

## Key points

The main objectives for the article are:

- To identify the essential functions that calcium exerts in our body.
- To describe calcium sources and the variability in their bioavailability.
- To review the current guidelines for calcium and vitamin D intake according to The Institute of Medicine of the National Academy of Sciences.
- To describe the mechanisms implicated in calcium absorption and metabolism.
- To outline the health consequences of calcium deficiency or excess according to the new scientific evidence.

## Glossary

**Calbindin D** Transcellular calcium transport protein involved in calcium absorption (9 kD form) and renal calcium reabsorption (28 kD form)

**Calmodulin** Calcium binding protein that undergoes conformational changes to affect cell signaling

**Osteopenia** Defect in bone mass less severe but potentially leading to osteoporosis

**Osteoporosis** Defect in bone mass and microarchitecture resulting in porous and brittle bones with normal mineral to collagen ratio

**Parathyroid hormone** Eighty-four amino acid polypeptide hormone released from the parathyroid gland in response to low circulating calcium concentrations

**Rickets** Disorder of bone characterized by poor mineralization

**TRPV5, TRPV6** Calcium channels for transcellular calcium transport, members of the Transient Receptor Protein superfamily

**Vitamin D** Family of fat-soluble secosteroids, comprised of cholecalciferol (synthesized from dermal conversion of 7-dehydrocholesterol) and ergocalciferol (from irradiated plant sources); the form of vitamin D that reflects nutritional status is 25(OH) vitamin D, derived from the hydroxylation of cholecalciferol or ergocalciferol in the liver; another hydroxylation step in the kidney results in 1,25(OH)<sub>2</sub> vitamin D, or calcitriol

## Introduction

Calcium is a divalent cation with a molecular weight of  $40 \text{ g mol}^{-1}$ . It is the fifth-most abundant element in the human body, making up approximately 1000–1200 g of total body weight in an adult. Over 99% of calcium is present in bones and teeth of the body, whereas less than 1% is distributed among cells and extracellular fluid. Calcium circulates bound to albumin (40%), sulfates, phosphate and citrates (10%), or as ionized calcium (50%) in concentrations that are tightly maintained at  $\sim 10 \text{ mg dL}^{-1}$  ( $2.5 \text{ mmol L}^{-1}$ ) by sensitive homeostatic processes (Song, 2017). A steep gradient between extracellular or cellular organelle and cytosolic calcium concentrations allows for a rapid flux of calcium into the cell to activate cell-signaling (Weaver and Heaney, 2014). Calcium is lost from the body daily in urine and through the gastrointestinal tract and skin, so calcium intakes must be sufficient to balance these obligate losses. The calcium economy is regulated through parathyroid hormone (PTH) and the conversion of 25(OH) vitamin D to 1,25(OH)<sub>2</sub> vitamin D that it promotes, resulting in increased renal reabsorption of calcium, resorption of calcium from bone, and more efficient absorption of dietary calcium when circulating calcium concentrations are low (Song, 2017). Adequate calcium intake is critical for the achievement of peak bone mass in the first several decades of life, the retention of bone during middle adulthood, and the minimization of bone loss during the last several decades of life. Both skeletal and nonskeletal roles for calcium in human health continue to be explored.

## Functions

Over 99% of the body's calcium occurs in bone where it is deposited on a cartilage matrix as hydroxyapatite ( $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ ); over 30% of bone mineral is calcium. Bone provides structural integrity and also serves as a reservoir of calcium. The remaining <1% of the body's calcium is present in blood, extracellular space, muscle, and other tissues. Maintenance of constant serum calcium concentrations at approximately  $10 \text{ mg dL}^{-1}$  ( $2.5 \text{ mmol L}^{-1}$ ) is critical for a number of cellular functions (Song, 2017). Disorders of calcium metabolism are pretty frequently in routine clinical practice. Hypocalcemia is not as frequently seen as hypercalcemia is, but it can be potentially life-threatening if not appropriately recognized and swiftly treated (Goyal et al., 2021). Intracellular calcium is bound within organelles such as the nucleus, endoplasmic reticulum, and vesicles, with cytosolic calcium approximately 104 times less concentrated than that of the extracellular fluid and organelles. Therefore, rapid changes in cytosolic calcium concentrations occur with the influx of extracellular or sequestered calcium. In the best known cell signaling pathway, intracellular calcium binds to calmodulin, resulting in conformational changes in the protein to trigger cellular events. Resumption of normal cell concentrations requires extrusion of calcium via pumps or sequestration via calcium binding proteins. Muscle contraction, nerve conduction, cell movement and differentiation, cell division, cell-to-cell communication, and secretion of hormones such as insulin are all dependent on intracellular calcium signaling. These functions are largely protected from dietary fluctuations in calcium intake until deficiency becomes extreme. Nonetheless, marginal levels of intake may not only affect skeletal health but predispose to subtle changes in cellular conditions that contribute to alterations in cellular metabolism (Weaver and Heaney, 2014).

## Dietary calcium intake

### Sources

There are striking inequities in calcium intake between rich and poor populations (Cormick y Belizan, 2019). Calcium intakes in some regions of the world average less than 400 mg (10 mmol) per day. Across the 74 countries with data, average national dietary calcium intake ranges from 175 to 1233  $\text{mg day}^{-1}$ . Many countries in Asia have average dietary calcium intake less than 500  $\text{mg day}^{-1}$ . Countries in Africa and South America mostly have low calcium intake between about 400 and 700  $\text{mg day}^{-1}$ . Only Northern European countries have national calcium intake greater than 1000  $\text{mg day}^{-1}$ . Average calcium intake is generally lower in women than men (Balk et al., 2017).

Dietary intake of calcium in the US is typically 900–1200 mg (22.5–30 mmol) per day unless supplements are consumed. Approximately 65–75% of dietary calcium is consumed in dairy products, 8–10% in fruits and vegetables, 5% in grains, and the rest from all other sources. Whereas in China, only around 7% of total calcium intake comes from dairy products, while most comes from vegetables (30%) and legumes (17%) (Cormick and Belizan, 2019; Weaver and Heaney, 2014). One serving of dairy products (i.e., 250 mL milk or yogurt or 40 g cheese) contains approximately 300 mg (7.5 mmol) of calcium. Grains consumed in substantial amounts in bread or maize products can be important sources of calcium, although this is a less bioavailable source than dairy products. Other foods high in calcium are tofu set with a calcium salt, kale, broccoli, and calcium-fortified juices and cereals. Also, calcium present in mineral drinking waters is an important quantitative source of calcium intake. Supplement use is reported in over 40% of the US population overall, and in nearly 70% of older women (Cormick and Belizan, 2019).

In countries or regions where calcium intake is low, milk-based products tend not to be a major component of the diet, and thus a higher percent of total calcium intake is supplied by plant products. Other sources of calcium are experimentally used by the food industry, such as eggshells (Palacios et al., 2021). To some extent, calcium requirements may depend on other nutrients that enhance or inhibit calcium absorption or utilization. Recognizing the presence of low calcium intake is necessary to develop national strategies to optimize intake (Balk et al., 2017).

**Table 1** Current intake recommendations for calcium.

Group	Age range	EAR (mg)	RDA/AI (mg)	UL (mg)
Infants	0–6 months	–	200	1000
	6–12 months	–	260	1500
Children	1–3 years	500	700	2500
	4–8 years	800	1000	2500
Males	9–18 years	1100	1300	3000
	19–50 years	800	1000	2500
	51–70 years	800	1000	2000
	>70 years	1000	1200	2000
Females	9–18 years	1100	1300	3000
	19–50 years	800	1000	2500
	51–70 years	1000	1200	2000
	>70 years	1000	1200	2000
Pregnant Lactating	No changes in age-appropriate intakes advocated			

Abbreviations: EAR, estimated average requirement; RDA, recommended dietary allowance; AI, adequate intake recommendation; UL, tolerable upper intake level. RDAs are established for all age groups except infants.

Source: Institute of Medicine (2011).

The Institute of Medicine of the National Academy of Sciences (IOM, 2011), currently called National Academy of Medicine, reviewed guidelines for calcium and vitamin D intake in 2011 and updated recommendations for US and Canadian populations (Table 1). These recommendations are based on the most current data available regarding the amount of dietary calcium i.e., required to optimize bone calcium deposition or maintenance, accounting for estimates of fractional absorption and usual losses. In contrast to previous reports suggesting that a considerable number of people in the US were at risk of consuming inadequate amounts of calcium, more recent national data suggest that most population groups, other than adolescent girls, are generally consuming adequate amounts of calcium with reference to the new Estimated Average Requirements.

## Metabolism

### Balance

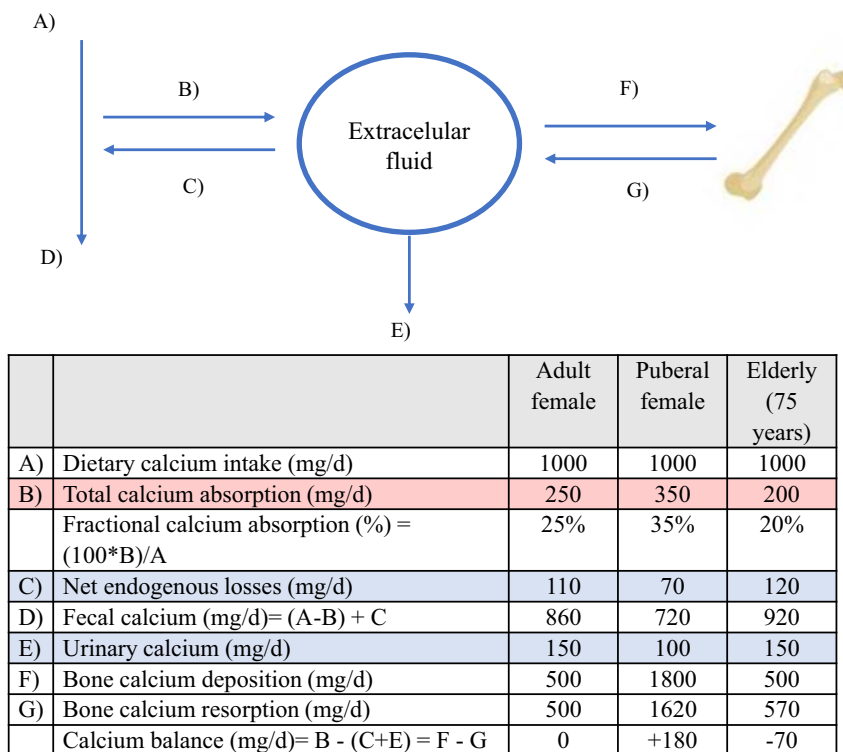

Calcium balance can be calculated as the difference between calcium entering the body through absorption of dietary calcium and obligate losses of calcium through urine, gastrointestinal tract, and skin. When uptake exceeds losses, an individual is in positive calcium balance, and net bone calcium accrual occurs, although bone continually remodels such that bone calcium turns over entirely every 5 or 6 years. Negative balance occurs when dietary intake is insufficient to cover losses, despite mechanisms to conserve body calcium (Song, 2017). Typically, approximately 25% of dietary calcium is absorbed in adults and delivered to the exchangeable calcium pool, which turns over 20–30 times per day. A remarkably large amount of calcium is filtered through the kidneys, approximately 10,000 mg (250 mmol) per day, of which approximately 98% is reabsorbed, so that urinary excretion of the mineral is only 100–200 mg (2.5–5 mmol) per day. Calcium balance benefits from increased dietary intake up to a “threshold,” above which excess calcium is excreted rather than contributing to bone mass. These thresholds are highest during periods of growth. Differences in calcium economy also exist between racial/ethnic groups, such that the lower urinary calcium and better calcium conservation in African-Americans relative to Caucasians probably contributes to their higher bone mineral density. Aspects of calcium balance for a typical adult, pubertal and elderly female are shown in Fig. 1.

## Absorption

### Mechanisms

Dietary calcium is complexed to food constituents such as proteins, phosphate, and oxalate, from which it needs to be released before absorption. Conditions that promote the solubility of calcium may enhance its absorption, and achlorhydria may therefore impair calcium absorption, as has been shown with some calcium supplements when consumed in a fasted state (Weaver and Heaney, 2014).

Calcium crosses the intestinal mucosa by both active and passive transport. The active process is saturable, transcellular, and occurs primarily in the duodenum. This pathway is upregulated during calcium deficiency and predominates when calcium intakes are low. Luminal calcium enters the enterocyte from the microvillus border of the apical plasma membrane via a calcium channel

**Fig. 1** Hypothetical example of calcium balance on 1000 mg day<sup>-1</sup> dietary calcium intakes in an adult woman, pubertal girl and elderly woman. Calcium uptake by the body is indicated by the red fill, losses by the blue fill. The difference between calcium intake and losses must equal the difference between bone deposition and resorption, as the extracellular fluid compartment calcium concentration remains constant, although bone turnover rates are higher during growth. Calcium absorption efficiency is higher in the girl, and endogenous losses are lower due to smaller body size. Note that the pubertal female and the elderly is not consuming the RDA for calcium, and a higher intake would favor a greater calcium balance.

and is translocated to the basolateral membrane where it is released through another calcium channel. Calbindin D<sub>9k</sub>, a calcium binding protein regulated by the hormonal form of vitamin D, 1,25(OH)<sub>2</sub>D vitamin D, transports calcium across the enterocyte following its uptake through an apical membrane channel, TRPV6, and calcium is extruded via an ATPase, PMCA1. Details of this process are still under review, and other transcellular processes may exist (Weaver and Heaney, 2014).

The passive transport pathway is no saturable and paracellular. It occurs throughout the small intestine and is unaffected by PTH and relatively independent of 1,25(OH)<sub>2</sub> vitamin D, although this metabolite has been found by some investigators to increase the permeability of the paracellular pathway. A substantial amount of calcium is absorbed by passive transport in the ileum due to the relatively slow passage of food through this section of the intestine. The amount of calcium absorbed by passive transport is proportional to the intake and the bioavailability of calcium consumed (Weaver and Heaney, 2014).

Although fractional calcium absorption increases in response to low calcium intake, this compensatory mechanism is incomplete, and total calcium absorption increases in relation to calcium intake. The efficiency of calcium absorption also varies throughout life. It is highest during infancy, time when the absorption fraction can range from somewhat above 60% with lower intakes to about 30% with higher intakes. As the infant transitions into childhood, fractional calcium absorption declines, only to rise again in early puberty, a time when modeling of the skeleton is maximal. A calcium absorption rate of 28% before puberty, 34% during early puberty (the age of the growth spurt), and 25% 2 years after early puberty has been reported. Fractional absorption remains about 25% in young adults (IOM, 2011), and then declines with age (by approximately 2% per decade after menopause). During pregnancy, calcium absorption doubles, although inter-individual variation is high. Thus, the active transport pathway is most efficient when calcium requirements are high: during infancy, adolescence, and pregnancy. Increased absorption is also observed during primary hyperparathyroidism, sarcoidosis, and estrogen and growth hormone administration. Physiological/pathological factors, which decrease intestinal calcium absorption include low serum 1,25(OH)<sub>2</sub> vitamin D, chronic renal insufficiency, and hypoparathyroidism. Metabolic status also influences calcium absorption such that severe obesity is associated with higher calcium absorption and dieting reduces the fractional calcium absorption by 5% (IOM, 2011).

### Bioavailability

Dietary factors that may inhibit calcium absorption include phosphate, oxalate, phytate, and fiber. Fermentation of bread during leavening reduces phytate content, making calcium more bioavailable. Fiber in fruits and vegetables can also inhibit calcium absorption; the uronic acids in hemicellulose are strong calcium binders, as is the oxalic acid present in high concentrations in foods

such as spinach. Calcium bioavailability from beans is approximately half and that from spinach approximately one-tenth of the bioavailability from milk. In contrast, calcium absorption from low-oxalate vegetables, such as kale, broccoli, and collard greens, is comparable to that of milk (Weaver and Heaney, 2014). Therefore, veganism is associated with a low calcium intake, which has less bioavailability, and people who are following a vegan diet should be aware of the risk of potential dietary deficiencies (Bakaloudi et al., 2021).

Most calcium salts used in food fortification for human consumption have a bioavailability ranging from 20% to 40%. Their solubility, source, interaction with the food and whole meal, and bioavailability vary widely. Calcium citrate malate has been shown to have greater absorption compared with other salts (Palacios et al., 2021), and it may be recommended instead of the less costly calcium carbonate in individuals with achlorhydria or if supplements cannot be taken with a meal.

Dietary fat does not affect calcium absorption except in individuals with diseases that impair fat absorption (e.g., short bowel syndrome, celiac disease, and pancreatitis), where calcium may form an insoluble “soap” with the unabsorbed fat in the alkaline lumen of the small intestine. Neither dietary phosphorus nor a wide range of phosphorus-to-calcium ratios affect intestinal calcium absorption.

Factors that increase calcium absorption include protein (or specific amino acids, lysine, and arginine). Lactose improves calcium absorption in young infants, in whom absorption of calcium is predominantly by passive transport, but in adults, lactose has little effect on the efficiency of calcium absorption (Weaver and Heaney, 2014). New research also suggests that certain oligosaccharides, such as inulin, may enhance absorption of calcium. It is possible that these prebiotics function through a variety of mechanisms to enhance the solubility of luminal calcium and improve the ability of the enterocyte to bind and take up calcium. In addition to these mechanisms, current evidence suggests that prebiotic fibers may offer an alternative approach to enhance calcium absorption through altering gut microbiota to improve bone health ultimately (Cao et al., 2020). According to a recent study, an inulin intake of at least 8–10 g day<sup>-1</sup> supports calcium absorption and total body bone mineral content/density in adolescents through its known mechanisms of action (Bakirhan and Karabudak, 2021).

### Nutrient interactions

Calcium can inhibit iron and zinc absorption, although this interaction may not be an issue at typical levels of calcium intake. The mechanism by which this occurs remains controversial, but the inhibition probably occurs within the mucosal cells rather than in the intestinal lumen. This interaction is of concern because calcium supplements are taken by many women who may have difficulty maintaining adequate iron stores. The inhibitory effect on iron absorption is relatively unimportant when iron stores are adequate (ferritin 50–60 µg L<sup>-1</sup>), but consideration should be given to monitoring the iron status of menstruating women with low iron stores who take calcium supplements. There is no inhibitory effect when calcium and iron supplements are consumed together in the absence of food, and inhibition may be less with calcium citrate. Moreover, evidence shows no effect on iron status of prolonged calcium supplementation taken at the same time or separate of meals (Cormick and Belizan, 2019; Weaver and Heaney, 2014).

Earlier, it was common to restrict dietary calcium in patients with a history of calcium oxalate stones. More recent studies have suggested that dietary calcium restriction is not recommended for stone formers with nephrolithiasis; on the contrary, diets with more than 1 g of calcium per day could be protective against stone formation. Kidney stones are mainly composed of calcium combined with oxalate or phosphate. The calcium remaining in the intestine would impede the absorption of products associated with the risk of renal stones, such as oxalates, and the intake of calcium supplements during meals would decrease the absorption of oxalates and thus the formation of stones (Cormick and Belizan, 2019).

### Calcium losses

Very large amounts of calcium are filtered by the kidney each day, but nearly all is reabsorbed throughout the nephron, such that typically, 100–200 mg (2.5–5 mmol) of calcium is excreted in urine daily. Most calcium is reabsorbed passively in the proximal tubule, whereas active absorption takes place in the distal convoluted tubule via a calcium channel, TRPV5, and transcellular movement via calbindin D<sub>28k</sub>, a calcium transport protein. Dietary calcium has a relatively small impact on urinary calcium in adults (e.g., only 6–8% of an increased dietary calcium intake is excreted in the urine); in children, increased intake is utilized for bone accretion rather than excreted. The major food components that affect urinary calcium are protein, phosphorus, caffeine, and sodium. For each 50 g increment in dietary protein, approximately 60 mg (1.5 mmol) of additional calcium is lost in urine (Weaver and Heaney, 2014). The higher amounts of phosphorus consumed concurrently with a high-protein diet can blunt, but not eliminate, this phenomenon. Dietary phosphorus (as well as intravenously administered phosphorus) increases PTH synthesis and subsequently stimulates renal calcium reabsorption, reducing the urinary excretion of calcium. Caffeine causes a transient loss of urinary calcium through diuresis. It has been shown repeatedly in animals and humans that dietary sodium, in the form of salt (NaCl), increases urinary calcium excretion. On average, for every 2300 mg (100 mmol) of sodium excreted in urine, there is an approximately 24–40 mg (0.6–1 mmol) loss of calcium in free-living healthy populations of various ages. Thus, when urinary calcium excretion is excessive it is often recommended to limit salt intake. Diets that produce more alkaline metabolic conditions, such as those with potassium-rich fruits and vegetables, may reduce calcium losses through the buffering effects of potassium bicarbonate on metabolic pH (Weaver and Heaney, 2014).

Endogenous losses of calcium occur in the gastrointestinal tract as cells are sloughed and calcium-containing pancreatic and bile secretions are released during digestion. Endogenous losses are proportional to body size and average approximately 2 mg kg<sup>-1</sup>

day<sup>-1</sup> in adults and 1.5 mg kg<sup>-1</sup> day<sup>-1</sup> in children. Greater losses may occur under some conditions that affect gut integrity, such as protein-losing enteropathies. Because of the difficulties in measuring endogenous losses, requiring balance studies that utilize calcium stable isotope tracers, these losses are typically estimated rather than directly measured. Dermal losses of calcium occur on the order of approximately 25 mg day<sup>-1</sup>, but may increase with sweating, and are as well typically estimated rather than measured (Weaver and Heaney, 2014).

### Hormonal control

The principal regulators of calcium homeostasis in humans and most terrestrial vertebrates are PTH and 1,25(OH)<sub>2</sub> vitamin D, the active form of the vitamin (Fig. 2). PTH is a single-chain polypeptide i.e., released from the parathyroid when a decrease in the circulating calcium concentration is detected by parathyroid gland calcium-sensing receptors. It restores extracellular calcium concentrations by increasing the renal reabsorption of calcium and decreasing phosphate reabsorption, and by enhancing the renal conversion of 25(OH) vitamin D to the active, hormonal form of the vitamin, 1,25(OH)<sub>2</sub> vitamin D, and by stimulating the resorption of bone to release calcium. In turn, 1,25(OH)<sub>2</sub> vitamin D enhances calcium absorption through the active pathway. PTH release is inhibited when serum calcium and 1,25(OH)<sub>2</sub> vitamin D increase or when serum phosphate is decreased. The highly regulated interactions among PTH, calcium, 1,25(OH)<sub>2</sub> vitamin D, and phosphate maintain blood calcium levels at remarkably constant levels despite significant changes in calcium intake or absorption, bone metabolism, or renal function. PTH regulation of circulating calcium concentration occurs on a minute-by-minute basis, and acute PTH administration leads to release of the rapidly turning over pool of calcium near the bone surface. Chronic administration of PTH increases osteoclast cell number and activity. Interestingly and paradoxically, intermittent PTH administration is anabolic, increasing formation of trabecular bone (Weaver and Heaney, 2014).

There are two sources of vitamin D: the diet (where it is found as vitamin D<sub>2</sub> (ergocalciferol) or vitamin D<sub>3</sub> (cholecalciferol)) or synthesis in skin during exposure to ultraviolet radiation (sunlight). The vitamin enters the circulation and is transported on a vitamin D binding protein to the liver, where it is hydroxylated to 25(OH) vitamin D—the major circulating form of the vitamin. It is hydroxylated again in the kidney to 1,25(OH)<sub>2</sub> vitamin D, or calcitriol, the most active metabolite of the vitamin. Vitamin D acts through nuclear receptors to enhance production of proteins involved in calcium absorption, as well as renal calcium

**Fig. 2** Regulatory system for maintaining calcium homeostasis via the PTH-vitamin D axis. 1,25(OH)<sub>2</sub> vitamin D works with PTH to enhance calcium availability from bone and kidney.

reabsorption and bone calcium resorption in concert with PTH. Because dietary sources of vitamin D are relatively uncommon (e.g., fatty fish) and endogenous production through cutaneous exposure of 7-dehydrocholesterol to UVB radiation may be limited by latitude, season, skin tone, or availability of cutaneous precursors (i.e., in the elderly), inadequate vitamin D status has become an area of concern globally. Although debate remains regarding optimal 25(OH) vitamin D concentrations, sustained elevated PTH levels occur at low 25(OH)D concentrations, contributing to the bone loss that occurs in vitamin D deficiency. This secondary hyperparathyroidism causes increased osteoclastic activity and calcium loss from bone, and contributes to osteoporosis (Weaver and Heaney, 2014).

Other hormones also affect calcium metabolism, although whether they function directly or via the PTH-vitamin D pathway is not always delineated. Notably, estrogens are necessary for the maintenance of balance between bone resorption and accretion. The decrease in serum estrogen concentrations at menopause is the primary factor contributing to the elevated rate of bone resorption that occurs at this stage of life, contributing to osteoporosis. Testosterone also inhibits bone resorption, and lack of this hormone with aging can contribute to osteoporosis in men. It may work through the growth hormone/insulin-like growth factor-1 (IGF-1) axis, which stimulates cartilage formation, the formation of 1,25(OH)<sub>2</sub>D vitamin D, and intestinal calcium absorption. IGF-1 stimulates osteocalcin production, which is required for bone mineralization. Thyroid hormones stimulate bone resorption, and calcium metabolism abnormalities occur in both hyper- and hypothyroidism. Insulin stimulates collagen production by osteoblasts and impairs the renal reabsorption of calcium. Glucocorticoids, sometimes used to treat conditions such as osteoid arthritis, inflammatory bowel disease, and asthma, inhibit both osteoclastic and osteoblastic activity, impair collagen and cartilage synthesis, and reduce calcium absorption. Excessive bone loss often occurs with glucocorticoid treatment or when excessive amounts of the hormone are secreted, such as in Cushing's disease (Weaver and Heaney, 2014).

### Influence of life stages

The total body calcium content of the newborn infant is approximately 30 g (0.75 mol), with most skeletal calcium accrued during the third trimester of pregnancy. The efficiency of calcium absorption is highest during infancy (approximately 60%), and the amount absorbed from breast milk does not appear to be affected by calcium consumed in solid foods.

Childhood remains a time of bone mineral accrual, culminating in the pubertal growth spurt, when calcium absorption increases and bone calcium retention peaks at 200–300 mg (5–7.5 mmol) per day under the orchestration of growth hormone, IGF-1, and sex steroids. Rates of bone calcium deposition and net calcium accrual peak in girls just before menarche and decline thereafter; peak rates of calcium accrual occur approximately 1.5 years later in boys and bone mineralization persists later in boys as well. Forty percent of adult bone mass is acquired during pubertal growth, and while bone mass may continue to accumulate until approximately 30 years of age, relatively little is gained after 18 years of age. Thus, it is important to optimize bone mineralization during growth to ensure adequate bone mineral stores are present to defer the risk of osteoporosis later in life (Weaver and Heaney, 2014).

During pregnancy, a relatively small amount of calcium, approximately 625–750 mmol, is transported to the fetus. Most of this calcium is thought to be obtained through greater efficiency of maternal intestinal calcium absorption, possibly induced by increases in 1,25(OH)<sub>2</sub>D vitamin D production. For this reason, a greater calcium intake during pregnancy is probably not required, although urinary calcium excretion also increases as plasma volume expansion increases the filtered load of the kidneys. Most studies have reported that there is no increase in intestinal calcium absorption during lactation even when dietary intake of the mineral is relatively low. Changes in biochemical markers and kinetic studies using isotopes indicate that the source of much of the calcium secreted in breast milk is the maternal skeleton, as well as more efficient renal reabsorption and subsequently lower urinary excretion of the mineral. Bone calcium is restored at the end of lactation as the infant is weaned, when ovarian function returns and menstruation resumes. At this time, intestinal calcium absorption increases, urinary calcium remains low, and bone turnover rates decline to normal levels. There is no strong evidence that lactation per se or maternal calcium intake during lactation affect later risk of osteoporosis in women. Thus, there is no strong rationale for increasing maternal calcium intake during lactation. Breast milk calcium concentration is relatively unaffected by maternal intake, and it remains stable throughout lactation (Weaver and Heaney, 2014).

Menopause begins a period of bone loss that extends until the end of life. It is the major contributor to higher rates of osteoporotic fractures in older women. The decrease in estrogen at menopause is associated with accelerated bone loss, particularly of the spine; in the first five postmenopausal years, approximately 15% of skeletal calcium may be lost. Calcium absorption becomes less efficient, and urinary calcium excretion increases, resulting in a declining calcium balance of approximately 30 mg day<sup>-1</sup>. Hormone replacement therapy was an effective means of improving calcium balance and bone health, but is generally no longer recommended in this age group due to other potential health risks (e.g., increased risk of cardiovascular outcomes such as coronary heart disease and stroke). Bone turnover markers (such as serum N-terminal propeptide of type I procollagen and C-terminal collagen cross-link) are biological molecules liberated during bone formation or bone resorption, can be detected in blood or urine and have been suggested as an additional tool to monitor the response of treatment of osteoporosis. Nevertheless, these new markers remain emerging and are primarily used in research studies (Song, 2017). Calcium supplements alone have only a moderate impact in preventing postmenopausal bone loss, although calcium and vitamin D supplements are recommended to complement other therapies to treat osteoporosis.

## Race and genetics

Dietary calcium intake and fecal calcium excretion explained almost 85% of the heterogeneity of calcium retention. Chinese adults could maintain a positive calcium balance with plant-based diets at calcium intakes as low as 300 mg/d through increasing fractional calcium absorption and decreasing calcium excretion in urine and feces (Fang et al., 2016).

## Health consequences of calcium deficiency

### Skeletal

Between 60% and 80% of the variance in peak bone mass is explained by genetics, including polymorphisms in the vitamin D-receptor gene and in genes responsible for IGF-1 and collagen production. Moreover, dietary and lifestyle factors besides calcium contribute to bone health, and studies that have provided calcium supplements have often concurrently provided vitamin D, making it difficult to distinguish calcium-specific effects. Nonetheless, it is accepted that calcium intake is critical for assuring optimal bone mass and its preservation (Balk et al., 2017; Cormick and Belizan, 2019; Li et al., 2018). Studies of calcium supplementation in children have shown modest improvements in skeletal mineralization, and although these gains may be transient, with unsupplemented children acquiring similar levels of bone mineral content later, they may help prevent fractures. Studies of calcium or calcium and vitamin D supplementation during menopause have also demonstrated modest gains in bone mineral density, particularly among those whose calcium intakes are lowest (Weaver and Heaney, 2014).

Other skeletal effects of low calcium diets include rickets observed in equatorial regions of the world, where calcium intakes are extremely low and vitamin D status is typically adequate. Calcium deficiency occurs in children who are somewhat older than those in whom vitamin D-deficient rickets might appear (i.e., 1–3 years of age versus infancy), and is resolved with provision of calcium rather than vitamin D. It is possible that susceptibility of some children to rickets is due to efficiency of calcium utilization that might be explained by different vitamin D receptor types.

### Nonskeletal

Calcium has been investigated as a protective agent in a variety of chronic diseases, including cancer, cardiovascular disease, hypertension, gastrointestinal diseases, metabolic syndrome and other important diseases (Das and Choudhuri, 2021; Li et al., 2018). Appropriate calcium intake has shown many health benefits, such as reduction of hypertensive disorders of pregnancy, lower blood pressure particularly among young people, prevention of osteoporosis and colorectal adenomas, lower cholesterol values, and lower blood pressure in the progeny of mothers taking sufficient calcium during pregnancy (Cormick and Belizan, 2019). Most data come from observational studies linking dietary calcium intake to these outcomes, and associations may therefore be explained by overall healthful dietary patterns that are associated with increased calcium intake. Data from intervention trials have been less consistent in demonstrating benefits of calcium on these health outcomes, but data from high quality trials with chronic disease incidence as primary outcomes are lacking. The best evidence to date is for a protective effect of calcium on colorectal cancer. There is debate about the role of calcium on cardiovascular outcomes, with some metanalysis showing an increased risk with increased calcium intake, whereas other data demonstrate no effect or protective effects. Calcium supplementation reduces risk of pre-eclampsia among pregnant women on low calcium intakes (Weaver and Heaney, 2014). Diabetic patients also show characteristic potassium, magnesium, phosphate, and calcium depletion and have been found a homeostatic mechanism that links calcium and diabetes mellitus.

Calcium-rich diets may play a role in energy regulation and reduce the risk of obesity by maintaining low intracellular calcium concentrations in adipocytes, reducing lipogenesis. Although this metabolic pathway has been elucidated, application of calcium-rich diets has not always favored weight loss in controlled trials (Das and Choudhuri, 2021).

In the immune system, calcium signals play a central role in various cellular functions such as proliferation, differentiation, apoptosis, and numerous gene transcriptions (Park et al., 2020). Different microRNAs (small non-coding RNA which regulate the gene expression post-transcriptionally) have been studied recently to elucidate the mechanisms implicated in the protective effect of calcium on chronic diseases. Deregulated microRNAs may have a central role in severe diseases, including cancer, heart disease and a wide range of immune disorders (Diener et al., 2018; Park and Kho, 2021).

## Health consequences of calcium excess

Excessive calcium intakes can rarely be achieved through diet, but with increasing utilization of supplements some groups may be particularly susceptible to consequences of calcium excess. Hypercalcemia, circulating calcium above  $12 \text{ mg dL}^{-1}$  ( $3 \text{ mmol L}^{-1}$ ), is the acute effect of calcium excess and is associated with weight loss, fatigue, heart arrhythmias, and soft tissue calcification. In addition, it may result in hypercalciuria and affect renal function, resulting in the so-called milk-alkali syndrome. Kidney stones may result from the precipitation of calcium oxalate in renal tissue, and are more likely to be associated with supplemental rather than dietary calcium, which may be protective. An association of prostate cancer with excess calcium intake is being explored. A recent meta-analysis of clinical trials showed that the use of calcium supplements was significantly associated with the increased

risk of cardiovascular and coronary heart disease by 15%, specifically in postmenopausal women (Li et al., 2018; Myung et al., 2021). These data suggest that calcium supplementation should be prescribed and taken cautiously, accounting for individual patients' risks and benefits. It is desirable to reach the recommended contributions through food, whenever possible (Li et al., 2018).

## Conclusion

Calcium is the fifth most abundant element in the human body, and it has numerous structural and regulatory functions. Marginal intake levels may affect skeletal health and lead to changes in cellular conditions that contribute to alterations in cellular metabolism.

Dairy products are the best source of calcium in quantity and quality due to their bioavailability. Nowadays, there is a large gap between countries in calcium intake, and it is mandatory to develop national strategies to improve and optimize intakes. The absorption of this mineral changes throughout life, being relevant during childhood and puberty to achieve peak bone mass.

Calcium has a crucial role in skeletal disease such as osteoporosis, and it is considered a protective agent in a variety of chronic diseases, including cancer, cardiovascular disease, hypertension, gastrointestinal diseases and metabolic syndrome.

## Key points

- Define and describe the types and main functions of carbohydrates
- Distinguish carbohydrates, according to their chemical structure and polymerization
- Define and classify monosaccharides
- Describe stereoisomerism, physical properties and chemical reactions exhibited by monosaccharides
- Briefly describe sugar alcohols and their importance
- Outline the most important oligosaccharides and polysaccharides and explain their physical properties and chemical reactions

## Introduction

Carbohydrates are the most abundant constituents of cereals, fruits, vegetables, and legumes and a dietary staple in most countries. Carbohydrate oxidation is the main energy-yielding pathway in the majority of human cells and the most important energy source in human nutrition. They contribute to the texture and flavor of foods and diet variability and palatability.

Carbohydrates are polyhydroxy aldehyde or ketone molecules and their derivatives. They comprise a group of substances with different structures and varying physical, chemical and physiological properties. Dietary carbohydrates are important in maintaining glycemic homeostasis, and gastrointestinal health.

## Functions and types of carbohydrates

Carbohydrates are chemically stable organic molecules and comprise of carbon, hydrogen and oxygen atoms (Nelson and Cox, 2017). They are produced in green plants containing the green pigment chlorophyll, by the conversion of carbon dioxide and water, utilizing solar energy, a process known as photosynthesis.

Carbohydrates, also known as saccharides or glycans, are polyhydroxy aldehydes or ketones, or substances hydrolyzed to produce such compounds (Nelson and Cox, 2017). Some carbohydrate molecules have the empirical formula  $(CH_2O)_n$ , but others may also contain nitrogen, phosphorus, or sulfur.

Carbohydrates are compounds of great biological importance and have an extensive role in all forms of life. They provide energy through oxidation and comprise the greatest part of caloric intake in most human diets (Lewis, 2000). They serve as a short-term energy reserve for bodily functions, form metabolic intermediates and provide the carbon backbone for synthesis of biochemical substances and cell components (Nelson and Cox, 2017). They form part of the structural framework of the nucleotide genome sequence. Furthermore, they are part of structural constituents of cells and tissues. Carbohydrates are linked to proteins and lipids and have important functions in cell interactions.

Carbohydrates are classified depending on their chemical structure and their degree of polymerization into the following categories: sugars (monosaccharides and disaccharides), polyols (sugar alcohols), oligosaccharides and polysaccharides (World Health Organization, 1998). Table 1 displays carbohydrates based on their chemical structure. “Saccharide” is derived from the Greek word *sakcharon*, meaning sugar. Monosaccharides and disaccharides are jointly called sugars. Polyols (sugar alcohols) are monosaccharide and disaccharide derivatives that have nutritional importance.

## Monosaccharides

### Classification

Monosaccharides are the simplest form of carbohydrate and cannot be further hydrolyzed to smaller subunits (Nelson and Cox, 2017). They are comprised of a single polyhydroxy aldehyde (the aldoses) or a ketone unit (the ketoses). Monosaccharides with three, four, five, six, and seven carbon atoms in their backbones are called, according to their chain length, trioses, tetroses, pentoses, hexoses, and heptoses respectively. The two simplest monosaccharides are glyceraldehyde, an aldotriose, and dihydroxyacetone, a ketotriose. The most nutritionally important monosaccharides are the pentoses (5-carbon atom skeleton), e.g., ribose, and the hexoses (6-carbon atom skeleton), e.g., glucose. Other examples of monosaccharides include fructose, galactose, and xylose.

The most nutritionally important and abundant monosaccharide is glucose, which is used as the major cell fuel in the human body and can be found unbound in body tissues and fluids (Lewis, 2000). Glucose is the building block of several polysaccharides. Galactose is the monosaccharide produced from the hydrolysis of lactose, which is present in milk (Ball et al., 2014). It can also be synthesized from glucose in the human body. Galactose can be used as cell fuel, but it is also a component of glycolipids, found in nerve cells. Fructose (levulose) is present in honey and fruits, and can also be used as cell fuel. Fructose is the sweetest of all monosaccharides.

**Table 1** Chemical classification of carbohydrates.

<i>Class</i>	<i>Subgroup</i>	<i>Components</i>
Sugars	Monosaccharides	Glucose, fructose, galactose
	Disaccharides	Sucrose, lactose, maltose
Polyols (sugar alcohols)	Monosaccharide derivatives	Erythritol, xylitol, mannitol, sorbitol
	Disaccharide derivatives	Lactitol, isomalt, maltitol
Oligosaccharides	Malto-oligosaccharides	Maltodextrins
	Non-digestible oligosaccharides	Raffinose, stachyose, fructo-oligosaccharides, verbacose
Polysaccharides	Starch	Amylose, amylopectin, modified starches
	Non-starch polysaccharides	Cellulose, hemicellulose, pectins, hydrocolloids (gums)

Adapted from World Health Organization (1998). Carbohydrates in Human Nutrition. Report of a Joint FAO/WHO Expert Consultation. FAO Food and Nutrition Paper 66, 1–140.

**Table 2** Some nutritionally important monosaccharides and monosaccharide derivatives.

Class	Species	Significance
Hexoses	D-glucose	Major cell fuel, unbound in body fluids and tissues, building block of several polysaccharides
	D-fructose	Cell fuel, constituent of sucrose
	D-galactose	Cell fuel, constituent of lactose
	D-mannose	Constituent of plant cell wall polysaccharides and gums
Pentoses	L-arabinose, D-xylose	Constituent of plant cell wall polysaccharides
	D-ribulose, D-xylulose	Metabolite in pentose pathway
	D-ribose	RNA constituent
Uronic acids	D-glucuronic, D-galacturonic	Constituent of plant cell wall polysaccharides
	D-mannuronic, D-guluronic	Constituent of algal polysaccharides
Sugar alcohols	D-glucitol, D-xylitol	Food ingredient, sweetener
	D-galactitol	Metabolite of galactose
Deoxysugars	D-deoxyribose	DNA constituent
	D-deoxygalactose	Constituent of algal polysaccharides
	L-fucose	Constituent of bacterial polysaccharides
	L-rhamnose	Constituent of pectic plant polysaccharides
Aminosugars	D-glucosamine, D-galactosamine	Constituent of aminosaminoglycans, cartilage

Aldose or ketose derivatives of monosaccharides can be produced by substitution of a hydroxyl group or by oxidation of a carbon atom to a carboxyl group to supply esters, ethers or deoxy and amino compounds (Lewis, 2000). In addition, monosaccharides can form sugar alcohols and sugar acids (uronic, aldonic, and aldaric acids). When they are attached to proteins and lipids, important compounds are synthesized, such as glycoproteins, proteoglycans and glycolipids. These compounds have important structural and functional roles. The most important monosaccharides and monosaccharide derivatives and their significance are outlined in Table 2.

### Stereoisomerism and nomenclature

Carbohydrates demonstrate stereoisomerism. In general, stereoisomers have the same chemical and structural formulas, but different spatial arrangement of their atoms (Nelson and Cox, 2017).

Monosaccharides have optical isomers, which is a type of stereoisomer (Nelson and Cox, 2017). If a molecule's mirror image is non-superimposable on itself, then it has an optical isomer. These non-superimposable mirror images are named enantiomers of each other. Asymmetric or chiral carbons are carbons with different functional groups attached to them. The presence of chiral carbons in monosaccharides gives rise to optical activity. Optical activity is the phenomenon occurring when polarized light is passed through a solution of monosaccharide compounds, during which the plane of light will be rotated either to the left (Levrorotatory or L form) or to the right (Dextrorotatory or D form). Consequently, similar structures of the same monosaccharide are produced, namely of the D or the L configuration. Monosaccharides of the D form are biologically significant and nutritionally important, because most naturally occurring monosaccharides are D stereoisomers, and metabolic and digestive enzymes are specific for them. Monosaccharides that have a different configuration about a single carbon atom are called epimers.

For simplicity, three-dimensional monosaccharide structures are drawn as straight chain molecules using Fischer projection formulas (Fig. 1). However, in aqueous solutions, monosaccharides with five or more carbon atoms exist mainly as cyclic or

**Fig. 1** D-glucose molecule shown as open chain and as a cyclic pyranose ring in the  $\alpha$  and  $\beta$  configuration.

ring structures (Nelson and Cox, 2017). This is another type of stereoisomerism exhibited by monosaccharides, in which the carbonyl group has formed a covalent bond with the oxygen of a hydroxyl group along the chain. This stereoisomerism results from a general reaction between alcohols and aldehydes or ketones, to form hemiacetals or hemiketals.

Cyclization can produce two stereoisomers of the  $\alpha$  and  $\beta$  configuration, binding either in the “front” or in the “back” of the carbon atom (Nelson and Cox, 2017). Monosaccharide isomers, which have different configuration about the hemiacetal or hemiketal carbon atom, are named anomers and the carbonyl carbon atom is named anomeric carbon. Generally, an equilibrium mixture of the straight and the cyclic form exists in monosaccharide solutions. Carbohydrates can change spontaneously between the two  $\alpha$  and  $\beta$  configurations by forming an intermediate straight chain, a process called mutarotation. The pentoses form furanose rings (5-carbon ring) and the hexoses form pyranose rings (6-carbon ring). For example, D-glucose occurs in solution as a hemiacetal where the unbound hydroxyl group at C-5 has attached to the C-1 of the aldehyde, resulting in an asymmetric carbon and two potential anomers,  $\alpha$ -D-glucose and  $\beta$ -D-glucose. Fig. 1 illustrates D-glucose in its pyranose form in the  $\alpha$  and  $\beta$  configuration. The isomerization produces compounds with different properties and has major metabolic importance, because of enzyme specificity for particular stereoisomers.

The nomenclature for monosaccharides specifies the configuration at each anomeric carbon (for example,  $\alpha$  or  $\beta$ ), the optical rotation (for example, D or L) and the common name of the monosaccharide (for example, glucose).

### Physical properties

Monosaccharides are usually colorless and crystalline solids at room temperature (Ball et al., 2014). They exhibit increased solubility in water. Monosaccharides are much more water soluble than other molecules of similar molecular weight. For example, glucose can dissolve in very small amounts of water (1 g glucose to 1 mL of water) to form a syrup. On the contrary, they are insoluble in nonpolar organic solvents. Furthermore, they exhibit limited solubility in pure alcohols, but are very soluble in aqueous alcohol solutions, so these solutions are widely used for extraction and analysis. The majority of monosaccharides are characterized by their sweet taste.

### Chemical reactions

The chemical properties of monosaccharides are established by the functional groups they contain (Ball et al., 2014). Hydroxyl groups accessible for reactions are present in all carbohydrate molecules (Shendurse and Khedkar, 2016). Most monosaccharides exist in cyclic hemiacetals. However, when they are in solution, they exist in equilibrium with the aldehydes or ketones in open chain conformation. Consequently, they undergo chemical reactions of aldehydes, ketones, alcohols and hemiacetals.

#### Oxidation to produce sugar acids

Since the cyclic hemiacetal forms of monosaccharides exist in equilibrium with the open chain aldehydes, they undergo oxidation to form carboxylic acids. (Stoker, 2013). Consequently, monosaccharides are reducing sugars, meaning that they are capable of getting reduced without being hydrolyzed. A reducing sugar will contain an aldehyde group (e.g., glyceraldehyde), a hydroxyketone group (e.g., fructose) or a cyclic hemiacetal group (e.g., glucose).

Oxidation results in three types of acids, depending on the type of oxidizing agent used:

- Mild reagents oxidize the aldehyde end of the monosaccharide resulting in aldonic acids: Tollen’s reagent ( $\text{Ag}^+$  in aqueous ammonia), Fehling reagent ( $\text{Cu}^{2+}$  complex with tartrate ion), and Benedict’s reagent ( $\text{Cu}^{2+}$  complex with citrate ion). The Fehling and Benedict’s reagents produce a brick red copper (I) oxide product and the Tollen’s reagent results in silver mirror formation, and therefore confirm the presence of monosaccharides in solution (Stoker, 2013).
- Strong oxidizing agents oxidize both ends of the monosaccharide simultaneously to produce aldonic acids (Stoker, 2013).
- Enzymes catalyze the oxidation of the primary alcohol end of the monosaccharides, without oxidizing the aldehyde end and produce alduronic acids (Stoker, 2013). These enzymes are called oxidases and are substrate specific. For example, the enzyme glucose oxidase catalyzes only the conversion of  $\beta$ -D-glucopyranose (not the  $\alpha$ -D-glucopyranose) to D-glucono- $\delta$ -lactone.

#### Reduction to produce sugar alcohols

Monosaccharides are powerful reducing agents toward a range of metal salts in alkaline solution, due to the presence of aldo- and keto-groups and formation of hemiacetal or acetal groups (Lewis, 2000). The extent of reduction differs among different monosaccharides. The carbonyl group in a monosaccharide (either an aldose or a ketose) goes through reduction, using a hydrogen catalyst. Important compounds formed in this way are sugar alcohols, which typically have a sweet taste. For example, sorbitol is produced by reduction of the aldo group of glucose. Sugar alcohols are utilized widely in the industry, as sweeteners, since they do not promote tooth decay.

#### Reactions in alkaline solutions (Maillard)

Monosaccharides when present in weak alkaline solutions result in the isomerization of the aldose-keto group, referred as enolization (Lewis, 2000). In stronger alkaline solutions, they produce a series of degradation compounds, saccharinic acids, which condense repeatedly to generate a series of highly colored products, in the presence of ammonia, amino acids and proteins. This

reaction, known as Maillard reaction, results in the browning of food products, and it is utilized in the food industry for the production of caramel colors.

### Ester formation

Monosaccharides contain hydroxyl groups and react with acids to form a variety of esters (Nelson and Cox, 2017). The phosphate esters play a major role in carbohydrate metabolism. For example, the first step of glycolysis involves the production of the glucose 6-phosphate ester in a reaction catalyzed by the enzyme glucokinase in the presence of adenosine triphosphate (ATP). Uronic acids react with alcohols to form esters. The methyl esters of uronic acids are the most important in determining the physical properties of uronans.

### Ether formation

Monosaccharides undergo substitution reactions with methyl iodide to produce methyl ether derivatives (Lewis, 2000). These compounds have been used to identify the structure of polymers, because the site of nonmethyl substituted groups is indicative of the site of the branch points after hydrolysis. Monosaccharides undergo acetylation, which occurs on the free or the reduced molecule, to produce acetylated alditols. These volatile compounds have been used to identify sugar mixtures by Gas Liquid Chromatography (GLC).

## Disaccharides

Disaccharides are composed of two monosaccharide units joined together by acetal formation (Nelson and Cox, 2017). One monosaccharide plays the role of a hemiacetal and the other one plays the role of an alcohol; the resulting ether bond is a glycolytic linkage (Stoker, 2013). Glycosidic bond is the bond formed by the condensation of the hydroxyl group of one monosaccharide hemiacetal with another monosaccharide hydroxyl group. Disaccharides are linked together with glycosidic bonds in the  $\alpha$  or  $\beta$  orientation. The common nomenclature for disaccharides specifies the order of monosaccharide units, the configuration at each anomeric carbon, and the carbon atoms involved in the glycosidic bond(s).

### Sucrose

Sucrose is a non reducing disaccharide and it is the most abundant disaccharide found in plants (Stoker, 2013). Sucrose consists of a molecule of an  $\alpha$ -anomeric carbon 1 of glucose linked together with a  $\beta$ -anomeric carbon 2 of fructose, resulting in an  $\alpha$ -1,2-glycosidic bond (Fig. 2A). Sucrose is a commercial product of sugar cane and sugar beet.

### Maltose

Maltose is a reducing disaccharide and is encountered in corn syrup, malt and germinating seeds (Stoker, 2013). Maltose is mainly produced by partial hydrolysis of starch and consists of two glucose units linked by an  $\alpha$ -1,4 glycosidic bond (Fig. 2C).

### Lactose

Lactose is a reducing disaccharide found in milk and dairy products (Stoker, 2013). Human milk contains 7–8% lactose, whereas cow's milk contains 4–5% lactose. Lactose consists of galactose and glucose linked by a  $\beta$ -1,4 glycosidic bond (Fig. 2B).

A number of important disaccharide derivatives are synthesized by substitution of a hydroxyl group or by oxidation of a carbon atom to a carboxyl group, such as glycoproteins and glycolipids (Lewis, 2000). These compounds have important structural and functional roles. Some nutritionally important disaccharides and disaccharide derivatives and their significance are outlined in Table 3.

Disaccharides have similar physical and chemical properties to their corresponding monosaccharide constituents (Nelson and Cox, 2017). Disaccharides are very soluble in water and insoluble in organic polar solvents (Lewis, 2000). Sucrose is extremely soluble in water, while lactose is soluble to a lesser extent. Disaccharides have similar reducing properties with monosaccharides, due to the presence of an aldo- or a keto-group and formation of hemiacetal or acetal groups. However, sucrose is a non-reducing sugar, since it has no free hemiacetal group. Disaccharides in mild acidic conditions are hydrolyzed to their constituent monosaccharides. They are also hydrolyzed in specific enzymatic solutions; therefore, enzymatic hydrolysis is a useful method for the analysis of sugar mixtures. Disaccharides undergo esterification reactions, as do monosaccharides. Sucrose, for example, reacts with fatty acids to produce nondigestible esters, which have similar properties to triacylglycerols.

### Sugar alcohols

Sugar alcohols (polyols, polyhydric alcohols, polyalcohols, alditols or glycitols) are monosaccharide and disaccharide derivatives that have the aldehyde or ketone moiety reduced to an alcohol (Yebra-Biurrun, 2005). They occur naturally in many fruits and vegetables or can be produced industrially from sugars, primarily by enzymatic hydrolysis or fermentation (Wang, 2003). They have

**Fig. 2** The molecular structures of (A) sucrose (B) lactose and (C) maltose.

**Table 3** Some nutritionally important disaccharides and disaccharide derivatives.

Class	Species	Significance
Disaccharide	Sucrose	Constituent of fruits, vegetables and sweetener
	Lactose	Milk and dairy products
	Maltose, isomaltose	Constituent of starch
	Trehalose	Food additive and constituent of mushrooms
	Lactulose	Lactose derivative, laxative
Disaccharide alcohols	Maltitol	Constituent of starch, sweetener
	Lactitol	Constituent of lactose, sweetener

a sweet taste and are used extensively in the industry as sugar substitutes and thickeners (Awuchi, 2017). Most commonly used are the monosaccharide derivatives sorbitol, mannitol, xylitol and erythritol, the disaccharide derivatives isomalt, maltitol and lactitol, as well as the sugar alcohol mixture hydrogenated starch hydrolyzates (HSH).

Sugar alcohols have received increased attention, because of their desirable properties: relative sweetness, cooling sensation in the mouth, limited digestion and absorption (Awuchi, 2017). They provide low caloric content, blunted glycemic response, and reduced risk for dental caries. Every sugar alcohol can have the health claim, according to the United States Food and Drug Administration (FDA) and European Commission, that is “does not promote tooth decay” (Food and Drug Administration, 2005; European Food Safety Agency, 2011). Sugar alcohols have been approved by the FDA as Generally Recognized as Safe (GRAS) or as food additives (American Dietetic Association, 2004). The Joint Expert Committee on Food Additives (JECFA) of the World Health Organization (WHO) has not specified an acceptable daily intake (ADI) for sugar alcohols, placing no limits for their use (World Health Organization, 2021).

Nonetheless, their excessive consumption may cause gastrointestinal distress, such as diarrhea, flatulence and bloating, with the exception of erythritol (Awuchi, 2017). The majority of people develop tolerance to sugar alcohols and increased consumption diminishes the gastrointestinal side effects. Table 4 outlines the relative sweetness and food energy of the most commonly encountered sugar alcohols.

### Mannitol

Mannitol is utilized as a sweetener, bulking and texturing agent. It is naturally occurring in figs, olives, larches, edible fungi, yeast, seaweed and exudates of some tress (Grembecka, 2015).

**Table 4** Sugar alcohols' relative sweetness.

Name	Sweetness (relative to sucrose = 1.0)	Food energy (kcal gram <sup>-1</sup> ) (sucrose = 4.0)	Sweetness per food energy (relative to sucrose = 1.0)	Food energy for equal sweetness (relative to sucrose = 100%)
Erythritol	0.8	0.21	15	6.7%
Hydrogenated starch hydrolyzates (HSH)	0.4–0.9	3.0	0.52–1.2	83–190%
Isomalt	0.5	2.0	1.0	100%
Lactitol	0.4	2.0	0.8	125%
Maltitol	0.9	2.1	1.7	59%

Sorbitol	0.6	2.6	0.92	108%
Xylitol	1.0	2.4	1.6	62%

Adapted from Awuchi, C. (2017). Sugar Alcohols: Chemistry, Production, Health Concerns and Nutritional Importance of Mannitol, Sorbitol, Xylitol, and Erythritol. *International Journal of Advanced Academic Research* 3(2), 32–66.

Mannitol is approximately half as sweet as sucrose and non-cariogenic. It has a pleasant taste and a low caloric value. It is only partially taken up by the small intestine (Awuchi, 2017). It has a minimal effect on blood glucose, much smaller than the effect of sucrose (Grembecka, 2015). Mannitol inhibits moisture absorption from the air and sugar crystallization, and is chemically inert (Awuchi, 2017). Mannitol has low solubility in water, limited solubility in organic solvents (for example ethanol), and is almost completely insoluble in ether, ketones and hydrocarbons (Awuchi, 2017). Mannitol is an isomer of sorbitol and has a different orientation of the hydroxyl group at carbon 2. It has a cooling effect in the mouth, because it has a negative heat of solution. It is stable at all temperatures and has a high melting point (Grembecka, 2015).

Mannitol is obtained from the reduction of mannose. Industrial methods of mannitol production include industrial synthesis, biosynthesis, chemical process, fermentation etc. The most common industrial method is fructose hydrogenation, and it is derived from starch or sucrose (Awuchi, 2017).

Mannitol is extensively utilized in the pharmaceutical and nutraceutical industry, to make chewable tablets, granulated powders and to mask the bad taste of certain drugs (Awuchi, 2017). Furthermore, it is used in the food industry to lengthen the shelf life of packaged products, as a bulking agent and in chewing gum (Awuchi, 2017; Grembecka, 2015). Mannitol is utilized in the medical field as a diuretic medication to reduce ocular and intracranial pressures (Awuchi, 2017). Furthermore, it is used for the treatment of high blood pressure. Mannitol may facilitate drug crossing across the blood-brain barrier and may prevent kidney failure and cerebral edema in various surgeries. It is also known as an antioxidant and a scavenger of hydroxyl radicals (Grembecka, 2015).

### Xylitol

Xylitol is mainly utilized as a sweetener. It is naturally occurring in fruits and vegetables and can be obtained from berries, oats, mushrooms, corn husks and sugar cane (Awuchi, 2017).

Xylitol has about a third fewer calories than sucrose, with the same sweetness and no unpleasant aftertaste (Awuchi, 2017). About half of xylitol is taken up by the small intestine and 50–75% is metabolized in the liver or by the intestinal flora (Grembecka, 2015). Xylitol has a low glycemic index and has a minimal effect on blood glucose (Awuchi, 2017). Its metabolism does not need the presence of insulin and it has a cooling effect, since it has a negative heat of solution (Grembecka, 2015). Xylitol is non cariogenic and may cause tooth remineralization and decrease plaque formation (Grembecka, 2015).

Xylitol may be produced by xylan, found in wood material and subsequently hydrolyzed to xylose (Grembecka, 2015). Industrial production of xylitol occurs by catalytic hydrogenation of xylose or by microbial, fungal or yeast fermentation from xylose or hemicellulosic hydrolyzate (Awuchi, 2017).

Xylitol is widely used in the pharmaceutical, nutraceutical and food industries, in products as pastilles, chewing gums and candies, since it has few gastrointestinal side effects and desirable properties (Grembecka, 2015; Awuchi, 2017).

### Sorbitol

Sorbitol (also known as glucitol) has a sweet, cool and pleasant taste and it is widely utilized as a sweetener, humectant, softener, texturizing and anti-crystallizing agent (Grembecka, 2015). Sorbitol is naturally occurring in apples, pears, peaches, nectarines, apricots, prunes, dates, raisins and in some vegetables (Grembecka, 2015).

Sorbitol is 60% sweeter than sucrose, with fewer calories and non-cariogenic. As previously stated, sorbitol is an isomer of mannitol. Sorbitol is different than mannitol in physical characteristics, food sources and uses (Awuchi, 2017). It is 20 times more soluble in water than mannitol and it is encountered as a liquid and crystalline solid (Grembecka, 2015). It has a cooling effect in the mouth, since it has a negative heat of solution, similar to xylitol. Sorbitol is chemically inert and stable at all temperatures, and does not take part in Maillard browning reaction (Grembecka, 2015). It can be readily compressed, but it is also highly hygroscopic.

Sorbitol is produced by glucose reduction from corn syrup (Awuchi, 2017). Industrially, it is produced from concurrent catalytic hydrolysis and hydrogenation of maize starch under pressure (Awuchi, 2017).

Sorbitol is widely used in the pharmaceutical, nutraceutical, food and cosmetics industries. It is used in several different products, including mints, cough syrups, chewing gum, confectionery, baked goods and chocolate (Grembecka, 2015). Sorbitol is also used in the production of Vitamin C and may have a laxative effect if consumed excessively.

### Erythritol

Erythritol is used as a sweetener for industrial applications. It is naturally occurring in vegetables, fruits (melon, peaches), mushrooms and fermented foods (Grembecka, 2015).

Erythritol has a clean sweet taste, with no aftertaste, and is 60–70% sweeter than sucrose (Awuchi, 2017; Grembecka, 2015). It has almost no calories, it is non-cariogenic. The majority of erythritol (60–90%) is taken up in the small intestine, but it is excreted in the urine almost intact and it has no effect on blood glucose (Awuchi, 2017; Grembecka, 2015). Since minute amounts undergo intestinal fermentation, laxative effects are not usually observed unless excessive amounts are consumed (Grembecka, 2015).

Erythritol demonstrates a strong cooling effect, very similar to xylitol, and among the strongest of all sugar alcohols (Awuchi, 2017). Its taste resembles to sucrose, when blended with artificial sweeteners, other sugar alcohols or stevia (Grembecka, 2015). Its sweetness can be greatly enhanced (by about 30%) by the addition of very small amounts of artificial sweeteners. Erythritol, like sorbitol, does not take part in Maillard browning reaction and is stable in changes of temperature and pH (Grembecka, 2015).

In contrast to other sugar alcohols, erythritol is not produced directly by catalytic hydrogenation of erythrose, due to the elevated cost of erythrose (Grembecka, 2015). Industrial production of erythritol occurs by enzymatic hydrolysis of maize starch and subsequent fermentation of glucose (Awuchi, 2017).

Erythritol is used in the pharmaceutical, nutraceutical and food industries, in products such as chewing gums, candy, ice cream and beverages. It is also used to mask aftertaste of other sweeteners and improve micrological stability, texture and mouthfeel (Grembecka, 2015).

## Oligosaccharides

Oligosaccharides consist of short chains of monosaccharide units (usually 3–9 monosaccharides), covalently linked to form large units (Groff and Gropper, 2000). They are named trioses, tetroses, etc., denoting the number of carbons in their molecule. Oligosaccharides are distributed widely in plants, and when digested yield their constituent monosaccharides. The major oligosaccharides consist of the raffinose series, formed by the linkage of galactose, sucrose and glucose units, and the maltose series, formed by the linkage of glucose units. Some nutritionally important oligosaccharides and their significance are outlined in Table 5. The common nomenclature for oligosaccharides specifies the order of monosaccharide units, the configuration at each anomeric carbon, and the carbon atoms involved in the glycosidic linkage(s).

### Physical properties

Oligosaccharides generally exhibit properties similar to mono- and disaccharides with similar functional groups, but some oligosaccharides with nine monosaccharide units may exhibit similar properties to polysaccharides (Lewis, 2000). Oligosaccharides are less soluble in aqueous alcohol solutions than monosaccharides, and their solubility decreases as the number of monosaccharide units increases.

### Chemical reactions

Oligosaccharides in mild acidic conditions are hydrolyzed to their constituent monosaccharides (Lewis, 2000). The fructofuranosyl linkages of the fructooligosaccharides are quite susceptible to acid hydrolysis. Oligosaccharides are also susceptible to enzymatic hydrolysis. The maltooligosaccharides can be rapidly hydrolyzed by glucosidase enzymes. Furthermore, they undergo esterification reactions.

**Table 5** Some nutritionally important oligosaccharides.

<i>Class</i>	<i>Species</i>	<i>Significance</i>
Maltoses	Maltotriose, maltotetraose	Constituent of starch
Raffinoses	Raffinose, stachyose, verbascose	Constituent of vegetables and legumes
Fructoses	Fructotriose	Constituent of cereals, tubers
Lactoses	Fucosyl lactoses	Constituent of human breast milk

## Polysaccharides

Polysaccharides consist of long chains ( $>9$ ) of monosaccharide residues linked by glycosidic bonds (Nelson and Cox, 2017). These compounds consist of several hundred or even thousands of monosaccharide units. The properties of polysaccharides are determined by the species of monosaccharides in the polymer backbone, the type of linkages between residues, and the extent and type of chain branching.

Glucans are polymers of glucose and the major polysaccharides in the diet (Groff and Gropper, 2000). The most important glucans are starch, glycogen, and cellulose. Glycogen is the short-term storage form of glucose in animal tissues. Starch is the most common digestible storage polysaccharide in plants and cellulose is a major structural component of plant cell walls (Fig. 3). Some nutritionally important polysaccharides and their significance are outlined in Tables 6 and 7.

Polysaccharide molecules can be linear or branched (Lewis, 2000). Branches can be formed through any unlinked hydroxyl group, and vary from alternating and consecutive single unit branches to multiple unit branches (ramified structure). Polysaccharides with  $\alpha$  linkages have a helical shape, e.g., the amylose starch molecule, while those with  $\beta$  linkages generally have a linear or flat ribbon-like molecule, e.g., cellulose (Fig. 3).

## Starch

The most important, abundant and digestible polysaccharide in human nutrition is starch. Starch comprises of large chains of  $\alpha$  linked D-glucose residues (Nelson and Cox, 2017). There are two forms of starch: amylose and amylopectin. Both forms of starch can be found in cereals, potatoes, legumes and other vegetables, with amylopectin comprising 80–85% and amylose 15–20% of total starch.

Amylose is a linear, unbranched form of starch, which consists of  $\alpha$ -1,4 linked glucose units (Fig. 3A). Amylose forms a flexible chain and its molecules are shaped into a helix. This tight conformation of the amylose molecules result in a decreased digestion rate compared to other starches. Amylose helices bind to iodine molecules, resulting in a blue purple color, which is often used to confirm the presence of starch.

Amylopectin is a branched-chain polymer, which consists primarily of  $\alpha$ -1,4-linked glucose units with occasional  $\alpha$ -1,6 linked glucose units (Ball et al., 2014). The  $\alpha$ -1,6-glycosidic bond in amylopectin is responsible for the branching. An amylopectin molecule may include thousands of glucose molecules. Branching occurs every 25–30 glucose units and disrupts the helical structure of amylopectin. As a result, when amylopectin binds to iodine molecules, a less intense reddish color is produced compared to amylose.

Starches are usually insoluble in water because they have a high molecular weight (Stoker, 2013). Starches, similarly to other polysaccharides, form thick colloidal dispersions when heated in water solutions, since they contain large number of hydroxyl groups. Consequently, they are used as thickening agents.

**Fig. 3** (A) Five units of an  $\alpha$ -1,4-D-glucopyranose chain form a starch molecule (amylose) (B) Four units of a  $\beta$ -1,4-D-glucopyranose chain form a cellulose molecule.

**Table 6** Some nutritionally important polysaccharides.

<i>Class</i>	<i>Species</i>	<i>Significance</i>
Glucans	Starch	Storage polysaccharide in plants
	Glycogen	Short-term storage form of glucose in animal tissues
	Cellulose	Major structural component of plant cell walls
Galactans		Major constituents of noncellulosic matrix of plant cell wall
Xylans		Constituents of mature plant tissues
Mannans		Storage forms in several plants
Uronans	Galacturonans	Major components of water-soluble pectic fraction of plants
	Mannuronans	Components of algal polysaccharides
	Guluronans	Components of algal polysaccharides

**Table 7** Some nutritionally important starch and nonstarch polysaccharides.

<i>Class</i>	<i>Species</i>	<i>Significance</i>
Starch	Amylose, amylopectin	Most common digestible plant polysaccharides
Nonstarch	Cellulose	Major component of plant cell wall
	Pectin	Constituent of plant cell wall, food additive
	Hemicellulose	Constituent of plant cell wall
	Gums, mucilages	Plant hydrocolloids, food additives
	Algal polysaccharides	Constituents of algae and seaweed, food additives

## Glycogen

Glycogen is a branched polysaccharide, similar to amylopectin, consisting of both  $\alpha$ -1,6, and  $\alpha$ -1,4 glycosidic bonds (Ball et al., 2014). Glycogen is more highly branched than amylopectin, and branching occurs every 8–12 glucose units. Glycogen branches are shorter than amylopectin branches. Glycogen is degraded into D-glucose to produce energy.

All mammalian cells comprise of glycogen, but it is found more abundantly in liver (4–8% by tissue weight) and muscle (0.5–1.0% by tissue weight) (Ball et al., 2014). During fasting periods, the organism initially utilizes glycogen to achieve metabolic balance. The majority of glycogen is stored in skeletal muscle, since the body is comprised of a significantly greater muscle mass compared to liver.

## Cellulose

Cellulose is a long, unbranched polysaccharide, similar to amylose, consisting of  $\beta$ -1,4-glycosidic bonds (Ball et al., 2014). Cellulose consists of 300–3000 glucose units and it has a very rigid and extended structure. Cellulose is an important structural polysaccharide and the most plentiful organic compound on the planet. Furthermore, it forms part of plant cell walls.

The majority of animals do not have the enzymes to break down cellulose, but it promotes intestinal contraction and digestion (Ball et al., 2014). Ruminant animals, such as cows, sheep and goats, break down cellulose, with the assistance of bacterial colonies in their digestive track and the use of multiple stomachs to provide additional time needed for cellulose digestion. Other animals (for example horses) have longer intestinal tracts, while others (for example rabbits) have the ability to re-digest food so that cellulose can be processed. Cellulose is an important compound in various industrial processes, since it is part of wood, paper, cotton, cellophane, rayon, linen, nitrocellulose, etc.

## Dietary fiber

Dietary Fiber generally refers to complex carbohydrates which compose the cells walls and structural components of plants (World Health Organization, 1998). Good sources of fiber include whole cereal grains, fruits and vegetables. Dietary fiber may be soluble in water, for example pectin. Soluble fiber binds to other carbohydrates and delays digestion and absorption, therefore assisting in maintaining stable blood glucose levels. Insoluble fiber, such as cellulose, bulks up stool and aids in intestinal waste elimination.

Dietary fiber consumption has potential important health benefits, including general gastrointestinal health and prevention of several non-communicable diseases, through blood cholesterol reduction and regulation of blood sugar levels (World Health Organization, 1998).

### Physical properties

Polysaccharides are insoluble in water, and have no sweet taste (Nelson and Cox, 2017). In general, they form colloidal solutions in water, while some other polymers are extremely insoluble in water and require prior treatment with acid, alkali or organic solvents to get them to dissolve (Lewis, 2000). For example,  $\beta$ -1,4 mannans and glucans (e.g., cellulose) are very insoluble due to hydrogen bonding between parallel chains. On the other hand, arabinoxylans are readily soluble in water, because the arabinosyl chains inhibit hydrogen bonding. Galactomannans are also readily soluble in water, producing viscous solutions, and are used as food additive gums. The  $\alpha$ -linked glucans (e.g., amylose and amylopectin) have completely different solubilities. The  $\alpha$ -1,4 amylose is very soluble in warm water and forms colloidal solutions. When the amylose chains cool down, they form an amylose gel, which subsequently forms an insoluble crystalline material. Amylopectins are also very soluble in hot water, but do not form an insoluble crystalline material to the same degree as amylose.

### Chemical reactions

Polysaccharides show slower reactions rates than other saccharides due to steric effects. Polysaccharides usually contain one reducing group at the terminal end of the polymer chain and, as a result, have low reducing properties.

Polysaccharides are also hydrolyzed to their constituent monosaccharides by acid hydrolysis, but the conditions necessary for complete hydrolysis depend on the solubility of the polymers (Lewis, 2000). The majority of polysaccharides (e.g., starch) are completely hydrolyzed under weak acidic conditions. On the contrary, cellulose requires treatment with strong acid for several hours prior to hydrolysis, and subsequent heating under weak acidic conditions for the completion of the reaction. The uronans are very resistant to complete acid hydrolysis and generally produce disaccharides of aldobiuronic acids. Acid hydrolysis of polysaccharides results in extensive losses of their monosaccharide constituents.

Polysaccharides are more efficiently hydrolyzed to their monosaccharide constituents using specific enzymes (Stoker, 2013). Fungal enzymes act specifically for the hydrolysis of different polysaccharides. The  $\alpha$ -1,4 glycosidic linkages in starch can be hydrolyzed by various  $\alpha$ -amylases (e.g., salivary and pancreatic), producing maltose and isomaltose. The  $\beta$ -1,6 glycosidic linkages in amylopectin are not as easily hydrolyzed and require the presence of the fungal enzyme pullulanase to complete the hydrolysis.

Polysaccharides can also produce ester compounds (Lewis, 2000). For example, galacturonans, which are composed of an  $\alpha$ -1,4 galacturonic acid chain with integrated rhamnose units, form salts with cations and may be esterified with methoxyl groups.

### Conclusion

Carbohydrates are compounds of great biological importance and have an extensive role in all forms of life. Carbohydrates vary enormously from short and compact sugar molecules to long and highly branched polysaccharide chains. They are encountered in every living cell and provide energy, structural support, and metabolic efficiency. Carbohydrates are nutritionally important as a dietary staple and have extensive industrial applications.

## Key points

- Outline and describe the process of starch and disaccharide digestion, absorption and transport
- Explain factors that influence carbohydrate assimilation
- Discuss the process of breakdown of glucose, fructose and galactose for energy production
- Explain the process of glucose production by the liver and kidneys
- Describe the control mechanisms that regulate carbohydrate metabolism
- Discuss the principal diseases from defects in carbohydrate metabolism

## Introduction

Carbohydrates are an inexpensive and versatile staple of developed and developing countries, accounting for 40–80% of consumption. Simple and complex carbohydrates are important human dietary components. Digestible carbohydrates provide energy and nutrients for the human body. They include monosaccharides (glucose, fructose and galactose), disaccharides (sucrose, lactose and maltose), oligosaccharides (components of polysaccharide breakdown), and polysaccharides (mainly starch), as well as sugar alcohols (sorbitol, mannitol, xylitol and erythritol). Nondigestible carbohydrates, which are also described as dietary fiber, are present in carbohydrate rich foods and are not assimilated by the human body.

All carbohydrates, in order to be utilized by the human body, need to be broken down to monosaccharides through enzymatic cleavage of the glycosidic bond, which is the bond that unites different monosaccharides to form large and complex carbohydrate molecules. In human metabolism, all simple sugars (monosaccharides and disaccharides) are converted into glucose, which is the circulating form of carbohydrates in the bloodstream. Appropriate regulation of glucose metabolism is necessary for cell function and essential for health and survival.

## Starch digestion

Carbohydrate digestion occurs with the secretion of the enzyme  $\alpha$ -amylase by the salivary and pancreatic exocrine glands in the mouth and small intestine respectively, and it is completed by the secretion of oligosaccharidases in the apical membrane of the intestinal mucosal cells (Leturque and Brot-Laroche, 2013; Gray, 2000).

The digestion of starch starts in the mouth with mastication and enzymatic conversion of starch to dextrins and maltose, catalyzed by salivary  $\alpha$ -amylase (Gray, 2000). When the masticated bolus of food mixes with the acidic stomach secretions, salivary  $\alpha$ -amylase becomes inactive, since it requires neutral pH for activity (Leturque and Brot-Laroche, 2013). However, salivary  $\alpha$ -amylase seems to be protected by the starch content of the meal and may pass into the duodenum, where it will continue to break down starches, with the help of pancreatic  $\alpha$ -amylase (Rosenblum et al., 1988). Then, the majority of starch comes in contact with large amounts of pancreatic amylase inside the duodenal lumen, which subsequently cleave glycosidic bonds and complete the digestion process in the upper part of the small intestine (Leturque and Brot-Laroche, 2013).

The two major starches are amylose, consisting of linear segments with  $\alpha$ -1,4 glycosidic bonds, and amylopectin, which is a complex form of starch, consisting of both linear and branched segments with  $\alpha$ -1,6 glycosidic bonds (Gray, 2000). The active enzyme amylase binds to the interior glycosidic bonds of amylose and specifically to five consecutive glucose subunits with high affinity, leading to the production of pentasaccharides (oligosaccharides with five glucose units linked together) (Leturque and Brot-Laroche, 2013). The resulting pentasaccharide is hydrolyzed to produce the trisaccharide maltotriose and the disaccharide maltose, which are the final products of amylose digestion and cannot be broken down by the amylase due to low affinity for the enzyme's active site (Gray, 2000).

Amylopectin is also digested by amylase, but results in different end products than those of amylose. While amylase binds and cleaves the  $\alpha$ -1,4 glycosidic bonds of amylose, it cannot bind and cleave the  $\alpha$ -1,6 glycosidic bonds of amylopectin nor can it bind to adjacent  $\alpha$ -1,4 bonds, due to structural angulation inhibition of binding (Leturque and Brot-Laroche, 2013). Consequently, the digestion of amylopectin produces branched oligosaccharides called  $\alpha$ -dextrins, as well as maltose and maltotriose (Gray, 2000).

Salivary and pancreatic amylases break down amylose to produce glucose oligosaccharides and disaccharides with  $\alpha$ -1,4 glycosidic bonds, and amylopectin to produce glucose oligosaccharides and disaccharides with  $\alpha$ -1,4 and  $\alpha$ -1,6 glycosidic bonds (Leturque and Brot-Laroche, 2013). In both cases, free glucose molecules account for only a small amount (about 4%) of the digestion products released (Yook and Robyt, 2002).

The brush border of the small intestine contains an ample amount of oligosaccharidases, which consist primarily of  $\alpha$  glucosidases, and catalyze the final reactions of starch digestion by cleaving the  $\alpha$ -1,4 glycosidic bonds between glucose molecules one at a time (Semenza and Auricchio, 1991). Alpha glucosidases (i.e., sucrase,  $\alpha$ -dextrinase, glucoamylase, and trehalase) have the ability to break down  $\alpha$ -1,4 glycosidic bonds, but they bind with high affinity to the substrate indicated by their nomenclature (Gray, 2000). All these enzymes work in a complementary manner and generate unbound glucose to be transported into enterocytes (Gray, 2000). In the case of maltose, digestion is catalyzed by two  $\alpha$  glycosidase enzymes, maltase-glucoamylase and sucrase-isomaltase, which work synergistically to completely digest starches into glucose molecules (Leturque and Brot-Laroche, 2013).

## Digestion of disaccharides

In addition to maltose digestion, an end product of starch breakdown, humans have the capacity to hydrolyze unique linkages present in sucrose, lactose, and trehalose. The hydrolysis of these disaccharides occurs with the action of disaccharidases found on the luminal surface of enterocytes (Leturque and Brot-Laroche, 2013). The hydrolysis of sucrose (table sugar) is carried out by the sucrase–isomaltase enzyme, and produces glucose and fructose (Leturque and Brot-Laroche, 2013). The hydrolysis of lactose (milk sugar) is carried out by the lactase–phlorizin hydrolase enzyme, and produces glucose and galactose (Gray, 2000). The hydrolysis of trehalose (sugar found in yeast and fungi) occurs by trehalase and produces two molecules of glucose (Leturque and Brot-Laroche, 2013).

### Undigested glycosidic bonds

Complex carbohydrate molecules, known as dietary fiber, include oligosaccharides with  $\alpha$ -galactosidic linkages (i.e., raffinose, stachyose, verbascose, and ajucose), polysaccharides with glucose or fructose molecules joined together by  $\beta$ -glycosidic bonds (cellulose, inulin), heteropolysaccharides (hemicelluloses, gums and mucilages) with various sugar molecules and types of bonds (Leturque and Brot-Laroche, 2013). These complex carbohydrate molecules cannot be digested from pancreatic and intestinal enzymes, since the human body cannot break down  $\beta$ -glucosyl or fructosyl and  $\alpha$ -galactosyl bonds (Gray, 2000). Instead, dietary fiber molecules remain intact and pass through, from the ileum to the colon, where they are metabolized by intestinal bacteria (Leturque and Brot-Laroche, 2013).

### Absorption

Starch and disaccharide digestion produce the monosaccharides glucose, galactose and fructose (Gray, 2000). Glucose consists of the largest quantity of absorbed carbohydrate (~80%) and galactose and fructose only account for a small amount (~20%). The body quickly absorbs and transports the simple sugars, which enter the portal circulation via the capillaries of the intestinal villi and are transported to the liver. In the liver, fructose and galactose are converted to glucose, which is either used immediately for energy or it is stored in the form of glycogen. Liver can store approximately 4–8% of its mass in the form of glycogen, which can be readily converted to glucose for the production of energy (Ball et al., 2014).

### Transport

Glucose, fructose and galactose are transported through the enterocytes by facilitated diffusion via a family of transporters known as glucose transporters (GLUT). Glucose and galactose are isomers and structurally related, therefore, they utilize the same glucose transporter, called sodium glucose transporter or SGLT1 (Gray, 2000). The passage of glucose and galactose through the apical membrane of the intestinal villi requires the presence of 2  $\text{Na}^+$  ions for each molecule of glucose or galactose respectively (Leturque and Brot-Laroche, 2013). On the contrary, fructose is transported into the enterocyte utilizing the glucose transporter GLUT5, a brush border protein which is not dependent on  $\text{Na}^+$  (Gray, 2000). All three monosaccharides exit the enterocyte towards the blood stream through another sugar transporter GLUT2 (Leturque and Brot-Laroche, 2013).

### Factors affecting carbohydrate assimilation

Initially, the factors influencing dietary carbohydrate assimilation are degree of mastication and length of time in the oral cavity, which determine the digestion by salivary amylase (Gray, 2000). Then, the carbohydrates consumed are transported to the stomach and become exposed to an acidic pH, which stops the action of salivary amylase (Leturque and Brot-Laroche, 2013). Gastric emptying of the ingested food varies based on its nutrient composition. For example, presence of nondigestible carbohydrate (dietary fiber) and high osmolarity (sucrose sweetened foods) will slow down gastric emptying (Gray, 2000). The stomach contents are then transported to the small intestine, a process that is highly efficient yet variable, depending on the composition of ingested food (Leturque and Brot-Laroche, 2013). When healthy intestinal and pancreatic function is present, there is no significant disturbance of assimilation of nutrients due to intestinal mobility (Gray, 2000).

Certain physicochemical properties of carbohydrate foods, for example crystallization, moisture, physical barriers, may influence the degree of starch digestion (Leturque and Brot-Laroche, 2013). Furthermore, dietary carbohydrates naturally occur in foods in combination with hydrophobic proteins, which may hinder the luminal interaction of glucose moieties within the starch molecule with polar amylases. Processing of dietary carbohydrate, including cracking, milling and cooking, will facilitate the binding of amylase to starch. Consequently, based on factors affecting starch digestion, a small amount (1–10%) of the ingested starch will pass undigested and will be hydrolyzed by colonic bacteria (Leturque and Brot-Laroche, 2013).

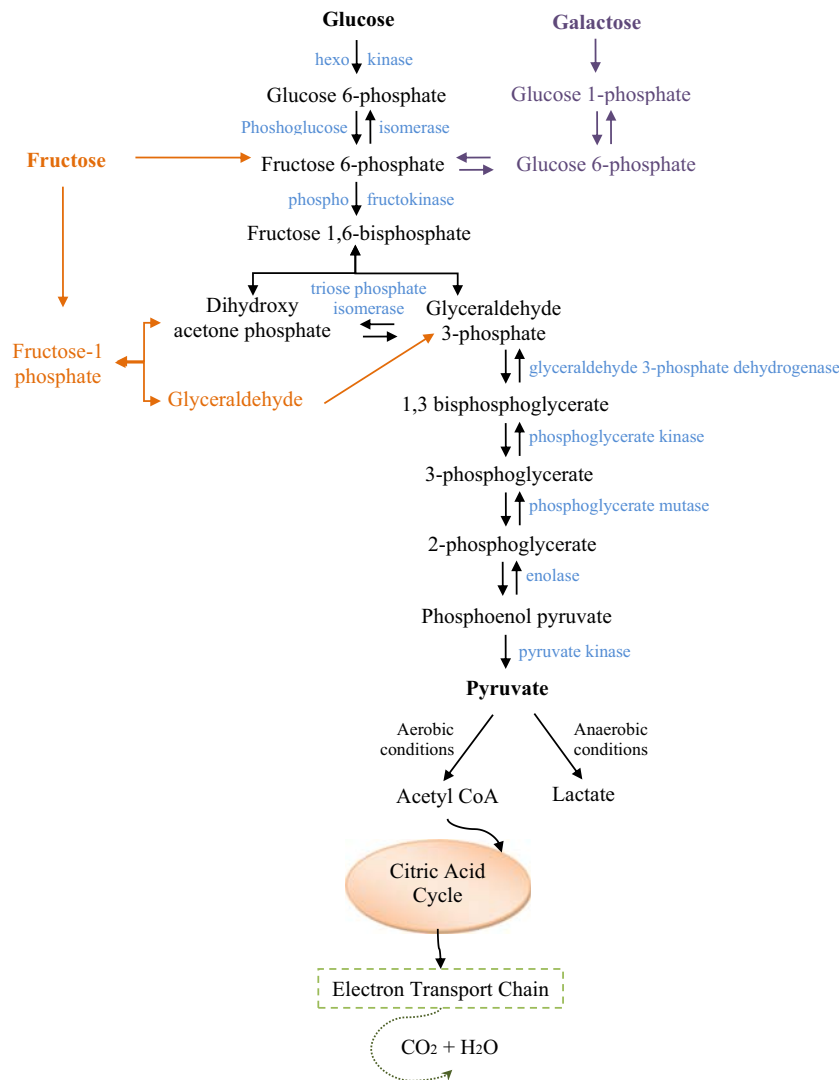

## Carbohydrates and energy metabolism

### Glucose

The breakdown of glucose can be divided into two major parts: the anaerobic conversion of glucose to pyruvate, known as glycolysis and the aerobic breakdown of pyruvate to carbon dioxide ( $\text{CO}_2$ ) and water ( $\text{H}_2\text{O}$ ), which comprises the tricarboxylic acid cycle and the electron transport chain (Nelson and Cox, 2017).

Glycolysis is the series of enzymatic steps, leading to the breakdown of one molecule of glucose for the production of two molecules of pyruvate (Fig. 1). Glycolysis occurs in the cytosol of different cells, and all human cells are capable of carrying out the process of glycolysis (Nelson and Cox, 2017). However, the largest part of glycolysis occurs in the liver, muscle and adipose tissue (McGrane, 2013).

The fate of pyruvate is determined by the cell type and the availability of oxygen (Nelson and Cox, 2017). In the absence of oxygen, pyruvate is reduced to lactate in the cytosol (Wong, 2021). This would occur in the muscle during strenuous exercise, when the demands for energy are high (Nelson and Cox, 2017). In cells that do not contain mitochondria, such as the erythrocytes, the glycolysis pathway is the only mechanism of energy production.

**Fig. 1** Outline of glucose metabolism, with entry points for fructose and galactose.

In the presence of oxygen, pyruvate is converted to acetyl coenzyme A (acetyl CoA) in the mitochondria, enters the tricarboxylic acid cycle and subsequently the electron transport chain (Wong, 2021). As a result, pyruvate is fully oxidized to CO<sub>2</sub> and H<sub>2</sub>O and large amounts of energy are produced.

### Fructose and galactose

Fructose and galactose enter the glycolytic pathway through their conversion to intermediate compounds (Fig. 1). This occurs primarily in the liver and, as a result, these two monosaccharides are not generally available for uptake by other tissues (Nelson and Cox, 2017). The end products of the catalysis of these monosaccharides are similar to glucose; however, when they are absorbed, they do not elicit the same hormonal response as glucose.

In the liver, fructose breakdown, known as fructolysis, is initiated by the conversion of fructose to fructose 1-phosphate catalyzed by fructokinase, and subsequent hydrolysis to glyceraldehyde and dihydroxyacetone phosphate catalyzed by fructose 1-phosphate aldolase (Wong, 2021). These products of hydrolysis can be used for further glycolytic conversion. Fructolysis in the liver bypasses the highly regulated step of phosphofructokinase and can produce a large amount of glycolytic metabolites (Nelson and Cox, 2017). In the muscle and kidney cells, fructose can enter the glycolysis pathway through its conversion to fructose 6-phosphate, prior to the highly regulated phosphofructokinase step (McGrane, 2013).

In the liver, galactose enters the glycolytic pathway through its phosphorylation to galactose 1-phosphate and subsequent epimerization to glucose 1-phosphate (Nelson and Cox, 2017). This metabolic intermediate can either enter glycolysis by its conversion to glucose 6-phosphate or can be used in glycogen synthesis, depending on the nutritional state of the organism (McGrane, 2013).

## Glucose production by the liver and kidneys (glycogen)

### Gluconeogenesis

The biosynthesis of glucose from pyruvate, lactate, glycerol or other precursors is known as gluconeogenesis (Nelson and Cox, 2017). It is not a direct reversal of glycolysis, since several steps of glycolysis are irreversible (Wong, 2021). Gluconeogenesis mainly occurs in the liver and less in the kidney (Nelson and Cox, 2017). These tissues contain all the necessary enzymes for gluconeogenesis and the enzymatic activity of glycerol kinase, which allows glycerol to enter the gluconeogenic pathway at the level of glyceraldehyde 3-phosphate (Fig. 2).

In humans, liver glycogen stores can sustain the organism for 12–24 h without the ingestion of dietary carbohydrates (Nelson and Cox, 2017). After this period, the liver must produce glucose and transport it to other organs. Liver is the main gluconeogenic contributor (~90%), while the kidney produces glucose gluconeogenically to a lesser extent (~10%).

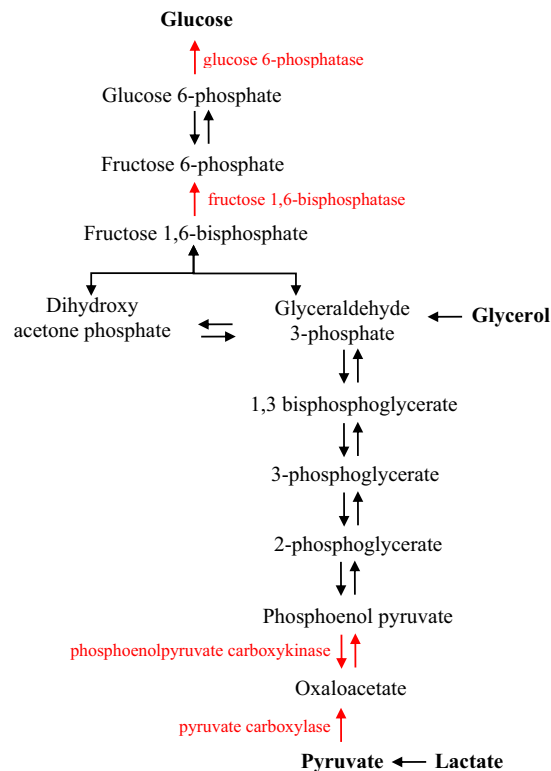

### Glycogenolysis

Glycogen is a branched polymer of glucose, which may contain over 100,000 glucose units (Wong, 2021). The breakdown of glycogen for the production of glucose units is known as glycogenolysis. Glycogen breakdown is initiated at the non-reducing ends of its branches. It consists of phosphorolysis of single glucose units by the cooperating enzymatic action of glycogen phosphorylase and the debranching enzyme (Nelson and Cox, 2017). The product of phosphorolysis, glucose 1-phosphate, needs the additional action of phosphoglucomutase to be converted to glucose 6-phosphate. The liver contains the enzyme glucose 6-phosphatase for hydrolysis of glucose 6-phosphate to free glucose and for export from the organ to target tissues. However, the muscle and the brain do not contain such an enzyme and the produced glucose 6-phosphate enters the glycolytic pathway for energy production. Glycogen is a very efficient storage form of glucose, having an overall storage efficiency of approximately 97%.

## Control of carbohydrate metabolism

### Hormonal regulation

Hormones regulate (activate or inhibit) specific enzymes which catalyze the reactions of metabolic pathways (Nelson and Cox, 2017). This is achieved mainly by covalent regulation or conversion of the enzymes into their active or inactive form (Groff and Gropper, 2000). Furthermore, hormones can regulate enzymes by induction or regulation of their transcription. Regulation

**Fig. 2** Outline of gluconeogenesis, with entry points for lactate and glycerol. The reactions shown in red are distinctive for gluconeogenesis, while the other reactions are common with glycolysis.

of the expression of specific genes controls the concentration of enzymes and transport proteins necessary for carbohydrate metabolism (Nelson and Cox, 2017).

### Insulin

When a meal is ingested, glucose is liberated from hydrolysis of dietary carbohydrate in the small intestine, and then it is absorbed into the blood. Increased glucose concentrations stimulate the production and secretion of insulin by the  $\beta$  cells of the pancreas (Nelson and Cox, 2017). Insulin promotes the transfer of glucose into the target cells (i.e., skeletal muscle, liver and adipose tissue) for utilization as energy, and for storage in the form of glycogen, primarily in the liver.

Insulin also stimulates glycolysis, by increasing the activity of glycogen synthase and the transcription of glycolytic enzymes (Stipanuk, 2013). Insulin inhibits gluconeogenesis, by decreasing the transcription of several gluconeogenic enzymes, and by moderating peripheral release of gluconeogenic precursors (Figs. 3 and 4). Insulin also increases the concentration of the glucose transporter GLUT4, resulting in increased glucose uptake by the skeletal muscle and adipose tissue (Nelson and Cox, 2017).

Fasting results in a decrease in insulin concentration and reduction of glucose uptake by the muscle and adipose tissue, which may use alternate forms of energy, such as free fatty acids (Stipanuk, 2013). Glucose then becomes available for uptake by the brain, red blood cells and renal medulla, which are strongly dependent on glucose for energy (Stipanuk, 2013; Nelson and Cox, 2017).

### Glucagon

Glucagon is a hormone secreted in the bloodstream by the  $\alpha$  cells of the pancreas in response to low glucose levels (Nelson and Cox, 2017). Glucagon counteracts the action of insulin and its main role is to stimulate hepatic glucose output and to maintain glucose homeostasis (Stipanuk, 2013). Glucagon stimulates glycogenolysis by activating glycogen phosphorylase, and inhibits glycogen synthesis by inactivating glycogen synthase (Fig. 4). Furthermore, glucagon stimulates gluconeogenesis by increasing the gene expression of gluconeogenic enzymes and blocking glycolysis (Groff and Gropper, 2000). In the liver, glucagon enhances the rate of gluconeogenesis by lipolysis, resulting in increased concentrations of free fatty acids and glycerol (Nelson and Cox, 2017).

### Catecholamines

Epinephrine and norepinephrine are catecholamines that have a regulatory effect on carbohydrate metabolism, which is mainly dependent on the type of adrenergic receptor present on each cell surface (McGrane, 2013). Catecholamine receptors are divided into two types: two  $\alpha$  ( $\alpha_1$ ,  $\alpha_2$ ) and three  $\beta$  ( $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ ) receptors (Nelson and Cox, 2017). The  $\alpha_1$  and  $\beta$  receptors stimulate catabolic reactions, while the  $\alpha_2$  receptor inhibits them (McGrane, 2013). The presence of catecholamine receptors on different cell

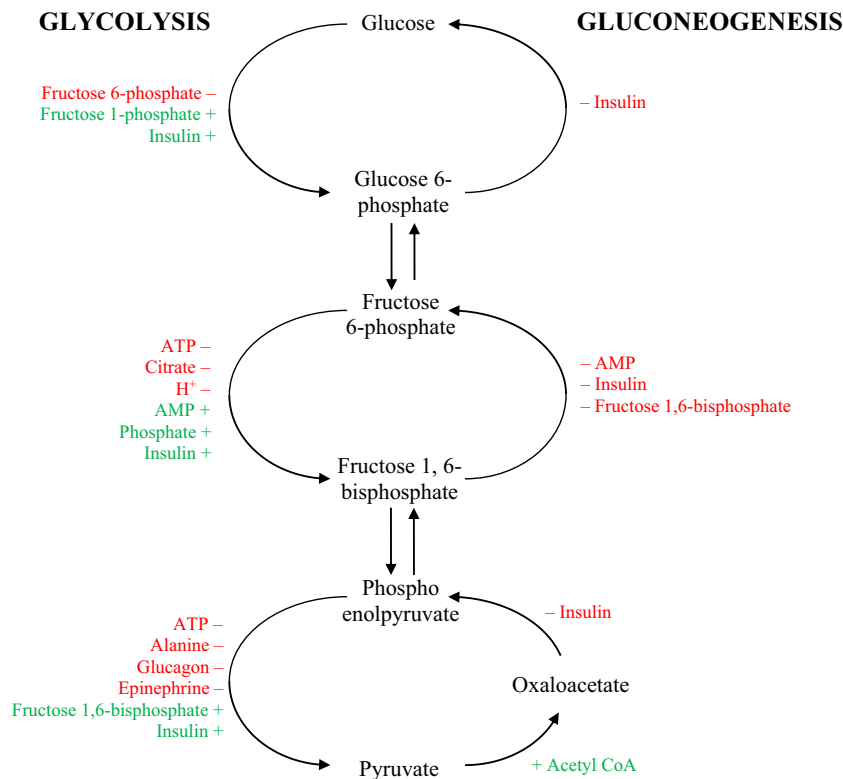

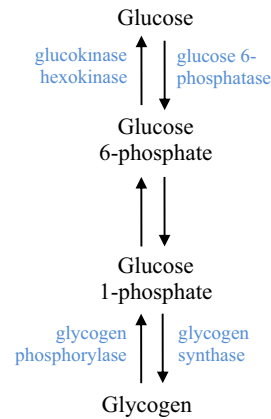

Fig. 3 Regulation of glycolysis and gluconeogenesis in the liver.

**Fig. 4** Points of regulation of glycogen synthesis and breakdown.

types explains the selective breakdown of stores from certain tissues. Specifically, when epinephrine stimulates  $\beta$ -receptors, there is an increase in the rate of glycogenolysis and gluconeogenesis in the liver and lipolysis in adipose tissue and muscle (McGrane, 2013). Furthermore, when epinephrine stimulates  $\alpha$ 1-receptors, there is an increase in the rate of glycogenolysis, and when it stimulates  $\alpha$ 2-receptors, there is a decrease in lipolysis (Nelson and Cox, 2017).

During fasting, catecholamine regulation has not been well elucidated, but hypoglycemia is known to cause a rise in catecholamine levels in adipose tissue and liver, and/or catecholamine release by the adrenal glands (Stipanuk, 2013; McGrane, 2013).

### Glucocorticoids

Glucocorticoids are steroid hormones, which are produced in reaction to mental or physical stress (McGrane, 2013). Glucocorticoids are responsible for suppression of insulin signaling. Cortisol, the principal glucocorticoid, stimulates hepatic glucose output and the expression of genes encoding for gluconeogenic enzymes, thus stimulating gluconeogenesis (Groff and Gropper, 2000). Cortisol is essential for the action of several hormones and has a much slower effect on hepatic glucose production in comparison to glucagon and the catecholamines.

### Allosteric enzyme regulation

Allosteric enzymes are activated or inhibited by substances produced in the pathway in which the enzymes function (Stipanuk, 2013). These substances are called modulators and can alter the activity of allosteric enzymes by changing their conformation (Groff and Gropper, 2000). Adenosine monophosphate (AMP), adenosine diphosphate (ADP), and adenosine triphosphate (ATP) are important modulators of allosteric enzymes in carbohydrate metabolism. The effect of ATP is opposed by AMP and ADP. When energy supply is adequate, ATP accumulates and negatively modulates enzymes which catalyze energy-producing or catabolic pathways, e.g., glycolysis (Stipanuk, 2013). When energy is depleted and ATP concentration is decreased, AMP and ADP accumulate. As a result, there is a need for energy production and a positive modulation of allosteric enzymes in catabolic pathways (Groff and Gropper, 2000). An increase in ATP inhibits further energy production and blocks glycolytic enzymes, while an increase in AMP or ADP stimulates glycolytic enzymes for energy production (Fig. 3).

### Directional shifts

The majority of enzymes catalyze reversible reactions and their action is highly dependent on the concentration of the reactants involved (Groff and Gropper, 2000). An increase in the concentration of one reactant will drive the reaction in the direction that results in the breakdown of the reactant and the achievement of homeostasis. An example of a directional shift is the interconversion of glucose 1-phosphate and glucose 6-phosphate. During glycogenolysis, the concentration of glucose 1-phosphate increases and the reaction is driven toward the production of glucose 6-phosphate (McGrane, 2013). During glycogen synthesis and gluconeogenesis, the concentration of glucose 6-phosphate increases and the reaction is driven toward the production of glucose 1-phosphate and subsequently toward the formation of glycogen (Groff and Gropper, 2000).

### Regulation of gene expression

Gene expression regulation enables the human body to respond to changes in nutrient concentration. During increased availability of a specific nutrient, there is no need for expression of the genes encoding for enzymes involved in the metabolism of that nutrient.

Gene expression is highly regulated by hormones, which respond to the concentration of nutrients in the blood (Nelson and Cox, 2017). Selective expression of specific genes plays a major role in regulation of carbohydrate metabolism.

Hormonal and nutrient concentrations affect several regulatory domains of genes, which encode for enzymes involved in anabolic and catabolic pathways (Nelson and Cox, 2017). Insulin and glucose concentrations increase messenger ribonucleic acid (mRNA) levels and transcription rates of the glycolytic enzymes, and decrease those of the gluconeogenic enzymes. On the contrary, glucagon has the opposite effect of insulin.

### Glycogen synthesis and breakdown

The regulatory mechanism of glycogen synthesis and breakdown involves two counteracting enzymes: glycogen synthase and glycogen phosphorylase (Fig. 4). Insulin activates glycogen synthase and, therefore, increases glycogen synthesis in the liver and muscle (McGrane, 2013). When blood glucose levels decrease, glucagon inhibits glycogen synthase, and activates glycogen phosphorylase for the breakdown of glycogen in the liver (Nelson and Cox, 2017).

## Diseases of carbohydrate metabolism

### Carbohydrate malabsorption

Carbohydrate malabsorption is manifested by the inability to metabolize fructose, glucose, or galactose (Leturque and Brot-Laroche, 2013). Carbohydrate malabsorption causes undigested disaccharides to reach the colon, which are converted to short-chain fatty acids, carbon dioxide and hydrogen gases by colonic bacteria (Topping and Clifton, 2001). Part of the short-chain fatty acids produced are absorbed, hydrogen gases can be observed in the breath, and there is a rise in osmolarity and amount of liquid and gas in the lower intestinal area and colon (Leturque and Brot-Laroche, 2013). As a result, mild symptoms of abdominal pain, discomfort and diarrhea occur in adults, while more severe symptoms of vomiting occur in infants. If carbohydrate malabsorption is not treated, it causes deficit of energy and micronutrients, which may result in unwanted weight loss and developmental delays.

### Fructose intolerance and essential fructosuria

Fructose intolerance and essential fructosuria are the two genetic defects of fructose metabolism (van den Berghe, 1995). Fructose intolerance is an autosomal recessive disease, caused by a genetic defect of fructose 1-phosphate aldolase (aldolase B) in the liver (McGrane, 2013). The symptoms of aldolase B deficiency start when the infant is exposed to fructose. Aldolase B deficiency results in phosphate depletion and fructose 1-phosphate accumulation in the liver (van den Berghe, 1995). Consequently, gluconeogenesis and glycogenolysis are blocked, resulting in inhibition of protein synthesis and subsequent liver failure (McGrane, 2013). Essential fructosuria is triggered by a defect in the gene coding for fructokinase (van den Berghe, 1995). This disease is not harmful and does not have any symptoms. It causes fructose to be excreted in the urine and to be converted to fructose 6-phosphate in the muscle and adipose tissue (McGrane, 2013).

### Glucose and galactose malabsorption

Glucose and galactose malabsorption is caused by a gene mutation of the glucose and galactose transporter SGLT1 which impairs its transport function (Leturque and Brot-Laroche, 2013). It is diagnosed at an early age and can be lethal if not treated by elimination of glucose and galactose from the diet (Meeuwisse and Dahlqvist, 1968). Patients with this disease can digest fructose, but not sucrose, since sucrose is converted to fructose and glucose. It is possible for patients to improve tolerance to glucose and galactose as they get older (Leturque and Brot-Laroche, 2013).

### Lactose deficiency or lactose intolerance

All infants are born with some degree of lactase activity, which enables them to digest the lactose present in breast milk or formula. Lactose deficiency or intolerance usually occurs after weaning due to a reduction in lactase expression, resulting in complete loss or decline of lactase activity in intestinal cells (Nelson and Cox, 2017). As a result, lactose passes partly undigested into the large intestine, where colonic bacteria convert it to toxic compounds, which cause abdominal pain and diarrhea. Furthermore, undigested lactose causes intestinal water retention by enhancing intestinal osmolarity (Nelson and Cox, 2017). Lactose intolerance in adults is very common, and it is resolved by avoiding or decreasing consumption of dairy products. Furthermore, another approach to treating lactose intolerance is using enzyme replacement in commercial milk products, including treatment with lactase (Leturque and Brot-Laroche, 2013).

### Glycogen storage diseases

Several types of glycogen storage disorders are caused by gene mutations encoding for enzymes, which are implicated in glycogen metabolism. Von Gierke disease (type I glycogen storage disease) is a rare autosomal recessive trait caused by a deficiency in glucose 6-phosphatase in the liver, kidney and intestine (McGrane, 2013). It is presented in early infancy, and it is characterized by fasting hypoglycemia, hepatomegaly, and recurrent acidosis (Dunger and Holton, 1994). Genetic defects in glucose 6-phosphatase, glucose

6-phosphatase translocase, or the pyrophosphate transporter result in a metabolic imbalance and inability of the liver to maintain glucose homeostasis by either glycogenolysis or gluconeogenesis (McGrane, 2013).

Hers' disease (type IV glycogen storage disease) is another rare autosomal recessive disorder and it is caused by a defect in glycogen phosphorylase function (McGrane, 2013). It is presented in childhood, and it is characterized by hypoglycemia, hepatomegaly and growth delay (Fernandes and Chen, 1995).

McArdle's disease (type V glycogen storage disease) is caused by deficiency of the phosphorylase kinase gene in the liver and muscle (McGrane, 2013). It is presented in adulthood and it is characterized by progressive muscle weakness and glycogen accumulation. This disease causes exercise intolerance, due to reduced ability to release glucose from glycogen to meet the increased energy requirements. However, hypoglycemia and hepatomegaly are not present.

Phosphorylase kinase deficiency is an X-linked recessive trait and it is caused by absence of phosphorylation and activation of glycogen phosphorylase (McGrane, 2013). It occurs more frequently than glycogen phosphorylase deficiency and it has similar symptoms.

Cori's disease (type III glycogen storage disease) is caused by a mutation in the debranching enzyme (McGrane, 2013). It is presented in infancy and it is characterized by glycogen accumulation in liver and muscle, fasting hypoglycemic convulsions, hepatomegaly, and myopathy (Dunger and Holton, 1994). The symptoms of hypoglycemia and hepatomegaly often decrease at the age of puberty (McGrane, 2013).

## Diabetes mellitus

Diabetes mellitus is a chronic disease characterized by high levels of blood glucose (impaired glucose tolerance), and results from defects in insulin secretion, insulin action or both. Diabetes mellitus is a major cause of premature mortality, stroke, cardiovascular disease, peripheral vascular disease, congenital malformations, perinatal mortality, and long- and short-term disability. Diabetes mellitus is diagnosed by increased fasting plasma glucose (hyperglycemia), by glucose presence in the urine (glycosuria), or by elevated glucose values during an oral glucose tolerance test. There are four principal types of diabetes mellitus: type 1, type 2, gestational diabetes, and monogenic diabetes.

### Type 1 diabetes

Type 1 or juvenile or insulin-dependent diabetes is caused by autoimmune pancreatic  $\beta$  cell exhaustion and loss of insulin secretion. Onset of the disease occurs when most of the pancreatic  $\beta$  cells have been destroyed by the immune system (Stipanuk, 2013). This form of diabetes is generally diagnosed in children and young adults, and it accounts for approximately 5–10% of all cases of diabetes mellitus (Centers for Disease Control and Prevention, 2017).

Type 1 diabetes usually develops in children, teenagers or young adults, but it can be diagnosed at any age (Centers for Disease Control and Prevention, 2017). In patients with type 1 diabetes, when pancreatic  $\beta$  cells are damaged, additional metabolic problems with glucagon secretion by the pancreatic  $\alpha$  cells develop (Stipanuk, 2013). Hormonal dysfunctions result in dysregulation of macronutrient metabolism observed in diabetic patients. Postprandial hyperglycemia causes decreased suppression of glucagon secretion by the pancreatic  $\alpha$  cells, dysregulation of hepatic glucose output, and dysfunctional rate of gastric emptying following a meal (Stipanuk, 2013). Since type 1 diabetics cannot produce insulin, the treatment for this type of diabetes involves insulin injections.

### Type 2 diabetes

Type 2 or non-insulin-dependent diabetes is a complex heterogeneous disorder caused by interactions of various genetic and environmental factors. It is characterized by insulin resistance, obesity, a sedentary lifestyle, and occasionally by decreased insulin secretion. The majority of the cases of diabetes mellitus are type 2 (Centers for Disease Control and Prevention, 2017).

Type 2 diabetes usually develops after 40 years of age, but it has become increasingly prevalent in younger children and adolescents, as a result of increasing rates of obesity and physical inactivity (Stipanuk, 2013). Type 2 diabetics have a wide range of plasma insulin values, but are insulin resistant. Insulin resistance is the inability of the muscle, liver or fat cells to respond to insulin and remove plasma glucose from the circulation. Initially, this condition is compensated by increased insulin secretion by the pancreatic  $\beta$  cells and maintenance of healthy blood glucose levels, but eventually the pancreas is not able to secrete enough insulin and hyperglycemia develops. Dietary changes, weight loss and increased physical activity, as well as oral diabetic medication may be used to treat and control type 2 diabetes, enhancing insulin action. However, insulin injections may also be used as treatment.

### Gestational diabetes

Gestational diabetes is a condition characterized by high blood glucose levels in pregnant women without previously diagnosed diabetes (Centers for Disease Control and Prevention, 2019). Gestational diabetes is usually diagnosed in the second half of pregnancy by abnormal values in an oral glucose tolerance test. Gestational diabetes increases the mother's risk of elevated blood pressure during pregnancy and of a cesarean delivery (Center for Disease Control and Prevention, 2019). It also increases the risk of having a premature baby with health problems, including hypoglycemia and being very large for gestational age (Center for Disease Control and Prevention, 2019). Gestational diabetes is treated by dietary modification, increase in physical activity, and potentially insulin injections. Blood glucose should be closely monitored during pregnancy and after delivery. Gestational diabetes is usually ameliorated after childbirth, but it increases the future risk of developing type 2 diabetes for the mother and the baby.

### Monogenic diabetes

Monogenic diabetes mellitus is a rare case of the disease caused by mutations in a single gene and is diagnosed by genetic testing (National Institute of Diabetes and Digestive and Kidney Diseases, 2017). In the United States, these cases account for 1–4% of all cases of diabetes (National Institute of Diabetes and Digestive and Kidney Diseases, 2017). Most cases of monogenic diabetes are treated with insulin or oral medications. The two main types of monogenic diabetes are neonatal diabetes mellitus (NDM) and maturity-onset diabetes of the young (MODY).

NDM occurs up to 1 in 400,000 infants in the United States, usually in newborns and young infants (National Institute of Diabetes and Digestive and Kidney Diseases, 2017). These infants do not produce enough insulin, resulting in hyperglycemia. NDM is often misdiagnosed as type 1 diabetes, however, type 1 diabetes is very seldom seen in infants younger than 6 months old. Half of infants with NDM develop permanent neonatal diabetes mellitus, while the other half of infants develop a temporary condition which disappears in infancy and may appear at a later time. NDM is characterized by frequent urination, rapid breathing, and dehydration and is diagnosed by increased glucose levels in blood or urine. Most fetuses with NDM suffer from intrauterine growth retardation, but appropriate treatment may ameliorate growth and development.

MODY occurs usually in adolescence or early adulthood and it accounts for nearly 2% of all diabetes cases in the United States in young adults and children below 20 years old. MODY cases are characterized by mild hyperglycemia. MODY is often misdiagnosed as type 1 or type 2 diabetes.

### Summary

Carbohydrates are an important source of energy in the human diet. All carbohydrates, in order to be utilized by the human body, need to be broken down to simple sugars. Carbohydrate digestion begins in the oral cavity and it is completed in the apical membrane of the intestinal mucosal cells. The monosaccharides produced (glucose, fructose and galactose) are transported through the enterocytes to the blood stream, principally in the form of glucose. Glucose is then aerobically or anaerobically broken down to produce energy, and is subject to hormonal regulation, allosteric enzyme control, and regulation of gene expression. Defective regulation of carbohydrate metabolism is the cause for a variety of diseases, which have mild to serious implications for human health.

## Key points

- Provide a brief overview of the dietary sources of carbohydrates
- Examine the main sources of dietary intake of carbohydrates
- Relate health issues associated with carbohydrate intake
- Summarize studies and evidence on the most important health issues associated with carbohydrate intake
- Discuss the method of carbohydrate restriction for weight management
- Outline the recommendation of various authorities on total carbohydrate, added/free sugar and fiber intake

## Introduction

Carbohydrates are an important energy source in the human diet. They generally supply about 40% of our energy requirement in developed countries and up to 80% in developing countries. Carbohydrates have been considered a fundamental source of nourishment and an inexpensive and versatile staple of the diet. The current global emphasis for healthy eating focuses on increasing carbohydrate consumption in the form of vegetables, fruits, legumes and whole grains.

## Dietary sources

The major sources of carbohydrates are cereals, consisting of over 50% of carbohydrate consumed in both developed and developing countries, followed by sweeteners, root crops, pulses, vegetables, fruit and milk products (World Health Organization, 1998). Carbohydrate and nutrient intake in general can be estimated using data from food production and balance sheets, household surveys and individual assessments (World Health Organization, 1998).

In developing countries, the majority of carbohydrate comes from a single food source, for example rice, cassava, or corn (World Health Organization, 1998). Carbohydrates are a significant medium for micronutrients (vitamins and minerals), and other nutritionally important elements, like phytochemicals. When a single carbohydrate food source is consumed in developing countries,

diets can suffer from nutritional deficiencies. Therefore, variety in carbohydrate intake is very important, in order to provide to maximize nutrient sufficiency and health benefits.

The type and composition of dietary carbohydrates varies greatly among different food products. Dietary carbohydrates can be predominantly found in the form of sugar (monosaccharides and disaccharides) and starch or non-starch polysaccharides. Furthermore, in the food industry, they can be used in the form of hydrolyzed cornstarch, high-fructose corn syrups, modified starches, gums, mucilages and sugar alcohols.

## Sugars

The term “sugar” includes monosaccharides and disaccharides (Brody, 1999). The most common monosaccharides are glucose (or dextrose), fructose and galactose. Glucose is found in fruits, honey, maple syrup and vegetables. Glucose is also formed from sucrose hydrolysis in honey, maple syrup and invert sugar, and it is produced from starch hydrolysis in corn syrups. The properties of glucose are important for improving food texture, flavor and palatability. Glucose is the major cell fuel, and the principal energy source for the brain (Nelson and Cox, 2017). Fructose is found in honey, maple sugar, fruits and vegetables. Fructose is also formed from sucrose hydrolysis in honey, maple syrup and invert sugar. It is commonly used as a sweetener in soft drinks, bakery products and candy, in the form of high-fructose corn syrups. Galactose is found primarily in milk and dairy products.

The most common disaccharides are sucrose, lactose and maltose (Brody, 1999). Sucrose is mostly found in sugar cane and beet, and in lesser amounts in honey, maple syrup, fruits and vegetables. The properties of sucrose are important in improving viscosity, sweetness, and flavor of baked foods, ice cream, and desserts. Maltose is formed from starch digestion and it is also produced from the germination of grain for malt liquors. Lactose is found in milk and dairy products, and is not as sweet as glucose or sucrose.

### Natural vs. added or free sugars

Sugars occur naturally in fruits, vegetables and milk. These sugars are different from “added” or “free” sugars which are sugars that have been incorporated as part of food processing and preparation. These sugars can include sucrose, syrups and honey, and sugars from concentrated fruit or vegetable juices (US Food and Drug Administration, <https://ask.usda.gov/s/article/>).

The European Food Safety Authority (EFSA) defines “added sugars” as sucrose, fructose, glucose, starch hydrolyzates and other isolated sugar preparations utilized in the processes of food preparation and manufacturing (European Food Safety Authority, 2010).

The World Health Organization uses the term “free sugars” and defines them as sugars “added to foods and beverages by the manufacturer, cook or consumer, and sugars naturally present in honey, syrups, fruit juices and fruit juice concentrates” (World Health Organization, 2015). The Scientific Advisory Committee on Nutrition (SACN) of the United Kingdom defines “free sugars” as “all monosaccharides and disaccharides added to foods by the manufacturer, cook or consumer, plus sugars naturally present in honey, syrups and unsweetened fruit juices” (Scientific Advisory Committee on Nutrition, 2015). This definition excludes naturally occurring sugars and captures the consumption of high fructose corn syrup.

Global sugar consumption has increased over the last decade from 130 to 178 million tones (World Cancer Research Fund International, 2015). This increase has been driven by an increase in the sugar consumption in developing countries (Siervo et al., 2014). Even though there is a decline of sugar consumption in the developed countries, sugar intake is still high, consisting of approximately 20% of total dietary energy intake. This is due, in particular, to increased consumption of added or free sugars, as a result of their greater use in beverages and foods.

## Polysaccharides

### Starch

Starch is the most important and abundant food polysaccharide. Starch is predominantly derived from plant seed, such as wheat, maize, rice, oats and rye, and from plant roots, such as potatoes (World Health Organization, 1998). Legumes and vegetables also contribute to the starch content of the diet. Bread and pasta are popular forms of starch, while tropical starchy foods, such as plantains, cassava, sweet potatoes and yams are increasingly contributing to carbohydrate intake. Starch accounts for 20–50% of total energy intake, depending on the total carbohydrate consumption (World Health Organization, 1998).

### Non-starch

Non-starch polysaccharides (NSP), formerly referred to as “dietary fiber,” can either be soluble or insoluble and are mainly derived from cereals, especially wholegrain (World Health Organization, 1998). Wheat, rice and maize are good sources of insoluble NSP, while oats, rye and barley are good sources of soluble NSP. Vegetables are also good sources of NSP, both soluble and insoluble. Intakes of NSP range from about 19 g/day in Europe and North American countries to 30 g/day in rural Africa (World Health Organization, 1998).

### Dietary fiber

Dietary fiber generally refers to complex carbohydrates, which compose the cells walls and structural components of plants (World Health Organization, 1998). Good sources of fiber consist of whole cereal grains, fruits, and vegetables. Dietary fiber may be soluble in water, for example pectin. Soluble fiber binds to other carbohydrates and delays digestion and absorption, therefore assisting in maintaining stable blood glucose levels. Insoluble fiber, such as cellulose, bulks up stool and aids in intestinal waste elimination. Dietary fiber consumption has potential important health benefits, including general gastrointestinal health and prevention of several non-communicable diseases, through blood cholesterol reduction and regulation of blood sugar levels (World Health Organization, 1998).

The definition of dietary fiber has been inconsistent for many decades. Various definitions have emerged and different methods of quantifying dietary fiber have been utilized during the past decades. Several authorities have provided official definitions of dietary fiber, in order to facilitate analysis of research studies, and provide comparable intake recommendations and food labeling guidelines.

In the United States, the Institute of Medicine (IOM) of the National Academies of Science has defined Dietary Fiber as “non-digestible carbohydrates and lignin that are intrinsic and intact in plants” (Institute of Medicine, 2005). IOM defined Functional Fiber as “isolated nondigestible carbohydrates that have beneficial physiological effects in humans”. Furthermore, Total Fiber has been defined as the sum of Functional and Dietary Fiber (Institute of Medicine, 2005).

EFSA has defined dietary fiber as non-digestible carbohydrates plus lignin (European Food Safety Authority, 2010). This definition includes NSP (cellulose, hemicelluloses, pectins, hydrocolloids), resistant oligosaccharides, fructo and galacto-oligosaccharides, other resistant oligosaccharides, resistant starch (physically enclosed starch, some types of raw starch granules, retrograded amylose, chemically and/or physically modified starches), and lignin associated with the dietary fiber polysaccharides (European Food Safety Authority, 2010).

According to the WHO, dietary fiber is defined as a heterogeneous mixture of polysaccharides and lignin that cannot be degraded by the endogenous enzymes of vertebrate animals (World Health Organization, 2003). WHO makes a distinction of water-soluble and water-insoluble fiber. Examples of water-soluble fibers are pectins, gums, mucilages and some hemicelluloses, while water-insoluble fibers are cellulose and some hemicelluloses.

A formal definition for fiber has been recently incorporated in Codex Alimentarius, which is a collection of standards, codes of practice, guidelines and recommendations (Codex Alimentarius, 2017). At the 2008 meeting of the Codex Committee on Nutrition and Foods for Special Dietary Uses, dietary fiber was defined as carbohydrates with 10 or more subunits, which cannot be hydrolyzed by endogenous enzymes of the human small intestine and can belong to the following categories:

1. Naturally occurring edible carbohydrates
2. Carbohydrates obtained from food raw material by physical, chemical or enzymatic methods, and scientifically shown to have a physiological effect or health benefit
3. Synthetic carbohydrates scientifically shown to have a physiological effect or health benefit

This comprehensive definition has generated the need for the development of an integrated analytical method for the determination of total dietary fiber. The American Association of Cereal Chemists International and the Association of Official Analytical Chemists International have previously developed methods for measurement of dietary fiber and dietary fiber components. Under the supervision of these two international organizations, a method has been developed for determination of total dietary fiber. This method was successfully evaluated by interlaboratory testing (McCleary et al., 2010, 2012). Modification of this method has been made to improve several of its aspects and, as a result, the Rapid Integrated Total Dietary Fiber method has been developed and evaluated by interlaboratory testing (McCleary and Cox, 2017).

### Health effects of carbohydrates

Carbohydrates are the major energy source in most human diets. Since the majority of amino acids and lipids can be converted to glucose via gluconeogenesis, there is no absolute requirement for carbohydrates (Institute of Medicine, 2005). Furthermore, in the absence of dietary carbohydrates, the human body can utilize the products of lipolysis of stored triacylglycerol or ketone bodies, for the production of energy. This process known as ketogenesis may supply energy to the brain, heart and skeletal muscle (Nelson and Cox, 2017).

Carbohydrates are stored in the human body as glycogen, mainly in the liver and muscle. The human body has a limited storage capacity for carbohydrates compared to fat. The total amount of carbohydrates stored in tissues as glycogen and circulating in the blood as glucose is less than a day's energy supply (Nelson and Cox, 2017). Diets high in carbohydrate ensure adequate glycogen storage available for immediate energy utilization. Carbohydrates are the preferred energy source for the human brain, and have an important role in reducing protein breakdown when energy intake is inadequate.

Dietary carbohydrates are absorbed in their hexose form (glucose, fructose, galactose) and provide 15.6 kJ per gram (3.75 kcal per gram) of energy. Although sugars and polysaccharides provide similar amounts of energy, they differ in their physiological and metabolic properties. The effects of carbohydrate-containing foods on blood glucose levels during digestion and absorption are variable, depending on the type of dietary carbohydrate. Post-prandial glucose response is reduced when glucose absorption is slow.

Several studies have demonstrated that foods which are absorbed slowly and those which have not been greatly processed may have greater health benefits, compared to rapidly absorbed and highly processed foods ([Institute of Medicine, 2005](#)). In order to quantify the absorption and digestion rate of carbohydrate foods, glycemic index (GI) and glycemic load (GL) have been utilized. GI and GL are measures of the blood glucose response after carbohydrate consumption. GI is the area under the curve of the blood glucose increase 2 h after carbohydrate ingestion of a set amount of a particular food (for example, 50 g) as compared to the blood glucose increase 2 h after the ingestion of the same amount of a reference food (white bread or glucose). GI is influenced significantly by the carbohydrate type and physical determinants of digestion rate (intact vs. ground grains, cooked vs. uncooked food and soluble fiber content). GL is the product of GI and the content of available carbohydrate, and considers both the quality and the amount of carbohydrate present in a particular food ([Brouns et al., 2005](#)). GI (and also GL) is determined mostly by the type of carbohydrates in a particular food, and to a small degree by the food matrix of the meal, that is the amount of protein and fat the meal contains. Beneficial effects of low GI foods have been linked to reduced glucose response after a meal and several positive health outcomes.

The role of carbohydrates in health is a growing area of research and has received a great amount of interest in the past decade.

### Carbohydrates and nutrient density

Increased sugar consumption has generated a concern in the recent years, because of the potential to displace the micronutrient content of the diet by increasing “empty calories” and energy intake. There is some evidence that essential nutrient intake decreases with increasing total sugar intake ([Institute of Medicine, 2005](#)). However, sugar intake has not been shown to accurately predict micronutrient ingestion. Moderate intakes of sugar coincide with sufficient nutrient intake. The risk of low micronutrient status is increased for individuals with a diet high in sugars and low in total energy intake, as in the case of children or people on restrictive diets ([Institute of Medicine, 2005](#)). Data analysis on food intake of preschool children suggests that the intake of some micronutrients (calcium, zinc, thiamin, riboflavin and niacin) is inversely related to sugar intake. However, the dilutional effects of sugars may be somewhat distorted by the fact that some rich sources of added sugars are also fortified with micronutrients, as in the case of breakfast cereals. The IOM of the National Academies of Science, using national food intake data, reported that a clear dilutional effect on micronutrient intake starts when sugar intake approaches 25% of total calories.

Several human studies have demonstrated that diets rich in NSP may reduce the bioavailability of minerals, such as iron, calcium, and zinc ([Institute of Medicine, 2005](#)). Nevertheless, this effect may be attributed to the presence of phytate, which inhibits the absorption of those minerals, rather than the NSP content of the diet ([Institute of Medicine, 2005](#)).

### Carbohydrate and obesity

Several studies have been conducted to establish an association between sugar ingestion and total energy intake ([Institute of Medicine, 2005](#)). There have been consistent reports of a negative association between sugar intake and body mass index in adults and children ([Scientific Advisory Committee on Nutrition, 2015](#)). Some ad lib dietary studies have shown that diets low-in-sugar are associated with weight loss, maybe as a result of reduced calorie intake ([Institute of Medicine, 2005](#)). Foods high in sugars or GI are highly palatable and can create a potential risk for energy overconsumption and weight gain ([Institute of Medicine, 2005](#)). However, there is insufficient evidence to support this claim or confirm the role of GI on body weight regulation ([Scientific Advisory Committee on Nutrition, 2015](#)). Foods high in sugar have high energy density, and thus decreasing their consumption can assist in weight reduction. On the contrary, foods rich in NSP are bulky and, as a result, induce greater satiety when ingested. Consequently, diets rich in NSP may be useful for obesity prevention, since they prevent energy overconsumption and assist in weight control ([European Food Safety Authority, 2010](#)).

The consumption of sugar-sweetened drinks may contribute to weight gain because of the low satiety of liquid foods ([Institute of Medicine, 2005](#)). Short-term human studies have shown that sugar-sweetened drink consumption results in an increase of total energy intake ([Scientific Advisory Committee on Nutrition, 2015](#)). Consumption of these drinks has been associated with childhood obesity ([Scientific Advisory Committee on Nutrition, 2015](#)).

### Carbohydrate and cardiovascular disease

Dietary carbohydrates influence risk factors for the development of cardiovascular disease. A diet rich in carbohydrates, in the form of whole grain cereals, fruits and vegetables, may assist in the increase of the antioxidant and phytonutrient content of the diet, therefore reducing the risk of heart disease ([World Health Organization, 2003](#)). Certain NSP have been shown to reduce plasma total and low-density lipoprotein cholesterol and, therefore, result in lowering the risk of coronary heart disease in the short-term ([Scientific Advisory Committee on Nutrition, 2015](#)). Nevertheless, this effect has not been demonstrated with NSP-containing supplements or in the long-term ([Institute of Medicine, 2005](#)). Dietary fiber has been shown to lower blood pressure in dietary interventions, which is an additional benefit for protection against heart disease ([World Health Organization, 2003](#)). Furthermore, dietary fiber has been associated with lower incidence of cardiovascular disease in prospective cohort studies ([Scientific Advisory Committee on Nutrition, 2015](#)).

On the contrary, a high intake of carbohydrates (>65% of total calories), especially in the form of refined sugars and starch, may increase serum triacylglycerol levels and adversely affect plasma lipoprotein profile ([Institute of Medicine, 2005](#)). Short-term studies

show a consistent relationship between sugar consumption and elevation of triacylglycerol levels, as well as a decrease in plasma high-density lipoprotein levels, which could result in increased atherosclerosis and heart disease risk ([Scientific Advisory Committee on Nutrition, 2015](#)). However, longitudinal cohort studies have failed to show a consistent association of sugar consumption and cardiovascular disease, mainly because of the confounding factors associated with increased heart disease risk ([Institute of Medicine, 2005](#)).

High GI diets have been shown to slightly increase hemoglobin A1c, total serum cholesterol and triacylglycerols, and decrease high-density lipoprotein levels and urinary C-peptide in diabetic and hyperlipidemic individuals ([Scientific Advisory Committee on Nutrition, 2015](#)). On the contrary, low GI diets have been shown to decrease cholesterol and triacylglycerol levels in dyslipidemic individuals ([Scientific Advisory Committee on Nutrition, 2015](#)). Nonetheless, there are insufficient studies performed on healthy individuals, and further research on the role of GI on lipid profile and cardiovascular risk factors is warranted.

### **Carbohydrates and type 2 diabetes**

There is little evidence from prospective studies to support a positive association between total dietary carbohydrate consumption and type 2 diabetes risk ([Institute of Medicine, 2005](#)). Some evidence suggests that rapidly digested refined sugars, which have a high GI, may increase the risk of type 2 diabetes ([Scientific Advisory Committee on Nutrition, 2015](#)). Short-term studies have shown that decreasing the GI of a meal can improve glucose tolerance and insulin sensitivity in healthy people ([Scientific Advisory Committee on Nutrition, 2015](#)). Furthermore, the substitution of high GI with low GI carbohydrates can decrease post-prandial glucose and insulin levels ([Institute of Medicine, 2005](#)).

Some studies have demonstrated a protective effect of cereal fiber and whole grain consumption against type 2 diabetes ([Institute of Medicine, 2005](#); [Scientific Advisory Committee on Nutrition, 2015](#)).

### **Carbohydrates and dental caries**

Prospective cohort studies show that the quantity and frequency of dietary sugar intake play a significant role in the development of dental caries ([World Health Organization, 2015](#); [Scientific Advisory Committee on Nutrition, 2015](#)). Dental caries is a multifaceted disease, affected not only by the frequency and type of sugar consumed, but also by oral hygiene, fluoride supplementation and use ([Scientific Advisory Committee on Nutrition, 2015](#)). Despite the increase in sugar consumption, the incidence of dental caries has decreased worldwide, because of the increased use of fluoride and improvement of oral hygiene ([World Health Organization, 2015](#)).

Dental caries results from the loss of minerals from the tooth enamel in the presence of acid ([Scientific Advisory Committee on Nutrition, 2015](#)). Fermentation and hydrolysis of dietary sugars occur in the oral cavity, and reduce the pH of the mouth ([Scientific Advisory Committee on Nutrition, 2015](#)). Saliva has the ability to neutralize and repair the loss of minerals from this process ([Scientific Advisory Committee on Nutrition, 2015](#)). When this loss of minerals exceeds the capacity of saliva to remineralize the tissues, tooth decay occurs ([Scientific Advisory Committee on Nutrition, 2015](#)).

Data indicates that dental caries are reduced in countries where sugar intake is below 15–20 kg per person per year ([World Health Organization, 2003](#)). This figure translates to a daily intake of 40–55 g per person and to a total energy intake of 6–10% ([World Health Organization, 2003](#)). Worldwide ecological studies and randomized controlled trials have consistently shown a relationship between high sugar consumption, mainly sucrose, and tooth demineralization and tooth decay ([Scientific Advisory Committee on Nutrition, 2015](#); [World Health Organization, 2003](#)). When annual sugar consumption increases over 15–20 kg per person per year, dental caries also increase ([World Health Organization, 2003](#)).

### **Carbohydrate and cancer**

Case-control studies have shown that colorectal cancer risk increases with high intakes of sugar-rich foods, while other studies have failed to prove such a relationship ([Institute of Medicine, 2005](#)). Therefore, there is insufficient evidence to support the role of sugar in the risk for colorectal cancer.

On the contrary, increased dietary fiber consumption in the form of fruits, vegetables and cereals has been shown to be protective against colorectal cancer ([Institute of Medicine, 2005](#); [Scientific Advisory Committee on Nutrition, 2015](#)).

Carbohydrate foods are a good source of phytoestrogens, which may protect against breast cancer ([Institute of Medicine, 2005](#)). However, due to the fact that studies related to carbohydrate intake and breast cancer have been inconsistent, it is not possible to establish an association ([Institute of Medicine, 2005](#)).

Prospective cohort study data indicate a negative association of prostate cancer risk with high fructose intakes; however, evidence on the role of sugar consumption on prostate cancer risk is scarce ([Institute of Medicine, 2005](#)). Some data suggest that increased fiber intakes are related to decreased prostate cancer risk ([Institute of Medicine, 2005](#)).

### **Carbohydrates and gastrointestinal health**

High intakes of NSP and dietary fiber have been shown to contribute to the prevention and treatment of constipation, to the decrease of intestinal transit times, and to the increase of fecal mass ([Institute of Medicine, 2005](#); [Scientific Advisory Committee](#)

on Nutrition, 2015). Population studies have linked the prevalence of hemorrhoids, diverticular disease and appendicitis to NSP intakes, although there are several dietary and lifestyle confounding factors that could directly affect these relationships (Institute of Medicine, 2005). High carbohydrate diets may be related to bacterial growth in the gut, and subsequent reduction of acute infective gastrointestinal disease risk (Institute of Medicine, 2005).

### Low carbohydrate or ketogenic diets

Carbohydrate restriction has been investigated for many decades, as part of diabetes management, especially before insulin therapy was available (Katz and Meller, 2014). Carbohydrate restriction was also used as a treatment tool for childhood epilepsy (Swink et al., 1997). Recently, carbohydrate restriction has gained popularity in the arena of obesity management. The Atkins diet was the first to gain popularity, followed by the South Beach diet, the Zone diet, and the ketogenic diet. These diets restrict carbohydrates below a given level, either below 100 g per day or even below 50 g per day. By restricting carbohydrates, these diets shift the body's metabolism from glucose utilization to fat oxidation. Fat and protein composition of these diets is variable, but the main determinant of a low carbohydrate or ketogenic diet is the reduction of dietary carbohydrates.

The low carbohydrate diet is based on the Carbohydrate-Insulin Model of obesity (Ludwig and Ebbeling, 2018). This model proposes that a diet high in carbohydrates results in post-prandial increased insulin secretion, causing excess energy storage in adipose tissue, and subsequent weight gain. Carbohydrate has the strongest effect on insulin secretion, and this effect depends on the type and amount of carbohydrate consumed. Protein also has an effect on insulin secretion, but this effect is counterbalanced by glucagon secretion. Dietary fat does not have an appreciable effect on insulin secretion. When carbohydrates are restricted, two metabolic pathways are turned on: gluconeogenesis and ketogenesis (Brouns, 2018). Gluconeogenesis occurs due to the reduced flux of glucose to the tissues. However, the process of gluconeogenesis ceases when substrates become unavailable, and ketogenesis occurs to provide ketone bodies as an alternate energy source. Subsequently, reduced insulin levels promote lipolysis and increase the supply of fatty acids. These fatty acids are used for fuel or are further converted to ketone bodies, which can also be utilized as energy, even by the brain and nervous system through metabolic adaptation.

Low carbohydrate diets decrease appetite due to higher satiety of increased protein intake, regulation of appetite control hormones, and potential appetite suppression by ketone bodies (Paoli et al., 2013). They result in increased lipolysis, reduced lipogenesis, and increased metabolic efficiency (Paoli et al., 2013; Barber et al., 2021).

Short to medium duration intervention studies have demonstrated that low carbohydrate diets are effective for weight loss and have metabolic health benefits (Katz and Meller, 2014; Boden et al., 2005; Volek et al., 2008). Low carbohydrate diets have been shown to reduce hunger and promote fat loss, which may contribute to adherence to a weight loss diet. Furthermore, carbohydrate restriction seems to improve insulin sensitivity and glycemic control in diabetic and pre-diabetic subjects (Barber et al., 2021; Goldenberg et al., 2020). When longer term trials are considered, the metabolic benefits of low carbohydrate diets diminish (Goldenberg et al., 2020).

Potential risks associated with low carbohydrate diets are essentially attributed to increased protein intake and entail possible kidney damage, because of increased levels of nitrogen turnover. However, animal studies, meta-analyses and human trials do not show any kidney damage associated with high protein intake (Paoli et al., 2013). Another health issue with very low carbohydrate diets (<50 g per day) may be acidosis, but that does not occur in individuals with normal insulin functions (Paoli et al., 2013). Long term safety of low carbohydrate diets remains to be evaluated.

Despite the metabolic health benefits of carbohydrate restriction, low carbohydrate diets remain controversial (Barber et al., 2021). Nonetheless, they have been shown to be an effective weight loss tool in short to medium-term studies (Katz and Meller, 2014). Studies are lacking to demonstrate a health benefit and safety in the long term.

### Requirements and recommendations

The recommendation for total carbohydrate intake from various authorities is starting from 45% up to 75% of total energy intake. It is a broad range of intake, and it is meant to represent population consumption, and provide an adequate macronutrient balance, increased dietary fiber intake, and sufficient energy requirements. High variability exists in added/free sugar intake recommendation, but most authorities agree that there should be a reduction in consumption of added/free sugars. Increased dietary fiber intake is recommended, at a level over 25 g per day, due to the positive health benefits associated with high levels of consumption. Dietary recommendations for total carbohydrate, added/free sugars, and dietary fiber from various authorities are summarized in Table 1.

More specifically, the IOM of the United States recommended in 2005 a range of carbohydrate intake of 45–65% of total energy intake and provided a Recommended Dietary Allowance (RDA) of 130 g of total carbohydrates per day for adults, which was based on the average minimum amount of glucose needed daily by the brain. The expert panel of IOM suggested a maximal intake of less than 25% of energy from added sugars, based on the dilutional effect of added sugars on certain micronutrients. IOM proposed that total sugar intake can be decreased by limiting foods high in added sugars and consuming naturally occurring sugar products, like milk, dairy products, and fruit. The IOM did not specify dietary requirements or recommendations for NSP consumption, but provided recommended intakes for fiber, which includes NSP. Adequate intake of total fiber, according to the IOM, should be

**Table 1** Dietary recommendations for total carbohydrate, added or free sugars and dietary fiber.

Authority - year adopted	Carbohydrates (% of total energy)	Free/added sugars (% of total energy)	Dietary fiber (daily intake)
Institute of Medicine (IOM) - 2005	45–65%	< 25%	38 g for men 25 g for women
Scientific Advisory Committee on Nutrition (SANS) - 2015	50%	<5%	30 g
European Food Safety Authority (EFSA) - 2010	45–60%	No limit set	25 g
World Health Organization (WHO) - 2003	50–75%	<5–10%	>25 g

Data sources: [Institutes of Medicine \(2005\)](#), [SANS \(2015\)](#), [EFSA \(2010\)](#), [WHO \(2003\)](#) and [Mann et al. \(2007\)](#).

approximately 38 g per day for men and 25 g per day for women, based on an adequate intake of 14 g per 1000 kcal per day of total fiber.

Similarly, the SACN of the United Kingdom proposed in 2015 the consumption of total carbohydrates to comprise half of the total dietary intake (50% of total energy intake). This estimate was proposed to achieve an adequate macronutrient intake (adequate fat and protein balance). SACN estimated that the dietary recommendation for free sugars should not be higher than 5% of total energy intake, in order to provide a 5% reduction in energy, and lead to a moderate weight loss for most individuals ([Scientific Advisory Committee on Nutrition, 2015](#)). SACN recommended that the average adult population intake for dietary fiber should be 30 g per day, from a wide variety of sources ([Scientific Advisory Committee on Nutrition, 2015](#)). This recommendation by SACN was based on the positive health benefits associated with high dietary fiber intake, especially in colorectal function and cardiovascular risk factors ([Scientific Advisory Committee on Nutrition, 2015](#)).

EFSA has also published dietary reference values for the intake of carbohydrates and dietary fiber ([European Food Safety Authority, 2010](#)). EFSA recognized that an intake of 130 g per day will sufficiently cover the glucose requirements for the brain. EFSA acknowledged that this level of intake is not adequate to cover energy needs in terms of acceptable intakes of fat and protein. Consequently, EFSA proposed a range of intake of total carbohydrates from starchy foods and from simple sugars of 45–60% of total energy intake, partly based on current levels of intake and dietary patterns. The EFSA panel found insufficient evidence to pose an upper limit for sugars or added sugars and proposed such recommendations to be considered at a national level. However, the EFSA panel set a minimum daily intake of 25 g for dietary fiber, based on health benefits associated with high fiber intakes. These benefits, according to EFSA, included decreased risk of coronary heart disease and type 2 diabetes, as well as improved weight control.

The Joint Committee of Food and Agriculture Organization (FAO) and the WHO published in 2003 a report regarding the role of carbohydrates in human nutrition, and recommend the consumption of 55–75% of total energy in the form of carbohydrates from a variety of sources ([World Health Organization, 2003](#)). This lower limit has been recently revised to 50–75% to align with other authorities ([Mann et al., 2007](#)). The Joint FAO/WHO committee suggested that free sugars should be restricted to less than 10% of total energy. A recent WHO publication proposed that the consumption of free sugars should be further restricted to less than 5% of total energy intake, in order to further decrease the risk of dental caries ([World Health Organization, 2015](#)). WHO reports recognized that there is no direct causal link between sugar consumption and chronic disease, but acknowledged that sugars increase the energy density of the human diet significantly and that high sugar drinks are associated with childhood obesity. Furthermore, WHO proposed that people should consume more than 400 g per day of fruits and vegetables, and that the majority of carbohydrates should originate from NSP, principally from cereals, vegetables, legumes, and fruits. This recommendation, according to WHO, should provide adequate amounts of NSP (>20 g per day) and dietary fiber (>25 g per day).

## Conclusion

Carbohydrates are an important energy source in the human diet. Research studies confirm the health promoting role of dietary fiber and non-starch polysaccharides in improving cardiovascular disease risk and promoting colorectal health. Furthermore, they demonstrate a link of increased sugar consumption to obesity and dental caries. Therefore, public health nutrition guidelines propose an increase in consumption of carbohydrates in the form of fruits, vegetables, legumes and whole grains, and concurrent reduction of added/free sugars in order to promote health and well-being.

### Key points

The main objectives for the chapter are:

- To describe the structure and classification of carotenoids.
- To summarize the main chemical, physical and electrochemical properties of carotenoids.
- To describe the effect of processing and storage conditions in carotenoid levels and bioavailability.
- To enumerate the main carotenoids sources.
- To describe the physiology of carotenoids.
- To outline the main effects of carotenoids on health.

### Glossary

**Carotene** A carotenoid formed only from carbon and hydrogen, such as lycopene,  $\beta$ -carotene, and  $\alpha$ -carotene

**Carotenoid** A family of pigments with a characteristic conjugated double bond system, widely distributed in nature

**Isoprenoid** Compounds formed from the basic five-carbon building block, isoprene

**Polyene** An organic compound containing many double bonds, especially one having double bonds in a long aliphatic hydrocarbon chain

**Provitamin A carotenoids** The subfamily of carotenoids that have appropriate chemical structures for vitamin A formation. The most important of these carotenoids are  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin

**Xanthophyll** Oxygenated carotenoids, such as  $\beta$ -cryptoxanthin, lutein, and zeaxanthin

## Introduction

Carotenoids are fat-soluble pigments which can be found in a wide variety of plants but also in animals, algae, fungi and bacteria. Majority of carotenoids are tetraterpenoids lipid compounds made of eight isoprenoid units with a 40-carbon skeleton and possess a C22 central unit consisting of nine conjugated double bonds and an end group at both ends of the polyene chain. Carotenoids can be classified into two groups regarding the presence or absence of oxygen in their molecules: Carotenes (non-oxygenated) and Xanthophylls (contains oxygen atoms). The *de novo* synthesis of carotenoids does not occur in humans, and they are primarily obtained from fruit and vegetables but also from several animal-derived foods such as salmon and eggs (Maoka, 2020). More than 1204 natural carotenoids have been identified in the nature in 722 source organisms, and approximately 40 are present in the human diet. Nevertheless, only 6 carotenoids ( $\beta$ -carotene,  $\alpha$ -carotene, lycopene and the oxy-carotenoids lutein, zeaxanthin and  $\beta$ -cryptoxanthin) represent the 90–95% of the total carotenoids detected in human plasma (Olmedilla et al., 2001).

Carotenoids can show both antioxidant and pro-oxidant characteristics depending on conditions and so many of the known actions and functions of carotenoids can be directly attributed to their physico-chemical properties. From a nutritional point of view, the importance of carotenoids lies in their provitamin A activity, in their antioxidant capacity and their beneficial effect on the prevention of various diseases such as cancer, eye and vascular disorders, among others (Böhm et al., 2021).

## Structure and classification

Carotenoids are lipid-soluble pigments widely distributed in nature and are present in photosynthetic bacteria, some species of archaea and fungi, algae, plants, and animals. Chemically the majority of naturally occurring carotenoids are tetraterpenoids made of eight isoprenoid units with a 40-carbon skeleton and possess a C22 central unit consisting of nine conjugated double bonds and an end group at both ends of the polyene chain (Maoka, 2020) (Fig. 1).

There are seven different terminal groups:  $\psi$ ,  $\beta$ ,  $\gamma$ ,  $\epsilon$ ,  $\phi$ ,  $\chi$ , and  $\kappa$ . In general terms, the terminal rings  $\beta$ ,  $\gamma$ , and  $\epsilon$  rings are formed from  $\psi$  ends, whereas  $\phi$ ,  $\chi$ , and  $\kappa$  rings are formed from  $\beta$  end groups (Fig. 2) (Fernandes et al., 2018; Maoka, 2020). Depending on the presence or absence of rings in their molecules, they can be classified into two main groups: cyclic or acyclic carotenoids, respectively (Meléndez-Martínez et al., 2019).

Carotenoids can also be classified into two groups regarding the presence or absence of oxygen in their molecules: Carotenes and Xanthophylls (Fig. 3). Carotenes (as  $\beta$ -carotene,  $\alpha$ -carotene,  $\gamma$ -carotene, lycopene, phytoene and phytofluene) are non-oxygenated carotenoids that may be linear or possess cyclic hydrocarbons at one (monocyclic) or both (bicyclic) ends of the molecule. Xanthophylls are carotenoids containing oxygen atoms that are usually hydroxy, epoxy, carboxy, or carbonyl groups. Most of the oxygen substituents appear on  $\beta$ -ionyl ring positions (as  $\beta$ -cryptoxanthin, lutein, zeaxanthin, la meso-zeaxanthin, astaxanthin, canthaxanthin and fucoxanthin), although 5,8-epoxides (such as flavoxanthin) and apo-carbonyls (as  $\beta$ -citaurin) are known (Maoka, 2020).

Apart from these two general classifications of carotenoids as cyclic or acyclic or carotenes and xanthophylls, other subgroups of carotenoids can be distinguished by their structure. Some carotenoids have a 45- or 50-carbon skeleton, which are called higher carotenoids. On the other hand, carotenoids composed of carbon skeletons with fewer than 40 carbons are called apocarotenoids. Apocarotenoids correspond to products that are generated by oxidative cleavage of carotenoids, catalyzed by a family of enzymes called carotenoid excision dioxygenases (Fernandes et al., 2018).

Finally, some of the carotenoids also act as precursors of vitamin A, allowing their classification into provitamin A group ( $\beta$ -carotene,  $\alpha$ -carotene and  $\beta$ -cryptoxanthin) and non-provitamin A carotenoid group.

## Stereochemistry

Due to the presence of double bonds in carotenoid molecules, geometrical isomers may exist considering the relative position of substituents around a planar carbon-carbon double bond, thus existing all-trans (all-E) or cis (Z) (cis/trans or Z/E) isomers, which markedly differ in shape. For instance,  $\alpha$ - and  $\beta$ -carotene that differ only in the position of a double bond in the cyclic end-group can both show further cis/trans-isomerism along the terpene chain. In general, the (all-E) isomers of carotenoids are the most stable and therefore the most abundant. Although the presence of cis isomers in foods and other matrices can be attributed to isomerization caused by factors such as heat or light, it has been established that some can also occur naturally, as in the case of acyclic carotenoids such as phytoene or phytofluene (Meléndez et al., 2019).

**Fig. 3** Examples of carotenes and xanthophylls.

Furthermore, many carotenoids have chiral centers in their molecules (carbon atoms to which four different substituents are attached), so that different optical isomers can exist ([Meléndez et al., 2019](#)). Classic examples of carotenoids with a chiral center are zeaxanthin and astaxanthin. Two optical isomers (3R-3'R)-zeaxanthin and (3R-3'S)-zeaxanthin, commonly referred to as meso-zeaxanthin and (3S, 3'S)-zeaxanthin are found in the macula lutea of the human retina. Conversely, optical isomers different from astaxanthin, (3R, 3'R), (3S, 3'S) and (3R, 3'S or meso), are found in marine organisms in varying proportions ([Fernandes et al., 2018](#)) ([Fig. 4](#)).

### Biosynthesis

All isoprenoids are derived from two common precursors of five carbon atoms (C5), the isopentenyl diphosphate (IPP) and its isomer dimethylallyl diphosphate (DMAPP), which can be generated from two different metabolic pathways, the mevalonate pathway (MVA) and the Methyl Erythritol 4-phosphate pathway (MEP). DMPA condenses with three IPP molecules and geranyl-geranyl diphosphate (GGDP) is produced, from which two molecules are condensed, in a reaction catalyzed by phytoene synthase (PSY), producing phytoene (the first carotene, which is colorless). The phytoene goes through a series of desaturation reactions to finally obtain the lycopene molecule (first carotenoid with color), which can take two routes. In the first of them, by the

Fig. 4 Optical isomers of zeaxanthin and astaxanthin.

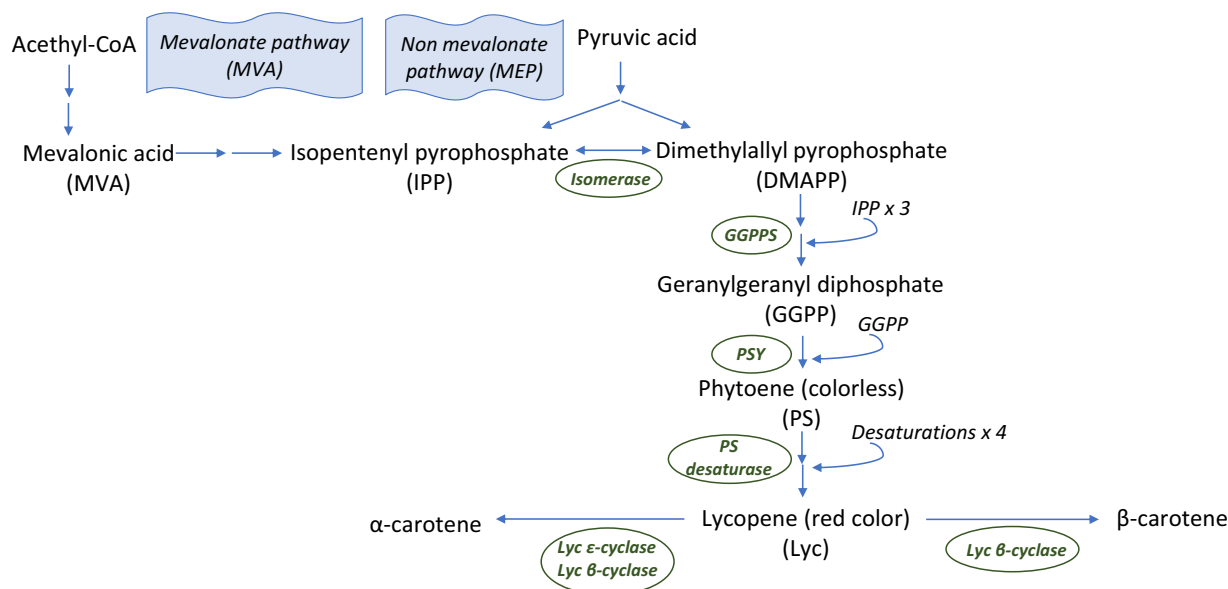

action of the  $\epsilon$ -lycopene cyclase ( $\epsilon$ -LCY) one of the ends of the lycopene is cycled and with the action of the  $\beta$ -lycopene cyclase ( $\beta$ -LCY) the other end is cycled, obtaining the  $\alpha$ -carotene. By the second way, the two ends are cycled with the help of the  $\beta$ -LCY, obtaining the  $\beta$ -carotene. From these two compounds, through oxidation reactions catalyzed by  $\epsilon$ - and/or  $\beta$ -carotene hydroxylases and zeaxanthin epoxidase, xanthophylls are formed (Maoka, 2020) (Fig. 5).

## Properties

### Chemical and physical properties

In general, carotenoids are hydrophobic molecules and are soluble only in organic solvents such as acetone, methanol, diethyl ether, hexane, chloroform and pyridine, among many others. Due to its hydrophobic character, they are associated with lipophilic sites in cells, such as bilayer membranes. Polar substituents such as hydroxyl groups decrease their hydrophobicity and alter their orientation with respect to membranes. Lycopene and  $\beta$ -carotene are aligned parallel to membrane surfaces to maintain a hydrophobic environment, whereas the more polar xanthophylls such as lutein become oriented perpendicular to membrane surfaces to keep their hydroxyl groups in a more hydrophilic environment (Gruszecki and Strzalka, 2005). These differences can affect the physical nature of a membrane as well as its function.

However, it must be taken into account that they are soluble in aqueous environments if they are integrated into liposomes or cyclic oligosaccharides such as cyclodextrins. In addition, their association with proteins or glycosylation reactions also allow them to be present in aqueous media. Carotenoproteins have been found mainly in plants and invertebrates, but intracellular

MVA: Mevalonate pathway; MEP: Methyl Erythritol 4-phosphate pathway; GGPPS: Geranylgeranyl diphosphate synthase; PSY: Phytoene sintasa

Fig. 5 Biosynthetic pathways of carotenoids.

$\beta$ -carotene-binding proteins have been found in bovine liver and intestine and in livers of the rat and ferret. In addition, a xanthophyll-binding protein has been found in human retina and macula. Carotenoids are also present in nature as crystalline aggregates (lycopene in chromoplasts) or as fine dispersions in aqueous media ( $\beta$ -carotene in oranges). Typically carotenoid molecules are very sensitive to elevated temperatures and to the presence of oxygen, acid, and light when in solution, and are subject to oxidative degradation (Meléndez et al., 2019).

### Electrochemical properties

What sets carotenoids apart from other molecules and gives them their electrochemical properties is their conjugated double bond (c.d.b.) system. In this alternating double and single bond system,  $\pi$ -electrons are delocalized over the entire polyene chain. This polyene chain imparts characteristic electronic spectra and photophysical and photochemical properties to this group of molecules. The highly delocalized  $\pi$ -electrons require little energy to reach an excited state so that light energy can cause a transition. The length of the conjugated polyene or chromophore affects the amount of energy needed to excite the  $\pi$ -electrons. The longer the conjugated system, the easier it is to excite, so longer wavelengths of light can be absorbed, but for there to be a perceptible coloration, at least seven c.d.b are necessary. Thus phytoene, having three conjugated double bonds, and phytofluene, having five, are colorless, zeta-carotene having seven conjugated double bonds, absorbs light at  $\sim 400$  nm and appears yellow, neurosporene having nine, absorbs light at  $\sim 451$  nm, and appears orange, and lycopene having eleven conjugated double bonds, absorbs at  $\sim 472$  nm, and appears red.

The UV-Vis absorption spectrum of carotenoids is of interest to clarify their structure. Usually there are three wavelengths of maximum absorption ( $\lambda_{\max}$ ) whose value depends on the number of c.d.b. and the solvent used for the measurement. In addition, the  $\lambda_{\max}$  increases with the length of the chromophore, so that the unconjugated double bonds do not significantly affect the spectrum. However, when there are c.d.b. in a ring,  $\lambda_{\max}$  appears at shorter wavelengths compared to non-cyclic carotenoids with the same number of c.d.b. Carbonyl groups conjugated with the polyenic chain also increase the length of the chromophore, while the hydroxyl and methoxyl groups do not affect the chromophore. The spectrum of cyclic carotenoids in which the chromophore extends to the rings presents a hypsochromic and hypochromic displacement, as occurs in zeaxanthin, while the spectrum of carotenoids with carbonyl groups conjugated with the polyenic chain presents a bathochromic displacement, as it occurs in astaxanthin. When comparing the spectrum of Z isomers with respect to those of all-E isomers, it is observed that the maximum absorption is located at values between 2 and 6 nm lower and that a new absorption band appears in the ultraviolet region (Meléndez-Martínez et al., 2019).

### Reaction with reactive oxygen species

Carotenoids are synthesized in photoautotrophic and in heterotrophic organisms as antioxidants to protect especially against reactive Oxygen Species (ROS) that are mainly produced as a result of aerobic metabolism or in response to biotic and abiotic stresses. The major members of the ROS family include free radicals like superoxide anion radicals  $O_2^{\cdot-}$ , hydroxyl radicals  $HO^{\cdot}$ , peroxy radicals ( $ROO^{\cdot}$ ) and non-radicals like  $H_2O_2$  and  $^1O_2$ . Among the various defense strategies, carotenoids are very efficient quenchers of singlet oxygen and scavengers of other reactive oxygen species (Stahl and Sies, 2003).

Carotenoids belong to the most efficient physical quenchers of  $^1O_2$ , both *in vitro* and *in vivo* and protect organisms from photosensitized formation and accumulation of  $^1O_2$  because they can absorb the radiation energy from the photosensitizer preventing the transfer of excitation energy to ground state oxygen and because the triplet energy level of carotenoids is close or below that of  $^1O_2$  and they can also efficiently drain the excitation energy from  $^1O_2$ . Thus, a prominent function of carotenoids is the protection of the photosynthesis apparatus from damage under high light conditions. This includes quenching of photosensitized triplet chlorophyll as the first line of defense and of singlet oxygen once formed by reaction with triplet chlorophyll (Sandmann, 2019).

The reaction of carotenoids as scavengers of both short-lived and long-lived oxidizing radicals has been investigated. In homogeneous solutions reaction pathways have been found to depend on both the nature of the reacting free radical and the structure of carotenoid. There are four generally accepted major types of reactions of free radical scavenging by carotenoids: (1) addition reactions, (2) oxidation, (3) reduction, and (4) hydrogen atom abstraction (Ribeiro et al., 2018).

- (1) Adduct formation  $R\text{-Car}^{\cdot}$  by radical addition ( $ROO^{\cdot}$ ,  $HO^{\cdot}$ , ...) to the carotenoid polyene chain. This adduct can react with another radical species and form a non-radical product ( $R\text{-Car-R}$ ) with low concentration of oxygen.
- (2) Removal of an electron from the conjugated system of the carotenoid by oxidizing radical species ( $R^{\cdot+}$ ) possessing high redox potential, leading to the formation of a carotenoids radical cation  $\text{Car}^{\cdot+}$  with a delocalized unpaired electron.
- (3) Reduction of carotenoids, resulting in the formation of a carotenoid radical anion ( $\text{Car}^{\cdot-}$ ).
- (4) Hydrogen atom abstraction from the carotenoid results in the formation of a resonance-stabilized radical  $\text{Car}^{\cdot}$ .

### Carotenoids as pro-oxidants

Although at low oxygen pressure, carotenoids act as a chain breaking antioxidants, at high oxygen pressure they are readily autoxidized and exhibit pro-oxidant activity. With higher concentrations of oxygen, the carotenoid radical ( $\text{Car}^{\cdot}$ ) may react with dioxygen

(O<sub>2</sub>) forming a carotenoid peroxy radical (Car-OO·) (auto-oxidation). These radicals act as pro-oxidants as they cause lipid (LH) peroxidation and promote oxidative damage in other biomolecules (e.g., DNA, proteins). Hydrophobic lipid (LOO·) may react with carotenoids to produce oxidation products that will be further metabolized and eliminated from the body (Ribeiro et al., 2018).

### Effects of storage and processing

Carotenoids are susceptible to oxidative degradation and isomerization resulting from storage and processing conditions (Dias et al., 2021). These reactions result in both loss of color and biological activity and formation of unpleasant volatile compounds. Degradation occurs on exposure to oxygen, light, heat, and conditions that destroy cell walls and ultrastructural integrity. Degradation is accelerated by the presence of metals, enzymes, unsaturated lipids, and prooxidants. Heating can also promote isomerization of the naturally occurring all-trans to various cis isomers, affecting bioavailability, the color saturation and can change the antioxidant activity of the compounds. Food processing (e.g., blanching, home cooking, pasteurization, and drying) affects bioavailability by macerating tissues, destroying or weakening cell ultrastructure, denaturing or weakening complexes with proteins, and cleaving ester linkages, thereby releasing carotenoids from the food matrix. Processing can also result in carotenoid degradation and, to alleviate such problems, some advanced processing methods (e.g., non-thermal and vacuum processes) have been proposed (Böhm et al., 2021; Dias et al., 2021). Processed foods are frequently fortified with carotenoids for example, annatto, an extract from the seeds of the *Bixa orella* tree containing the carotenoids bixin and norbixin, is added to butter, margarine, and processed cheese to give a yellow-orange color to these products. Similarly, tomato oleoresin is added to processed tomato products, increasing lycopene content while enhancing their attractive red color and increase nutritive value or enhance attractiveness.

### Dietary sources

Carotenoids cannot be synthesized by humans; therefore, they must be obtained from dietary sources.

Fruit and vegetables are considered the most important sources for carotenoids in the human diet. However, the contribution of some animal food must not be overlooked: egg yolk, dairy products (milk, butter, etc.) and seafood may provide a significant amount of certain carotenoids.

The richest sources are highly pigmented in red, orange, and yellow colors, depending on the type of main carotenoid contained. For example, β-carotene, α-carotene, β-cryptoxanthin, lutein, and zeaxanthin are yellow to orange, and they responsible for giving foods as carrot, kale, apricot, mango, egg yolk, butter, orange cheeses ... their colors. The carotenoid lycopene is red, and it is responsible for giving tomato, watermelon, papaya, pink grapefruit and others their colors. Xanthophylls, astaxanthin and canthaxanthin, are responsible to provide the pink color of salmon, which they obtain from eating small crustaceans and krill. By other hand, it is important to highlight that carotenoids are also present in green leafy vegetables, but they are masked by chlorophyll color. All these foods provide approximately 40 carotenoids in the human diet. Table 1 lists the contain of the most common carotenoids found in some foods from USDA database reference (USDA, 2021).

Moreover, an European Database of carotenoids levels in food has been published in 2021 (Dias et al., 2021).

Finally, it is important to take into account that the variable carotenoid content in food products is affected by diverse nature factors: for example genotype, seasons and climatic conditions of the production area (temperature, amount of sunlight, degrees of stress from extremes in climate such as drought, heat, and cold), agronomic factors (reduced irrigation, high salinity or electrical conductivity, high leaf to fruit ratio, nitrogen fertilization ...), cooking, and storage and processing conditions as mentioned above.

## Physiology

### Digestion

Digestion of food in the stomach increases accessibility of carotenoids for absorption by maceration in acid and digestive enzymes. The acidic environment of the stomach helps to disrupt cell walls and other cellular ultrastructure of raw fruits and vegetables and causes further breakdown of cooked foods to release carotenoids from food matrices in which they are contained or bound. Carotenoids in green leafy vegetables are found in chloroplasts; those in fruit are located in chromoplasts. Absorption studies comparing plasma levels of β-carotene and retinol after consuming fruit versus green leafy vegetables show that β-carotene is more efficiently absorbed from fruit, indicating that chloroplasts (or the bonds linking chloroplast proteins and carotenoids) are more resistant to disruption in the digestive tract than chromoplasts. Thus, the location of a carotenoid in the cell affects its accessibility.

Moreover, carotenoid isomerization also affect the intestinal absorption of carotenoids, being cis isomers more bioavailable. The isomerization can occur in the acidic gastric milieu. Lycopene present in fruits and vegetables occurs almost exclusively as the all-trans isomer, but is converted in the stomach to cis isomers. Although almost 100% of lycopene in red tomatoes is in the all-trans form, plasma and tissue profiles show that cis isomers make up more than 50% of the total lycopene present. However, studies show that no trans/cis isomerization of β-carotene occurs in the stomach. Evidence has been found for transfer of a significant portion of both β- and α-carotene to the fat phase of the meal in the stomach, which would increase bioavailability of these carotenoids for absorption.

**Table 1** Carotenoid content (mg per 100 g fresh weight) in foods.<sup>b</sup>

Carotenoid	Concentration (mg per 100 g fresh weight)	Food <sup>a</sup>
Lycopene	27.0–776.0	Gac aril
	1.14–3.42	Tomato ( <i>Tomatoes, red, ripe, raw, year round average</i> )
	3.04–5.59	Watermelon ( <i>Watermelon, raw</i> )
	4.7–5.5	Guava ( <i>Guavas common, raw</i> )
	0.68–3.67	Papaya ( <i>Papayas, raw</i> )
$\beta$ -carotene	0.16–3.36	Grapefruit, pink ( <i>Grapefruit raw, pink and red, all areas</i> )
	20.0–82.7	Gac aril
	1.99–21.0	Carrot ( <i>Carrot, raw</i> )
	1.38–4.71	Cantaloupe ( <i>Melons, cantaloupe, raw</i> )
	2.16–3.83	Kale ( <i>Kale, raw</i> )
	4.03–16.0	Sweet potato ( <i>Sweet potato, raw, unprepared</i> )
	3.97–8.9	Spinach ( <i>Spinach, raw</i> )
	6.95	Turnip greens ( <i>Turnip greens, raw</i> )
	0.62–1.77	Apricot ( <i>Apricots, raw</i> )
	0.18–0.57	Tomato ( <i>Tomatoes, red, ripe, raw, year round average</i> )
	1.36–8.38	Squash, butternut ( <i>Squash, winter, butternut, raw</i> )
	2.72–4.57	Swiss chard ( <i>Chard, swiss, raw</i> )
	0.19–1.68	Mango ( <i>Mangos, raw</i> )
	1.0–5.4	Collards ( <i>Collards, raw</i> )
	0.25–2.34	Grapefruit, pink ( <i>Grapefruit raw, pink and red, all areas</i> )
Lutein + zeaxanthin	4.46–8.56	Kale ( <i>Kale, raw</i> )
	0.67–10.2	Parsley ( <i>Parsley, fresh</i> )
	9.5–15.9	Spinach ( <i>Spinach, raw</i> )
	3.13–5.99	Collards ( <i>Collards, raw</i> )
	0.43–2.06	Broccoli ( <i>Broccoli, raw</i> )

<sup>a</sup>The reference name of the food identified in the USDA database is shown in brackets.<sup>b</sup>All data have been obtained from USDA database, except Gac aril Wimalasiri et al. (2017).

In the intestinal lumen (Fig. 6) where carotenoids are released from the food matrix, cleavage of carotenoproteins and fatty acid esters by carboxylic ester hydrolase (CEH), which is secreted by the pancreas, can occur. Carotenoids are then solubilized into lipid micelles (Reboul, 2019).

### Absorption

Carotenoid absorption is saturable and somewhat specific (e.g., all-*trans*- $\beta$ -carotene is preferentially absorbed to *cis*- $\beta$ -carotenes and  $\alpha$ -carotene). The presence of other carotenoids can affect the absorption of carotenoids into intestinal mucosal cells, because one carotenoid can compete for or facilitate the absorption of another. Human studies show that  $\beta$ -carotene decreases lutein absorption, whereas lutein has either no effect or a lowering effect on  $\beta$ -carotene absorption. The inhibitory effect of lutein on  $\beta$ -carotene absorption might be partly attributed to the inhibition of the  $\beta$ -carotene cleavage enzyme by lutein, shown in rats.  $\beta$ -carotene also seemed to lower absorption of canthaxanthin, whereas canthaxanthin did not inhibit  $\beta$ -carotene absorption. Studies showed that  $\beta$ -carotene increased lycopene absorption, although lycopene had no effect on  $\beta$ -carotene.  $\alpha$ -Carotene and  $\beta$ -cryptoxanthin show high serum responses to dietary intake compared to lutein. In addition, *cis* isomers of lycopene seem to be more bioavailable than the all-*trans*, and selective intestinal absorption of all-*trans*  $\beta$ -carotene occurs, as well as conversion of the 9-*cis* isomer to all-

**Fig. 6** Bioavailability of carotenoids. CEH: carboxylic ester hydrolase (secreted by the pancreas). Adapted from Chacón-Ordóñez and Esquivel (2013).

*trans*  $\beta$ -carotene. It is clear, then, that selective absorption of carotenoids takes place into the intestinal mucosal cell. These results, as well as cell culture and isotope data suggest that much of carotenoid absorption is controlled by an active transport mechanism (Fig. 5). A major receptor facilitating this absorption is scavenger receptor B1 (SRB1), which also facilitates the absorption of cholesterol and vitamin E. However, abolishing SRB1 activity does not completely abolish carotenoid absorption, which can also occur through passive diffusion. SRB1 may also have a role in the differential accumulation of carotenoids in some tissues, such as increased carotenoid uptake in the retina.

Carotenoids are more efficiently absorbed when accompanied by at least a small amount of fat. The amount of fat for optimal carotenoid absorption seems to differ among carotenoids. For example, lutein esters require more fat for optimal absorption than  $\beta$ -carotene. These differences have not been quantified for each carotenoid. In addition, the presence of a nonabsorbable, fat-soluble component decreases carotenoid absorption. Sucrose polyester, a nonabsorbable fat replacer decreased carotenoid levels in plasma by 10–60%. The extent of this inhibition depends on the amount of nonabsorbable compound ingested, as well as the particular carotenoid under consideration. The mechanism for this inhibition is apparently similar to the action of fiber, i.e., sequestration. The type of fat that is ingested along with carotenoids will also affect carotenoid absorption. As macerated food passes into the intestinal lumen, carotenoids freed from the food matrix then become incorporated into micelles, consisting of free fatty acids, monoglycerides, phospholipids, and bile acids. Many other factors can affect intestinal absorption such as micelle size, phospholipid composition, and solubilization of carotenoids into mixed micelles, and concentration of available bile salts, among others.

Another complicating factor in the intestinal mucosal cell is the partial conversion of provitamin A carotenoids ( $\beta$ - and  $\alpha$ -carotenes and cryptoxanthin) to vitamin A (primarily to retinyl esters). Therefore, in absorption studies these metabolic reactions must be accounted for in measuring intestinal transport. Non-provitamin A carotenoids such as lycopene, lutein, and zeaxanthin are incorporated intact, although some cleavage can occur (Reboul, 2019).

### Transport

In the intestinal mucosa, both carotenoids and retinyl esters are incorporated into chylomicrons and secreted into the lymph for transport to blood. In blood, lipoprotein lipase rapidly degrades chylomicrons, and the liver sequesters the resulting carotenoid-containing fragments. The liver then secretes carotenoids back into the bloodstream in association with hepatic very low-density lipoproteins (VLDL). Most carotenoids in fasting plasma are carried by low-density lipoproteins (LDL) and high-density lipoproteins (HDL). Seventy-five percent of the hydrocarbon carotenoids, e.g., lycopene and  $\beta$ -carotene, are associated with LDL, the rest is associated with HDL and, in smaller amounts, with VLDL. More polar carotenoids such as lutein and zeaxanthin are found equally distributed between HDL and LDL. After ingestion, carotenoids first appear in the bloodstream in chylomicrons, resulting from excretion from intestinal mucosal cells (4–8 h). HDL carotenoid levels peak in the circulation between 16 and 28 h; LDL carotenoid levels peak between 24 and 48 h. The bloodstream then transports carotenoids to different tissues (e.g., liver, prostate gland, fat, ocular macula) where they are sequestered by various mechanisms (Reboul, 2019).

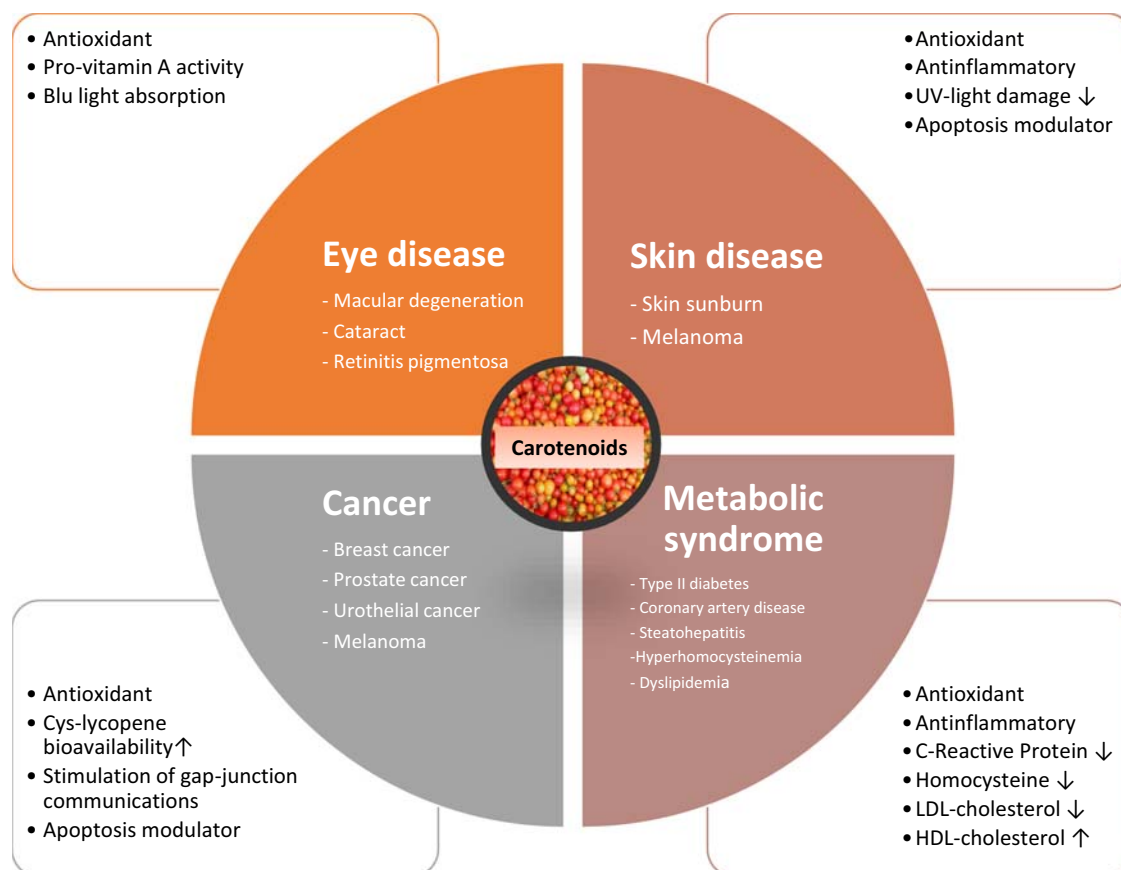

### Tissue distribution

In general, carotenoid concentrations in serum and tissues reflect concentrations contained in the food that is ingested. Carotenoids have been found in various human organs and tissues. These include human liver, lung, breast, cervix, skin, adipose, and ocular tissues. Only about 20 of them have been detected in the human body, and only 6 of these represent the 90–95% of the total carotenoids detected in human plasma:  $\alpha$ -Carotene,  $\beta$ -carotene,  $\beta$ -cryptoxanthin, lutein, zeaxanthin, and lycopene (Olmedilla et al., 2001).

The major storage organs are adipose tissue (probably because of its volume) and the liver. Tissues containing large amounts of LDL receptors seem to accumulate high levels of carotenoids, probably as a result of nonspecific uptake by lipoprotein carriers. Preferential uptake, however, is indicated in some cases. For example, unusually high concentrations of phytoene in the lung,  $\zeta$ -carotene and phytofluene in breast tissue, lycopene in the prostate and colon, lycopene,  $\beta$ -carotene, and phytofluene in cervical tissue, and lutein and zeaxanthin in ocular tissues have been found.

### Effects of carotenoids on health

Numerous studies indicate that carotenoids and their metabolites play a role in combating oxidative damage and other degradative reactions that are harmful to human health. Most of these functions seem to be related to their antioxidant nature and ability to dissipate energy from light and free radical-generating reactions. Some carotenoids ( $\alpha$ -carotene,  $\beta$ -carotene and  $\beta$ -cryptoxanthin) are also precursors of vitamin A, an essential nutrient. Much research is still required to shed light onto mechanisms involved in these functions. Other fascinating roles in nature are also being discovered, for example, the signaling of apparent good health and consequently good potential parenting in birds by the red coloration of beaks, which seems to serve as an attractant to prospective mates. All this mechanism of actions they play significant roles in promoting human health and reducing the risk of chronic diseases. Different studies have provide that all these mechanisms of action may provide desirable health benefits to reduce the risk of the development of chronic diseases such as eye and skin disease, type II diabetes, coronary artery disease, cancer, etc. (Fig. 7) (Böhm et al., 2021).

**Fig. 7** Mechanism of action of carotenoids against chronic diseases. Adapted from Cicero and Colletti (2017).

## Conclusions

Carotenoids are fat-soluble pigments that cannot be synthesized by humans, so they must be obtained from dietary sources, being present in the human diet around 40 of the 1204 natural carotenoids existing in nature. The richest sources are those highly pigmented in red, orange, and yellow colors. Fruit and vegetables are considered the most important sources for carotenoids in the human diet. However, the contribution of some animal food such as egg yolk, dairy products and seafood is also important. During storage and processing, carotenoids are susceptible to oxidative degradation and isomerization, resulting from exposure to oxygen, light, heat. This situation affects their bioavailability and antioxidant activity and must be kept in mind. Only about 20 carotenoids have been detected in the human body (liver, lung, breast, cervix, skin, adipose, and ocular tissues), and only 6 of them ( $\alpha$ -carotene,  $\beta$ -carotene,  $\beta$ -cryptoxanthin, lutein, zeaxanthin, and lycopene) are mainly detected in human plasma. Some carotenoids are precursors of vitamin A, an essential nutrient. Other carotenoids and their metabolites provide desirable health benefits to reduce the risk of the development of chronic diseases such as eye and skin disease, type II diabetes, coronary artery disease, cancer, etc., linked to their antioxidant nature and their ability to dissipate energy from light and free radical-generating reactions.

### Key points

- Carotenoids are a group of phytochemicals that are not currently considered essential nutrients
- Bioavailability of carotenoids from foods is very important, especially when consuming plant-based diets
- Carotenoids have been implicated in mitigation of various diseases such as age-related macular degeneration (AMD) and cataract, certain cancers and cardiovascular disease
- Lutein and zeaxanthin, xanthophyll carotenoids, are found in a specific location in the human retina

### Glossary

**Antioxidants** Compounds that neutralize free radicals in the body formed from normal biological processes

**Bioaccessibility** The amount of a nutrient or compound of interest that is released from food and available for absorption

**Bioavailability** How much of a compound of interest is absorbed from food and available for physiological function or storage

**Bioconversion** The amount of active compound that is formed from an absorbed precursor

**Bioefficacy** The amount of active compound that is made by the body from how much was theoretically contained in food or a supplement

**Carotenoids** A group of compounds found in fruits and vegetables, which generally consist of hydrocarbon isoprenoid groups

**Hydrocarbon carotenoids** Carotenoids that do not contain oxygen but are composed of hydrogen and carbon chains

**Xanthophylls** Oxygen-containing carotenoids

## Introduction

The colors of many fruits and vegetables are due to carotenoids (**Fig. 1**). Over 700 carotenoids have been identified in nature. Humans absorb carotenoids from the foods that we consume whereas many other animals do not circulate carotenoids. Carotenoids are considered an important class of phytochemicals, which are compounds derived from plants that may or may not have nutritional value. Many carotenoids circulate in humans and the most commonly studied include  $\beta$ -carotene,  $\alpha$ -carotene,  $\beta$ -cryptoxanthin, lycopene, lutein, and zeaxanthin. Carotenoids are nutritionally significant because about 50 of them are cleaved by the body to make vitamin A. These are known as provitamin A carotenoids and the three most abundant in fruit and vegetables are  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin (Tanumihardjo et al., 2010). Provitamin A carotenoids, especially  $\beta$ -carotene, provide less than one-half of the vitamin A supply in North America, but provide more than one-half in Africa and Asia (Haskell, 2013).

Dietary recommendations for the intake of specific carotenoids have not been established due to lack of evaluation of scientific evidence. To date, carotenoids are not considered essential nutrients (Institute of Medicine, Food and Nutrition Board, 2000). Current dietary recommendations for vitamin A are 900 retinol activity equivalents (RAE) for men and 700 RAE for women (Institute of Medicine, Food and Nutrition Board, 2001). An RAE is equivalent to 1  $\mu$ g of retinol, the active form circulating in humans and the storage form of vitamin A when esterified to fatty acids as retinyl esters. The vitamin A recommendations for infants and children are less than adults and range from 300 to 600 RAE dependent upon age (Institute of Medicine, Food and Nutrition Board, 2001). If dietary preformed vitamin A is not sufficient, consumers need to consume sufficient amounts of carotenoid-rich fruits and

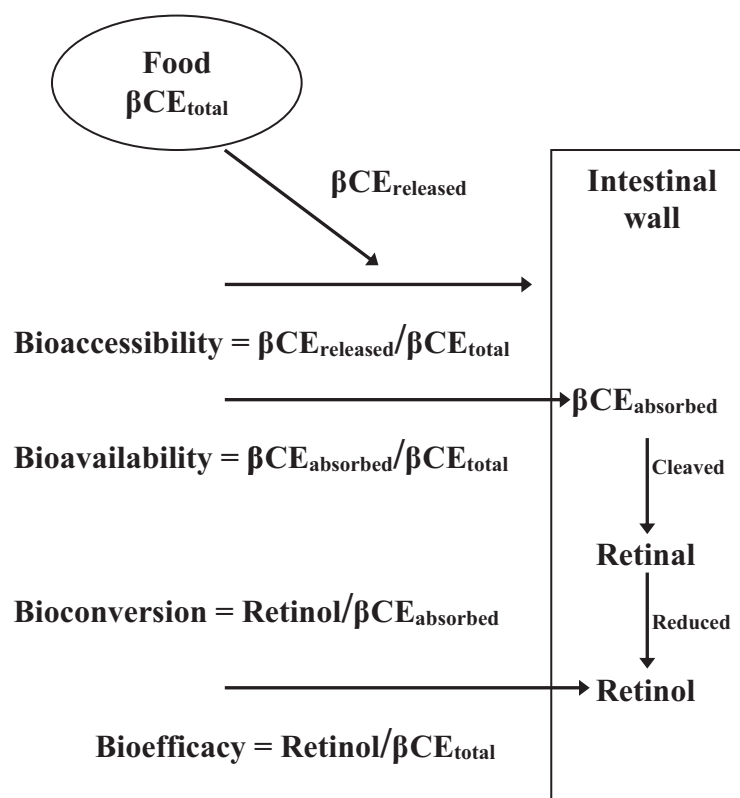

**Fig. 1** The structures of the most common carotenoids found in the human body. Three of them,  $\beta$ -carotene,  $\alpha$ -carotene and  $\beta$ -cryptoxanthin, can be used by the body for vitamin A. All carotenoids are antioxidants found in fruit and vegetables.

vegetables to meet their daily vitamin A requirement, achieve optimal dietary carotenoid intake, and lower the risk of certain chronic diseases. In 2001, the Institute of Medicine established the amount of carotenoids needed to provide vitamin A from foods as 12  $\mu\text{g}$   $\beta$ -carotene or 24  $\mu\text{g}$  other provitamin A carotenoids to yield 1 RAE ([Institute of Medicine, Food and Nutrition Board, 2001](#)). Currently, high-dose pharmacological supplementation with carotenoids is not advised. Despite this, a tolerable upper intake level, the maximum daily amount of a nutrient that appears to be safe, has not been established for any individual carotenoid; although, supplemental  $\beta$ -carotene at 20 mg/day or more is likely contraindicated for use in current, heavy smokers based on the studies described below.

Many factors affect the release and absorption of carotenoids from foods ([Fig. 2](#) from [Tanumihardjo et al., 2010](#)). When most sources of dietary vitamin A are from provitamin A carotenoids, bioavailability from the food matrix becomes important. Bioavailability of preformed vitamin A, i.e., retinol and retinyl esters, is not a major concern because 80–95% is absorbed when adequate fat is consumed at the same time. Foods that are high in preformed retinol (e.g., liver, eggs, and fortified milk), however, are not consumed by everybody due in part to the cost of animal-source foods and availability ([Haskell, 2013](#)). When discussing carotenoids from fruit and vegetables, there are four terms that need to be defined: bioaccessibility, bioavailability, bioconversion, and bioefficacy ([Tanumihardjo et al., 2010](#)) (see [Table 1](#)).

- Bioaccessibility refers to how much carotenoid is released from the food and available for absorption.
- Bioavailability is how much carotenoid is absorbed from that released from the food and available for physiological function.

**Fig. 2** A schematic outlining the path of provitamin A carotenoids as  $\beta$ -carotene equivalents ( $\beta\text{CE}$ ) as they move out from the food into the intestinal wall. The definition of terms associated with understanding provitamin A release, absorption and conversion to retinol are illustrated: bioaccessibility, bioavailability, bioconversion, and bioefficacy.  $\beta\text{CE}$  refers to  $\beta$ -carotene equivalents and is usually equal to  $\beta$ -carotene plus  $\frac{1}{2}$   $\alpha$ -carotene and  $\frac{1}{2}$   $\beta$ -cryptoxanthin. Reproduced with permission from the [Tanumihardjo et al. \(2010\)](#).

**Table 1** Terms which are associated with the provitamin A carotenoid value of foods based on  $\beta$ -carotene and subsequent utilization as retinol.

Term	Definition	100%
Bioaccessibility	$\beta$ -Carotene released	1 $\mu\text{mol}$ released
	$\beta$ -Carotene in food	1 $\mu\text{mol}$ in food
Bioavailability	$\beta$ -Carotene absorbed	1 $\mu\text{mol}$ absorbed
	$\beta$ -Carotene in food	1 $\mu\text{mol}$ in food
Bioconversion	Retinol formed	2 $\mu\text{mol}$ formed
	$\beta$ -Carotene absorbed	1 $\mu\text{mol}$ absorbed
Bioefficacy	Retinol formed	2 $\mu\text{mol}$ formed
	$\beta$ -Carotene in food	1 $\mu\text{mol}$ in food

- Bioconversion relates to the provitamin A carotenoids and is defined as the amount of retinol that is formed from absorbed provitamin A carotenoids.
- Bioefficacy encompasses all of the biological processing of provitamin A carotenoids and is the amount of retinol formed from the amount of carotenoid contained in the food or supplement.

The study of provitamin A carotenoid bioefficacy from foods is important in international health because the most frequently consumed sources of vitamin A are fruit and vegetables. A 100% bioefficacy means that 1  $\mu\text{mol}$  of dietary  $\beta$ -carotene provides 2  $\mu\text{mol}$  of retinol in the body; however, 100% bioefficacy does not actually occur in the process of digestion and provitamin A carotenoid uptake by the body. Determining bioefficacy is an important research endeavor due to the introduction of provitamin

A-enhanced staple crops into countries at risk for vitamin A deficiency (Tanumihardjo et al., 2010). Staple crops targeted for provitamin A-enhancement, a process known as biofortification, include sweet potato, maize, cassava, and rice.

Once in the body, carotenoids can act as potent antioxidants, which are substances that neutralize free radicals formed from the natural metabolic processes of cells. Free radicals damage tissues and cells through oxidative processes. While free radical formation is a natural process in the body, environmental factors such as smoking and pollution can increase free radical load and thus increase disease risk. Carotenoids may counter these influences by functioning as antioxidants and quenching oxygen-containing free radicals (Landrum, 2013). At the whole-body level, some population studies have indicated that certain carotenoids from either dietary intake or blood concentration data are associated with better immune response, lower rates of age-related macular degeneration (AMD) and cataract, as well as lower risk for certain cancers, cardiovascular disease, and osteoporosis. These diseases and degenerative processes are linked to reactive oxygen species cascades (Landrum, 2013). The associations between specific carotenoids and decreased risk of various diseases are summarized in Table 2. Some of these purported health effects may be due to their function as antioxidants.

Blood levels of specific carotenoids are often used as biomarkers for fruit and vegetable intake to strengthen dietary intake data or show compliance to an intervention (Howe et al., 2009). A wide variation in analytical methods exists and standardization between laboratories does not routinely occur. Nonetheless, higher blood concentrations have been favorably correlated with certain disease states. In a review, total carotenoid,  $\alpha$ -carotene,  $\beta$ -carotene, lycopene, and lutein concentrations were significantly inversely associated in women with breast cancer compared with controls who had not developed breast cancer in multiple studies (Kim et al., 2021). Vitamin A concentrations in contrast were usually not influenced by breast cancer risk. Nonetheless, vitamin A concentrations are homeostatically controlled and affected by inflammation, which are known confounders in their interpretation. Carotenoids may be protective against or utilized during breast cancer. Furthermore, the Nurses' Health Study, which included a cohort of over 83,000 women, also showed a significant inverse association between dietary  $\beta$ -carotene intake and breast cancer risk (Zhang et al., 1999). This was especially strong for premenopausal women with a family history of breast cancer or high alcohol consumption. Other prospective studies, however, have had mixed results (Kim et al., 2021).

### Hydrocarbon carotenoid: $\beta$ -Carotene

$\beta$ -Carotene is one of the most widely studied carotenoids, both for its vitamin A activity and its abundance in fruits and vegetables. Epidemiological studies have often pointed to the abundance of dietary carotenoids as being protective against many diseases. Diets rich in fruits and vegetables are recommended to reduce the risk of disease and promote optimal health. Current dietary guidelines for a 2000-calorie intake level recommend 4.5 cups of fruit and vegetables each day (U.S. Department of Agriculture and U.S. Department of Health and Human Services, 2020).

When removed from the plant matrix and administered as supplements, however, these benefits sometimes disappear. For example, lung cancer is a leading cause of death in many countries and the  $\beta$ -Carotene and Retinol Efficacy Trial (CARET) in the 1990s set out to test whether  $\beta$ -carotene conferred cancer protection. CARET was an intervention study based on a number of observations that showed high levels of  $\beta$ -carotene from food sources were protective against lung cancer; however, the trial demonstrated an increased risk for lung cancer in the treatment group over the control (Christen et al., 2000). A similar outcome was observed in the  $\alpha$ -Tocopherol  $\beta$ -Carotene (ATBC) Study Group (1994). Although evidence clearly exists showing an association between  $\beta$ -carotene and enhanced lung function, as in the CARET study, the ATBC trial also found an increase in lung cancer rates among smokers. It is plausible that the lung cancer had already been initiated in the smokers and supplementation with  $\beta$ -carotene could not prevent development. Subsequent studies in ferrets showed that the amounts of  $\beta$ -carotene commonly consumed from fruit and vegetables were protective against lung damage but higher amounts, equivalent to those in CARET, increased the formation of abnormal tissue in the lung (Liu et al., 2003). The ATBC study also showed an increased incidence of angina pectoris, a mild warning sign of heart disease characterized by chest pain, among heavy smokers (Rapola et al., 1996).

In both the CARET and ATBC interventions, much higher doses of  $\beta$ -carotene were used than could be obtained from the typical diet, and the blood levels attained were two to six times higher than the 95th percentile of  $\beta$ -carotene in a survey of a representative sample of the United States population. Thus, it remains unclear whether  $\beta$ -carotene is a pro-carcinogen or an anti-carcinogen. The

**Table 2** A summary of epidemiologic and/or clinical studies where carotenoids and a significant association to a specific disease risk has been shown in at least one study.<sup>a</sup>

Carotenoid	Cardiovascular disease	Cataract	Macular degeneration	Lung cancer	Prostate cancer	Bone health
$\beta$ -Carotene	Yes	–	–	Yes <sup>b</sup>	–	–
$\alpha$ -Carotene	Yes	–	–	Yes	Yes	–
$\beta$ -Cryptoxanthin	Yes	–	–	Yes	–	Yes
Lycopene	Yes	–	–	Yes	Yes	Yes
Lutein/zeaxanthin	Yes	Yes	Yes	Yes	–	–

<sup>a</sup>For a more complete discussion of the association of specific carotenoids to cardiovascular disease please refer to Ciccone et al. (2013); and for cancer please refer to Rowles and Erdman (2020).

<sup>b</sup>The opposite finding has been observed in clinical trials with smokers.

associations for lower disease risk observed in epidemiologic studies may reflect other protective dietary agents or an interaction between dietary components. Furthermore, people with higher intake of fruits and vegetables may have healthier lifestyles that contribute to their lower risk of chronic diseases. The higher disease risk observed in clinical trials may be correlated to high dose  $\beta$ -carotene with yet unidentified mechanisms, the limited treatment duration, and/or the timing of the interventions in regard to cancer development due to a history of heavy smoking. More research on  $\beta$ -carotene's biological actions is needed to explore mechanisms. Current consensus is that the beneficial effects of  $\beta$ -carotene are associated with dietary consumption, whereas the harmful effects in some subpopulations are with supplements at pharmacological levels.

Another explanation for a lack of beneficial outcome with  $\beta$ -carotene supplementation may be that not all people respond to  $\beta$ -carotene treatment. A number of polymorphisms in the  $\beta$ -carotene cleavage enzymes have been identified (Ross and Moran, 2020). Furthermore, individuals who do not respond to  $\beta$ -carotene supplementation may be better at converting it to vitamin A, which could be driven by vitamin A status. Blood response to  $\beta$ -carotene supplementation may also be inversely related to body mass index (BMI) due to increased sequestration of lipophilic  $\beta$ -carotene by fat stores present in people with larger BMI. However, some individuals with larger BMI's do not necessarily have a high body fat percentage, but rather increased lean muscle mass.

Excellent food sources of  $\beta$ -carotene include carrots, winter squash, red-orange sweetpotato, and various types of dark green leafy vegetables. No deficiency or toxicity has been observed from dietary  $\beta$ -carotene intake, although high intakes can be associated with yellow pigmentation of the skin because carotenoids are stored in adipose tissue, a condition known as hypercarotenoderma (Tanumihardjo et al., 2015). Supplements containing  $\beta$ -carotene are common. In a large observational/intervention study in postmenopausal women, the Women's Health Initiative, approximately 50% reported using a supplement containing  $\beta$ -carotene. The Women's Health Initiative included both a clinical trial and observational study with more than 160,000 women and outcomes have been reviewed (Cauley and Crandall, 2020). The Physicians' Health Study II also included  $\beta$ -carotene as an intervention to determine the balance of risks and benefits of this carotenoid with cancer, cardiovascular disease, and eye disease (Christen et al., 2000).

#### Hydrocarbon carotenoid: $\alpha$ -Carotene

$\alpha$ -Carotene, another carotenoid frequently quantified in food, has provitamin A activity. Based on its structure, it is converted to one molecule of biologically active retinol after central cleavage and twice the molar amount is equivalent to the retinol from  $\beta$ -carotene (Tanumihardjo and Howe, 2005). Like other carotenoids, it has antioxidant and possibly anti-carcinogenic properties, and may enhance immune function as well. Some, but not all, epidemiological studies observed that higher  $\alpha$ -carotene intake was associated with lower risk of cardiovascular disease and cancer, whereas others did not (Rowles and Erdman, 2020). High dietary intake of  $\alpha$ -carotene was associated with decreased prostate cancer risk (Rowles and Erdman, 2020). Clinical trials to test isolated  $\alpha$ -carotene's influences in humans have not been conducted to date. This is probably because  $\alpha$ -carotene is usually associated with ample amounts of  $\beta$ -carotene when found in fruits and vegetables and singling out dietary  $\alpha$ -carotene is difficult.

$\alpha$ -Carotene is especially high in orange carrots and some pumpkins; high serum concentrations are associated with carrot and pumpkin intake. Serum  $\alpha$ -carotene concentrations were elevated in children who developed hypercarotenoderma during mango season (Tanumihardjo et al., 2015).  $\alpha$ -Carotene is found in some combined carotenoid supplements.

#### Xanthophyll: $\beta$ -Cryptoxanthin

$\beta$ -Cryptoxanthin has provitamin A activity and may be more bioefficacious than  $\alpha$ -carotene even though theoretically both carotenoids supply one vitamin A molecule based on structure (Tanumihardjo and Howe, 2005). This is likely due to the bipolar nature of  $\beta$ -cryptoxanthin. Several epidemiological studies suggest that dietary  $\beta$ -cryptoxanthin is associated with lower rates of lung cancer and improved lung function in humans (Burri et al., 2016). A pooled analysis of dietary carotenoid intake and cancer risk, which included seven cohort studies, identified  $\beta$ -cryptoxanthin intake as protective against lung cancer even after evaluating smoking status (Mannisto et al., 2004). The beneficial effects for  $\beta$ -cryptoxanthin suggested by these results, however, could be merely an indicator for other antioxidants and/or a measure of a healthy lifestyle that are more common in people with high dietary intakes of  $\beta$ -cryptoxanthin. However,  $\beta$ -carotene was not associated with lung cancer risk in the same analysis (Mannisto et al., 2004).

In tissue culture,  $\beta$ -cryptoxanthin has a direct stimulatory effect on bone formation and an inhibitory effect on bone resorption (Yamaguchi, 2012). In postmenopausal women from Italy and the United States,  $\beta$ -cryptoxanthin was lower in women with osteoporosis than those without (Tanumihardjo and Binkley, 2013), perhaps due to increased utilization. On the other hand serum retinol concentrations were lower (Tanumihardjo and Binkley, 2013). Further investigations are needed to elucidate the action of  $\beta$ -cryptoxanthin in bone health.

No deficiency or toxicity has been observed from dietary  $\beta$ -cryptoxanthin intake. The best food sources for  $\beta$ -cryptoxanthin are oranges, papaya, peaches, tangerines, and yellow and orange maize. Tropical fruit intake is directly proportional to  $\beta$ -cryptoxanthin blood concentrations.

#### Hydrocarbon carotenoid: lycopene

Lycopene, while having no provitamin A activity, is a potent antioxidant with twice the activity of  $\beta$ -carotene for quenching singlet oxygen and 10 times the antioxidant activity of  $\alpha$ -tocopherol in some model systems. The antioxidant potential of food chemicals

varies widely according to location in the body and the presence of other body chemicals. Epidemiological evidence shows an inverse association between lycopene consumption and the incidence and development of certain cancers (Rowles and Erdman, 2020). This association is especially strong for prostate cancer, which is the most common cancer among men in western countries and the second leading cause of cancer death in American men. Prostate cancer rates in Asian countries are lower, but appear to be increasing rapidly due to change in lifestyle. The current consensus is that high consumption of tomatoes or high circulating concentrations of lycopene are associated with risk reduction for prostate cancer (Rowles et al., 2017). Animal and cell culture studies were reviewed to determine mechanisms of action (Applegate et al., 2019). Some studies have suggested that tomato products are more protective against prostate cancer than isolated lycopene. Epidemiologic studies have also observed lower rates of bladder, cervical, and breast cancers as well as cancers of the gastrointestinal tract among people with high intake of lycopene (Rowles and Erdman, 2020). The discovery of significant concentrations of lycopene in specific tissues in the body, in addition to prostate, suggests that lycopene may play a role in these tissues, i.e., plasma, testes, adrenal glands, liver, and kidney.

Lycopene, as an antioxidant, may be protective against heart disease by slowing down the oxidation of polyunsaturated fats in the low-density lipoprotein particles in the blood. Epidemiological and clinical studies show that higher blood lycopene concentrations are associated with lower risk and incidence of cardiovascular disease (Ciccone et al., 2013). The evidence for protective cardiovascular effects is compelling, because studies have shown an improvement in cardiovascular parameters with higher blood concentrations of lycopene but it is usually linked to increased intake of fruit and vegetables (Ciccone et al., 2013).

In addition to links with cancer and cardiovascular effects, lycopene intake was associated with lower risk for hip and nonvertebral fractures in the Framingham study (Sahni et al., 2009). Serum concentrations of lycopene were also noted to be lower in mid-western postmenopausal women with osteoporosis perhaps indicating higher utilization because dietary intake did not differ (Tanumihardjo and Binkley, 2013). Finally, higher intake of fruits and vegetables is associated with better lung function, and specifically, high tomato intake is associated with higher timed expiratory volume.

While the body of evidence seems strong, several studies have found either no or weak associations between lycopene consumption and disease. Some of this may be explained by the fact that blood lycopene concentrations were much lower in these studies than in those that showed a beneficial effect. Dietary-based studies should include blood sampling to further define the range of blood lycopene concentrations in the population and ideally with method standardization so that studies can be directly compared. The prostate cancer association is usually stronger for cooked tomato products rather than raw tomatoes or total lycopene intake (Rowles and Erdman, 2020). This supports the idea that whole foods with a broad array of nutrients and non-nutritive bioactive components are important for overall health rather than isolated compounds. The beneficial effects of tomatoes may be increased by processed, concentrated products that enhance the nutrient bioavailability.

The major food source of lycopene globally is tomatoes and tomato products. In the United States, more than 80% of dietary lycopene comes from tomatoes. Other sources include watermelon, pink grapefruit, and red carrots. Red carrots are especially prevalent in India and China.

### Xanthophylls: lutein and zeaxanthin

Lutein and zeaxanthin, structural isomers, are non-provitamin A carotenoids that are measurable in human blood and tissues. Lutein and zeaxanthin are the xanthophylls that constitute the macular pigment of the human and non-human primate retina (Mares, 2016) and they may be important in cognitive function (Johnson, 2014). Biological functions include light absorption, oxidative stress protection, and inflammation mitigation. The relative concentration of lutein to zeaxanthin in the macula is distinctive. Zeaxanthin is more centralized and lutein predominates toward the outer area of the macula (Mares, 2016). A putative xanthophyll binding protein has been described that may explain the high variability of people to accumulate these carotenoids in eye tissues. Increased lutein intake from both food sources and supplements is positively correlated with increased macular pigment density, which is theorized to lower risk for macular degeneration. AMD is the leading cause of irreversible blindness in the elderly in developed countries. AMD adversely affects the central field of vision and the ability to see fine detail. Some, but not all, population studies suggest lower rates of AMD among people with higher levels of lutein and zeaxanthin in the diet or blood (Mares, 2016). Possible mechanisms of action for these carotenoids include antioxidant protection of the retinal tissue and the macular pigment filtering of damaging blue light.

Free radical damage is also linked to the development of cataracts, which causes opaqueness in the lens of the eyes. Cataract remains the leading cause of visual disability in the United States and about one-half of the 30–50 million cases of blindness throughout the world. Cataract is treatable, but blindness occurs because individuals have either chosen not to correct the disease or do not have access to the appropriate medical treatment. Several epidemiological studies have shown inverse associations between the risk of cataracts and carotenoid intake (Mares, 2016). Lutein and zeaxanthin are found in the lens and are thought to protect cells in the eye against oxidative damage, which may prevent cataract.

Human data on the consumption of lutein and zeaxanthin is important to understand disease prevention. Lutein may protect against some forms of cancer and enhance immune function, but the evidence is mixed (Rowles and Erdman, 2020). Lutein may work in concert with other carotenoids such as  $\beta$ -carotene to lower cancer risk due to anti-mutagenic and anti-tumor properties.

Major dietary sources of lutein and zeaxanthin include corn, green leafy vegetables, and eggs. Lutein tends to be the predominant isomer in foods although some varieties of maize contain significant amounts of zeaxanthin. One complicating factor that requires better understanding is the bioavailability of lutein from food sources and supplements. The food matrix is an important factor influencing lutein bioavailability and the amount and type of food processing generally influences the bioavailability of all

carotenoids. For example, the processing of spinach does not affect bioavailability of lutein, but it does enhance that of  $\beta$ -carotene. Bioavailability studies have been conducted with lutein supplements and/or foods containing lutein (Mares, 2016). In humans, lutein from vegetables seems to be more bioavailable than that of  $\beta$ -carotene; however, this may be partially explained by bioconversion of  $\beta$ -carotene to vitamin A. Competition between carotenoids, such as lutein and  $\beta$ -carotene, for incorporation into chylomicra has been noted in humans consuming vegetables and supplements. The amount of fat consumed with the lutein source also affects bioavailability, as higher fat increases the bioavailability of lipid-soluble carotenoids. Lutein from egg yolk and oil-based supplements is very bioavailable due to the fat matrix. Due to potential health benefits, lutein and zeaxanthin supplements are sold commercially and incorporated into some multivitamins. Levels of these xanthophylls in single supplements vary widely, and neither benefit nor safety have been adequately studied (Mares, 2016). Lutein supplements are often derived from marigold flowers.

### Further steps in carotenoids and health research

Fruit and vegetable consumption, good sources of many antioxidants including carotenoids, is a preventative measure for many diseases. Most of the epidemiological evidence suggests that carotenoids are a very important class of phytochemicals. While some of the effects may be attributable to a diet high in fruits and vegetables, and an overall healthy lifestyle, the presence of specific carotenoids localized in different areas of the human body lend evidence to their overall importance in optimal human health. Non-invasive methods have been developed to assess carotenoid levels in the skin and eye. Large-scale studies that determine carotenoid levels in blood, skin, and the eye may lead to a better understanding of their importance in human health and disease prevention. Additional epidemiologic studies to further strengthen the associations that have been observed in populations are needed.

Study design and statistical analyses vary across published work and no one study can give conclusive evidence. An integrated multidisciplinary approach to study the functions and actions of carotenoids in the body is necessary to fully understand the role of carotenoids in health and disease prevention. This includes comparisons of carotenoids in whole fruits and vegetables and their effect on human health and well-being. High fruit and vegetable intake is associated with a decreased risk of cancer, cardiovascular disease, diabetes, AMD and osteoporosis. Removing any one class of phytochemicals from the intricate matrix of the whole plant may not give the same beneficial outcome in terms of human health. Considering that the average intake of fruit and vegetables is still less than recommendations, programs that promote their consumption may be more effective at preventing disease in the long-term than using individual pharmacological carotenoid supplements.

A question that remains is whether or not carotenoids can be considered nutrients. A variety of phytochemicals contained in fruits and vegetables, including carotenoids, are assumed to be needed for optimal health and reduction of chronic disease risk, but have not been classified as nutrients. Daily Reference Intakes are still not available for any carotenoid (Ross and Moran, 2020). Factors have been defined that categorize substances as nutrients: (1) they must be obtained from the diet because the body cannot synthesize the bioactive form, and be used for growth, maintenance, or tissue repair; (2) studies must be done to determine the essentiality of the substance and its specific function in the body and these are typically randomized, controlled interventions in humans (Courtney Gaine et al., 2013); (3) the concentration in specific tissues needs to be defined, and consumption and/or supplementation must result in tissue concentration increases and improved tissue function, such as has been done for lutein and zeaxanthin (Mares, 2016); and (4) accurate intake assessment needs to be defined with biomarkers identified to assess status (Courtney Gaine et al., 2013).

A large body of observational studies suggests that high blood concentrations of carotenoids obtained from food are associated with chronic disease risk reduction. However, there is little evidence of their specific role in the body. Lutein and zeaxanthin are the only carotenoids found in a specific tissue, the macular region of the retina, which seem to have specific functions. Providing lutein in the diet increases macular pigment in humans. Animal studies show that a diet low in lutein can deplete macular pigment, but the influence on the health of the eye is not yet well-understood. To further our understanding, large randomized prospective intervention trials need to be conducted to explore the essentiality of lutein supplementation for reducing ocular disease risk in humans. Although the evidence is mounting for lutein, to date, no specific carotenoid has been classified as an essential nutrient.

### Key points

- Understand the basis for establishing nutrient reference values for choline and its classification as an essential nutrient.
- Identify the key metabolic fates of choline and the physiological functions of these metabolites.
- Appreciate global differences in nutrient reference values for choline and relevant food sources of choline.
- Comprehend challenges in understanding choline's relationship to health outside of choline restriction, including its biochemical heterogeneity in the diet, heterogeneity in the endogenous capacity to synthesize choline, and reliance on self-reported dietary intakes in prospective cohorts.
- Distinguish different aspects of nutritional genomics and choline, including genetic factors that influence choline requirements and choline's ability to influence gene expression.

### Introduction

Choline (IUPAC name 2-hydroxyethyl(trimethyl)azanium hydroxide) is a water-soluble, quaternary saturated amine found in foods of animal and plant origin (Fig. 1). Choline can be found in the diet as a composite of 6 metabolites that contain a choline moiety and contribute to total dietary choline intakes: free choline, phosphocholine (phoCho), glycerophosphocholine (GPC), phosphatidylcholine (PC) and sphingomyelin (SM). Choline natively found in foods, as well as added in the form of various lecithin emulsifiers (commonly derived from egg and soy), is predominantly PC; one exception to this

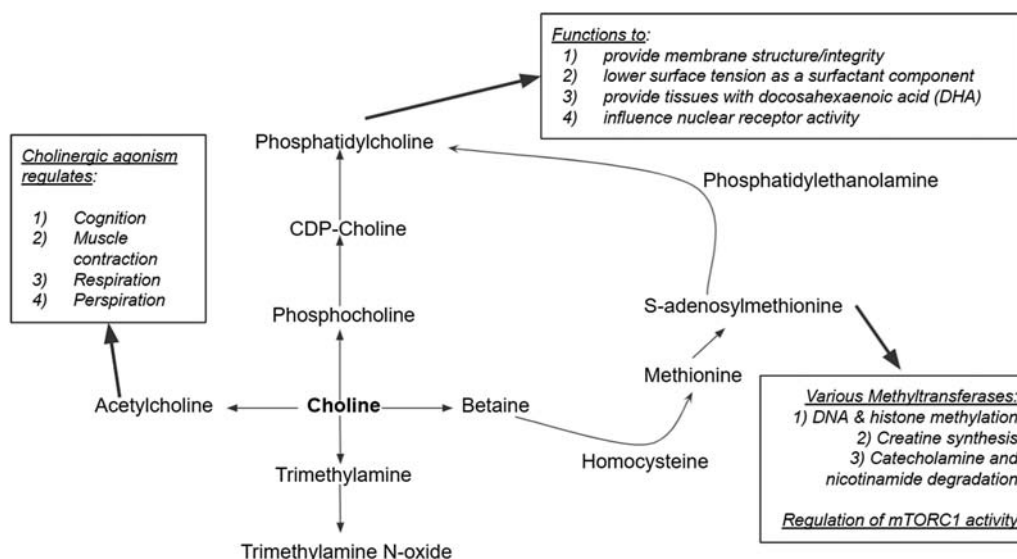

**Fig. 1** Secondary chemical structure of choline molecule.

observation is during infancy, whereby breastmilk and some infant formulas provide substantial amounts of water-soluble choline-containing compounds (Holmes-McNary et al., 1996; Davenport et al., 2015; Shunova et al., 2020). Dietary supplements containing choline are typically in the form of PC, as water-soluble choline salts (e.g., choline-chloride, bitartrate), or as CDP-choline (citicoline).

The requirement for a source of choline in the diet was established for numerous animal species throughout the 20th century, with the earliest evidence indicating the nutritional importance of choline in preventing fat accumulation in the liver (Best and Huntsman, 1935). The buildup of triacylglycerols in the liver is a common phenotype across animal species when subjected to choline deficient diets (National Research Council (US) Subcommittee on Laboratory Animal Nutrition, 1995), including humans (Institute of Medicine, National Academy of Sciences (1998)), and is linked to the requirement for choline to produce PC and facilitate hepatic lipoprotein export. A series of dietary depletion-repletion studies in men and women across the reproductive lifecycle (i.e., pre- and post-menopausal) have demonstrated that choline restriction (<50 mg/day), in most participants, manifests in elevated circulating markers of liver (alanine amino transferase, ALT; aspartate aminotransferase, AST) and muscle (creatine phosphokinase, CPK) dysfunction/damage, an effect that is reversible by choline repletion (Zeisel et al., 1991; Niculescu et al., 2006; Fischer et al., 2007, 2010a,b). The requirement for dietary choline is inherently influenced by the hepatic capacity to synthesize a choline moiety de novo in the form of phosphatidylcholine, generated by the triple methylation of phosphatidylethanolamine catalyzed by the enzyme, phosphatidylcholine N-methyltransferase (PEMT) (Vance, 2013). The PEMT pathway relies on methyl donors, contributed by choline itself, or other dietary compounds, including betaine, methionine, and folates/vitamin B12. PEMT activity, discussed further below, is also regulated by estrogen availability (Resseguie et al., 2007), with men and postmenopausal women who are not utilizing estrogen replacement therapy being most sensitive to increased markers of organ dysfunction when placed on choline deficient diets. Thus, factors influencing PEMT activity, as well as the availability of other dietary one carbon metabolism nutrients, influence the de novo capacity to synthesize choline and subsequent dietary choline needs.

The requirement for choline relates to its incorporation into 3 primary metabolite pools (Fig. 2): (1) **phosphatidylcholines** (Kennedy, 1954; Bremer and Greenberg, 1960), that play a critical role in membrane structure and integrity, provide a source of the potent secondary messenger, diacylglycerol, facilitate lipoprotein assembly and export, serve as critical pools of polyunsaturated fatty acids and have recently been described as nuclear receptor ligands; (2) **acetylcholine** (Dale, 1914; Cohen and Wurtman, 1976), a neurotransmitter capable of binding nicotinic and muscarinic receptors in both the neuronal and non-neuronal cholinergic system, linking choline supply to cholinergic regulation of learning, memory, mood, skeletal and cardiac muscle function, and respiration; (3) **betaine** (Mann and Quastel, 1937), a major methyl donor capable of regenerating methionine from homocysteine and contributing to the universal methyl donor pool of S-adenosyl methionine (SAM); betaine is also an important osmolyte in the kidney and is notably present in the diet in high (mg) quantities. In addition to these classical metabolite pools, it has long been known that choline also contributes to trimethylamine (TMA), and the trimethylamine N-oxide (TMAO) (Simenhoff et al., 1976), which has received considerable attention for its relationship to a wide variety of chronic diseases and speculation about choline's influence on circulating TMAO concentrations and disease (discussed further below). It is evident that choline's entry into such diverse metabolites and their associated metabolic pathways provide underlying biological plausibility through which choline intakes may exert its influence on health and disease across the lifestyle.

**Fig. 2** Simplified schematic of choline metabolism and functions of its metabolites.

## Physiology and metabolism

### Intestinal absorption and handling

Few if any gastric factors have been found that influence choline absorption and choline appears relatively stable in the stomach. Upon entry into the small intestine, lipid and water-soluble choline are subjected to differential metabolism dependent upon their chemical structure. PCs must be hydrolyzed by the actions of phospholipase A2 to a free fatty acid and lysophosphatidylcholine (LPC) prior to uptake by the enterocyte (Fox et al., 1979) or further metabolized to glycerophosphocholine and an additional free fatty acid. LPC can be recylated in the enterocyte to regenerate PC and/or incorporated into chylomicrons (Hui, 2016), or further hydrolyzed and degraded into a free fatty acid, glycerophosphate and free choline, with the latter capable of entering the portal vein as a source of choline for use by the liver or other peripheral tissues.

Water-soluble forms of choline are absorbed and/or degraded to free choline in the intestinal environment and taken up by the enterocyte. As a cation, choline cannot readily cross the cell membrane lipid bilayer via passive diffusion and requires specific transporters at the plasma membrane. In the intestine, evidence indicates that choline is efficiently absorbed in the jejunum and ileum via a substrate-specific and sodium-independent carrier-mediated transport system (Saitoh et al., 1992; Kamath et al., 2003); this transporter is likely a member of the 5-member, plasma and mitochondrial membrane-associated SLC44 family, of which SLC44A2 and A4 have been detected in the small intestine (Traiffort et al., 2013), while SLC44A1 appears localized to the large intestine (Wang et al., 2020).

Few investigations employing isotopic techniques have been undertaken to determine the relative bioavailability of different choline forms in animals or humans. Studies in rodents utilizing radioactive CDP-choline demonstrate near 100% bioavailability after being hydrolyzed to free choline in the intestine (Galletti et al., 1985). Studies employing chick growth assays comparing choline chloride relative to PC natively in soybean, corn, or peanut meal suggest significant effects of the plant food matrix on relative PC bioavailability, with soy and peanut exhibiting >70% bioavailability and canola exhibiting lower estimates (<35%), despite canola meal containing significantly higher total choline (Emmert and Baker, 1997). Heat treatment did not significantly influence growth and inclusion of meals alongside choline chloride treatment did not influence growth promotion. Unknown factors in the food matrix or potentially food particle microstructure might influence PC bioavailability.

The availability of choline is also limited by microbial leaching in the oral cavity and throughout the gastrointestinal tract (Chao and Zeisel, 1990). A bacterial gene cluster (choline-utilization cluster or *Cut*) encoding a glycy radical enzyme with choline trimethylamine-lyase activity (*CutC*) and a glycy radical-activating protein (*CutD*) are essential for microbiota metabolism of choline to TMA (Craciun and Balskus, 2012), and ultimately, leaching of luminal choline from the host. Colonization of gnotobiotic mice with the TMA-producing species *C. sporogenes* resulted in significant depletions of fecal choline, reductions in serum choline, elevated cecal TMA and increased serum TMAO, indicative of significant utilization of luminal choline (a composite of diet-derived choline compounds and biliary PC) (Romano et al., 2015). The relative loss of a choline dose to microbial metabolism likely depends on its form, as water-soluble choline compounds result in greater TMA formation than PC (Zeisel et al., 1983), consistent with PC digestion resulting in limited free choline availability to the microbiota. The high bioavailability of water-soluble choline compounds in the small intestine, coupled to their strong TMAO increasing capacity, has led to preliminary investigation indicating that the small intestinal microbiota, as well as the large intestinal microbiota, contributes to TMAO (Stremmel et al., 2017). This poses a challenge for identifying how gut microbial composition influences TMAO formation and quantifying its contribution to net choline losses, given that the small bowel microbiome is markedly different from that in stool (Leite et al., 2020), the primary sample matrix available for microbiome assessment in human population studies.

### Transport and metabolism

Following absorption and intracellular metabolism, free choline enters the portal vein and undergoes primary hepatic metabolism. Alternatively, lipid-soluble choline containing moieties (PC, LPC) facilitate chylomicron formation and export into the lymphatic system. Ultimately, free choline enters the aqueous phase of plasma, whereas phosphorylated choline compounds are found as components of lipoproteins. Investigations into the tissue-level metabolic fate of different forms of dietary choline in postnatal rat pups employing radioactively labeled ( $^{14}\text{C}$ ) choline chloride, phosphocholine, glycerophosphocholine and PC have reveal significantly different distribution and kinetic profiles (Cheng et al., 1996). The 3 water-soluble choline metabolites appears rapidly and reaches peak levels between 1 and 5 h in the blood and liver whereas PC takes 5–8 h to appear in blood and remains elevated in blood for at least 24 h.

Tissues uptake phosphorylated choline forms via lipoprotein mediated mechanisms; additionally, LPC can transport bound to albumin, for which a transporter of the major facilitator superfamily, Mfsd2a, has recently been characterized as a sodium-dependent transporter (Nguyen et al., 2014), with high expression levels in tissues with barrier functions (e.g., blood-brain barrier, placenta, mammary gland). Tissue uptake of free choline is facilitated by several transporters (Lockman and Allen, 2002), with a major role for the aforementioned, SLC44 family, of which SLC44A1 has received been most well-characterized. Cholinergic neurons additionally express a high affinity, sodium-dependent choline transporter, CHT1 (encoded by *SLC5A7*) at the presynaptic nerve terminal; the activity of this transport is typically the rate-limiting step for acetylcholine synthesis. A third, low-affinity, sodium-independent transport system is nearly ubiquitously expressed across tissues, facilitated by organic ion transporters (encoded by *SLC22*), and contributes to choline supply for phospholipid synthesis (Michel et al., 2006).

Following uptake, all nucleated cells possess the capacity to produce PC from choline via the CDP-choline pathway (Fagone and Jackowski, 2013). Free choline is rapidly phosphorylated within the cytoplasm of the cell, a reaction catalyzed by choline kinase and then activated to CDP-choline via CTP:phosphocholine cytidylyltransferase, the second and rate-limiting step of the CDP-choline pathway typically localized to the nucleus. CDP-choline subsequently undergoes condensation with diacylglycerol via the enzyme choline phosphotransferase to form a PC species (Henneberry et al., 2002). Synthesized PC has multiple metabolic fates depending on the tissue; it can be exported as PC, degraded by phospholipases to form LPC and/or free choline, exported into bile, used to produce surfactant (lung) or donate its phosphocholine group to ceramide to facilitate sphingomyelin (SM) production.

In the hepatocyte and kidney, choline uptake also results in its oxidation to betaine via the activity of choline dehydrogenase (encoded by *CHDH*), first producing betaine aldehyde, and subsequently betaine via the activity of betaine aldehyde dehydrogenase (Zhang et al., 1992). The hepatocyte and kidney are also major sites of expression for betaine homocysteine methyltransferase (encoded by *BHMT*), an enzyme that catalyzes the transfer of a methyl group from betaine to homocysteine, producing methionine and dimethylglycine (DMG) (Obeid, 2013). This pathway serves as an alternate pathway for methionine regeneration from homocysteine via methionine synthase activity, an enzyme that utilizes 5-methyltetrahydrofolate and vitamin B12 as cofactors and links choline intakes and metabolism to folate and vitamin B12. Methionine can subsequently be activated to S-adenosylmethionine (SAM) and used by methyltransferases for a wide-variety of reactions, including placement of DNA and histone methylation (epigenetic marks), and synthesis of neurotransmitters, hormones creatine and phospholipids. In addition to serving as a source of methyl donors, SAM was recently shown to bind a previously uncharacterized protein, now referred to as SAMTOR; SAM binding to SAMTOR disrupts SAMTOR's interactions with GATOR1, a major direct inhibitor of the mammalian target of rapamycin (mTOR) complex 1, thus linking SAM availability to the regulation of cell growth and nutrient sensing (Gu et al., 2017). The other product of BHMT activity, DMG, can be further metabolized to sarcosine and glycine, and its methyl groups utilized in folate-mediated one carbon metabolism.

The hepatocyte expresses, nearly exclusively, the phosphatidylethanolamine N-methyltransferase (PEMT) pathway of PC synthesis (Vance, 2013), a prominent consumer of methyl groups from SAM. Thus, choline can produce PC through the CDP-choline pathway directly or produce PC indirectly through its oxidation to betaine and donation of methyl groups to SAM, ultimately used by PEMT. This redundant pathway of PC synthesis in hepatocytes provides not only a mechanism to produce a choline moiety de novo during times of dietary choline inadequacy, but also produces a PC species that is enriched with the omega 3 fatty acid, docosahexaenoic acid (DHA), (DeLong et al., 1999; Watkins et al., 2003). In addition to regulation by SAM supply and SAH concentrations, PEMT is also regulated transcriptionally by estrogen (Resseguie et al., 2007, 2011), a major determinant of its activity, and contributor to reduced sensitivity of premenopausal women and postmenopausal women on hormone replacement therapy to organ dysfunction when placed on low choline diets.

In cholinergic neurons, as well as some non-neuronal tissues, a major metabolic fate of choline is the synthesis of acetylcholine (Beckmann and Lips, 2013). In neurons, choline acetyltransferase catalyzes acetylcholine synthesis from choline and acetyl-CoA. In the extracellular space, acetylcholine can bind to both the ligand-gated cation channel nicotinic receptors, and the G-protein coupled muscarinic receptors. In non-neuronal tissues, including cell types of the integumentary, respiratory, digestive, immune and reproductive systems, acetylcholine can be synthesized by choline acetyltransferase, as well as carnitine acetyltransferase activities (White and Scates, 1990). Acetylcholine degradation to yield free choline and acetate is predominantly achieved via acetylcholinesterase, whereby choline can be recycled for metabolic use.

Choline that is metabolized by the enteric microbiota to TMA is passively absorbed into portal circulation and metabolized by flavin monooxygenase 3 (FMO3) in the hepatocyte, yielding TMAO (Al-Waiz et al., 1987a,b; Lang et al., 1998). TMAO serves general roles as an osmolyte and protein stabilizer in physiological systems, though its functional role in humans remains less clear.

## Excretion

Excretion of choline occurs as either choline or one of its primary metabolites. Dietary choline forms can be found in the feces, as well as TMA and TMAO. Feces also contains choline metabolites derived from enterocyte sloughing and PC-derived from bile that is not reabsorbed during enterohepatic recycling; in mice, the latter is a major route for PC loss in the liver, and genetic loss of the multiple drug-resistant protein 2 (MDR2 in mice; MDR3 in humans), responsible for exporting PC into bile, protects *PEMT* knockout mice fed choline deficient diets from rapid liver failure (Igolnikov and Green, 2006). Small amounts of choline and its metabolites are lost in the urine, through skin and hair loss, and from exhalation of formate.

## Dietary recommendations and choline adequacy

### Dietary reference intakes

In 1998, the United States' Food and Nutrition Board of the Institute of Medicine (now National Academies of Medicine (NAM)) established "Adequate Intake" (AI) values for choline (DRI Dietary Reference Intakes choline - Books - NCBI, no date). AI values are typically determined when dose-response relationships are unclear and an established average requirement (EAR) cannot be determined; in the case of choline, the use of depletion-repletion studies, repleting with a single dose of 7 mg choline/kg body weight, led to limited confidence in the intake of choline needed to prevent markers of hepatic organ dysfunction and reliance on this value as

**Table 1** Nutrient reference values for dietary choline intakes.

EFSA adequate intakes (2016)		NAM adequate intakes (1998)	
Age/life-stage	mg choline/day	Age/life-stage	mg choline/day
7–11 months	160	7–12 months	150
1–3 years	140	1–3 years	200
4–6 years	170	4–8 years	250
7–10 years	250	9–13 years	375
11–14 years	340	14–18 years	M: 550 F: 400
15–17 years	400		
Adults	400	Adults	M: 550 F: 425
Pregnancy	480	Pregnancy	450
Lactation	520	Lactation	550

the AI. For the adult, the choline AI is 550 mg/d for men, and 425 mg/day for non-pregnant women; for pregnant and lactating women, a factorial approach was used to estimate the amount of choline deposited in fetal tissues and secreted in human milk to adjust the AI to 450 mg/d and 550 mg/d, respectively. All other age group DRIs were derived from body weight adjustment methods and/or consideration of the amount of choline in human milk. The upper limit (UL) for choline for adults is 3500 mg/day, a value linked to reduced likelihood of fishy body odor and hypotension, after consideration of an additional safety factor. In 2016, the European Food Safety Authority (EFSA) updated the Dietary Reference Values (DRVs) for choline following a request from the European Commission (European Food Safety Authority, 2016). The EFSA panel relied on similar data, with some additional feeding and supplementation trials, to derive the DRVs. For all adults, the AI was established for all adults as 400 mg/day, based on the amount of choline needed to replete 70% of individuals who demonstrated organ dysfunction in depletion-repletion studies. For pregnancy and lactation, the AI values were determined to be 480 mg/day and 520 mg/day respectively. A summary of EFSA and NAM nutrient reference values can be found in [Table 1](#). Choline does not yet have a DRI value for the newly established Chronic Disease Risk Reduction (CDRR) value from the NAM. Dose-response data and assessment of hard endpoints continue to limit establishment of stronger DRIs with outcomes beyond preventing organ dysfunction as seen in depletion-repletion studies ([Table 1](#)).

### General population

Despite its name, the establishment of an Adequate Intake value over an EAR for choline precludes assessment of the proportion of the population at risk of inadequacy. Analysis of the National Health and Nutrition Examination Survey in the United States indicates that few individuals >9 years of age consume the respective AI for their age grouping and life-stage (Wallace and Fulgoni, 2016, 2017). Generally, males consume more choline than females, though the predominant determinant of high choline intakes and likelihood of achieving the AI relates to egg consumption; eggs contain around 235 mg choline per 100 g (143 kcal) serving, making them a rich source of choline (predominantly PC) in the diet. Other protein foods (meat, poultry, and seafood) also contribute meaningfully (~100 mg/d) to choline intakes. Foods less commonly consumed in the general population, such as beef liver, shrimp, oysters, salmon, cauliflower and asparagus, are relatively rich sources of choline on a per 100 g and per kilocalorie basis. Common food sources of choline and betaine and their nutrient content are shown in [Fig. 3](#). No subpopulation groups achieve the UL for choline, a value that is extremely challenging to achieve without significant supplement utilization. In infants, choline contents of formulas vary substantially, with few formulas exhibiting choline compositions similar to human breastmilk (utilizing PC or free choline, as opposed to glycerophosphocholine or phosphocholine) (Shunova et al., 2020).

### Clinical populations

Choline is not known to exhibit significant drug-nutrient interactions; needs may be higher in individuals with long-term methotrexate use but evidence from non-rodent models is limited (Varela-Moreiras et al., 1995; Hardwick et al., 2014). No dietary reference values have been clearly established by authoritative bodies focused on guideline setting in the clinical population. However, some clinical populations may exhibit altered choline intakes, exhibit low intakes and/or increased losses of choline. Patients with genetic mutations in FMO3 exhibit trimethylaminuria, resulting from a buildup of trimethylamine and inability to oxidize TMA to TMAO; patients limit excessive dietary choline intakes to limit TMA buildup and the associated fishy body odor (Schmidt and Leroux, 2020).

Choline losses are likely greater in clinical populations characterized by impaired intestinal homeostasis, including intestinal failure, exocrine pancreas insufficiency, and small intestinal bacterial overgrowth, though rigorous investigation is generally lacking. Studies of patients with cystic fibrosis and exocrine pancreas insufficiency demonstrate significant choline losses (as PC and

**Fig. 3** Total choline and betaine content in selected foods, raw or cooked. The source for the data was the USDA Database for the Choline Content of Common Foods (Release Two) available at <http://www.ars.usda.gov>.

LPC, primarily) in the stool, and supplementation improves low plasma choline/PC, and improve elevated homocysteine levels (Chen et al., 2005; Innis et al., 2007; Bernhard, 2021). Patients with impaired intestinal function regularly receive parenteral nutrition (PN); parenteral choline is not readily available, limited by its stability in solution long-term. Patients on long-term PN often exhibit liver disease associated with PN or underlying causes of PN (i.e., intestinal failure) that may result from choline deficiency, though other dietary and metabolic factors also likely contribute to the observed broad liver dysfunction (Burrin et al., 2014). Choline supplementation to cohorts of adult patients receiving PN appears to improve hepatic steatosis, as well as memory impairments (Buchman, 2009); particular concern over choline nutriture in the enterally and PN-fed preterm infant has emerged, given the importance of choline for brain development, reduced exposure to high *in utero* choline concentrations and recently observed low PEMT activity and thus, capacity to generate choline de novo (Goss et al., 2020). Calls to action to develop a readily available source of choline for adult and pediatric PN formulations have been increasingly made (Vanek et al., 2012, 2015). A commercial choline chloride product has recently completed phase 2 studies in intestinal failure-associated liver disease and received Fast Track designation from the United States' Food and Drug Administration.

Plasma choline is altered in several other patient populations, such as burns, sepsis and elective abdominal surgery, as well as being present in high quantities in renal dialyzate; however, few cohort studies have assessed functional consequences of these alterations and/or controlled trials testing the impacts of choline supplementation.

### Assessment of choline intake and status

Objective biomarkers of choline intake and status would be beneficial in assessing dietary adequacy of both populations and individuals, as well as serving as an adequate exposure variable in the assessment of choline's relationship to health outcomes in prospective cohort studies. Unfortunately, such biomarkers are broadly lacking.

Hepatic choline levels have been suggested to be the best marker of choline status, consistent with low choline availability in the hepatocyte resulting in hepatic triacylglycerol accumulation; whether other tissue choline content, or a related metabolite, may serve as a better marker of choline status, remains less well-characterized, though advances in proton magnetic resonance spectroscopy (MRS) allow for the *in vivo* quantification of free choline, glycerophosphocholine and phosphocholine in tissues (Mazzetti et al., 2013). A biomarker of choline status should clearly track with dose-response changes in choline intake and be strongly associated with health and disease. Plasma choline and its metabolites are frequently measured as markers of choline status, typically by liquid chromatography/electrospray ionization, stable isotope dilution (tandem) mass spectrometry, though other methods to measure choline, such as colorimetric kits, are available. Fasting plasma choline levels do not always track with moderate changes in choline intake (Veenema et al., 2008; Abratte et al., 2009), and rarely drop below 4.5  $\mu\text{M}$  in individuals consuming deficient diets; nevertheless, fasting plasma choline levels, particularly in repleted individuals previously consuming low intakes and in those consuming high supplemental intakes, can be responsive to choline intakes. Plasma choline levels should be considered as not only an

indicator of dietary intakes but a composite of its relative degree of absorption, endogenous synthesis, release and metabolism of choline stores, relative partitioning toward other metabolites (e.g., betaine), and losses in urine.

Recent attempts to relate varying dietary choline intakes (~25, 50 and 100% of the AI) to hepatic choline contents, as measured by MRS, have not demonstrated a clear linear correlation, though technical challenges may have influenced this finding (Horita et al., 2021). Plasma betaine levels showed clear correlation with dietary choline intakes in this study; however, variation in choline intakes were achieved through bread rolls fortified with choline chloride, a readily oxidizable form of choline, and may not be a clear indicator of dietary choline adequacy in the general population, which consumes primarily PC. While discovery work examining gene expression and metabolomic signatures of choline deficiency work has yielded promise (Niculescu et al., 2007; Sha et al., 2010), stronger evidence is needed to find readily measurable correlates of varying choline intakes, considering both water- and lipid-soluble intakes forms, that ideally track with tissue choline contents.

Given the lack of readily measurable indicators of choline status and intake adequacy, assessment at the population and individual level relies heavily on self-reported dietary intakes. Underreporting of dietary intakes likely results in choline underreporting; comparisons between 3-day dietary records and known choline intakes in a metabolic ward suggest that absolute choline intakes are significantly underreported by self-reported dietary measures, but that choline intakes per kilocalorie are not (Fischer et al., 2005). While not supported by this study, additional concern exists that, in free living individuals consuming self-selected diets with significant proportions of processed foods, choline intakes will be significantly influenced by the lecithin content of foods, a factor not captured by most recall methodologies or in nutrient composition databases for many commercially available foods. Concerns about inadequate choline intakes may be complemented with additional functional tests, including liver functional tests and CPK, to assess the potential for dietary inadequacy; notably, however, dietary choline depletion-repletion studies suggest that choline's effect on many readily available liver function tests is subtle and may not necessarily fall outside of "normal" clinical ranges.

## Emerging areas of investigation

While current nutrient reference values (NRVs) continue to rely on choline depletion-repletion studies to assess dietary requirements for choline, growing bodies of evidence link choline to health outcomes beyond preservation of normal liver and muscle dysfunction.

### Pregnancy

NRVs from NAM and EFSA for pregnancy are ultimately derived from studies conducted in non-pregnant participants with adjustments based on assumptions about the amount of choline needed to support fetal growth. To date, no NRVs are based on functional outcomes related to alterations in fetal development and offspring health and/or reduced pregnancy complications. Pregnancy is a physiological state that stresses choline metabolism, with evidence from animal models demonstrating depletion of maternal hepatic choline contents, despite consuming dietary intakes adequate to prevent abject organ dysfunction; such a depletion is pronounced as gestation progresses as the placenta increasingly transfers choline to the fetal compartment (Sweiry et al., 1986; Ilicol et al., 2002); fetal cord plasma exhibits a choline concentration 5–10X higher than maternal plasma (Zeisel et al., 1980; Yan et al., 2012). Feeding of choline deficient diets to dams further stresses choline needs and has broad consequences for fetal neurodevelopment, impairing neurogenesis and angiogenesis in the hippocampus, decreasing cell proliferation and increasing apoptosis, ultimately impairing several domains of cognition in adult animals (Meck et al., 1988; Albright et al., 1999; Cheng et al., 2008; Blusztajn et al., 2017).

A large body of literature in rodents demonstrate that maternal choline supplementation throughout gestation, beyond usual chow intakes, alters the development of fetal septohippocampal circuitry and improves postnatal spatial learning and memory, as well as attention, phenotypes in the offspring (Strupp et al., 2016; Blusztajn et al., 2017). Doses used in the rodent literature are typically 4X the standard chow diet and achieved via supplementation with water-soluble choline salts. In humans, a small body of literature during health pregnancy has investigated choline supplementation's impact on infant cognitive development (Cheatham et al., 2012; Ross et al., 2013; Caudill et al., 2018). Of the 3 studies, 2 utilized phosphatidylcholine (750 mg and 900 mg/d) in free-living pregnant women and one controlled feeding trial (Caudill et al., 2018) compared 930 vs 480 mg choline/d, with the differential achieved via choline chloride. One PC trial and the one choline salt trial demonstrated cognitive improvements, whereas the largest trial, utilizing PC, demonstrated null effects. Trials are diverse with regard to design and methods used to assessment infant cognitive development, and future trials, with dose-response (>2 arm) designs and consideration of dietary form are required to better understand choline's link to cognition and refine NRVs. Evidence for prenatal choline supplementation in alcohol-exposed pregnancies in both preclinical models and human trials has also demonstrated promise to buffer against alcohol's toxic impacts (Zeisel, 2011; Coles et al., 2015; Jacobson et al., 2018; Sawant et al., 2019).

Choline intakes in rodent models and in some epidemiological investigations are also linked to the risk of birth defects (Shaw et al., 2004, 2009; Chan et al., 2010); however, no trials have been designed to assess these relationships in humans. To date, significant amounts of choline are still absent from commercial prenatal vitamins, and insufficient physical space in existing prenatal vitamin supplements precludes fortification with significant quantities of choline without increasing supplement size.

Limited investigation has linked choline intakes to reduced risk of maternal pregnancy complications. A recent post-hoc analysis of the aforementioned Caudill et al. feeding trial observed that the higher choline intake arm (930 mg/d), relative to the lower intake arm (480 mg/d) resulted in lower placental and circulating levels of the vascular endothelial growth factor (VEGF) decoy receptor, soluble fms-like tyrosine kinase 1 (sFLT1), a finding identified by microarray analysis of placental tissue. sFLT1 is an anti-angiogenic factor secreted by the placenta and has been causally linked to pre-eclampsia (PE) (Ives et al., 2020). While many dietary factors have been investigated for their link to PE risk, future observational and intervention investigation are needed to assess the potential for dietary choline supplementation to reduce PE risk.

### TMAO and cardiovascular disease

Choline was originally suggested to be potentially cardioprotective, due to its role as a major dietary methyl donor and maintaining homocysteine levels in a normal range (da Costa et al., 2005; Olthof et al., 2005). However, choline's role as a dietary TMA(O) precursor has led to concern that choline intakes may promote cardiovascular disease. In prospective cohorts, TMAO exhibits a dose-response relationship, per 1  $\mu\text{mol/L}$  increment, with major adverse cardiovascular events, making it an attractive candidate for therapeutic targeting (Heianza et al., 2017). Whether TMAO represents a causal factor in disease development has been questioned, as elevated TMAO may be a marker of other underlying factors such as a pathogenic gut microbiota, insulin resistance, an inducer of FMO3 activity (Miao et al., 2015), and/or altered kidney function (TMAO levels are much higher in advanced renal disease (Pelletier et al., 2019)); experimental evidence, however, suggests that TMAO is likely a causal mediator of disease risk. In mechanistic investigations, TMAO has been shown to impair reverse cholesterol transport, promote macrophage inflammation, reduced bile acid pool sizes, and increased platelet aggregation, ultimately resulting in increased foam cell formation, atherosclerotic plaque volume, and risk of thrombosis (Zeisel and Warrier, 2017). Cellular mediators of the response to TMAO are an active area of investigation; recent advancements have indicated that TMAO's impact on metabolic disease is mediated via its binding and activation of protein kinase R (PKR)—like endoplasmic reticulum kinase (PERK), a branch of the unfold protein response in the endoplasmic reticulum (Chen et al., 2019). Efforts are ongoing to test the potential of CutC/CutD inhibitors to reduce TMA production and assess its impact on cardiovascular events (Roberts et al., 2018).

Randomized controlled trials manipulating dietary choline and observing its effect on cardiovascular disease endpoint are unlikely, due to their impracticality, large financial investment, and inherent design challenges (e.g., reducing egg consumption, a major source of choline, also reduces dietary cholesterol, and may be replaced by foods with additional factors that influence CVD risk). Thus, investigations have been limited to rodent models of cardiovascular disease, and observational population studies with self-reported dietary choline intakes. In rodent models, findings are discordant for an effect of choline on atherosclerotic plaque volume. Indeed, the most common model, the ApoE knockout mouse, has been employed by several investigators feeding high ( $\sim 1\%$  choline) vs low choline ( $\sim 0.1\%$ ) diets, with several investigators observed increased atherosclerosis, and others finding no effect (Tang et al., 2015; Zhu et al., 2016; Geng et al., 2018; Aldana-Hernández et al., 2020, 2021). No effect of choline has also been reported in the LDL receptor knockout mouse. While not all investigators have reported plasma TMAO levels, those that have demonstrate striking variation in achieved levels (1.5–200  $\mu\text{M}$ ), suggestive of different microbiota composition and capacity to generate TMA from TMAO underlying variability in response to choline supplementation; variation in microbiota composition across vivariums has been reported, and affects other research domains dependent upon microbiota composition (e.g., inflammatory bowel disease) (Reinoso Webb et al., 2018). Null findings have generally achieved lower TMAO levels.

The translatability of these animal models to free-living humans consuming habitual choline intakes is uncertain. In addition to species differences in atherosclerosis, it should be noted that dietary manipulations in mice have utilized high doses of water-soluble choline salts (more readily metabolized to TMA), typically achieving very high TMAO levels, challenging the translation of these findings to human populations consuming predominantly PC with generally lower TMAO levels. To complement such animal models, investigations into dietary choline intakes in human cohort studies have been undertaken, but are challenging to interpret, due to their correlation with the associated food matrix; major sources of choline in the human diet are eggs, red meat, and dairy products, each with their own nutrient matrices that may contribute to cardiovascular risk increase or reduction. Additionally, individuals who consume low choline foods/diets may consume other foods that modify cardiovascular risk, obscuring or amplifying the risks associated with choline. Systematic reviews of dietary choline and CVD do not support a clear risk (Meyer and Shea, 2017), though individual cohorts have supported an association. The lack of an effect in the general population consuming predominantly PC may not be entirely surprising, given the complexity of TMAO generation; while diet is a precursor to TMA, persistent and substantial elevations in TMAO levels might require a pathogenic gut microbiota composition, alterations in FMO3 activity (notably regulated by insulin), and/or impaired capacity of the kidney to clear TMAO to achieve persistently elevated TMAO concentrations associated with clearly pathogenic levels. To date, estimates of the variance in plasma TMAO levels contributed by diet remain relatively small, with dietary factors such as fish and red meat, explaining the most variation (Krüger et al., 2017). Future studies in higher risk populations are needed to determine the degree to which diet influences plasma TMAO levels and whether this may result in likely risk reduction while still achieving intakes adequate to prevent nutrient deficiency phenotypes. Ultimately, efforts to make dietary recommendations based on modifying TMAO levels must take into account that fish, including fatty fish, are major sources of dietary TMA(O) (Cho et al., 2017), and that other dietary factors, such as a yet to be identified factor in red meat, appears to influence renal handling of TMAO (Wang et al., 2019).

### Neurocognitive health and aging

The relationship of dietary choline to neurocognitive health and disease has received some attention in the literature, though the evidence base is limited. Rationale for such investigations relate not only to acetylcholine synthesis and cholinergic agonism but to choline's role in SM production, a component of the myelin sheath, its role as a methyl donor and maintaining low homocysteine levels, and potential epigenetic effects (DNA & histone methylation). One investigation in the Framingham Offspring study has linked self-reported choline intakes to cognitive function and reduced white matter hyperintensity volume, following adjustment for several covariates (Poly et al., 2011). While evidence from long-term PN use results in neurocognitive abnormalities (as discussed above), evidence to support choline supplementation or increased dietary choline intakes on cognitive function in adults or in those with dementia is of low quality and lacking clear evidence (Higgins and Flicker, 2003; Leermakers et al., 2015), though individual acute studies demonstrate proof of principle neuromodulation by high dose choline supplementation (Naber et al., 2015). Dietary choline's relationship to age-related dementia, including Alzheimer's Disease, requires further investigation.

### Nutritional genomics of choline

Efforts to advance our understanding of choline requirement and links between choline intake and broader health outcomes should consider nutrient-genome interactions. Indeed, a growing body of evidence indicates that common genetic variants influence the risk of deficiency when fed choline-deficient diets, while altering choline metabolism. Choline, through several direct and indirect mechanisms, also influences gene expression. Consideration of the nutrigenetics and nutrigenomics of choline may refine and inform investigations aiming to bring clarity to choline's links to health and disease.

#### Nutrigenetics

Common genetic variants throughout one carbon metabolism-related genes have been the subject of several post-hoc analyses from choline intervention studies. In the choline depletion-repletion literature, single nucleotide polymorphisms in choline and folate metabolizing enzymes predict the odds of developing organ dysfunction when placed on choline deficient (folate, b12 and methionine replete) diets (Kohlmeier et al., 2005; da Costa et al., 2006); odds ratio were substantial for several variants, including a 25-fold increased odds for carriers of the *PEMT* variant, rs12325817, a polymorphism in the promoter region linked to impaired upregulation by estrogen. Several variants, such as those in *SLC44A1*, were also more prevalent in individuals who experienced elevated markers of muscle damage relative to liver damage (da Costa et al., 2014). Several of the described variants, such as those in the *PEMT* locus, are in linkage disequilibrium, and the prevalence of SNPs across typical racial/ethnic groupings varies considerably, with individuals of African descent having lowest frequency of *PEMT* risk alleles and choline kinase (*CHKA*) protective alleles. The impact of these variants on choline requirements outside the context of choline deficiency studies remains underexplored, with limited investigation into their impacts on choline partitioning and flux and some evidence indicating SNPs in *MTHFR* and *PEMT* influence maternal diet-breastmilk choline metabolite concentrations (Fischer et al., 2010a,b; Ganz et al., 2016, 2017). While proof of concept for the field of nutrigenetics and the potential for individualized nutrition, studies examining genetic variants in a prospective manner and their interactions with more usual choline intakes are required to realize the full potential of incorporating genotype subgroups into dietary guidance. Consideration of effect modification by genetic variants prospectively in all study designs assessing dietary choline intakes and its relationship to health and disease will be critical for explaining heterogeneity in response in a statistically rigorous manner.

#### Nutrigenomics

Epigenetics refers to heritable marks on both DNA and on the histone proteins that DNA wraps around to form the structure of chromatin; methylation is a common mark on both DNA and histones, and thus, choline's role as a methyl donor has led to significant investigation into the epigenetic mechanisms by which it influences gene expression and in which tissues. However, it is notably challenging to attribute gene expression and broader phenotypic changes to its role as a methyl donor relative to changes downstream of its other metabolic roles (e.g., cholinergic signaling; PC synthesis), and few multi-omic, systems biology approaches have been employed in the context of feeding different levels of choline. Early investigations employed methyl deficient diets, of which choline depletion was a component, with an emphasis on identifying hypomethylated genes associated with the development of hepatocellular carcinomas, including aberrant regulation of *KRAS* and *c-myc* (Bhave et al., 1988; Tsujiuchi et al., 1999). Choline was also a component of the methyl donor cocktail fed to agouti mice, resulting in hypermethylation at the *Avy* locus and both coat color and body composition changes (Waterland and Jirtle, 2003). Additional studies in rodents selectively altering choline both through depletion and supplementation have demonstrated global and gene-specific alterations in DNA methylation and histone methylation in the liver and frontal cortex at embryonic day 17, corresponding to the end of the period of gestation (E11-17) that is critical for improved cognition in offspring (Davison et al., 2009). A recent investigation in humans who consumed 930 mg vs 480 mg choline/d throughout the third trimester of pregnancy demonstrated elevated promoter methylation in 2 cortisol regulating genes (*CRH*; *NR3C1*), reduced placental expression of *CRH*, and lower cord plasma cortisol in response to higher choline supplementation (Jiang et al., 2012). Dimethylated histone H3 at lysine residue 9 was also significantly elevated. The causal

relationships between choline intake, altered epigenetic marks and changes in gene expression require further interrogation by emerging systems biology approaches, including single-cell sequencing technologies.

Nutrients, such as Vitamins A and D, classically modify gene expression via binding of nuclear receptors (i.e., serving as ligands); nuclear receptors are a family of protein transcription factors that bind consensus sequences of DNA and influence transcription. There is emerging interest in choline's effects on gene expression, secondary to the finding that specific PC species are ligands for nuclear receptors of the 5A family (Li et al., 2005; Ortlund et al., 2005; Musille et al., 2016; Petruzzelli et al., 2016). One member of this family, Liver Receptor Homolog-1 (LRH-1) has been shown to exhibit transcriptional and phenotypic responses to specific PC supplementation, though conflicting evidence exists to support the CDP-choline or PEMT pathway as the primary producer of LRH-1 ligands and both may play roles in producing specific PC species that bind LRH-1 (Lee et al., 2011; Wagner et al., 2016; Choi et al., 2020). Further investigation is needed to determine the effects of varying choline intakes on nuclear receptor ligand production and function.

Choline influences the transcriptome through various, more indirect stress responses when choline intakes are limited, secondary to altered mitochondrial membrane integrity and reactive oxygen species leakage, increased consumption of folates and associated uracil misincorporation and DNA strand breaks, and stimulation of apoptotic pathways (Zeisel, 2012). Such effects likely influence cell signaling networks and underlie the increased risk of cancer from inadequate choline intakes seen in animal models, though observational data in human populations supporting such links remains of low quality (Sun et al., 2016).

## Conclusion

Despite more than 3 decades since the seminal observation in humans that choline restriction compromises hepatic function in humans, many questions remain regarding dietary choline intakes relationship to health and disease. There is a great need to undertake dose-response feeding trials to establish an Estimated Average Requirement and Recommended Dietary Allowance for Choline, moving beyond the uncertain AI values. Evidence for increased choline requirements during pregnancy, significantly beyond current recommendations, to optimize neurocognitive health of the offspring continues to emerge, but more evidence is likely needed to see changes to DRIs and current obstetric practice. Choline serves as an important case study for all human nutrition as the field attempts to tackle "Precision Nutrition", given the complexity of measuring choline in the diet and assessing choline status, lack of clear surrogate intakes linking choline to health and disease outcomes outside of frank deficiency states, and the evidence pointing to significant nutrient-nutrient, nutrient-microbiota, and nutrient-host genome interactions.

## Absorption, Transport, and Storage

### Cholesterol absorption

Cholesterol in the intestinal lumen typically consists of one-third dietary cholesterol and two-thirds biliary cholesterol. The average daily diet contains 300–500 mg of cholesterol obtained from animal products. The bile provides an additional 800–1200 mg of cholesterol throughout each day as gallbladder contractions provide a flow of bile acids, cholesterol, and phospholipids to facilitate lipid digestion and absorption. Dietary cholesterol is a mixture of free and esterified cholesterol whereas biliary cholesterol is nonesterified and is introduced into the small intestine as a cholesterol–bile salt–phospholipid water-soluble complex. The only other source of intraluminal cholesterol is mucosal cell cholesterol, derived from either sloughed mucosal cells or cholesterol secreted by the mucosal cells into the intestinal lumen. Measurements of exogenous and endogenous cholesterol absorption in humans indicate that there is probably very little direct secretion of newly synthesized cholesterol from mucosal cells into the intraluminal contents.

Cholesterol absorption occurs primarily in the duodenum and proximal jejunum of the small intestine and is dependent on the presence of bile salts. In the absence of bile secretion, or in the presence of bile acid-binding resins, there is virtually no intestinal absorption of cholesterol. On average, humans absorb 50–60% of the intestinal contents of cholesterol, but there is a large inter-individual variance in absorption, with values ranging from as low as 20% to as high as 80%. Intestinal transit time is related to cholesterol absorption with slower transit times resulting in higher fractional absorption rates. Dietary factors that affect the relative percent absorption of cholesterol include the total mass of dietary cholesterol, the concentration of plant sterols in the diet, and the type and amount of dietary fiber. Studies suggest that the ratio of polyunsaturated to saturated fat (P:S) in the diet has little effect on cholesterol absorption rates in humans, nor does the amount of dietary fat.

Two interesting, and as yet undefined, aspects of cholesterol absorption are that it decreases as the mass of cholesterol increases above an intake of 1500 mg per day, and that the fractional absorption below this level is relatively constant for an individual. For example, at a daily cholesterol intake of 800 mg a subject might absorb 60% or 480 mg a day, whereas at a daily intake of 400 mg the absorption remains at 60%, equaling 240 mg a day absorbed. The quandary is, if the system can accommodate absorption of 480 mg at the high cholesterol intake, then why is the amount absorbed 240 mg at the low intake? Clearly the upper value of cholesterol absorption is achievable, yet at the lower intake level the absorption rate stays at a fixed fractional value. The mechanisms controlling this aspect of cholesterol absorption have not been defined.

Experimental evidence indicates that biliary cholesterol and dietary cholesterol are absorbed equally; however, the pattern of exogenous and endogenous cholesterol absorption differs along the length of the intestinal lumen. Dietary cholesterol enters

the small intestine solubilized in the oil phase of the stomach digest, whereas the binary cholesterol enters in the micelle phase of the bile. This differential distribution results in a greater absorption of biliary cholesterol in the upper portion of the small intestine with dietary cholesterol absorption increasing as the oil phase of the intestinal contents are hydrolyzed. As the oil phase is reduced, dietary cholesterol moves from the oil phase to the aqueous micelle phase and becomes available for absorption. In the case of cholesteryl esters in the diet, it is necessary that the esters are hydrolyzed by pancreatic cholesterol esterase (CEase) before the cholesterol is available for absorption. Pancreatic CEase requires the presence of bile salts for activity and may play a key role in the actual absorption process.

The process, and selectivity, of sterol absorption involves a complex interplay of regulated transporters, transporting sterols into and out of the enterocyte, and the assembly and secretion of chylomicrons into the lymph. The enterocyte takes up both cholesterol and phytosterols from the intestinal lumen by what appears to be a common sterol transporter or permease in the brush border membrane. Preliminary studies suggest that the Neiman–Pick C1 Like 1 (NPC1L1) protein is involved in this process. Once the sterols enter the enterocyte, the ATP-binding cassette (ABC) hemitransporters ABCG5 and ABCG8 function in the apical excretion of sterols back into the intestinal lumen. The selectivity of this process accounts for the higher absorption rates of cholesterol (50–60%) compared to the phytosterols, which are very poorly absorbed. Loss of ABCG5/G8 function results in excessive absorption of both cholesterol and phytosterols. Studies in mice have shown that ABCG5/G8 are expressed primarily in the liver and intestine, are coordinately up-regulated at the transcriptional level by dietary cholesterol intake, and require the liver X receptor  $\alpha$  (LXR $\alpha$ ), a nuclear receptor that regulates the expression of a number of key genes involved in lipid metabolism.

Evidence is accumulating that the fractional cholesterol absorption rates are regulated by one or more genetic determinants. The apolipoprotein (apo) E phenotype has a significant effect on fractional cholesterol absorption and appears to play a major role in determining the plasma lipoprotein response to changes in dietary cholesterol intake. Men with the apoE4 allele have a high cholesterol absorption rate whereas those with the apoE2 allele have a low cholesterol absorption efficiency. The absorption values for the more common apoE3/3 fall between the apoE2 and apoE4 patterns. Polymorphisms of the apolipoprotein A-IV and of the low-density lipoprotein (LDL) receptor gene have also been related to differences in fractional cholesterol absorption. These genetic variants affecting cholesterol absorption no doubt play a significant role in determining an individual's fractional absorption of cholesterol as well as accounting for much of the heterogeneity of plasma lipid responses to changes in dietary cholesterol intakes (see the Section on Dietary Cholesterol and Plasma Cholesterol below).

### Exogenous Cholesterol Transport

Cholesterol is absorbed in the unesterified state, whereas the cholesterol secreted into the lymph is 70–80% esterified. This esterification process generates a concentration gradient of free cholesterol within the mucosal cell, which could facilitate absorption rates. Cholesterol is esterified in intestinal mucosal cells by acyl-coenzyme A: cholesterol acyltransferase-2 (ACAT-2) to form cholesteryl esters, which are secreted from the basolateral surface of the enterocyte as part of the chylomicrons. At this stage it is assumed that cholesterol molecules from exogenous and endogenous sources are indistinguishable, and have similar effects on endogenous cholesterol and lipoprotein metabolism. Chylomicrons are large particles (>70 nm in diameter) composed mainly of triacylglycerols (95% by weight) and containing 3–7% cholesterol by weight, the esterified cholesterol localized in the hydrophobic core and the free cholesterol primarily in the hydrophilic outer layer. The data indicate that the amount of dietary cholesterol consumed has little effect on the cholesterol content of chylomicrons. The chylomicrons are released from the intestinal cells, enter the lymphatic system and are transported *via* the lymphatics (thoracic duct) to the bloodstream. Because chylomicrons are too large to pass through the capillaries, this is the only mechanism by which they can enter the bloodstream.

In the plasma compartment the chylomicrons pick up a number of apolipoproteins, which are required for intravascular metabolism of the particles. The initial metabolism of chylomicrons involves hydrolysis of the associated triacylglycerols by endothelial cell lipoprotein lipase (LPL) located in adipose, muscle, and heart tissues which results in production of chylomicron remnants. The chylomicron remnants, depleted of triacylglycerol and enriched with cholesteryl ester, are taken up by the liver *via* the LDL receptor-related protein (LRP). The ligand for hepatic uptake of the chylomicron remnant appears from various transgenic mouse studies to be the apo-E moiety of the particle. The clearance of chylomicrons from the bloodstream is rapid, with particles having a half-life of less than an hour. The liver cannot take up native chylomicrons but rather takes up the chylomicron remnant, which has lost approximately 90% of its triacylglycerol content and become relatively enriched in free and esterified cholesterol through the actions of the plasma cholesteryl ester transfer protein (CETP), which transfers cholesteryl ester from HDL to the apo-B-containing lipoproteins.

The chylomicron remnants taken up by the liver are subjected to lysosomal hydrolysis resulting in the release of the absorbed dietary and biliary cholesterol into the hepatocyte as free cholesterol. The influx of cholesterol contained in the chylomicron remnant has the ability to affect a number of regulatory sites of hepatic cholesterol metabolism, which function to maintain cholesterol homeostasis in the liver. The liver has four primary fates for the newly delivered cholesterol: catabolism to bile acids; secretion as biliary cholesterol; storage in lipid droplets as cholesteryl ester; or incorporation into very low-density lipoprotein (VLDL) for secretion from the liver.

### Tissue Uptake and Storage

The body pool of cholesterol is approximately 145 g with one-third of this mass localized in the central nervous system. The remainder of the metabolically active cholesterol pool exists in the plasma compartment (7.5–9 g) and as constituents of body

tissues. In humans, tissue cholesterol levels are relatively low, averaging 2–3 mg gm<sup>-1</sup> wet weight. Little information exists regarding changes in hepatic and extrahepatic tissue cholesterol concentrations with changes in dietary cholesterol intake. Animal studies, which are usually carried out using very high levels of dietary cholesterol, have shown that hepatic cholesterol can increase from 2-fold up to 10-fold, depending on the species and other dietary constituents, when dietary cholesterol is increased.

## Biosynthesis

### Tissue Cholesterol Synthesis

Cholesterol biosynthesis occurs in every nucleated cell in the body. Although it is often thought that the majority of cholesterol synthesis occurs in the liver, studies have shown that the bulk tissues of the body account for the overwhelming majority of endogenous cholesterol production. Hepatic cholesterol synthesis in humans is thought to contribute 10–20% of the total daily synthesis rate. Because the majority of cholesterol synthesis in the body occurs in extrahepatic tissues, and the only quantitatively significant site for excretion and catabolism of cholesterol is the liver, some 600–800 mg of cholesterol each day must be transported from peripheral tissues through the plasma compartment to the liver to account for daily cholesterol catabolism and biliary secretion. Approximately 9 mg cholesterol per kilogram body weight is synthesized by peripheral tissues every day and must be moved to the liver for catabolism *via* a process termed ‘reverse cholesterol transport’ (RCT).

RCT describes the metabolism, and important antiatherogenic function, of the HDL-mediated efflux of cholesterol from non-hepatic cells and its subsequent delivery to the liver and steroidogenic organs for use in the synthesis of lipoproteins, bile acids, vitamin D, and steroid hormones. A cellular ABC transporter (ABCA1) mediates the first step of RCT involving the transfer of cellular cholesterol and phospholipids to lipid-poor apolipoproteins. Lecithin:cholesterol acyltransferase (LCAT) mediated esterification of cholesterol generates spherical particles that continue to expand with ongoing cholesterol esterification and phospholipid transfer protein (PLTP) mediated particle fusion and surface remnant transfer. Larger HDL<sub>2</sub> particles are converted into smaller HDL<sub>3</sub> particles when CETP facilitates the transfer of cholesteryl esters from HDL onto apo-B-containing lipoproteins. The scavenger receptor B1 (SR-BI) promotes selective uptake of cholesteryl esters into liver and steroidogenic organs whereas hepatic lipase (HL) and LPL mediated hydrolysis of phospholipids and triglycerides. SR-BI mediates the selective uptake of cholesteryl esters from HDL and also LDL into hepatocytes and steroid hormone-producing cells without internalizing HDL proteins, which can recycle through the RCT sequence moving cholesterol from peripheral tissues to the liver.

### Regulation of Synthesis

The rate-limiting enzyme in cholesterol biosynthesis is 3-hydroxy-3-methylglutaryl coenzyme A (HMG- CoA) reductase, a microsomal enzyme which converts HMG-CoA to mevalonic acid in the polyisoprenoid synthetic pathway. Peripheral tissue cholesterol synthesis is much less responsive to regulatory factors compared with the liver, which is controlled by a variety of dietary, hormonal, and physiological variables. Studies indicate that endogenous cholesterol synthesis is significantly increased in obesity and in patients with the metabolic syndrome. Obesity, insulin resistance, and diabetes have pronounced effects on both cholesterol absorption and synthesis. Findings in type I diabetes appear related to low expression of ABCG5/G8 genes resulting in high absorption and low synthesis of cholesterol. Cholesterol absorption efficiency is lower and cholesterol synthesis higher in obese subjects with type II diabetes compared to obese subjects without diabetes, suggesting that diabetes modulates cholesterol metabolism to a greater extent than obesity alone. In a similar manner, low cholesterol absorption and high synthesis appears to be part of the insulin resistance (metabolic) syndrome.

Research shows that in most individuals, dietary cholesterol alters endogenous cholesterol synthesis and that this feedback regulation can effectively compensate for increased cholesterol input from dietary sources. The precision of these regulatory responses depends on a number of genetic factors, and data suggest that multiple genetic loci are involved. For example, family studies have shown that in siblings of low cholesterol absorption families, cholesterol absorption percentages are significantly lower, and cholesterol and bile acid synthesis, cholesterol turnover, and fecal steroids significantly higher than in siblings of high absorption families.

### Metabolism and Excretion

The body's metabolic processes cannot break the sterol rings of cholesterol and therefore must either catabolize cholesterol to other products, which can be excreted in the urine or feces, or directly excrete cholesterol in the bile, with a fraction of the biliary cholesterol lost daily as fecal neutral sterols. In humans, the major route of excretion is as biliary cholesterol (two-thirds of the total lost each day), with catabolism to bile acids and bile acid excretion being the second most important route, accounting for approximately one-third of the daily turnover.

For all practical purposes, the body must excrete daily an amount of neutral and acidic sterols equivalent to the combined inputs of total dietary and newly synthesized cholesterol. Given an average fecal excretion of 1020 mg a day with 250 mg as acidic sterols, it can be calculated that the 770 mg per day excreted as neutral steroids comes from unabsorbed biliary (650 mg) and unabsorbed dietary (120 mg) cholesterol (Table 1). It is easy to see that even small changes in the daily balance between a cholesterol input and output value of 1020 mg per day could, over years, result in significant tissue cholesterol accumulation.

## Bile Acid Synthesis

The results from numerous sterol balance studies carried out in subjects fed diets low and high in cholesterol indicate that in humans dietary cholesterol has little effect on fecal bile acid excretion rates. This finding is in striking contrast to results from studies in some rodent models, which show that intake of pharmacological doses of dietary cholesterol can result in several-fold increases in bile acid synthesis and excretion. In contrast, some rodent species and nonhuman primates have little if any increase in bile acid excretion with increased intakes of cholesterol. Although there have been a few reports of enhanced bile acid excretion on a high-cholesterol diet in some patients, this does not appear to be a major regulatory response in humans.

## Biliary Cholesterol Secretion

The majority of cholesterol entering the intestinal tract is biliary cholesterol. Biliary cholesterol secretion averages 1000 mg per day as part of the bile system and enters as free cholesterol already solubilized with bile acids and phospholipids. Both cholesterol absorption by enterocyte and biliary cholesterol secretion by hepatic cells are regulated by expression of the half-transporters ABCG5 and ABCG8. Studies in animals have shown that treatment with a LXR agonist decreases cholesterol absorption, increases biliary cholesterol secretion, and increases fecal neutral sterol excretion. Studies in transgenic mouse models demonstrate that increased expression of ABCG5 and ABCG8 increases biliary neutral sterol secretion and reduces intestinal cholesterol absorption, leading to increased neutral sterol excretion and cholesterol synthesis.

## Fecal Excretion

The only route of significant cholesterol excretion is through fecal excretion of neutral sterols. The combination of unabsorbed biliary and dietary cholesterol accounts for the total neutral sterol output, and under most conditions equals 750–850 mg a day. Dietary patterns or drugs that interfere with intestinal cholesterol absorption result in increased fecal neutral steroid excretion. In the colon, intestinal bacteria are able to metabolize cholesterol to a variety of neutral steroids as well as to nonsteroid end products. There have been some studies suggesting that the intestinal metabolism of cholesterol by bacteria, which can be altered by diet and drugs, can influence endogenous cholesterol metabolism as well as plasma cholesterol levels. What these relationships might be and the mechanisms involved have not been defined.

## Metabolic Function

### Steroid Hormones

Daily production of steroid hormones is quantitatively a very small fraction of the daily turnover of dietary and newly synthesized cholesterol in the body. For men, the average daily excretion of steroid hormones is approximately 50 mg per day, whereas in women the value can be substantially higher depending on the menstrual phase.

## Bile Acid Synthesis

The enterohepatic circulation of bile acids is essential for fat and cholesterol digestion and absorption. Each day the bile acid pool (approximately 3–5 g) cycles through the intestine 6–10 times. The absorption of bile acids by the ileum is very effective and 98–99% of bile acids secreted in the bile are returned to the liver *via* the portal vein. The small amount of bile acids lost each day as fecal acidic steroids are replaced through the conversion of hepatic cholesterol to the primary bile acids, cholic acid, and chenodeoxycholic acid. This catabolism of cholesterol can be as little as 250 mg per day up to 500 mg per day depending on the diet. The bile acids represent the only major catabolic product of cholesterol metabolism and in humans account for some 25–30% of the daily loss of cholesterol from the body.

**Table 1** Average cholesterol metabolism values for a 70 kg adult

<i>Cholesterol pools and flux</i>	<i>Mass</i>
Cholesterol pool (70 kg adult)	160 g
Plasma cholesterol pool	8 g
Dietary cholesterol intake	300 mg day <sup>-1</sup>
Absorption (average 60%)	180 mg day <sup>-1</sup>
Synthesis (12 mg kg-day <sup>-1</sup> )	840 mg day <sup>-1</sup>
Total cholesterol input	1020 mg day <sup>-1</sup>
Bile acid synthesis (=fecal excretion)	250 mg day <sup>-1</sup>
Neutral steroid excretion	770 mg day <sup>-1</sup>

### Very Low-Density Lipoprotein Synthesis

The endogenous pathway for cholesterol transport focuses on the liver with the synthesis and secretion of VLDL particles. Cholesterol in these triacylglycerol-rich particles comes from multiple sources: endogenous synthesis, diet, and plasma lipoproteins. Catabolism of VLDL by LPL leads to formation of intermediate-density lipoproteins (IDL), which can either be taken up by the liver or undergo further metabolism to form LDL. Low-density lipoproteins contain apo-B<sub>100</sub> and account for 60–80% of the plasma cholesterol in most individuals. During lipolysis of VLDL triacylglycerol, the lipoproteins containing apo-B becomes enriched with cholesteryl ester through the plasma CETP-catalyzed net transfer of cholesteryl ester from HDL. This process, termed reverse cholesterol transport, moves cholesterol from extrahepatic tissues to HDL to VLDL-IDL-LDL and eventual uptake by the liver. Some 70% of the LDL degraded each day is degraded by the hepatic LDL receptor pathway.

### Dietary Cholesterol and Plasma Cholesterol

The effect of dietary cholesterol on plasma cholesterol levels has been an area of considerable debate. In 1972 the American Heart Association recommended that dietary cholesterol intake should average less than 300 mg per day as part of a 'heart-healthy', plasma cholesterol-lowering diet. Since that initial recommendation, a number of other public health dietary recommendations in the USA have endorsed the 300 mg daily limit. Interestingly, few dietary recommendations from other countries contain a dietary cholesterol limitation. The evidence for a relationship between dietary cholesterol and plasma cholesterol indicates that the effect is relatively small, and that on average a change of 100 mg per day in dietary cholesterol intake results in a  $0.057 \text{ mmol l}^{-1}$  ( $2.2 \text{ mg dl}^{-1}$ ) change in plasma cholesterol concentrations. Studies have also shown that the majority of individuals are resistant to the plasma cholesterol-raising effects of dietary cholesterol (nonresponders) and have less than the predicted response. In contrast, a segment of the population (estimated to be between 10% and 20%) are sensitive to dietary cholesterol (responders) and exhibit a greater than expected plasma cholesterol response to a change in dietary cholesterol intake. To date there are no defined physiological or clinical characteristics to differentiate responders from nonresponders, but studies suggest that the apo-E phenotype plays a role, as does the clinical condition of combined hyperlipidemia. Data also suggest that sensitivity to dietary cholesterol is associated with sensitivity to dietary fat, and that overall adiposity may also play a role. Although on a population basis the plasma cholesterol response to dietary cholesterol is relatively small, and in most epidemiological analyses not related to hypercholesterolemia, some individuals are sensitive to dietary cholesterol changes and, if hypercholesterolemic, would experience plasma cholesterol reduction with dietary cholesterol restrictions. For the majority, however, dietary cholesterol restrictions have little effect on plasma cholesterol levels.

## Dietary Sources

### Dietary Cholesterol Intake Patterns

Dietary cholesterol intakes in the USA have been declining, from an average of 500 mg a day in men and 320 mg a day in women in 1972 to levels in 1990 of 360 mg a day in men and 240 mg a day in women. This decline arises in part from dietary recommendations to the American public to reduce total and saturated fat intake and to reduce dietary cholesterol daily intake to less than 300 mg, and in part from the increased availability of products with reduced fat and cholesterol content. Major efforts in the early 1970s by public health agencies and advertising emphasized reducing dietary cholesterol as a means to lower plasma cholesterol levels, leading to a high degree of consumer concern regarding cholesterol-containing foods and demand for low-cholesterol products. Today, practically all foods sold in the USA are labeled for their cholesterol content and their percentage contribution to the daily value of 300 mg for cholesterol.

### Major Dietary Sources

The major sources of cholesterol in the diet are eggs, meat, and dairy products. A large egg contains approximately 185 mg of cholesterol and contributes some 30–35% of the total dietary cholesterol intake in the USA. Meat, poultry, and fish contribute 45–50%, dairy products 12–15% and fats and oils 4–6%. In the USA, the range of dietary cholesterol intakes is 300–400 mg per day for men and 200–250 mg per day for women; thus for much of the population the national goal of a dietary cholesterol intake of less than 300 mg a day has already been met.

## Key Points

- Chromium cannot currently be considered an essential element.
- No definitive symptoms of chromium deficiency have been established.
- Chromium supplementation has no effects on body mass or composition.
- Chromium supplementation has no clinically significant effects on the symptoms of insulin resistance or type 2 diabetes.
- Chromium supplementation appears safe at doses of 1 mg/day or less.

## Glossary

**Adequate Intake (AI)** The recommended daily intake of a nutrient estimated to meet or exceed the amount needed to maintain adequate nutrition for most people in a particular life stage and gender group. An AI is established when not enough information is available from scientific research to determine a Recommended Dietary Allowance.

**Estimated Average Requirement (EAR)** A nutrient intake value estimated to meet the requirement of half the healthy individuals in a group.

**Recommended Daily Allowance (RDA)** Average daily level of intake sufficient to meet the nutrient requirements of nearly all (97%–98%) healthy people. RDAs vary by age, gender and whether a woman is pregnant or breastfeeding.

**Total Parenteral Nutrition (TPN)** Nutrition administered into the body through the veins, bypassing the process of eating and digestion, used when patients cannot eat or absorb enough food through tube feeding formula or by mouth to maintain good nutrition status.

**Upper Limit (UL)** Also called the Tolerable Upper Intake level. The largest daily intake of a nutrient considered safe for most people. Intake of more than the UL may be harmful.

## Introduction

In the presence of air and water, trivalent chromium,  $\text{Cr}^{3+}$ , is the stable form of chromium. This is the oxidation state relevant to human nutrition. Hexavalent chromium,  $\text{Cr}^{6+}$ , particularly in the form of chromate or dichromate, is also present in the environment, usually as a result of industrial activity. Chromate and dichromate are kinetically stable but thermodynamically unstable, which is responsible for their toxic, mutagenic, and carcinogenic properties when inhaled. Over the last thirty years, the status of chromium (as  $\text{Cr}^{3+}$ ) has gone from being an essential element for which supplementation was suggested to being an essential trace element whose need would be met by a well-balanced diet to not being considered an essential element for lack of convincing evidence. Despite its current status and the lack of clear demonstration of any beneficial effects from chromium supplementation,

chromium-containing supplements annually generate hundreds of million dollars in sales as these supplements are available over the counter in numerous forms including pills, chewing gums, sports drinks, and nutrition bars.

### Intake guidelines

The Institute of Medicine of the National Research Council of the Food and Nutrition Board of the National Academies of Science (US) established the first Estimated Safe and Adequate Dietary Intake (ESADDI) for chromium in 1980 at 50–200 µg/day for adults. Insufficient data existed for to set an Estimated Average Requirement (EAR) and consequently to develop a Recommended Daily Allowance (RDA). The ESADDI was left unchanged by the Council in 1989. However, after 1980 several studies found levels of chromium consumption for adults below 50 µg per day although equilibrium (positive net Cr balance) was achieved at these levels (Vincent and Brown, 2018).

Finally, in 2001, the Institute of Medicine reaffirmed insufficient evidence existed to set an EAR or consequently a RDA for chromium but found that the previous recommendations required modification. Consequently, AI of 35 µg per day and 25 µg per day for young men and women, respectively, were set based on estimated mean intakes (Institute of Medicine, 2001). (The AI is a replacement for the ESADDI). As an AI is more conservative than a RDA, the AI means that more than greater 98% of adult Americans would be chromium sufficient at ~30 µg chromium per day; hence, essentially all Americans are not chromium deficient. Thirty micrograms chromium per day is approximately the amount of chromium found in both nutritionist-designed and self-selected American diets, a function of the ubiquitous presence of chromium in foods at very low concentrations. More recently in 2014, the Panel on Dietetic Products, Nutrition and Allergies of the European Food Safety Authority determined “there is no evidence of beneficial effects associated with chromium intake in healthy subjects” and “the setting of an Adequate Intake for chromium is also not appropriate” (European Food Safety Authority, 2014).

The United States and Canada need to reexamine the status of chromium as the 2001 Institute of Medicine recommendations are outdated.

### Lack of symptoms of deficiency

The reason that the chromium requirements and status of chromium have been modified with time is no symptoms of chromium deficiency have been definitively established (European Food Safety Authority, 2014). The most commonly cited support for chromium potentially being an essential element is case studies of patients who developed insulin resistance and received total parenteral nutrition (TPN) supplemented with chromium. However, the evidence is rather limited, being less than 10 case studies reporting beneficial effects (Vincent, 2017). In these case studies, subjects on TPN received ~5–16 µg of chromium per day before their TPN was supplemented with chromium. Given the average Adequate Intake of 30 µg chromium per day and assuming 1% of chromium is absorbed, an individual on a typical American diet would have ~0.3 µg of chromium enter the bloodstream daily. Thus, subjects (before the TPN was supplemented with chromium) were receiving several fold more chromium than should be necessary based on the AI and cannot be considered to have been chromium deficient. Subjects in the studies treated with TPN supplemented with chromium received an additional 12–250 µg of Cr per day. The supplemented diet clearly provided supra-nutritional, rather than nutritionally relevant, quantities of chromium. Additionally, care must be taken in interpreting these case studies as the conditions of the subjects before entering the studies varied considerably as did their time on TPN, the amount of chromium received, and several other variables.

Thus, no relationship can be established between the results of these case studies and chromium deficiency, although the studies could hint at a pharmacological effect in humans with altered glucose or carbohydrate metabolism (Vincent, 2017). In analyzing the results of studies of chromium supplementation of TPN patients, the European Food Safety Authority determined that “it is unclear on the basis of these case reports whether deficiency of chromium could be considered the only cause of glucose intolerance in these patients, whether deficiency of chromium has occurred in these patients, and whether chromium deficiency occurs in healthy populations” (European Food Safety Authority, 2014).

Chromium holds a similar status in Europe in terms of farm animal nutrition. The Panel on Additives and Products or Substances Used in Animal Feed (FEEDAP) in 2009 determined that “No symptoms of Cr deficiency in animals have been demonstrated in experimental conditions or observed in the field. The FEEDAP Panel considers that no evidence exists of essentiality of Cr(III) as trace element in animal nutrition and consequently no Cr<sup>3+</sup> requirements could be established (EFSA Panel on Additives and Products or Substances Used in Animal Feed, 2009).”

### Body mass

During the late 1980s and early 1990s, advertisements touting chromium, particularly as chromium picolinate, became commonplace in popular media, rocketing sales of chromium dietary supplements. However, because of the lack of “competent and reliable scientific evidence”, the Federal Trade Commission (FTC) of the United States in 1997 ordered entities associated with the nutritional supplement chromium picolinate to stop making several representations (Federal Trade Commission, 1997). These representations include that chromium picolinate reduces body fat; causes weight loss; chromium picolinate causes weight loss without dieting or exercise; chromium picolinate causes long-term or permanent weight loss; chromium picolinate increases lean body

mass or builds muscle; chromium picolinate increases human metabolism; chromium picolinate controls appetite or craving for sugar; chromium picolinate reduces serum cholesterol; chromium picolinate lowers elevated blood sugar levels; chromium picolinate is effective in the treatment or prevention of diabetes; or 90% of US adults do not consume diets with sufficient chromium to support normal insulin function, resulting in increased risk of obesity, heart disease, elevated blood fat, high blood pressure, diabetes, or some other adverse effect on health.

A recent review of the effects of chromium on body mass and body composition concluded “the preponderance of experimental findings emphasizes the conclusion that Cr(III) supplementation, regardless of dosage ( $\sim 200$  to  $\sim 1000$   $\mu\text{g/d}$ ), is neither a significant promoter of body mass loss nor a facilitator of body fat loss or body mass accretion of adults. Only studies with questionable experimental quality report beneficial changes in body composition after Cr(III) supplementation” (Lukaski, 2018).

## Dietary sources

Chromium is present in essentially all foods but at very low concentrations. Dependable tables of chromium contents of foods are lacking as insufficient data exists to determine whether the chromium content of foodstuffs measured to date are truly reflective or dependent on locality and other variables. During the processing of food, particularly in stainless steel (normally  $\sim 10$ – $40\%$  chromium) equipment, the concentration of chromium increases; thus, the majority chromium in some foods may come from processing. Foods reported to rich in chromium (i.e.,  $>100$  ppb) include broccoli, black pepper, and certain beers; however, the reported contents for vegetables must be considered carefully as the amount of chromium coming from soil contamination can vary. The low concentrations of chromium in food, the ease of contamination, and the low suggested dietary requirement for chromium make preparation of a low-chromium diet difficult. Given the amount of chromium in the diet that comes from modern processing, the chromium intake of early humans should have been limited; thus, humans possibly could have evolved on a diet containing significantly less chromium than the current diets of people of developed nations (upon which the AI's are based).

## Digestion

Understanding any potential biological effects from dietary chromium requires establishing how chromium is transported and distributed in the body. Approximately only  $\sim 1\%$  of chromium ingested orally is absorbed, with the rest lost through the feces. Chromium is absorbed from the gastrointestinal tract by passive diffusion. Chromium supplements are believed to breakdown under the acidic conditions in the stomach, explaining the similar degree of absorption of chromium from organic complexes of chromium (e.g., chromium picolinate and chromium nicotinate) to that of chromium from inorganic chromium salts such as  $\text{CrCl}_3$  (Vincent and Edwards, 2018). This also explains why supplements with varying solubilities ( $\text{CrCl}_3$  is soluble in water, while chromium picolinate is only slightly soluble in water and chromium nicotinate is insoluble) have similar degrees of absorption. However, no studies have followed the forms of chromium present during digestion, although double radiolabeling experiments ( $^1\text{H}$  and  $^{51}\text{Cr}$ ) have shown that chromium and picolinate from chromium picolinate are rapidly divorced and have different fates in the gastrointestinal tract. Intestinal perfusate studies suggest while chromium is passively absorbed it could be actively transported out of the intestinal cells, as  $\sim 94\%$  of the chromium entering the cells was rapidly cleared from the cells (leaving only  $\sim 6\%$  behind to be stored) (Dowling et al., 1989). However, no membrane transport protein is known for chromium; thus, the mechanism for this potential transport is not known.

## Transport

The transport of chromium after absorption has been an active area of research in recent years.  $\text{Cr}^{3+}$  is generally believed to be transported from the bloodstream to tissues by the iron transport protein transferrin.  $\text{Cr}^{3+}$  is proposed to be transported from the tissues back to the bloodstream for elimination via the urine by the peptide low-molecular-weight chromium-binding substance (LMWCr). Notably, questions have arisen about the proposals, and not all data appears to be consistent with these proposals. The movement of  $\text{Cr}^{3+}$  by transferrin followed by LMWCr has been proposed to function as a chromium detoxification pathway and to be potentially be associated with the pharmacological action of chromium at high doses (Vincent and Edwards, 2018).

When provided orally to rats to rats, over  $80\%$  of the chromium in the bloodstream is bound to transferrin. Under physiological conditions, transferrin selectively binds  $\text{Fe}^{3+}$ , as the metal-binding sites have evolved to bind metal ions with large charge-to-size ratios. Transferrin possesses two lobes, the N-terminal and C-terminal lobes, sharing a significant degree of sequence homology; each lobe contains a ferric ion-binding site. In humans, transferrin has the potential to bind metal ions other than  $\text{Fe}^{3+}$  as the protein is normally about  $30\%$  saturated with  $\text{Fe}^{3+}$ . The binding of manganese and chromium, as their trivalent ions, may be physiologically relevant (Vincent and Love, 2012).

Cr-transferrin movement has been followed using  $^{51}\text{Cr}^{3+}$ -labeled transferrin administered intravenously to rats. Introduction of the labeled transferrin initiates a rapid movement of chromium from the bloodstream into the tissues (Clodfelder and Vincent, 2005). More than  $50\%$  of the chromium is transported to the tissues within  $30$  min resulting in the amount of labeled chromium in the tissues being maximal  $\sim 30$  min after injection. The movement from the bloodstream to the tissues is insulin-sensitive; plasma membrane recycling of transferrin receptors is sensitive to insulin as increases in insulin result in a stimulation of the movement of transferrin receptors from vesicles to the plasma membrane. The subsequent decreases in tissue chromium over time were

mirrored by increases in urine chromium. Consequently, transferrin, in an insulin-dependent fashion, can deliver chromium to tissues from which chromium is ultimately excreted in the urine. The removal of  $^{51}\text{Cr}$  from the blood is faster than the appearance of  $^{51}\text{Cr}$  in the urine; the lag in time indicates that the Cr-transferrin in the blood and chromium in the urine are not in direct equilibrium and that intermediates in the transport of chromium must be involved. One intermediate, LMWCr, has been identified, and recent studies of the binding and release of chromium from transferrin have suggested some of the intermediate steps.

Yet, the *in vivo* transport of chromium by transferrin has been questioned. The largest questions arise around the rate of chromium binding and release.  $\text{Cr}^{3+}$  has a  $d^3$  electron configuration in its normal octahedral or pseudo-octahedral coordination environment. This makes exchange of ligands at the metal center slow compared to those of most other first row transition metal ions. Transferrin binds chromium concomitantly with an equivalent of (bi)carbonate, making the binding of chromium first order in the concentration of bicarbonate; in the presence of approximately 25 mM bicarbonate (as in the bloodstream),  $\text{Cr}^{3+}$  binds tightly to transferrin in minutes. In the absence of added bicarbonate, loading of transferrin with  $\text{Cr}^{3+}$  requires up to two weeks. Whether  $\text{Cr}^{3+}$  loss from transferrin is fast enough to be physiologically relevant has been a question. Transferrin delivers metal ions to cells via endocytosis. While release of  $\text{Cr}^{3+}$  from transferrin is slow,  $\text{Cr}^{3+}$  is rapidly released at the pH of endosomes (pH  $\sim 5.5$ ) from the transferrin/transferrin receptor complex (Edwards et al., 2020). How  $\text{Cr}^{3+}$  moves from the endosome to the rest of the cell is unknown; however, a recent study has shown at pH 5.5 that LMWCr binds  $\text{Cr}^{3+}$   $\sim 250$ -fold faster in the presence transferrin/transferrin receptor complex, making the peptide a candidate for the carrier of  $\text{Cr}^{3+}$  across the endosomal membrane.

LMWCr is an oligopeptide 10 or 11 amino acids in length composed of only four different amino acids (glutamate, aspartate, glycine, and cysteine) with the majority of amino acids having carboxylate side chains. The first seven residues have been cleaved from the rest, and the resulting peptide has been sequenced yielding the sequence EEEEGDD. How the remaining glycine and cysteine residues are attached is unknown. LMWCr tightly and cooperatively binds four  $\text{Cr}^{3+}$  ions. Spectroscopic studies suggest that the chromic ions comprise an anion-bridged multinuclear assembly supported by carboxylates from the oligopeptide (Vincent and Edwards, 2018).

The intravenous injection of rats with  $^{51}\text{Cr}(\text{III})_2$ -transferrin results in the appearance of LMWCr loaded with  $^{51}\text{Cr}$ . LMWCr appears in the bloodstream where it is the only form of Cr other than transferrin and in the urine, where it is the only Cr-containing species. Approximately 50% of the  $^{51}\text{Cr}$  appeared in the urine within 6 h of injection of Cr-transferrin into the tail vein of rats in the absence of added insulin; insulin treatment concurrent with injection of  $^{51}\text{Cr}$ -labeled transferrin results in approximately 80% of the label appearing in the urine within 180 min, an appreciable enhancement in the movement of Cr from the blood to the tissues to the urine (Clodfelder and Vincent, 2005). LMWCr appears to be the mechanism by which Cr is bound in the tissues for elimination via the bloodstream and the urine.

## Toxicity

No Upper Limit (UL) could be established for trivalent chromium ion in 2001 by the Institute of Medicine (Institute of Medicine, 2001); no adverse effects could be convincingly associated with excess intake of chromium from food or supplements. In turn in 2003, the Scientific Committee on Food (SCF) found insignificant evidence to set an UL. Although the number of studies available from which to draw data was limited, no evidence of adverse effects was found to be associated with supplemental chromium intake up to a dose of 1 mg per day; this recommendation was specifically for sources of  $\text{Cr}^{3+}$  other than Cr picolinate (Scientific Committee on Food, 2003). Also in 2003, the Food Standard Agency (United Kingdom) has determined that doses up to 10 mg of chromium daily should be safe for humans (Expert Group on Vitamins and Minerals, 2003).

In 2005, the US FDA found that use of chromium supplements was safe up to 1 mg chromium per day, the highest amount used in clinical trials (Food and Drug Administration, 2005). A Tolerable Daily Intake (TDI) of 300  $\mu\text{g}$  chromium per kilogram body mass daily was derived from the lowest No Observed Adverse Effect Level (NOAEL) identified in a chronic oral toxicity study in rats by the EFSA Panel on Contaminants in the Food Chain in 2014 (CONTAM Panel) (EFSA Panel on Contaminants in the Food Chain, 2014).

The use of chromium supplementation is not without its concerns. For example, the use of supplemental chromium in TPN solutions has been questioned as subjects on TPN solutions providing 10 or more micrograms chromium per day accumulate chromium. As a result, the American Society for Parenteral and Enteral Nutrition (ASPEN) has made examining chromium requirements in parenteral nutrition their number one urgent priority (Vanek et al., 2012). To put the situation into perspective, TPN solutions currently provide 10–15  $\mu\text{g}$  chromium per day in the United States. Using the average AI for men and women of 30  $\mu\text{g}$  chromium per day and an  $\sim 1\%$  absorption efficiency for chromium, humans would have  $\sim 0.3$   $\mu\text{g}$  chromium entering their bloodstream daily; as a result, TPN solutions would provide to the bloodstream  $\sim 33$ –50 times more chromium than a standard diet. ASPEN has recommended that TPN without added chromium should be made available although no reported cases of chromium toxicity in patients on long term TPN are known.

While no significant health concerns have been clearly identified for commercial chromium supplements at current doses, questions about the use of chromium, in particular chromium picolinate, have been raised. The redox potential of Cr(III) shifts when bound to ligands binding through imine nitrogen atoms. Compounds with 4 or more imine nitrogens bound to Cr(III) are susceptible to undergoing oxidation to deleterious Cr(IV) and Cr(V) species, making the compounds clastogenic and toxic. Chromium picolinate with three coordinated imine nitrogens has a redox potential near the borderline for being susceptible to oxidation. Cell culture study and *in vivo* studies using mammals where the compound was administered intravenously or using fruit flies

suggest it is toxic and clastogenic, mutagenic, and possibly carcinogenic (Vincent, 2013). Yet, a study commissioned by the National Toxicology Program (National Institutes of Health) has found that providing chromium picolinate up to 5% of the diet of male and female rats and mice for 2 years had no conclusive deleterious health effects (Stout et al., 2009). This discrepancy between the studies probably arises from chromium picolinate dissociating in the gastrointestinal tract when provided orally. In the cell culture study and *in vivo* studies, the chromium picolinate molecule potentially reached cells intact (Vincent, 2013). Consequently, the supplement should not be used intravenously. The potential for deleterious effects probably arises from its redox potential compared to other current forms of supplemental chromium, which could possibly allow the chromic center of chromium picolinate to undergo redox chemistry *in vivo*.

## Chromium supplementation and human health

Currently chromium is not recommended for any clinical uses. Simply, no consistent dose-response relationships between chromium and a beneficial health outcome in humans have been established. One issue is that clinical studies have focused primarily on type 2 diabetic subjects, tend to have small subject pools, and tend not to be well designed. Agencies of the United States government have commissioned two meta-analyses on whether chromium affects symptoms of type 2 diabetes; both generated inconclusive results. In 2002 with funding from the Office of Dietary Supplements of the National Institutes of Health, only four quality studies were identified for analysis (Althuis et al., 2002). The second, published in 2007 and funded by the Department of Health and Human Services, identified 18 studies. The authors concluded Cr supplementation “may have a modest effect” on glucose metabolism in type 2 diabetics but that “large heterogeneity and the overall poor quality limit the strength of our conclusions” (Balk et al., 2007). Unfortunately, the positive effects of greatest magnitude used in the analysis came from the 12 studies ranked lowest in quality. Additionally, a trend was observed that commercial industry-sponsored studies were more likely to observe beneficial effects. A thorough review of the effects of chromium in human disease, focusing on recent meta-analyses, determined “the data from meta-analyses and [randomized clinical trials] utilizing Cr interventions continue to be mixed compared to more effective results with certain other therapies for the same diseases” as “the quality of the [randomized clinical trials] in the existing meta-analyses left much to be desired” (Costello et al., 2018).

The US Food and Drug Administration (FDA) received a petition in December 2003 from the nutraceutical company Nutrition 21 for eight qualified health claims. The claims were chromium picolinate may reduce the risk of insulin resistance; chromium picolinate may reduce the risk of cardiovascular disease when caused by insulin resistance; chromium picolinate may reduce abnormally elevated blood sugar levels; chromium picolinate may reduce the risk of cardiovascular disease when caused by abnormally elevated blood sugar levels; chromium picolinate may reduce the risk of type 2 diabetes; chromium picolinate may reduce the risk of cardiovascular disease when caused by type 2 diabetes; chromium picolinate may reduce the risk of retinopathy when caused by abnormally high blood sugar levels; and chromium picolinate may reduce the risk of kidney disease when caused by abnormally high blood sugar levels. At the conclusion of its review, the FDA issued a letter of enforcement discretion allowing only one qualified health claim for the labeling of dietary supplements stating “One small study suggests that chromium picolinate may reduce the risk of type 2 diabetes. FDA concludes that the existence of such a relationship between chromium picolinate and either insulin resistance or type 2 diabetes is highly uncertain” (Food and Drug Administration, 2005).

In recent years, the American Diabetes Association has been consistent in its position: “there is insufficient evidence to support the routine use of herbal supplements and micronutrients, such as ... chromium, to improve glycemia in people with diabetes” and “There is no clear evidence that dietary supplementation with vitamins, minerals (such as chromium and vitamin D), herbs, or spices ... can improve outcomes in people with diabetes who do not have underlying deficiencies, and they are not generally recommended for glycemic control” (American Diabetes Association, 2021).

Most recently, case studies examining intravenous infusions of chromium (generally 3 µg/h) as a treatment for glucose intolerance found chromium administration reduced insulin requirements for subjects with hyperglycemia. These studies may be suggestive of a pharmacological effect of chromium at supra-nutritional levels. However, drawing any firm conclusions is not possible based on the small number of subjects to date (Vincent, 2017). These case studies along with observation beneficial effects of chromium supplementation in rodent studies require supra-nutritional doses of chromium could suggest beneficial effects from chromium supplementation in humans are possible at higher doses than have been used to date in clinical trials. However, clinical trials using >10 mg chromium per day will be required before any definitive conclusions regarding potential beneficial effects of pharmacological doses of chromium in humans could be reached other than that no clinical effects are reliably and reproducibly reported at doses of 1 mg chromium per day.

## Pharmacological effects in rodents

Rodent models of diabetes and insulin resistance have been utilized to examine the effects of chromium supplementation (Vincent, 2014; Krejpcio, 2018). Studies suffer from the use of varying chemical forms of chromium supplements, the range of dosages utilized, the range of duration of treatment, and the numbers of different animal models examined.

While still preliminary, dividing these studies by the type of model utilized appears to be useful. Three models examined develop peripheral insulin resistance arising from related mutations; the JCR:LA-cp, Zucker obese, and Zucker diabetic fatty rats all have

mutations of the leptin receptor generating peripheral insulin resistance. When chromium is administered at a young age to these models, it generally has no effect on body mass and food intake. Chromium administration has little, if any, effect on fasting blood glucose levels but lowers glycated hemoglobin levels. Chromium administration also appears generally to be beneficial to lipid metabolism, lowering total cholesterol levels; however, effects on other lipid variables are inconsistent. In contrast, in Goto-Kakizaki rats, possessing hepatic insulin resistance opposed to peripheral insulin resistance, chromium supplementation does not lead to any significant effects. These conflicting results between the two types of genetic models might suggest the effects of chromium supplementation are primarily derived from the skeletal muscle (Vincent, 2014).

The effects of chromium supplementation of chemically induced insulin resistance models, most notably rats treated with streptozotocin or alloxan, have also studied. The results of chromium supplementation are too inconsistent to allow firm conclusions to be drawn. Finally, dietary models have also been examined. Chromium administration to rats on high-sugar diets results in increased insulin sensitivity. Similarly rats on high-fat diets generally have increased insulin sensitivity, although for both diets conflicting results have been observed. Several studies have looked at the effects of chromium supplementation on rats on high-fat diet that were also treated with streptozotocin. While these studies are similar in observing reduced cholesterol and triglycerides levels, other results, most notably fasting glucose and insulin levels and body mass changes, are not consistent (Vincent, 2014; Krejpcio, 2018).

These rodent studies have ultimately utilized pharmacologically, rather than nutritionally, relevant doses of chromium. This was demonstrated in a seminal study of “low-chromium” diets (Di Bona et al., 2011). Rats were provided the AIN-93G purified diet with no added chromium in the mineral mix (elemental analysis revealed less than 20 µg of chromium per kilogram of diet, the lowest quantity of chromium in a rat diet examined to date) and were kept in cages with no access to metal for six months. (The chromium content of this diet is similar to that of a human consuming the AI of 30 µg chromium daily). No differences in body mass, insulin sensitivity, or response to a glucose challenge were observed compared to rats on the complete AIN-93G diet (containing 1000 µg chromium per kilogram of diet). Adding additional Cr<sup>3+</sup> to the diet (200 or 1000 µg/kg) also had no effects on body mass but resulted in increased insulin sensitivity as measured by reduced areas under the curve for insulin concentrations in glucose tolerance tests. Consequently, insulin sensitivity was shown to increase as a function of added chromium but required supra-nutritional doses. In fact, this study suggests rats on the AIN-93G are already obtaining enough chromium to have beneficial effects on insulin sensitivity from supplementation. Thus, the basal chromium levels in rodent diets must be considered when designing experiments, and effects from supplemental Cr could be difficult to detect on top of beneficial effects from high chromium content in the basal diets. The Cr content of the AIN-93 diets needs to be reexamined, and Cr probably should be removed from the mineral mix.

### Molecular mechanism(s) of action

Several pathways have been proposed by which a chromium-containing biomolecule could manifest effects on insulin sensitivity. Research results both in *in vitro* and *in vivo* systems are contradictory, such that the state of the field is far from clear (Vincent, 2013). Attention has been focused on two mechanisms: the insulin signaling cascade, most specifically insulin receptor and Akt (protein kinase B), and on cholesterol synthesis and metabolism. Recently, mechanisms involving oxidative stress and cytokine generation have also been suggested (Nair, 2018).

One major concern with many *in vitro* studies is the forms of chromium utilized. Most commercial chromium supplements are believed to degrade in the gastrointestinal tract, so that the cells of the body never encounter the chromium-containing molecule comprising the supplement. For example, the best-selling supplement, chromium picolinate, is apparently toxic to cells *in vitro* but harmless at nutritional doses when given orally. Thus, the effects of adding the commercial supplements directly to cultured cells could have drastically different effects on insulin sensitivity, and the mechanisms thereof, than those of chromium *in vivo*, as presumably cells would normally be exposed to chromium as a complex with transferrin. The use of transferrin, which appears to be the form in which Cr<sup>3+</sup> is primarily transported into cells, would appear optimal, but no studies using Cr-containing transferrin to look for effects on insulin signaling in cultured cells have been reported. Additionally, control experiments using the free ligands, e.g., picolinic acid, are not often performed, leaving in doubt whether any observed effects arise from chromium, the chromium complex, or the free ligand.

*In vivo* studies have suggested potential targets for the origins of the effects of chromium at a molecular level; yet, results are not consistent, perhaps in part, because different chromium compounds in different doses in different animals and models have been utilized. One of the most notable studies because of its design suggested a role of chromium directly in the insulin signaling pathway. Cefalu and coworkers (Wang et al., 2006) observed increased phosphorylation of insulin receptor substrate-1 (IRS-1) tyrosine and kinase activity of IRS-1–associated phosphoinositol-3 (PI-3) in skeletal muscle after insulin stimulation in obese JCR:LA-cp rats administered chromium as chromium picolinate compared with obese controls. The enhanced signaling occurred without changes in the concentration of IRS-1, Akt, or PI-3 kinase; however, levels of phosphotyrosine phosphatase 1B, (PTP 1B) that dephosphorylates insulin receptor, were reduced. Reproduction of this study, potentially with another diabetes model, could be most significant to the field. Sreejayan and coworkers (Dong et al., 2008) found supplementation of sucrose-fed mice with chromium tris(phenylalanine) significantly enhanced insulin-stimulated Akt phosphorylation and membrane-associated glucose transporter-4 (Glut-4) in skeletal muscles. Cefalu and coworkers (Cefalu et al., 2002) also have found increased insulin-stimulated membrane-associated Glut-4 in JCR:LA-cp rats administered chromium as chromium picolinate. Yet, other studies

are not consistent with either of these sets of results, including observing changes in protein phosphorylation without insulin stimulation, observing changes in protein concentration, and failing to observe changes in PTP 1B levels or activity; however, a consensus does seem to appear that chromium supplementation augments insulin-dependent Glut-4 translocation under insulin resistant conditions (Hua et al., 2012). Increases in insulin-dependent Glut-4 translocation have also been observed in several *in vitro* studies as well and appears to be the most consistently observed effect from chromium administration.

## Conclusion

Currently, evidence does not support chromium being an essential trace element so that setting dietary guidelines is not appropriate. However, dietary chromium does not appear to have any toxic effects. Despite the lack of toxicity, chromium supplementation is not recommended for healthy individuals or individuals with any medical condition. Randomized clinical trials using higher doses of chromium than in current nutritional supplements potentially are required to determine whether chromium might have beneficial effects at supra-nutritional doses.

## Conflict of interest

The author has no known conflict of interest to acknowledge.

### Glossary

**Carbonium ion** A carbon ion with a positive charge.

**Chloroplasts** Light energy sequestering organelles in photosynthetic plants.

**Cytosol** The internal milieu of a cell.

**Endoplasmic reticulum** An internal cell compartment enclosed by membranes.

**Hemoglobin** The major iron protein in the blood.

**Noncarbonaceous** Not having the element carbon in the structure.

**Peroxisomes** An internal compartment in a cell.

**Ruminants** Cattle and such where a four-chambered rumen replaces the stomach.

**Surrogate metal** A metal that may act as a substitute.

**Transferrin** A protein that transfers iron to the tissues.

**Transition series** Belonging to a certain division of the Periodic Table of Elements.

### Introduction

The word ‘inorganic’ implies a noncarbon component. Such is true of inorganic cofactors, which consist mainly of metal ions and noncarbonaceous components. More importantly, one-third of all the enzymes require an inorganic cofactor for function. Their role

is by no means minor. Enzymes that exchange electrons between substrates or quench dangerous free radicals or reactive oxygen species use metal ion cofactors to lessen the risk of irreversibly modifying the structure of the enzyme. Some cofactors perform mainly structural roles; for example, stabilizing the overall shape of the enzyme so it is poised to act on a substrate. Its more common, however, for the cofactor to engage the substrate directly and assist the catalysis of the ensuing reaction. More recently attention has turned to metal ions as modulators of genetic expression. These understandings have promoted the view that cofactors may be more than just passive components in biological systems. Here, we define a cofactor as any nonenzyme component that promotes the catalytic prowess of an enzyme. The definition emphasizes function rather than structure. This article will expand the discussion on enzyme cofactors by focusing on the properties of their 'inorganic' counterparts.

## History

The nutritional history of the mineral elements, unlike the vitamins, had an early focus on domestic livestock foraging on mineral-poor soils. Typical symptoms were the crimping of wool in sheep, aortic rupture in pigs and cattle, and decrease in myelin in brains of newborn lambs. Symptoms were lessened sharply by supplementing the feed with salts of metal ions such as  $\text{CuSO}_4$ ,  $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2$ ,  $\text{ZnCl}_2$ . Reversing symptoms and reestablishing optimal growth to livestock provided the first solid evidence for the essentiality of metals in nutrition. Thus, no longer were metal ions in the blood and tissues of animals and humans considered a sign of toxic exposure. With this view instead came the realization that metals can be indispensable elements to the animal's health. An early study by Hart *et al.* showed that rebuilding hemoglobin to normal levels in an anemic rat required both iron and copper. Others showed a similar copper-iron interaction in humans. Coupled with the advent of semipurified diets in that same era, the science of nutrition made major steps forward in defining the importance of metal ions in biological systems and many of the studies tended to focus on their role with enzymes. The past decades have witnessed a tremendous interest in metal ions as cofactors and as regulators of enzyme activity in tissues and organs. These studies have focused not only what they do but also on how the system is able to adroitly handle potentially dangerous nutrients present in macro and micro quantities and ensure that their functionality and the organism's safety are realized.

## Macro- Versus Microminerals

Of the 27 nutritionally essential elements in the Periodic Table, nearly half are minerals, more specifically metal ions. Because they vary in quantity both in the diet and within the organism, minerals are divided into two major classes, the macro- and microminerals. A list of some of the more prominent ones in each class is shown in [Table 1](#). Macrominerals, which include sodium, potassium, magnesium, and calcium tend to be present in larger quantities both in the diet and the tissues. As such they perform functions that are attuned to their bulk; functions such as regulating osmotic balance, or forming the matrix of the skeleton, or providing high energy gradients to drive membrane transport. In contrast, the microminerals as their name implies are present in very small amounts in the tissues and have a much lower requirement for adequacy. Despite their scarcity, as a class the microminerals make up the bulk of inorganic cofactors. The reason for this will be made clear below (*see* Metal-activated Versus Metalloenzymes). This class, which is also referred to as trace elements or trace metals, includes iron, zinc, copper, manganese, etc. ([Table 1](#)). All of those mentioned in the table are known to perform cofactor functions with enzymes.

In determining their role with enzymes, it is important to realize that most of the microminerals make up the 3d transition series of elements in the Periodic Table of Elements. As transition metals, they can exist in multiple valence states and are capable of forming specific geometric complexes with proteins. More importantly, perhaps, the multivalency common with many of the micro metal ions permits them to exchange electrons between substrate and cofactor. Nonmetal microminerals such as selenium also has this property. In contrast nearly all metal ions in the macromineral category ( $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ) are monovalent and are not capable of donating or accepting electrons ([Table 1](#)).

Another important property of transition metals is the ability to bind firmly to the structure of the enzyme. Binding is generally through coordinate covalent bonds and exhibits a specific geometric pattern ([Figure 1](#)). The precision of the angles and distances in the binding pocket are a basis for pairing a particular metal with the enzyme. Macrominerals have more of a tendency to engage an enzyme by ionic attraction and thus their binding to the enzyme surface is much weaker. The differences in these two properties carries over to classifying inorganic cofactors on the basis of activation by the metal or having the metal be an integral part of the enzyme's structure.

## Metal-activated Versus Metalloenzymes

Freedom of movement carries over to the strength of binding when the mineral (as a biometal) engages the structure of an enzyme. Because biometals in the macromineral class tend to form bonds that are easily broken, the biometal exists in a state of equilibrium with the enzyme. Enzymes that use weakly bound cofactors are referred to as metal-activated; a term that signifies the enzyme can be primed to greater activity by adding its metal ion cofactor. Because the metal cannot be bound in a more permanent way, metal-activated enzymes typically lose activity during purification. An example is pyruvate kinase, which has a specific requirement for  $\text{K}^+$

**Table 1** Examples of inorganic cofactors

	<i>Stable biological form or valence</i>
<i>Macrominerals</i>	
Sodium	$\text{Na}^+$
Potassium	$\text{K}^+$
Calcium	$\text{Ca}^{2+}$
Magnesium	$\text{Mg}^{2+}$
Chloride	$\text{Cl}^-$
Phosphate	$\text{HPO}_4^{2-}$
<i>Microminerals</i>	
Iron	$\text{Fe}^{2+}$ , $\text{Fe}^{3+}$
Zinc	$\text{Zn}^{2+}$
Copper	$\text{Cu}^+$ , $\text{Cu}^{2+}$
Manganese	$\text{Mn}^{2+}$ , $\text{Mn}^{4+}$ , $\text{Mn}^{5+}$
Cobalt	$\text{Co}^+$ , $\text{Co}^{2+}$ , $\text{Co}^{3+}$
Molybdenum	$\text{MoO}_2^{2+}$ , $\text{MoO}_4^{2-}$
Nickel	$\text{Ni}^+$ , $\text{Ni}^{2+}$

**Figure 1** Some common geometries of metal complexes.

and is inactivated by dialysis (diffusion through a semiporous membrane). Another example is the class of enzymes referred to as kinases. These enzyme transfer the terminal phosphate group from ATP to the substrate, a reaction that requires  $\text{Mg}^{2+}$  to activate the substrate ( $\text{Mg}^{2+}$ -ATP).

In contrast, enzymes that have the metal ion bound firmly are referred to as metalloenzymes. Such enzymes have the metal ion bound mainly through coordinate covalent bonds. Because of the tight binding the metal ion is basically a firm fixture of the protein's structure. With few exceptions, metals in the micromineral class fit into the picture as cofactors for metalloenzymes. Tight binding precludes loss of the metal ion by dialysis or loss to weakly dissociating agents. Metal ion chelators with a strong affinity for the metal, however, can out-compete the enzyme for the metal ion and render the enzyme inactive. As prosthetic groups, metals in metalloenzymes have a stoichiometric relationship (metal ion–enzyme protein ratio expressed as a whole integer) with the enzyme and are seldom primed to greater activity by adding more metal ion to the enzyme. Spatial geometry is also a concern. Examples of the more common geometrical arrangements are shown in **Figure 1**. For metals in the first transition series one takes note of the  $3d$  orbitals. Examples of both classes of enzymes are shown in **Table 2**.

An exception to note in the table is selenium. Because selenium has properties similar to sulfur, selenium can replace sulfur in the structure of amino acids that make up the enzyme's structure. Thus, when functioning as a cofactor, selenium is present as selenocysteine and selenomethionine and not as elemental selenium coordinated to the protein structure. Another exception to note is in the enzyme  $\text{Cu}_2$ ,  $\text{Zn}_2$  superoxide dismutase. On rare occasions an enzyme may require more than one metal ion to perform catalysis. Other than those with Zn, enzymes and proteins with first transition series metal ions tend to be highly colorful. Consider, for example the beautiful red color of hemoglobin (iron), the green of chlorophyll or the blue color of ceruloplasmin (whose name means heavenly blue) associated with copper. **Table 2** gives some examples of metalloenzymes and the specific metal each has bound to the structure.

**Table 2** Metal-activated enzymes and metalloenzymes

<i>Metal or metal cofactor</i>	<i>Enzyme</i>	<i>Function</i>
Metal-activated enzymes		
K <sup>+</sup>	Pyruvate kinase	Synthesize pyruvate
Mg <sup>2+</sup>	Hexokinase	Phosphorylate glucose
–	DNAase	Cleave DNA
–	RNAase	Cleave RNA
–	ATPase	Cleave ATP
Metalloenzymes		
Cu <sup>2+</sup> , Zn <sup>2+</sup>	Superoxide dismutase	Destroy superoxide anion
Fe	Catalase	Destroy H <sub>2</sub> O <sub>2</sub>
Zn	Alcohol dehydrogenase	Metabolize alcohol
–	DNA polymerase	Synthesize DNA
Mn	Pyruvate carboxylase	Synthesize oxaloacetate
–	Arginase	Synthesize urea
Ca	Alpha amylase	Cleave glycogen, starch

## Individual Metal Cofactors

### Macrominerals

Although their presence in the diet and within the system far exceeds that of the microminerals, the macrominerals as a whole are not the category of abundance when considering enzyme cofactors. Examples of some of the more familiar are:

#### Sodium

As a monovalent ion, Na<sup>+</sup> is generally not considered a cofactor because one has yet to demonstrate an enzyme whose catalysis depends strictly on sodium ions. Sodium-activated enzymes often respond to surrogate metal cofactors such as Li<sup>+</sup> or even divalent cations. Sodium ions, however, form a major class as cotransporters for a series of transport proteins referred to as solute-linked carriers. Working with transporters for amino acids and sugars, sodium ion gradients across the membrane provide the driving energy for movement of amino acids, monosaccharides, etc. into cells.

#### Potassium

The potassium ion (K<sup>+</sup>) makes a rare appearance as a specific cofactor for *pyruvate kinase* in the glycolysis pathway. Both potassium and magnesium form no permanent bonds with their respective enzymes and hence act more as activators.

#### Magnesium

Magnesium ions (Mg<sup>2+</sup>) are required by a large number of enzymes referred to as *kinases*. Kinases transfer the terminal phosphate group of ATP to substrates. They figure prominently in many biochemical pathways such as glycolysis (*hexokinase*, *fructose-6-phosphate kinase*, *pyruvate kinase*), hormone responses mediated by cyclic AMP, cell signaling, and regulation of cell division. Mg<sup>2+</sup> also modulates muscle contraction by competing with Ca<sup>2+</sup> on proteins that trigger muscle contraction.

#### Calcium

As a group IIa metal ion, Ca<sup>2+</sup> is limited to a +2 valence state and serves primarily as a divalent cation in its interactions with enzymes. The role of Ca<sup>2+</sup> is limited mainly to structure stability although it is a cofactor for a limited number of important enzymes apart from the more familiar actin–myosin complex in muscle. *Alpha amylase* and *thermolysin* are two of the most familiar. As a free ion or working through calmodulin, calcium is better understood as an activator of enzymes in hormone-dependent cell signaling pathways. Enzymes, which have been referred to as Ca-ATPases and H<sup>+</sup>/Ca-ATPases are not to be mistaken as calcium-dependent. This is a misnomer in that the Ca<sup>2+</sup> is the object of the enzyme's action rather than the cofactor for activity. The ATPases comprise a large group of membrane-bound enzymes that either pump Ca<sup>2+</sup> from the cytosol into the endoplasmic reticulum or expel Ca from the cell through membrane channels.

### Micro (Trace) Minerals

#### Iron

Most iron enzymes engage iron either as heme or as a special arrangement of iron with sulfur groups referred to as iron–sulfur centers (Fe<sub>n</sub>S<sub>n</sub>) (Table 3). Iron in heme bears a striking resemblance to magnesium ion in chlorophyll (Figure 2). Heme, basically a porphyrin ring system with iron positioned in the center, is the most common form of iron in biological proteins. In cytochrome *c*, a common heme protein in the mitochondria, the axial ligands to the iron are occupied by histidine and methionine from the protein. Heme enzymes include *calalase* and *peroxidase*. As components of iron–sulfur centers, iron enters into multiple cluster

**Table 3** Important iron enzymes

Enzyme	Source	Function	Form of Fe
Cytochrome <i>c</i> oxidase	Mitochondria	Electron Transport	Heme
Aconitase	Mitochondria	Krebs Cycle	Fe <sub>4</sub> S <sub>4</sub>
Succinate dehydrogenase	Mitochondria	Krebs Cycle	Fe <sub>4</sub> S <sub>4</sub>
Catalase	Peroxisomes	H <sub>2</sub> O <sub>2</sub> destruction	Heme
Peroxidase	Peroxisomes	Peroxide destruction	Heme
Prolyl hydroxylase	Cytosol	Collagen Synthesis	Fe <sup>2+</sup>
Ribonucleotide reductase	Cytosol	DNA Synthesis	Fe–O–Fe
Cytochrome P450	Microsomes	Sterol Synthesis	Heme

**Figure 2** Heme iron in hemoglobin. Heme is a porphyrin ring with iron in the center. Four heme b groups are present in hemoglobin, the iron protein in erythrocytes. A similar structural arrangement is seen with magnesium in chlorophyll a from plants.

arrangements with cysteine residues on enzymes that offer a more direct contact with the protein. These centers differ in their complexity from the simple 2Fe–2S to the more elaborate 4Fe–4S (**Figure 3**). Iron in these centers binds substrates as well as transfer electrons and takes part in reactions involving dehydrations and rearrangements. Enzymes with iron–sulfur centers include *xanthine oxidase*, *succinate dehydrogenase*, *aconitase*, and *nitrogenase*. A third class, represented by *ribonucleotide reductase* has an FeO<sub>2</sub> cluster with a dioxygen as a peroxide-anion O<sub>2</sub><sup>2–</sup> straddled between two iron centers (**Figure 4**). This arrangement allows the enzyme to remove a hydrogen atom from a very stable C–H bond. No metal can replace iron in these complexes. Enzymes with a heme group generally are reddish-brown in color (depending on the oxidation state of the iron). The color led to early interest in these proteins and was the motivating factor behind naming heme proteins in the mitochondria ‘cytochromes’. Although only a relatively few soluble enzymes have iron as a cofactor, iron is especially prominent in membrane-bound proteins that comprise electron transport pathways. Examples of the latter include the cytochromes in the mitochondria, endoplasmic reticulum, and photosystems I and II in chloroplasts. Perhaps the most unusual iron protein is ferritin, a huge multisubunit iron storage protein that has the capacity to bind more than 2500–5000 iron atoms in its structure.

### Reactivity

The redox property of iron carries over to much of its chemistry as a cofactor. Iron is nearly always involved with the transfer of electrons and many times donates the electrons to a molecule of oxygen. Two important properties that fit that role are: (1) an iron atom can readily undergo reversible valence changes from Fe<sup>2+</sup> to Fe<sup>3+</sup>, which allows facile exchange of electrons, and (2) the ferrous–ferric ion pair has a relatively low electrochemical potential (–1.1 V), which allows iron to be on the high (reducing) end of an electron transport chain. In cytochrome P450 a single oxygen atom is transferred to the substrate after O<sub>2</sub> binds to Fe(II). In the mechanism the Fe(II)–O<sub>2</sub> complex is converted into FeO, which features an Fe(V) species that attacks the substrate and incorporates the single oxygen atom into its structure. Although higher valence states such as Fe(IV) and Fe(VI) are formed by the loss of additional 3d electrons, only rarely are these higher valences of Fe seen in biological systems. As noted above, *catalase* and *peroxidase*, two heme enzymes, use iron to engage dangerous oxidants. Both enzymes are located in the cytosol and in peroxisomes where harmful oxidation reactions occur during the course of normal metabolic events. Perhaps the most familiar iron-

**Figure 3** Iron-sulfur clusters. Both the  $\text{Fe}_2\text{S}_2$  and  $\text{Fe}_4\text{S}_4$  clusters are bound to the protein via cysteine residues. The iron in these complexes either engages a substrate or holds and passes electrons.

**Figure 4** Fe-O-Fe center in ribonucleotide reductase. The two iron atoms are in close juxtaposition to bind dioxygen as the peroxide-anion  $\text{O}_2^{2-}$ . Side chains of aspartic and glutamic acid residues as well as two histidine residues assist in linking the center to the protein. The center assists in the formation of a free radical that forms on a neighboring tyrosine residue (after Fraústo da Silva and Williams).

containing enzyme is *cytochrome c oxidase*, the terminal electron acceptor in the mitochondrial electron transport chain and the enzyme capable of splitting a molecule of oxygen to form water.

### Zinc

Zinc is perhaps the most ubiquitous and versatile of all metal cofactors. Sequencing the human genome exposed more than 900 proteins that have zinc-binding domains in their structure. Not all of these proteins function as enzymes, however. Hence, it is wrong to say zinc is a cofactor for 900 enzymes. Some of the better characterized zinc enzymes are shown in [Table 4](#).

**Table 4** Important zinc enzymes

Enzyme	Source	Function	Zn/protein
Alcohol dehydrogenase	Liver	Alcohol metabolism	4
Alkaline phosphatase	Placenta	Unknown	4
Carbonic anhydrase	Erythrocyte	CO <sub>2</sub> hydration	1
Carboxypeptidase	Pancreas	Protein catabolism	1
Glutamate dehydrogenase	Liver	Glutamate synthesis	2–6
Leucine aminopeptidase	Intestine	Peptide catabolism	4–6

Zinc-binding proteins that engage DNA, the so-called zinc finger proteins, are examples of nonenzyme protein but nonetheless proteins whose function in a noncatalytic way is dependent on zinc. Approximately 3% of the genome of mammals codes for zinc finger protein. As a cofactor, zinc can perform both structural and catalytic functions. In *carbonic anhydrase*, for example, Zn enters into a coordinate bond with the CO<sub>2</sub> substrate (Figure 5). In *carboxypeptidase*, zinc takes an active part in the cleavage of the peptide bond (Figure 6). Multisubunit enzymes such as *aspartate transcarbamylase* use Zn to coordinate the positions of the catalytic and regulatory subunits, a structural role. *Cu<sub>2</sub>, Zn<sub>2</sub> superoxide dismutase* requires zinc to position the copper atom in the channel accessed by the substrate HO<sub>2</sub><sup>•</sup>, another structural role. In zinc finger proteins, Zn<sup>2+</sup> contributes to the stability of the loop structure that contacts the major and minor grooves of DNA. These examples illustrate why zinc is an important companion to enzymes and proteins.

One of the lesser known, and perhaps less appreciated functions of zinc is that of a neurotransmitter that modulates neural activity in the brain. Although not to be considered a cofactor role because no enzyme appears to be involved in the action, zinc ions amass in synaptic vesicles and are released into the synaptic junction of glutamatergic neurons. Releasing zinc tends to modulate the activity of the neurons and thus control the impact of the glutamate.

### Reactivity

Zinc is considered a bland metal because it behaves as a divalent cation with weak geometric preference. It is perhaps this blandness that allows zinc to adapt to so many different enzyme environments. Zn exists in one valence state, Zn<sup>2+</sup>, and hence cannot donate or accept electrons. Zn<sup>2+</sup> ion is configured as a 3d<sup>10</sup>, which denotes a filled 3d orbital. For that reason, zinc complexes lack color and zinc itself behaves mostly as a cation. The Zn<sup>2+</sup> ion is capable of recognizing electron pairs (typical of a Lewis acid) and thus can enter into a coordinate bonding arrangement that polarizes groups to which it binds. This property allows zinc to increase the susceptibility of a chemical bond to attack. For example, Zn<sup>2+</sup> polarizes water, which makes the water behave more like hydroxide ion and be more effective in attacking the CO<sub>2</sub> to form HCO<sub>3</sub><sup>−</sup>:

in the reaction catalyzed by *carbonic anhydrase*. Another example is the use of zinc to polarize the ester or amide bonds thus promoting nucleophilic attack of water on the bond as in reactions catalyzed by *carboxypeptidase* and *aminopeptidase*.

### Copper

Copper, like iron, can donate and accept electrons. Thus like iron, Cu exists in multiple valence states; Cu<sup>+</sup> and Cu<sup>2+</sup> (cuprous and cupric) are the most stable. Copper enzymes, although not nearly as numerous as zinc, fill a variety of important biological

**Figure 5** Zinc in carbonic anhydrase. Zinc in the enzyme ‘activates’ a water molecule (1) creating a better nucleophile to attack the CO<sub>2</sub> (2). Once formed (3) the hydrated CO<sub>2</sub> as HCO<sub>3</sub><sup>−</sup> is displaced from the enzyme via a second water molecule (4) regenerating the active enzyme.

**Figure 6** Zinc in carboxypeptidase. In carboxypeptidase, zinc atom forms a binary complex with groups on the C-terminal end of the protein. Arrow shows that bond that will be cleaved with water. Only the C-terminus residue is released from the protein.

functions mostly with membrane-bound enzyme (Table 5). A common denominator to these, however, is the donor–acceptor electron fit the category of oxidoreductases, or more specifically ‘oxidases’, meaning they catalyze reactions in which electrons from the substrate are transferred to  $O_2$ . Copper enzymes can be simple or complex, depending on the number of Cu atoms in the enzyme. Simple enzymes generally contain one Cu per subunit. The more complex include the multicopper oxidases, which may have as few as four, e.g., *laccase*, or as many as eight copper atoms per enzyme e.g., *dopamine- $\beta$ -monooxygenase*. Copper in these enzymes exists in three different chemical environments referred to as type 1, type 2, and type 3 copper sites. *Ceruloplasmin*, for example, contains 6–7 Cu atoms in three distinct sites. The type 1 copper site gives a blue color to ceruloplasmin and other blue Cu proteins. The copper-binding sites in a multicopper oxidase form a triad consisting of one type 2 and two type 3 coppers arranged as an isosceles triangle. Oxygen binds to the two type 3 coppers at the base of the triangle. Examples of copper enzymes include *cytochrome c oxidase*, *lysyl oxidase*, and *ascorbate oxidase*.

### Reactivity

Because it is prone to accept electrons, Cu is a powerful oxidant in biological systems. The Cu sites in ceruloplasmin have the capacity to oxidize  $Fe^{2+}$  to  $Fe^{3+}$ , which prepares ferric ions to bind to transferrin and delivers iron to the organs and tissues. This reaction links iron with copper metabolism and could explain how an absence of copper in the diet impairs the transport of iron and causes anemia in humans. In  *$Cu_2$ ,  $Zn_2$  superoxide dismutase*, the  $Cu^{2+}$  at the active site removes the single nonbonding electron from one superoxide anion ( $O_2^-$ ) and transfers it to another:

Seldom is copper destined to perform only a structural role and many enzymes that possess copper as a cofactor use the metal at the active site. More recent studies have linked Cu ions with the formation of blood vessels, or angiogenesis. One of the more exciting discoveries yet to be fully understood is that depriving an animal or human of Cu delays or even inhibits the growth of cancerous tumors. From a nutritional perspective, this could mean that Cu is essential for the development of the microvascular system.

### Manganese

Whereas zinc may be the most common transition metal in enzymes, manganese is perhaps the least common. Part of the reason is that complexes of manganese with proteins tend to be weakly stable with a tendency to dissociate. Notable manganese metalloenzymes include *pyruvate carboxylase* and *manganese superoxide dismutase* in the mitochondria and *arginase* in the urea cycle. Manganese can also function as a metal-activating cofactor for many enzymes that require magnesium.

### Reactivity

Although manganese is not considered a redox metal based on reactivity, it nonetheless can exist in six oxidation states ( $Mn^{2+}$  to  $Mn^{7+}$ ) three of which ( $Mn^{5+}$  to  $Mn^{7+}$ ) are not seen in biological systems. The most common form of manganese is  $Mn^{2+}$ . The highest number of multiple valences of manganese occur in the *water splitting enzyme* that is found in chloroplasts of plants as part of photosystem II.

**Table 5** Important copper enzymes

Enzyme	Source	Function	Cu/protein
Ascorbate oxidase	Squash	Ascorbate catabolism	8
Ceruloplasmin	Plasma	Iron oxidation	6–7
Cytochrome c oxidase	Mitochondria	Electron transport	2
Dopamine- $\beta$ -monooxygenase	Adrenal	Noradrenaline synthesis	8
Lysyl oxidase	Aorta	Collagen, elastin synthesis	1
Superoxide dismutase	Erythrocyte	Superoxide radical destruction	2

### Cobalt

The role of cobalt as a cofactor is limited to its presence in vitamin B<sub>12</sub>. Cobalt can exist in three valence states, Co<sup>+</sup>, Co<sup>2+</sup> and Co<sup>3+</sup> with Co<sup>2+</sup> being the most common in 5'-deoxyadenosylcobalamin, the familiar form of vitamin B<sub>12</sub> coenzyme. Cobalt is bound by a planar ring system analogous to heme but with very special features. Cobalt (and nickel) are ions that may have figured more prominently in primitive systems when the atmosphere contained H<sub>2</sub> and CH<sub>4</sub> as common environmental gases. The argument has been made that as biological system gradually adapted to O<sub>2</sub> the necessity for these two metals became less.

#### Reactivity

Cobalt in the structure of vitamin B<sub>12</sub> resembles iron in heme by being bound in a square planar arrangement to a ring (corrin). Unlike heme, however, cobalt has two axial ligands that are free from the protein, which allows nonprotein groups to access the central metal from above and below the plane. In the octahedral complex, one axial position (the fifth coordinate) is normally occupied by a benzimidazole and the other by a methyl group (as in methyl cobalamin). The arrangement is unique and allows cobalt to form carbon-metal bonds with the potential for two different reactivities. The methyl group, for example, may be removed as a carbonium ion retaining both electrons on the cobalt, which then reverts to a less stable Co(I). This is typical of the reaction in which B<sub>12</sub> acts as a methyl donor. In positional rearrangements, cobalt retains only one electron and forms a stable Co(II) or *d*<sup>7</sup> ion with the release of a free radical. Free radicals are highly reactive and overcome energy barriers that would stymie other reactants. Thus, cobalt's chemical properties transfer groups as carbonium ions or highly reactive carbon-centered radicals. Both products are possible and hence explains the necessity for Co as a cofactor for a reaction that precede via a free radical mechanism. An example of the latter is the intramolecular rearrangement of methylmalonyl-CoA to succinyl-CoA as catalyzed by *methylmalonyl-CoA mutase*.

### Vanadium

A well defined biochemical function for vanadium in higher animals and humans is yet to be described. Recent reports of vanadium in bacteria and algae have provided clues as to the functional necessity of this metal in enzyme catalysis. Approximately 10 years ago, vanadium was found to be essential for the activity of *bromoperoxidase*, an enzyme found in brown and red algae. Shortly thereafter, a vanadium-dependent *iodoperoxidase* was characterized. Vanadium was also found in high concentrations in mushrooms and was shown to accumulate in large quantities in ascidians, specifically the blood cells (vanocytes) of these organisms. Speculation as to function of vanadium in microorganisms range from antimicrobial action to electron transfer and the trapping of oxygen. In higher animals, however, vanadium has been shown to have insulin-mimetic properties and to stimulate cell proliferation and differentiation. It is also believed to regulate phosphorylation and dephosphorylation reactions through control of ATPases, phosphatases, and adenylcyclase that have wide spread effects on cell functions. These are the most plausible understandings to date. However, it should be emphasized that vanadium has not been shown to be a specific activator (or inhibitor) of any enzyme in humans.

#### Reactivity

Vanadium is like molybdenum in being able to form both oxyanions and oxycations, VO<sub>4</sub><sup>2-</sup> (MoO<sub>4</sub><sup>2-</sup>), VO<sub>2</sub><sup>+</sup> (MoO<sub>2</sub><sup>2+</sup>, MoO<sub>2</sub><sup>+</sup>, and MoO<sub>2</sub><sup>2+</sup>) and sulfur centers as well, e.g., VS<sub>4</sub><sup>3-</sup> (MoS<sub>4</sub><sup>2-</sup>). Vanadate differs from molybdate in being a rather strong oxidizing agent, *E*~+.5 V at pH 7, which may relate to its electron transfer function in lower life forms but has questionable significance in humans.

### Molybdenum

Molybdenum is widely distributed in plants and animals. The metal exists in three valence states, Mo<sup>4+</sup>, Mo<sup>5+</sup>, and Mo<sup>6+</sup>. A limited number of redox reactions exploit the multivalence states. Molybdenum-dependent enzymes are found in pathways that metabolize purines, pyrimidines, pterins, aldehydes, and sulfites. A cofactor structure for molybdenum has been proposed (Figure 7) and referred to as molybdopterin. Enzymes that use the cofactor include *xanthine oxidase*, *sulfite oxidase*, and *aldehyde oxidase*. In microorganisms, molybdenum is a key metal for the fixation of nitrogen. *Xanthine oxidase* is the enzyme with importance relevance to a mammalian system.

#### Reactivity

A major nutritional concern of molybdenum is its ability to antagonize copper. Indiscriminant spraying of soils with molybdenum has been shown to affect the growth and productivity of ruminants. The effect relates to the formation of thiomolybdates in the rumen. The thiomolybdates interact and bind copper preventing its absorption from the rumen. Thiomolybdates have a very high affinity for copper almost to the exclusion of other metal ions. Lately, thiomolybdates have been used to control copper toxicity in Wilson's disease, a genetic disease of copper poisoning in humans.

### Nickel

As a cofactor, nickel occurs infrequently. About the only known occurrence of nickel is in microbial and plant enzymes such as *urease* from jack bean, soybean, rice, and tomatoes. There are roughly two gram-atoms of nickel per mole of the 96 000 dalton subunits of the enzyme. Other metalloenzymes containing nickel include Factor F430 found in the membrane of methanogenic bacteria, *carbon*

**Figure 7** Proposed structure for the molybdenum cofactor in nitrogenase. This center consists of a special pterin cofactor, a relative of tetrahydrofolate. The molybdenum engages two sulfur atoms as a dithiolate complex.

*monoxide dehydrogenase* and *hydrogenases I and II*. Nickel has drawn the attention of nutritionists because of the observation that nickel concentrations in serum of women rise sharply immediately after parturition.

### Reactivity

Some consider nickel the 'metal that was'. As biosystems evolved and moved from an atmosphere of no oxygen to one rich in oxygen, where methane and  $H_2$  have tended to be minimized as energy substrates, metals that formed a major cofactor in the anaerobic environment and used by the more primitive organisms such as archaeobacteria have been replaced in favor of a metal or cofactor more suitable to the present day environment. Thus, nickel, like cobalt may have had its greatest era in enzymes that catabolized  $CH_4$  or  $H_2$ .

### Other

Although metals such as Cr, Sn, As, and Sr are known to be essential for optimum growth and health of organisms as well as having a major influence on biological systems, cofactor functions for these metal ions have not been assigned because specific enzymes which may require them for activity have not been found.

## Nonmetal Mineral Cofactors

### Selenium

Selenium belongs to the category of redox nonmetals. Selenium is included in the same class with sulfur (sometimes referred to as metalloids), which implies that selenium should be able to substitute for sulfur in biological complexes. As a congener of sulfur, selenium becomes part of a protein's structure as selenocysteine and selenomethionine, not as a selenium atom ligated directly to the protein as a prosthetic group. The former are the active cofactors in selenium enzymes.

### Reactivity

Although a selenium ion is clearly capable of redox reactions, there is still little information available as to how selenium functions as a cofactor. Enzymes such as *glutathione peroxidase* are soluble enzymes that transfer electrons to and from substrates. Replacing the selenium with sulfur in the enzyme negates the activity. With only a few selenoenzymes available, there is little information as to the precise catalytic role of selenium. *Glutathione peroxidase* in the reduced (resting) form is believed to contain an ionized selenol that can react with either organic peroxides or  $H_2O_2$  according to the reaction (a) shown below: a selenol enzyme is

also believed to be an intermediate in the reaction (b) catalyzed by *5'-deiodinase*, the enzyme that catalyzes the removal of a single iodine atom from thyroxine, the major thyroid hormone. This T4 to T3 transition gives rise to the more active form of the hormone. Because the *5'-deiodinase* activity is suppressed in an iodine deficiency, there have reports of goiter-like conditions being manifest in people with low levels of selenium in the diet.

### Silicon

There is still some question as to whether silicon is a cofactor. It is included here because of the importance of silicon in a number of biochemical reactions leading to the synthesis of glycoproteins and polysaccharides in the extracellular matrix of connective tissue ground substance. Silicon as  $Si(OH)_4$  is very abundant in soils and minerals and is as common in human tissues as magnesium. In plants, especially grasses, silicon is a major component of a mineral skeleton and has a metabolic turnover nearly on a par with carbon. In humans, the highest concentrations of silicon occur in connective tissues such as aorta, trachea, tendon, bone, and skin. Lesser amounts are found in liver, heart, and muscle. The epidermis and hair are significantly high in silicon.

### Reactivity

Silicon, as silicic acid, has been shown to be required for maximal activity of *prolyl hydroxylase*, the enzyme that converts proline residues to hydroxyproline in collagen. High levels (0.2–2.0 mM) are needed to stimulate the enzyme, which catalyzes a rate-determining factor in collagen biosynthesis.

### Boron

Manipulating the boron content of a diet leads to a wide number of metabolic responses, which is testament to the potential importance of boron in human nutrition. Early studies reported increased levels of steroid hormones, testosterone, and estradiol in animals supplemented with boron. Further studies suggest that boron has a regulatory role in the metabolism of other minerals such as calcium and may affect bone metabolism. In a comparative way the role of boron is well established in vascular plants, diatoms, and marine algal flagellates. Zebra fish deprived of boron tend to suffer developmental defects. These data have impelled investigations into the biological functions of boron in higher vertebrates. To date, however, few studies have supported boron's essential role in vertebrates. In a comparison to Zebra fish, pregnant rats fed one-fiftieth the level of boron as control rats exhibited no impairment in fetal growth or development. Fewer two-cell embryos from the deficient rats, however, reached the blastocyst stage when cultured *in vitro*, suggesting boron deprivation did have an impact at a very early stage of development. Perhaps the strongest holdup to accepting boron as essential is the failure to define and link a specific organoboron compound with a physiological function. A report of boron associated with a naturally occurring antibiotic is an exception. The data, however, tend to support the notion that boron complexes with biological components are too unstable to be isolated and studied. This clearly has put a damper on the forward thrust of knowing boron's precise metabolic function.

### Conclusions

The mineral cofactors described here may be thought of as representing a special subset of the biominerals. Rather than contributing to skeletal mass and fluid homeostasis, however, mineral cofactors are more subtle and are devoted specifically to enzymes. The words 'mineral' and 'cofactor' combine to designate an inorganic component required by an enzyme in order to achieve optimum catalytic efficiency. In seeking a reason for mineral cofactors, one must consider that to meet its functional obligations, an enzyme faces many challenges. The protein surface can easily be modified chemically through interaction with substrates and the enzyme protein can readily lose its biological form through denaturation. Electrons and groups that are transferred to and from substrates have the potential to permanently modify the enzyme. This happens frequently and instead of undergoing repair, old enzymes are replaced by new ones. The mineral cofactors fit into the daily wear and grind by making the enzyme better able to stand up to the harsh environment of their existence. They also have been shown to be effective binders of substrate and to interact with oxidants and reductants in a facile manner. Some trace metals such as Zn can accept electron pairs in forming a covalent attachment that polarizes and facilitates rupture of the chemical bonds in the substrate. Other metals such as copper and iron can accept electrons from the substrate and pass them to oxygen. Catalysis and structure stability are the two primary functions of metals in enzymes. Many organic factors serve as electron-capturing and group-transferring agents. This suggests that metalloenzymes may backup enzymes with organic cofactors. This view is rather narrow and oversimplified because there are many enzyme-catalyzed reactions where only a metal will suffice, such as in the metalloenzymes that catalyze the destruction of oxygen radicals. In biology seldom does one factor become indispensable. What nutritionists refer to as essential metals are on the same level as vitamins in that they are needed in very small quantities to maintain a status quo system and, like vitamins, available strictly through the diet. One must, therefore, conclude that essential minerals and vitamins have common ground in the enzymes, which they literally permit to function.

## Key points

- The switch between cuprous and cupric states underpins the metal's essentiality in systemic substrate metabolism, energy production, tissue synthesis, neurotransmission and peptide endocrine activity.
- Elements of its roles and homeostasis are evolutionarily conserved thus enabling a systems biology approach to studying its essentiality.
- Reference intakes of copper for adults approximate 1.0-1.5 mg daily. It is widely distributed in the diet particularly in cereals and grains.
- The liver is the main regulator of systemic metabolism and homeostasis of copper by means of its sequestration with cysteine rich isoproteins, collectively called metallothionein.
- Two inborn errors of copper metabolism affecting its systemic distribution from the liver (Menkes Disease) and its biliary excretion (Wilson Disease) have highlighted the affects of low and high body burdens of copper.
- Copper excess may arise from environmental contamination, and may be predisposed by ecogenetic factors.
- Copper deficiency occurs in malnutrition states and with synthetic feeds. The is interest that foods rich in fructose or glucose may cause adverse cardiovascular effects in adults on low copper intakes.

## Introduction

For more background information and specific information covering points in the text the following reviews are recommended Crichton (2019), Davis and Mertz (1987), EFSA NDA Panel (2015), EFSA Scientific Committee (2022) *to be released shortly*. Moller and Aaseth (2022), Online Mendelian Inheritance in Man, [www.omim.org](http://www.omim.org), and Stern et al. (2007).

Copper (atomic number 29 and atomic weight 63.55) is an essential trace element. It was one of the first metals to have been isolated and used by man, this was about 10,000 years ago somewhere between present day Greece, and India. Certainly, the metal had been isolated before 3500 BC, which is when it was realized that adding tin (one part to nine parts copper) produced a harder more versatile material, namely bronze. After iron and aluminum, copper is the most widely used metal. Its abundance in the Earth's crust is 68 ppm, and although small amounts of metallic copper can be found naturally, most exist as an ore. Fifty percent of crustal copper occurs with iron as sulfide ores, chalcopyrite, bornite, chalcocite and covellite. Carbonate ores include malachite and azurite, and an oxide ore is cuprite. In its biological role and activity, copper is bound in proteins by N and S ligands provided by the amino acids histidine and cysteine. Copper has two oxidation states that are of physiological importance these are the cuprous ( $\text{Cu}^+$ ) which is easily oxidized, and cupric ( $\text{Cu}^{2+}$ ) which is the more abundant and stable. The oxidation of cuprous copper is controlled when the copper is bound in a complex as a cuproprotein. The two states have different coordination chemistries; cupric copper favors a planar configuration with 4N ligands, whereas cuprous ions form tetrahedral complexes involving 4S ligands. More complex structures involving two or more copper atoms and others with  $\text{Cu}^{3+}$  and  $\text{Cu}^{4+}$  states are known but, as yet their functions have not been fully characterized. One exception to this generalization is hemocyanin which is found in invertebrates

such as molluscs and arthropods. Hemocyanin contains two  $\text{Cu}^+$  atoms that interact to bind molecular oxygen reversibly at the low oxygen tensions and temperatures of the environment at which these creatures live; it is not found in mammals in whom hemoglobin has the same role. However, many cuproproteins found in humans and other mammals are ubiquitous and highly conserved thereby encouraging speculation that, like iron, copper may have been functionally important before, and indeed contributed to, the development of an aerobic environment on earth (Crichton, 2019).

The oxidation of cuprous to cupric copper generates free radicals which, in turn, can cause extensive functional and architectural tissue damage by oxidizing organic molecules such as lipids, proteins, and nucleic acids. Thus, to acquire, distribute, use, and excrete copper, organisms have had to evolve a system of specific protein carriers which forestalls the production of free copper ions and thereby minimizes the risk of oxidative toxicity. Similar systems of chaperoned traffic exist for other essential transition elements such as iron, zinc, and manganese. Since these elements have similar physicochemical properties, interactions may occur between them at separate stages of their respective trafficking systems, however, at normal levels of exposure each system has an accumulative specificity and selectivity which discriminates effectively for their delivery to their respective depots and functional sites. However, there is evidence that dietary iron, in some circumstances and high molar ratios, does interfere with the metabolism and utilization of copper.

## Copper function

Copper-dependent enzyme activities (Table 1) are crucial to energy metabolism and muscle efficiency, connective tissue and bone formation, neurotransmission and catecholamine synthesis, the turnover of peptide hormones, free radical elimination, iron trafficking and hemoglobin formation. The features of copper deficiency are described later. Genomic analyses indicate the existence of many potential copper binding motifs for which the proteins and functions have yet to be identified.

## Dietary sources and reference values

The copper content of some common foods is shown in Table 2. Good dietary sources of copper are seeds, grains, nuts (cashews and pecans), beans, wheat bran, crustacea, shellfish, cocoa products, and a relatively small component from liver. Although copper is naturally abundant in the liver, the amount in the livers of farmstock may have been enhanced either from the animals having been reared in areas which had been surface treated with slurry containing copper, or in the case of pigs from copper given to them as a microbicidal to alter their gut flora to prevent enteric infections, and improve their growth. These exposures and practices are subject to regulation and this should be considered in the appropriate perspective when preparing dietary advice for individuals and populations. The entry of copper into the food chain via vegetation is limited by the innate homeostatic regulation of copper uptake by plants and by factors such as the redox potential, alkalinity, and sulfur and molybdenum content of the soil which limit the availability of copper from soil to vegetation, and also to grazing livestock which ingest soil to the extent that in some areas, copper deficiency may be endemic in grazing livestock despite copper being abundant in the soil (Davis and Mertz, 1987).

The copper content of water delivered by copper piping can contribute significantly to intakes. Soft acidic water can leach copper from copper piping. If the copper content of water is  $0.1 \text{ mg L}^{-1}$  water contributes less than 10% of daily intake of copper, whereas if

**Table 1** Copper-dependent enzyme activities.

Cytochrome <i>c</i> oxidase	Mitochondrial oxidative phosphorylation transfer of electron to $\text{O}_2$
Dopamine- $\beta$ -hydroxylase	Norepinephrine and epinephrine synthesis
Tyrosinase	Tyrosine-dopa-dopaquinone-melanin production peptidylglycine $\alpha$ -amidating mono-oxygenase
Neuropeptide synthesis including melanocyte stimulating hormone Tryptophan 2,3-dioxygenase	Tryptophan to <i>N</i> -formyl-L-kynurenine
Indole 2,3-dioxygenase	Indole to 2-formylaminobenzaldehyde
Monoamine oxidases	Degradation of amines, e.g., serotonin, catecholamines, dopamine, and tyramine
Diamine oxidases	Degrades histamine and polyamines
(Cu–Zn) superoxide dismutase	Cytosolic antioxidant; $2\text{HO}_2 > \text{O}_2 + \text{H}_2\text{O}_2$ superoxide conversion
Lysyl (and hydroxylysine) oxidase	Collagen and elastin cross linking; lung, bone matrix, cardiovascular integrity
Uricase	Hepatic and renal metabolism of uric acid
Hephaestin	Ferroxidase for cellular export of iron
Ceruloplasmin	Plasma metallo/ferroxidase
Thiol oxidase	Formation of disulfide linkages

it is  $>1\text{--}2\text{ mg L}^{-1}$  upto 50% (i.e., 0.5 mg copper) of daily intake may derive from water. Whether or not this constitutes a potential benefit or hazard needs to be determined by a case-by-case risk assessment; this applies also to assessing the potential impact of using utensils made of copper alloys (e.g., brass) or of copper for cooking or for storing water, milks, and drinks.

Dietary reference values for copper for North America are given in [Table 3](#). Most advisory bodies give similar values either as a single value, or as a range (e.g.,  $1.0\text{--}1.2\text{ mg day}^{-1}$  in Australia and New Zealand). Some bodies, including that in the UK, do not think that additional intakes are necessary during pregnancy or lactation, considering that maternal adaptation such as increased absorption or mobilization of endogenous depots would meet the needs of pregnancy and lactation. The uncertainty of the information on copper nutrition in humans has meant that rather than estimating a range of lower, average, and population intake reference values, most agencies provide figures that are seen as adequate intakes e.g., the values from the European Union ([Table 4](#)). Failure to meet these intakes by individuals or groups of people is not diagnostic of deficiency but can be regarded as an indicator of a risk of deficiency. These uncertainties are the source of variability among the values produced by different advisory bodies and because such variations, no matter how small, could be barriers to trade there are international initiatives to harmonize approaches for the setting of reference values. The dietary intake of copper is approximately  $1\text{--}2\text{ mg day}^{-1}$ , but individual intakes of copper vary widely over 2–3 weeks, according to the pattern of intakes of rich sources of copper. Few dietary intake surveys are long enough to capture this variability. A tolerable upper intake limit, based on the risk of liver damage, of 10 mg for daily intakes of

copper over a lifetime has been advised in North America. In the European Union, an upper level of 5 mg has been recommended (EFSA NDA Panel, 2015; EFSA, 2022).

### Copper trafficking and kinetics

Knowledge of the acquisition, distribution, metabolism and excretion (ADME) i.e., the metallomics of copper has been deduced from studies in cell line systems *in vitro*, bacteria, yeasts, drosophila, xenopus, zebra fish, mice, sheep, and humans. Knockout models and inborn errors of metabolism in mammals have contributed appreciably, as have molecular biological techniques which have enabled the integration of information from these sources to demonstrate an appreciable evolutionary conservation of mechanisms for the acquisition and systemic utilization of copper in life forms (Nevitt et al., 2012). Studies of these processes in humans are hampered because there are few tracer forms of copper: the abundance of two natural stable isotopes of copper  $^{63}\text{Cu}$  and  $^{65}\text{Cu}$  of 69% and 31% make them difficult to use in tracer studies, as do the short half-lives of its radio isotopes ( $^{67}\text{Cu}$  –61.9 h and  $^{64}\text{Cu}$  –12.9 h).

The principal proteins in the trafficking pathways for copper are a high-affinity copper transporter, (CTR1) which functions as a trimer which forms a channel to enable an energy independent influx of copper into cells; two carriers involved with the energy-dependent efflux of cupric copper from cells, ATP7A ATPase and ATP7B ATPase; a depot protein, metallothionein, or more specifically isometallothioneins (MTN); and a number of target-specific chaperone carrier proteins that take copper to its functional sites. Additionally, there is a copper transport protein, transcuprein, in the circulation. These proteins are homologous to a varying extent with proteins with similar functions in bacteria and other species, in some of which proteins such as CTR1 homologs are essential for embryonic morphogenesis and cell differentiation, thereby raising interest in the copper dependence of this role, and speculation that CTR may have similar functions in human embryogenesis.

### Copper absorption (intestinal uptake of copper and its transfer to the body)

The intestine absorbs 5–90% or more of ingested copper. The higher figure relates to intakes of copper in aqueous solutions among which copper oxides are less well absorbed than acetate, sulfate, gluconate, and citrate salts. Otherwise, absorption varies considerably, approximately 10–60%, depending on the amount in the diet, the character of the diet and most importantly the host's need for copper. Copper is released from the dietary matrix by gastric acidity and proteolytic activity. Gastric mucosal uptake and transfer of copper have been modeled in animal models and plasma appearance curves after ingesting copper salts suggest that gastric absorption occurs in humans, but this is probably not a major route in normal physiology. The predominant site for uptake of copper in adults is the duodenum and proximal jejunum; however, in young animals, at least, the uptake of copper extends throughout the small intestine. The intraluminal solubility of copper and thus its availability for intestinal uptake is enhanced by an acid milieu, anions such as sulfate and nitrate, and low molecular weight ligands including sulfur amino acids, histidine, lactose, glucose, and starch, presumably after its hydrolysis to glucose. The uptake of copper from foodstuffs is impaired by Maillard reaction products produced during food preparation, and by interactions involving phosphate compounds (such as phytate), amino acids, magnesium, and calcium which precipitate copper in the gut lumen. Similarly, vitamin C, by oxidizing cuprous copper to cupric, impairs copper uptake in animal models, but this does not necessarily happen in humans.

The first stage of copper uptake is its aggregation by the mucus and glycocalyx on the enterocytic microvilli, whence it reaches membrane-associated reductases (STEAP2 and Dcytb) which convert any residual cupric to cuprous copper for translocation into the enterocyte. There are at least two mechanisms for enterocytic uptake of copper; one which is dependent on CTR1, which accounts for 70% or more of uptake, and one which probably uses the divalent metal transporter (DMT1). The former mechanism involves copper uptake into subapical vesicles in the enterocyte, and because this process occurs in the absence of CTR1, and has not been associated with DMT1-mediated uptake of other metals, it is thought that copper may be first taken up by endocytosis, it is not clear whether the metal is reduced before endocytosis or within the endosome. Then CTR1 transfers the cuprous metal out of the

vesicle. This endocytic route would be consistent with early literature reports of copper uptake. In the enterocyte, copper is either bound to metallothionein or to a chaperone, Atox1, which translocate the copper to ATP7A for vesicular transfer of the metal across the basolateral membrane into the portal circulation.

This association is not predictable, and neither is the effect of coincidental intakes of zinc and iron on copper uptake and transfer. When given in solution with copper both iron and zinc might reduce the systemic absorption and use of copper. Reduced red cell superoxide dismutase activity has been seen in infants given iron supplements, and it is possible that iron supplements impair the utilization of copper when given during the management of pan-malnutrition. However, when given in the complex milieu of diets and infant formulas the interactions are not always observed. In another context mentioned later persistent intakes of zinc can block intestinal transfer of copper by inducing enterocytic MTN.

A phenomenon that has not been fully explained is that high fructose and sucrose intakes apparently increase the risk of marginal intakes of copper, whereas isocaloric intakes of complex carbohydrates do not. This was first observed experimentally and may not be relevant to humans. However, in adults, experimental diets providing 0.7–1.0 mg of copper daily have induced cardiac dysrhythmias, conduction defects, bradycardia, and elevated low-density lipoprotein (LDL) cholesterol levels and reduced high-density lipoprotein (HDL) cholesterol levels in the circulation. These changes might have arisen from the character of the diet, i.e., the use of corn syrup, and the phenomena have not been reproduced or observed using more usual diets. Nonetheless, given the character of “Western Diets” there are concerns that copper inadequacy might be widespread in the population and partly responsible for common defects in lipid metabolism with adverse sequelae on cardiac health attributed to such diets (Harder et al., 2020).

Copper has several carriers in the portal circulation. These include transcuprein, albumin, and complexes with amino acids usually histidine, threonine, and glutamine. Copper is transported in the portal circulation to the liver and thence to the systemic circulation. Copper complexed with phosphatidic acid and fatty acids has been found in mesenteric lymph; this implies that some copper may bypass the liver and reach the systemic circulation via the thoracic duct. Usually, within 2 h of ingestion nearly all absorbed copper is taken up by the liver. This is mediated by cell membrane bound reductases and CTR1. The liver is the primary depot for copper, and the principal mediator of its systemic homeostasis, whereas fundamental control of homeostasis may depend on mitochondria (Baker et al., 2017).

In the hepatocyte, the copper joins a high turnover labile pool, probably centered on copper–glutathione complexes from which the metal is distributed to at least four targets: (1) a metallothionein pool; (2) the copper chaperone for Cu, Zn – SOD(CCS) to SOD1; (3) a series of chaperones involving COX 17 (with COX 19 and COX23) to COX 11 and SCO1 which is the chaperone; taking copper to mitochondrial inner membrane cytochrome *c*-oxidase or (4) to Atox1, for transport to ATP7B in the TGN which incorporates copper into apoproteins to form caeruloplasmin, and other cupric enzymes. It is noteworthy that knockout models of ATOX1 accumulate intracellular copper and develop a copper-deficient phenotype. Caeruloplasmin is then secreted into the circulation or excreted directly in the bile.

ATP7A and ATP7B transfer copper to apoenzymes, or into vesicles for export from the cell. The loss of either role is responsible for a specific disturbance of copper turnover; the absence of a normally functioning ATP7A is associated with Menkes disease and that of ATP7B with Wilson disease. These are discussed later. The difference between these two diseases and their variants can be appreciated from the different distributions of the two transporters. Although both are ubiquitous, ATP7A predominates in the kidneys, lungs, blood–brain barrier, gastrointestinal tract, and muscle, whereas ATP7B predominates in the hepatocytes where it is responsible for the synthesis of caeruloplasmin, and for the excretion of copper into the bile. There is little ATP7A in the liver. Within cells both ATP7A and ATP7B are usually distributed around the nucleus where they donate copper to apoenzymes in the Trans Golgi network (TGN). It is noteworthy that cisplatin and related anticancer agents are trafficked via CTR1 which mediates their uptake; additionally, cisplatins are excreted by ATP7B into the bile and therapeutic resistance to these compounds is associated with an upregulation of ATP7B.

MTN are ubiquitous intracellular monomeric polypeptides with a relative molecular mass of 6500 that contain 60 amino acids 30% of which are cysteine. MTN binds 6–10 atoms of copper, and it is induced among other things by endotoxemia, infections, calorie restriction, glucocorticoids, exercise, oestrogens, and hypothermia, as well as by zinc and, high exposure to copper. As has been said, MTN may have a role as a sequester of excess copper or a mobilisable depot of the metal.

### Copper distribution

Copper is probably distributed by the systemic circulation to peripheral tissues by the same complexes that are formed in the portal circulation and peripheral tissues are thought to take up and utilize copper in the same way as does the liver.

Caeruloplasmin contains 60–70% of copper in the circulation. It binds six atoms of copper and was thought to be a copper transport protein. However, evidence that caeruloplasmin has cuprous oxidase and ferroxidase activity, and a role in facilitating the binding of manganese to transferrin has prompted the revised concept that caeruloplasmin, and the related hephaestin are metallo-oxidases rather than just ferroxidases. The inherited deficiency of caeruloplasmin has little effect on copper trafficking and function but has appreciable effects on iron utilization.

The copper content of some tissues in adults and infants, and in the functional absence of ATP7A (Menkes’ disease) is shown in Table 5. The adult distribution, and metabolism of copper develops during infancy and early childhood. Overall, an adult human contains 50–120 mg of copper: 40% of this is in muscle; 15% in hepatocytes; 10% in brain, and 6% in blood. Approximately 60% of the copper in red blood cells is in superoxide dismutase. In plasma, 60–70% of copper is found in caeruloplasmin, 10–30% is associated with a transport protein transcuprein, and 15–20% is bound to albumin and amino acids.

**Table 5** Tissue copper content (mg g<sup>-1</sup> wet weight) in adults, infants, and infants with ATP7A dysfunction (Menkes Syndrome).

<i>Organ</i>	<i>Adults</i>	<i>Infants</i>	<i>Menkes syndrome</i>
Placenta		4.1–7.5	8.3–14.5
Liver	4.2–16.9	30–80	3–12
Brain	3.6–7.5	0.3–1.2	0.2–1.04
Intestine	1.2–3.4	4.1–7.5	6.4–12.4

### Copper excretion and homeostasis

The major route for systemic homeostasis of copper at customary intakes is hepato-biliary excretion; this accounts for 98% of excretion, and the rest is lost via urine. Hepato-biliary excretion involves ATP7B, and in a minor capacity ATP7A, secreting copper as a variety of complexes into vesicles which merge with the hepatocytic apical plasma membrane and transfer the copper and complexes into the bile for elimination. The excreted copper is not reabsorbed, the reason for this is unclear, and is lost in the feces.

The excreted copper pool may be supplemented by copper acquired from senescent intestinal cells and degraded caeruloplasmin.

At customary intakes, the amount of copper in the body is regulated by the changes in the amount of copper excreted by the liver. Usually, this entails the body retaining approximately 15% of absorbed copper and excreting the rest. The amount retained compensates loss of copper from shed epithelia (skin, intestinal, and other mucosae) and hair, menstruation, and adventitious blood loss. At times of increased copper need from potential deficiency, arising from inadequate intakes and depleted depots or from new tissue synthesis during growth or nutritional rehabilitation, hepatic excretion of copper is reduced, and intestinal uptake is increased; whereas with excessive copper exposure, hepatic excretion is increased, intestinal uptake and transfer are reduced, and at really high exposures increased metallothionein levels in the gut mucosa and liver, respectively, reduce intestinal transfer of the element, and increase its deposition in the liver. All these phenomena occur over a wide range of intakes and are deduced from a variety of studies in different models, but the adaptive phenomena at copper intakes between 0.8 and 7.5 mg daily at which absorption was 56% and 12%, respectively, have been well documented in humans. Note though that although the % absorption declined, the absolute amount of copper increased at the higher intake.

Studies at the cellular level show that when there is an increased need for copper both ATP7A and ATP7B traffic to and become tightly associated with the TGN; CTR1 increases in several tissues, and aggregates near the plasma membrane, while, in the enterocytes, CTR1 aggregates at the apical membrane.

High copper states in hepatocytes induce a migration of ATP7B from the TGN to cytosolic vesicular compartments that support biliary elimination of copper. In enterocytes, and other cells, increased copper leads to the endocytosis and degradation of CTR1, as well as the relocalization of ATP7A and ATP7B to cytosolic vesicles at the basolateral plasma membrane for transfer of copper into the blood. It is not known how these processes are regulated. A mechanism for the posttranslational regulation of ATP7B has been demonstrated. This involves a protein, COMMD1, which stabilizes ATP7B. However, the stability of COMMD1 itself depends on the protection from proteomic degradation which is mediated by X-linked Inhibitor of Apoptosis (XIAP). XIAP appears to be a copper sensor in that when it binds to copper it loses its inhibitory action on the proteomic degradation of COMMD1 and in turn ATP7B is degraded.

### Inborn errors of metabolism

Collectively inborn errors of copper trafficking have contributed considerably to the understanding of the systemic use of copper. A source of detailed information on these is the Website *Online Mendelian Inheritance in Man*. Two conditions, Menkes and Wilson diseases with respective incidences of 1:300,000 and 1:30,000 have captured interest.

The role of copper in the neurodegenerative condition, Menkes (MIM 309400) disease was suspected when its phenotypic similarity to copper deficiency affecting grazing sheep was realized. The defect is in the X chromosome gene (Xq21.1) for ATP7A and because this is an X linked recessive defect Menkes' Disease usually affects boys. The synthesis of a dysfunctional ATP7A results in the affected boy not being able to transfer copper out of the intestine effectively, and the copper which is transferred is neither distributed appropriately around the body or within organs and cells. The latter may accumulate copper but are unable to transfer it to apoenzymes: an illustration of this is that patients with Menkes have low circulating levels of copper and functioning caeruloplasmin, but the circulating level of immunoreactive apocaeeruloplasmin may be normal. Since ATP7A is responsible for the transfer of copper to the brain, this organ is affected by a severe copper deficiency. There is an accumulation of copper in the placenta, but the

baby has little or no features of copper deficiency when born. The boy presents after 3 months of age with developmental regression, apneic episodes, failure to thrive and a propensity to infection. This is a heterogeneous condition with a number of defects affecting the allele, and the functional implications of these are being explored in a number of mouse models of ATP7A dysfunction.

Defects in ATP7B synthesis result in Wilson disease (MIM277900), in which there is an inability to transfer copper to apoproteins, including caeruloplasmin, in the TGN and to excrete copper into the bile. There are more than 60 causative genetic mutations of the allele (13q14.3) and the genotype can to a certain extent predict both the age of presentation of the disease, which has been as early as 4 years, and its character. Usually, copper slowly accumulates in the liver and leaks into the circulation where it is deposited in a variety of tissues predominant among which, possibly because ATP7A is functioning normally, is the central nervous system (CNS). The onset of the disease is insidious; early biochemical evidence of liver damage is not detected because the patients have no symptoms or signs to prompt any investigations. However, liver damage has been found at 1 year of age in the sibling of a known case. Other than liver disease resembling hepatitis, or in later presentations, hepatic cirrhosis, the first evidence of disease is often deterioration in schoolwork, and neuromotor and psychiatric defects. Overall, in cases that have not been diagnosed until adulthood most tissues in the body are affected by copper deposition and associated oxidative damage. On a positive note, if the condition is detected early, patients can be “decoppered” with clinical improvement, by using a chelating agent such as D-penicillamine or trientine. Additionally, large oral doses of zinc which induces enterocytic metallothionein thereby blocking the transfer of copper taken up from the gut, or by tetrathiomolybdate with a view to mimicking the cause of copper deficiency in livestock by complexing dietary copper and preventing its uptake by the gut; it does work but its mechanism may involve inhibiting the function of ATOX1 and other metallochaperones.

Hypoceruloplasminemia (MIM 604290) is manifest by low circulating levels of caeruloplasmin and consequently low plasma copper levels, but with no other abnormalities. However, aceruloplasminemia (MIM 604290) in which there is a complete loss of ferroxidase (metallo-oxidase) activity has marked effects on iron metabolism with deposition of iron in tissues, including the CNS and basal ganglia, causing oxidative damage to tissues and resulting in endocrine and severe neurological disturbances. There have been case descriptions of humans with defects of the cytochrome *c* oxidase copper chaperones; a defect in SCO1 caused neonatal liver failure and encephalopathy, and defective SCO2 was linked to heart, brain, and muscle damage in an infant. Not all of these effects can be accounted for by loss of cytochrome *c* oxidase activity, so perhaps the SCOs have other roles.

## Measuring copper status

It is difficult to determine by a single measurement if an individual's copper status is deficient, adequate, or excessive. Easily accessible markers such as serum copper (reference range 10–22  $\mu\text{mol l}^{-1}$ ) or caeruloplasmin (reference range 0.9–2.65  $\mu\text{mol l}^{-1}$ ) concentrations represent a small proportion of the body pools of copper and are susceptible to many confounders. Since caeruloplasmin can contain up to 95% of the serum copper, measuring serum and plasma copper or caeruloplasmin is essentially measuring the same thing. However, caeruloplasmin levels, and copper, are increased as a component of the acute phase 1 reaction to infection, pregnancy, inflammation, and by estrogen, and hypoxia among other factors. Levels are low in copper deficiency but in human conditions the deficiency is invariably accompanied by conditions that increase caeruloplasmin levels, thus obscuring the deficiency marker. Only with severe copper deficiency are serum caeruloplasmin and copper levels reduced. Other approaches have been to measure copper-dependent enzyme activities in tissues with a rapid turnover such as erythrocyte superoxide dismutase, or platelet cytochrome *c* oxidase. Strategies based on measuring the non-caeruloplasmin component of circulating copper, multiple indices, or genomic and postgenomic markers of homeostatic adaptation are being explored. Currently, suspicion and alertness to the possibility of copper deficiency coupled with monitoring any response to copper supplements are the best clinical approaches to diagnosing copper deficiency, but this approach is not useful for large populations or for the subtle deficiency associated with multiple micronutrient deficiencies (McArdle 2021).

## Copper deficiency

Copper deficiency is seldom an isolated phenomenon, although it might occur as such in infants, children, and adults on synthetic diets, and parenteral or enteral nutrition. The appearance of copper deficiency in both term and ex-preterm infants develops when their hepatic deposits of copper are exhausted. Copper-deficient infants have presented at 4 weeks and 8 months of age. At 26 weeks of gestation the fetal liver has accrued 3 mg of copper, and at term this depot approximates 10–12 mg so early presentation of copper deficiency may involve defective accumulation of copper *in utero*. In recent clinical practice, copper deficiency is emerging as a complication of gastric surgery in the management of obesity.

The most common cause of copper deficiency is a complex of malabsorption and increased losses from the body because of hemolytic anemias, and gut infections and parasitism, causing protein losing enteropathies. These circumstances are widespread affecting perhaps 25% of the global population, in whom the effects on copper nutrition would be compounded by an absolute or relatively inadequate intake of copper.

The features of copper deficiency observed in infants and children with copper deficiency are listed in Table 6. They are the features of marked copper deficiency; the features in classic Menkes' disease are more marked with varicose vasculature, hernias, as well as neurodegeneration secondary to defective synaptogenesis and axon formation.

**Table 6** Features of copper deficiency in infants and children.

---

(Hypocupraemia, and hypoceruloplasminaemia) <sup>a</sup>
Hypochromic microcytic iron resistant anemia, Arrested maturation of erythroid and myeloid bone marrow
Neutropenia and propensity to infections
Hypotonia and muscle weakness, poor feeding failure to thrive
Pallor
Hypothermia, apneic episodes,
Skeletal change
Scurvy like bone changes: metaphyseal irregularities, epiphyseal flaring and cupping, bony spurs, and chip fractures
Epiphyseal porosis and separation
Periosteal reaction and subperiosteal new bone formation
Wormian bones, delayed bone maturation
Osteoporosis, fractures
Abnormal elastic and connective tissues, hernias tortuous vasculature, varices and aneurysms
Fishy odor: trimethylaminemia <sup>a</sup> hypoproteinemia with edema, neurodegeneration, developmental regression

---

<sup>a</sup>Not always evident.

The propensity to infections is attributable to neutropenia and reduced microbicidal activity of the cells secondary to loss of the respiratory burst and reduced superoxide dismutase activity.

## Copper excess

Exposure to excess copper can occur acutely, usually by ingestion of copper salts as free solutions, or by chronic exposure over an extended period. The upper levels mentioned earlier are set to help manage the latter risk. However, they do not prevent large systemic burdens of copper arising from failure to excrete copper as may occur with hepato-biliary obstruction, and Wilson disease. Additionally, patients receiving renal dialysis via a copper-based dialysis membrane may accumulate copper.

Ingested copper may come from water supplied via copper pipes. The metallic and salty bitter taste of copper in the water can be detected at concentrations of 2.5–3.5 mg copper per l. This is just below the threshold (4–5 mg L<sup>-1</sup>) at which nausea, retching, vomiting, and abdominal pain develop. The current regulatory limit advised by the World Health Organization for the copper content of water is 2 mg L<sup>-1</sup>, but a lower limit may be introduced. A high copper content in water might cause hair to turn green. Self-poisoning with copper salts, usually in suicide attempts, involves doses of 20–70 g of copper. In these circumstances, the above clinical features rapidly progress to hematemesis, diarrhea, and hypovolemic shock all of which reflect intestinal oxidative damage; following this systemic damage resulting in hemolysis, renal and liver failure develop. The stools and vomit may be green.

Chronic copper exposure from copper contamination during food storage and preparation was thought to contribute to the etiology and pathophysiology of the accumulation of copper seen in Indian Childhood Cirrhosis (ICC) (Idiopathic Copper Toxicosis), but it is now uncertain if the accumulated copper is a primary feature, or a secondary and variable sequel of exposure to another hepatotoxin. Thus, the precise role of the increased copper deposition as a toxicant is uncertain. ICC may be an ecogenetic condition in which patients have genetic predisposition to be abnormally sensitive to an environmental exposure. This is probably the case in Bavarian or Tyrolean liver disease that seems to be an autosomal recessive trait which only emerges with exposure to elevated copper intakes from the use of copper cooking utensils (Moller and Aaseth, 2022).

In contrast to the earlier comments on a possible endemic copper deficiency in Western populations, there are also concerns that the public is exposed to too much dietary copper, for example, via water supplies and that this predisposes the population to copper overload and an increased exposure to oxidative damage, which in the CNS might contribute to the development of Alzheimer's disease.

## Conclusion

Copper is an essential micronutrient with extensive roles in enzyme activities that are responsible for the integrity of connective tissue and bone matrix, the development of the nervous system, and the functioning of neurotransmitters, and, not least for effective energy metabolism. Two inborn errors of metabolism affecting copper have provided extensive information on severe copper

deficiency and copper overload. These are Menkes' disease and Wilson's disease, respectively, and their respective fundamental defects are the dysfunction of ATP7A and ATP7B which are energy-dependent copper transport proteins. The features of these conditions have facilitated a better understanding of how the body distributes and uses copper, and also of the subtler features of copper deficiency in particular. This has increased awareness that copper deficiency is probably a treatable component of most if not all malnutrition states. In public health nutrition there is probably a need for a thorough risk assessment of the risk of copper deficiencies and excesses in all populations and of the possible interactions with dietary intakes of fructose and glucose. These will be difficult to achieve until sound markers of adequacy, deficiency, and excess are available. It would be hoped that such markers could be forthcoming from increased information on the homeostatic control of copper turnover at cellular, organ and systemic levels.

Insight into copper's overall metabolism has been derived from observations of its metabolism in many life forms, genetic defects and conditions. The synthesis of this evidence demonstrates the potential role of metabolomics and systems biology and genomics in advancing biological and nutritional science.

## Key points

- Dietary fiber is an essential nutrient in the human diet that is crucial for human health
- Not all fiber is alike in both chemistry and physiological effect
- Fiber intake is about half of recommended intakes and often fiber supplements or fiber fortification is needed to obtain the recommended amounts of dietary fiber
- Differences in fermentation of fiber affect the physiological response to dietary fibers supporting that adaptation to increased fiber intake is essential in fiber advice
- Although dietary fiber has a known role in gut health, its effects extend beyond the gut with benefits for glycemic response, brain health, and cardiovascular health

## Introduction

Dietary fiber is widely recognized as beneficial for human health, and increased intake of certain fibers improves serum lipid concentrations, promotes regularity of bowel movements, improves blood glucose control, aids in weight maintenance, and improves immune function (Klosterbuer et al., 2011). Lack of agreement regarding what dietary fiber is and how it should be measured continues to confound the scientific literature on dietary fiber (Slavin, 1987). In 2001, the Food and Nutrition Board appointed a panel to develop a proposed definition of dietary fiber for North America (Dietary reference intakes: proposed definition of dietary fiber, 2001). Dietary fiber consists of non-digestible carbohydrates and lignin that are intrinsic to and intact in plants. Added or functional fiber consists of isolated, non-digestible carbohydrates that have beneficial physiologic effects in humans. Total fiber is the sum of dietary fiber and functional fiber (Slavin and Greenberg, 2003). The intent of these proposed definitions was to recognize the physiologic actions of fiber and its demonstrable health effects and to reduce the emphasis on dietary fiber as a constituent of food requiring quantification. The emphasis on the physiological benefits of isolated fibers will require that isolated fibers have clinical data that support their effectiveness in human clinical trials. Thus, many of the recent clinical trials of dietary fiber examine commercial fiber supplements and their link to a physiological endpoint.

## What is dietary fiber?

Recent definitions of dietary fiber have been offered by various groups and they all agree that dietary fiber is a group of carbohydrate polymers and oligomers (and lignin) that escape digestion in the small intestine and pass into the large bowel, where they are partially, or completely, fermented by the gut microbiota (Jones, 2013). Differences among definitions for fiber are found in three main areas: (1) Degree of polymerization; (2) Relationship to food and food processing; (3) Physiological effects (Fuller et al., 2016). Disagreements on these issues have led to confusion in fiber definition and labeling. For example, in the United States, fibers include oligosaccharides with a degree of polymerization of 3–9, whereas other bodies such as the Codex Alimentarius Commission (CAC) support that the national authorities should decide if carbohydrate polymers with a DP 3–9 should be included. This creates

challenges for measuring dietary fiber and databases of dietary fiber as total dietary fiber values will depend on whether the lower chain DP fibers are included.

The North American definition includes all resistant carbohydrates  $>3$  DP but requires that isolated fibers must show a physiological benefit to be included as dietary fiber sources on the Nutrition Facts label. Physiological benefits long accepted include improved laxation, serum lipid lowering, and glucose control (Slavin, 1987; Korczak and Slavin, 2020). Newer benefits such as improved mineral absorption or blood pressure control can also be accepted as physiological benefits of dietary fiber.

Definitions recognize that dietary fibers can be extracted from edible material (intrinsic) or modified and added back into a food (extrinsic). Because recommendations for dietary fiber are based on protective effects of intrinsic fiber on risk of cardiovascular disease, regulatory bodies have discussed the need to divide fiber into dietary fiber (intrinsic) and functional or added fiber (extrinsic). Earlier discussions linking fiber to physiological effects divided fiber into soluble and insoluble fractions (Slavin et al., 2009). Soluble fibers dissolve in water and may form a gel. They have been linked to blood lipid lowering and glucose control (Slavin, 1987). Soluble fibers survive transit through the small intestine and may be fermented in the gut to form short-chain fatty acids (SCFAs) such as butyrate, acetate, and propionate. Insoluble fibers do not dissolve in water and are the fibers we traditionally think of as roughage, fibers like cellulose and hemicellulose. These fibers are more closely linked to laxation. Because of these early associations between the solubility of fibers and physiological effects, many regulatory bodies allow foods to list total dietary fiber, soluble fiber, and insoluble fiber on labels.

### Classification of dietary fiber

Classifying fiber has challenged analytical chemists through the ages. Animal feeds originally measured crude fiber as the nondigestible carbohydrate that might be utilized by ruminants, but it was not well tolerated in monogastric animals. Crude fiber was referred to as the residue of plant-based food left after extraction with solvent, dilute acid, and dilute alkali (Dai and Chau, 2017). In 1953 Hipsley defined dietary fiber as a sum of indigestible constituents that made up the plant cell wall, encompassing the “unavailable carbohydrate.” Dietary fiber consists of remnants of edible plant cells, polysaccharides, lignin, and associated substances resistant to digestion by the alimentary enzymes of humans. Dietary fiber includes cellulose, hemicellulose, lignin, gums, mucilage, oligosaccharides, pectin, and other associated substances, including waxes, cutin, and suberin.

Dietary fiber chemistry is critical to classifying dietary fiber. Dietary fiber can be divided into noncellulosic polysaccharides, cellulose, and lignin. Human foodstuffs contain mainly noncellulosic polysaccharides, some cellulose, and little lignin (Slavin, 1987). The average content of noncellulosic polysaccharides, cellulose, and lignin for cereals is 75%, 17%, and 7%, respectively; for raw vegetables, 66%, 31%, and 3%, respectively; and for fruits, 63%, 20%, and 17%, respectively. Generally, fruits and vegetables tend to be higher in cellulose than cereals. Lignin is highest in fruits with edible seeds or in mature vegetables such as carrots or other root vegetables. Dietary fiber content of food depends on plant species, maturity, and components (i.e., leaf, root, or stem). Dietary fiber also includes cutin, waxes, and small amounts of proteins and lipids that are closely associated with the plant cell wall.

The solubility of dietary fiber was thought to help explain physiological effects, but more recent work suggests that solubility does not always predict physiological effects. Viscous, soluble fibers such as oat bran or psyllium are known to lower serum cholesterol and have health claims for their ability to lower blood lipids. Most other soluble fibers, for example, fructo-oligosaccharides, have no effect on blood lipids. Generally, only viscous, soluble fibers play a role in blood glucose control. Even in the 2001 Dietary Reference Intakes, the proposed definition of dietary fiber, it was concluded that separating soluble and insoluble fiber to predict physiological effects was problematic. Yet nutrition labels had already included this designator and consumers were told that insoluble fibers would aid in laxation and soluble fibers would lower blood lipids and improve glucose control.

Similar problems are seen with the belief that insoluble fibers aid laxation and soluble fibers do not. The increase in stool weight is caused by the presence of fiber in the colon, by the water that the fiber holds, and by partial fermentation of the fiber, which increases the amount of bacteria in stool (Slavin and Greenberg, 2003). Fiber in mixed diets including insoluble cellulose and hemicellulose are particularly effective promoters of normal laxation, as are cereal brans, psyllium seed husk, and methylcellulose in the form of supplements. If the fiber is rapidly fermented in the large bowel, as are many oligosaccharides, there is little increase in stool weight. But this rapid fermentation of easily fermented fiber can cause intestinal gas and discomfort in some individuals.

Studying dietary fiber in human subjects is difficult, as balance studies require collection of all food consumed and feces produced and measuring the fiber consumed and the fiber left over in feces. Balance studies must be done on controlled food intake and 5-day fecal composites collected as indicators of fiber surviving gut transit. Few contemporary studies exist to include in this review. Stephen et al. (2017) summarized the current state of knowledge on fiber definitions, sources, recommendation, intake and relationships to health in a comprehensive review paper of European fiber work. Disagreements on definitions of dietary fiber and methods of analysis continue, but there is more agreement that standardized definitions are first needed before there is agreement on analytical methods. Nutrient databases for dietary fiber, soluble fiber, and insoluble fiber continue to be lacking.

Cumming et al. (1978) fed 20 g/day of concentrated dietary fiber from carrot, cabbage, apple, bran, and guar gum to the controlled basal diet of nineteen healthy volunteers. Fiber from four commonly eaten food sources and guar gum produced very different response in colonic function. Fecal weight increased by 127% on bran and 20% on guar gum with carrot, cabbage, and apple producing intermediate changes in fecal weight. Differences were related to the intake of pentose-containing polysaccharides in the fiber, generally hemicelluloses. Individual variation in response to a given fiber was significant with stool weights ranging from 65 to 194 g/day on a controlled diet with tightly controlled fiber intake.

Mechanism of action of dietary fiber in the human colon by a novel method modified from nutrition for isolating bacteria found that the main component of human feces is bacteria (Stephen and Cummings, 1980). Cabbage fiber which is extensively broken down in the gut provides a readily useable substrate for stimulation of microbial growth, whereas wheat fiber remains largely undigested and retains water in the gut lumen. Additional work by this research group examined water-holding capacity and its relationship to fecal output in human subjects. Pectin had the greatest water holding capacity but produced the smallest change in fecal weight while bran had the lowest water holding capacity and produced the largest increase in fecal weight (Stephen and Cummings, 1979).

Early work with consumption of purified cellulose in humans, a poorly fermentable fiber, found that when purified cellulose, 16 g/day, was ingested with a semi-purified liquid diet only 8 % of the cellulose was broken down (Slavin et al., 1981). In contrast, more than half of the fiber in a habitual low fiber diet containing fruits, vegetables, and refined grains was degraded. This early work supports that the breakdown of fiber in the large intestine varies greatly depending on the chemical composition of the dietary fiber.

Fiber breakdown on enteral diets with and without fiber supplementation were examined and attempts made to relate fiber breakdown to breath gas production (McNamara et al., 1986). Subjects consumed enteral diets with 0, 30 and 60 g per day of soy polysaccharide, an isolated fiber source. Feces were collected, homogenized, dried, and analyzed for neutral detergent fiber (NDF). NDF was also determined in the diets to measure fiber balance. Fiber breakdown was extensive on all doses of fiber, about 90%. No relationship was found between fiber fermentability and production of breath gases, although there was large individual variability in the breath gas production levels. NDF from the soy polysaccharide fiber in the enteral formula was extensively fermented.

Our laboratory group studied differences in fiber fermentation when human subjects were fed controlled enteral diets with quick bread with 0 g, 10 g, and 30 g of dietary fiber as wheat bran and mixed vegetable fiber (Lampe et al., 1993). Each treatment was consumed for 23 days. Women and men seemed to respond differently to wheat bran and vegetable fiber regarding NDF excretion and breakdown. Fecal fiber excretion was greater in men than women; correspondingly, women tended to digest more fiber than men. This study again found large interindividual responses to dietary fiber and identified factors beyond fiber, such as gender, that alter the gut response to dietary fiber consumption.

Few metabolic studies on rigidly controlled diets have examined the effect of different fiber sources on fiber breakdown. Tucker et al. (1981) published a study on dietary fiber and personality factors as determinants of stool output as they had collected many fecal samples while fiber intakes were controlled at the USDA laboratory in Grand Forks, ND. Even when food and fiber intake was controlled, they found substantial individual differences in stool output. Personality measures were used to predict stool weight and fecal frequency and accounted for as much variance in stool output as did dietary fiber intake. They conclude that personality factors predispose humans to low stool output.

Grabitske and Slavin (2009) reviewed the gastrointestinal effects of low-digestible carbohydrates (LDCs) including definitions, classifications, and mechanisms of LDCs. LDCs are carbohydrates that are incompletely or not absorbed in the small intestine but are at least partly fermented by bacteria in the large intestine. Fiber, resistant starch, and sugar alcohols are types of LDCs. LDCs are increasingly added to processed foods because of potential health benefits including a reduced caloric content, reduced or no effect on blood glucose levels, and non-cariogenic effect. The benefits of LDCs are related to the inability of human digestive enzymes to break down completely the carbohydrates into absorbable saccharides and the subsequent fermentation of unabsorbed carbohydrates in the colon.

Thus, LDCs may affect laxation and cause gastrointestinal effects, including abdominal discomfort, flatulence, and diarrhea, especially at higher or excessive intakes. Current recommendations for fiber intake do not consider total LDC consumption nor recommend an upper limit for LDC intake based on potential gastrointestinal effects. In fact, the Institute of Medicine (IOM) did not set an Upper Limit (UL) for dietary fiber intake when fiber recommendations were finalized as it is accepted that humans are omnivores and can adapt to high intakes of dietary fiber. A vegan individual may consume 75 g of fiber per day or more. Of course this fiber comes from foods and is not isolated and potentially fed as a large bolus.

The term "laxation" refers to the elimination of feces (Grabitske and Slavin, 2008). Normal laxation varies widely among individuals. It is clinically defined as having a range of 3 bowel movements per week to 3 bowel movements per day. Stools are generally about 75% water, although this is highly variable and water content increases greatly with diarrhea. Of the remaining stool, about one-third is dead bacteria, one-third is undigested carbohydrate, and one-third is protein, fat mucus, dead cells, and inorganic material.

The frequency, consistency, composition, and weight of bowel movements are all indicators of bowel function and digestive health, but unlike blood, stool samples are generally not collected in large cohorts of healthy subjects. Stool weights are significantly related to fiber intake and studies find a wide range of stool weights, from 72 g/day to 470 g/day (Cummings et al., 1992). Different fibers have different effects on stool weight. Average increase in fecal weight per gram of fiber fed ranged from 5.4 g for wheat bran to 1.2 g for pectin (Cummings, 1993). This information supports why fiber sources high in insoluble fiber (wheat bran) were linked to increased stool weight and fiber sources high in soluble fiber (pectin) were linked to low stool weight.

Factors that affect laxation and digestive health are many. Lifestyle factors, diet, drugs, physical activity, and stress are all known to alter digestive function (Grabitske and Slavin, 2008). Personal factors including age, gender, genetics, the microflora, personality, food intolerances, and gastrointestinal pathology, such as celiac disease or lactose intolerance, will also alter digestive health. Bowel habits are also affected by changes in routine, such as travel or new work schedules. Typically, regular bowel habits depend on eating breakfast, a morning cup of coffee, or other habits. Drugs to alter bowel function and motility range from fiber supplements to irritants or other mechanisms. Antibiotics that decrease the gut microbiota will alter fiber fermentation in the gut and must be considered in any study of dietary fiber fermentation.

All the limitations to human studies of fiber fermentation and metabolism suggest more support for animal studies. Pigs are considered the monogastric animal with the closest digestive tract to the human, so findings from pig studies may provide insight to human physiology. The classification of potentially fermentable carbohydrates into soluble and insoluble is no longer enough for the information required to elucidate mechanisms by which dietary fiber has beneficial effects on monogastric health (Williams et al., 2019). Characteristics including fermentability (both kinetics of fermentation and end-products) are needed to help us understand how dietary fiber affects health in monogastric animals. Unfortunately, these in-vivo studies are expensive so results for in-vitro studies must inform our understanding of dietary fiber fermentation.

### What is resistant starch?

Of course, describing and measuring such a diverse mixture of non-digestible carbohydrates and associated substances is a major undertaking. Should non-digestible starch or resistant starch be included in dietary fiber? According to Codex, if resistant starch is naturally present in food, it could be classified as dietary fiber. However, if it is derived from an artificial synthesis, such as physical, enzymatic, or chemical synthesis, it should provide desirable physiological benefits to be considered as dietary fiber.

Foods naturally high in resistant starch include potatoes, cereals, whole grains, beans, legumes, rice, and bananas (Patterson et al., 2020). Barley, potatoes, and rice with higher amylose concentrations have more resistant starch than lower amylose varieties and foods cooked and then chilled have higher resistant starch than foods cooked without chilling. Resistant starch can also be produced from isolated starches and then added back to foods and beverages as dietary fiber, if allowed by local regulations on fiber definitions and labeling.

Starch has been divided into three fractions based on its digestive rate, including rapidly digesting starch, slowly digesting starch, and resistant starch. Resistant starch is a broad and diverse term and was originally divided into four types, i.e., physical inaccessible starch (RS1), ungelatinized starch granules (RS2), retrograded starch (RS3), and chemically modified starch (RS4). More recently, RS5 has been introduced as the amylose-lipid complex, which has a similar resistant mechanism toward starch digestive enzymes as RS3 (Li and Hu, 2022).

In the 1980s, RS was proposed and categorized as a kind of insoluble fiber as it could not be digested in the small intestine. Interest in RS grew as clinical data supported that resistant starch increased bacterial mass in feces, was a good substrate for growth of colonic microbiota, but preferentially increased production of the short chain fatty acid butyrate (Bird et al., 2010). Butyrate is the most important energy source for the colonocyte cell, increasing interest in resistant starch fermentation beyond its dietary fiber content (Carlson and Slavin, 2016).

Resistant starch intervention studies have been conducted on aging, insulin resistance, metabolic syndrome, kidney disease, and schizophrenia and it is thought to be particularly relevant for diseases characterized by dysregulated epithelial integrity and immune function, like inflammatory bowel disease (Dobranowski and Stintzi, 2021). The variable effects of RS on the gut microbiome are striking, with one subject showing increased butyrate production and another showing less butyrate production. Appreciate that measuring SCFAs production in human subjects is challenging as SCFAs are quickly absorbed in the colon and blood levels are not useful biomarkers of SCFA production.

### Fermentation of dietary fiber as a biomarker

Dietary fiber is classified based on chemical analysis and solubility, but also fermentability. As described, in vivo studies to measure fiber fermentation in human subjects are difficult to conduct and few recent studies have been published to add to the body of evidence on this topic. Thus, in vitro studies give us our best idea of differences in fermentation of dietary fibers of interest to human nutrition.

Although databases exist for the total dietary fiber, soluble fiber, and insoluble fiber content of many foods and fiber supplements, no accepted databases exist for fermentability of isolated fibers. Although fermentability is just one attribute of dietary fiber, the fermentation of fiber to yield “good bacteria” or associated metabolites (SCFAs) are critical data points for studies of prebiotics and postbiotics, discussed later in this review. The physiologic importance of SCFAs from nondigestible carbohydrate fermentation has been described and it is proposed that the degree of fermentability of a NDC, rather than the endpoints of clinical trials, may be appropriate for classifying it as a dietary fiber (Alexander et al., 2019). This need relates back to 2016 and the USA FDA releasing its first official definition of dietary fiber. Dietary fiber is defined as nondigestible soluble and insoluble carbohydrates with >3 monomeric units and lignin that are either intrinsic and intact in plants or isolated and synthetic and demonstrate a physiologic health benefit in humans. FDA reviewed the scientific literature and determined that 15 isolated and synthetic nondigestible carbohydrates had >1 beneficial physiologic effect. Included were cellulose, pectin, guar gum, locust bean gum, hydroxypropylmethylcellulose, beta-glucan, psyllium husk, mixed plant cell waters, arabinoxylan, alginate, inulin, and inulin-type fructans (fructooligosaccharides), high amylose starch/soluble corn fiber (resistant starch 2), galactooligosaccharides, polydextrose, and resistant maltodextrin/dextrin. Other isolated and synthetic NDCs are being evaluated for accepted physiologic effects. It should be noted the FDA has accepted the following physiological benefits: (1) Attenuation of blood glucose or insulin; (2) Lower fasting cholesterol concentration; (3) Improved laxation; (4) Increased gastrointestinal (GI) mineral absorption; and (5) Reduced energy intake 9 increased satiety. Production of fermentative end-products and change in the GI microbiota are not accepted physiological endpoints, although they are the endpoints of interest in prebiotic research.

Thus, in vitro studies that compare the fermentation aspects of isolated fibers are of mechanistic interest, they are not accepted as a measurement of prebiotic potential or fiber fermentation dynamics. Standard in vitro methods for fiber fermentability do not exist, but generally human donor fecal samples are used from healthy volunteers and then fiber samples incubated with the fecal slurries. Endpoints measured include fiber fermentation, gas production, pH changes, SCFA production, and changes in the microbiota. Recent work from our laboratory with resistant starches find differences in gas production with different resistant starches, but all were fermentable and promoted formation of beneficial SCFAs (Erickson et al., 2018). Examining the in vitro fermentation of commercial fiber supplements promoted as prebiotics found difference in production of *Bifidobacteria* and *Collinsella* (Carlson et al., 2017). All fibers were extensively fermented and produced beneficial SCFAs.

Earlier work found that shorter chain fructo-oligosaccharides exhibited more rapid fermentation than long-chain inulin in an in vitro fermentation (Stewart et al., 2008). Particle size and fraction of wheat bran also influenced SCFAs production in vitro (Stewart and Slavin, 2009). Five samples were compared: large-particle bran, small-particle bran, aleurone, coarse by-product, and fine-by-product. Small/fine particle size increased SCFA production compared with large/coarse particle size. The molar percentage of butyrate at 24 h was significantly greater for large-particle bran than the other sample. Bran characteristics and composition should be considered when manufacturing foods due to the diversity of physiologic effects.

Fiber blends of fibers with different fermentation rates were compared in vitro (Koecher et al., 2014). FOS and inulin were fermented most readily, but when included in blends, fermentation was slower and less gas was produced. This study suggested that fiber blends may be more useful in enteral products to combine the desirable solubility profile and fermentation profile for optimum health.

### What is a prebiotic?

The health effects of dietary fiber have been extensively reviewed and are accepted worldwide (Carlson et al., 2018). Prebiotics were first defined in 1995 and their definition has continued to evolve over time. Prebiotic dietary fibers are specific, microbiota-shaping compounds that function as a carbon source for growth of beneficial taxa, thus delivering a specific or selective change that confers the host health related to its metabolism of the prebiotic dietary fibers.

Most of the original prebiotics were also dietary fibers, including inulin, oligofructose, lactulose, and resistant starch. As there is no official method of becoming a prebiotic, other carbohydrates including galactooligosaccharides, tragalactooligosaccharides, polydextrose, wheat dextrin, acacia gum, psyllium, and partially hydrolyzed guar gum (PHGG), to name a few, have published studies that show that consumption of these fibers increases fecal levels of bifidobacterial or lactobacillus (Slavin, 2013). Often production of SCFAs in vitro have been used as a biomarker of prebiotic effect, since SCFAs are the byproduct of fiber fermentation.

Recent reviews have attempted to classify prebiotics based on in vitro studies and short-chain fatty acid production (Ashaolu et al., 2020). Isolated dietary fibers including resistant starch, pectin, hemicellulose, beta-glucan, and fructans were reviewed and their support for being a prebiotic offered. Regulatory acceptance of the importance of prebiotics beyond their ability to list their fiber content on the label is lacking.

The effect of fructans, prebiotics and fibres on the gut microbiome was reviewed (Swanson et al., 2020). Molecular studies confirmed the selective bifidogenic effect of fructans and galactooligosaccharides (GOS) in human population. Resistant starches, polydextrose and beta-glucan showed broader effects with more and different types of gut microbial species being enhanced, often including phylotypes of *Ruminococcaceae*. There was significant variation in magnitude of response and in individual responses to a specific fiber that may be due to numerous factors, including presence and relative abundance of microbial types, diet, genetics of the host, and intervention parameters, including intervention duration and fiber dose. The authors conclude that the field could benefit from a more systematic approach that will support defining the impact of prebiotics and fibers on the gut microbiome, identify biomarkers that link gut microbes to health, and address the personalized responses of an individual's microbiota to prebiotics and dietary fibers. Because the definition of prebiotics requires a health benefit, it is currently much easier to stay in the dietary fiber classification as definitions and regulatory approval are already realized.

Another recent review described dietary fibers as prebiotic, prebiotic candidates, or fibers without prebiotic potential (Rezende et al., 2021). Resistant oligosaccharides, fructans (FOS, oligofructose and inulin) and galactans are recognized in the literature as prebiotics according to the authors. Galactosides and some non-starch polysaccharides and resistant starches may act as prebiotic fibers or have prebiotic potential. They suggest that associated substances (non-carbohydrates) are considered dietary fibers but apparently have no prebiotic effect on humans. Intrinsic dietary fiber in plants with associated substances have never been studied for prebiotic potential, so this conclusion can be questioned. Proteins and fats have been described as prebiotics, so the lack of specificity for the term will continue to limit the labeling of products as "prebiotics" (Sanders et al., 2019).

So et al. (2018) published a systematic review and meta-analysis of dietary fiber intervention on gut microbiota composition in healthy adults. A total of 64 studies involving 2099 participants were included. Dietary fiber intervention resulted in higher abundance of *Bifidobacterium* spp. and *Lactobacillus* spp. as well as fecal butyrate concentration compared with placebo/low-fiber comparators. Subgroup analysis found that fructans and galacto-oligosaccharides led to significantly greater abundance of both *Bifidobacterium* spp. and *Lactobacillus* spp. compared with comparators. No differences in effect were found between fiber intervention and comparators for alpha-diversity, abundances of other prespecified bacteria, or other SCFA concentrations. The authors conclude that dietary fiber interventions, particularly for fructans and GOS lead to high fecal abundance of *Bifidobacterium* and *Lactobacillus*, but do not affect alpha-diversity. Most of the data has been generated because of the increased interest in prebiotics starting with their definition in 1995.

### Health benefits of fiber, prebiotics, and probiotics?

Gastrointestinal health and the gut microbiome is a rapidly emerging field and fiber, prebiotics, and probiotics are all dietary components that play a role in maintaining a healthy gut microflora (Carlson and Slavin, 2016; Liu et al, 2022). Generally, we consider prebiotics as fiber-like compounds that generate bacteria in the colon while probiotics are live bacteria that you consume. Synbiotics are often combining prebiotics and probiotics. Unfortunately, the marketplace is awash in these products and little regulatory oversight is available for these products. Prebiotics operate in the safe space of dietary fiber, an accepted nutrient in the human diet that can be measured by accepted analytical tools and regulatory approval throughout the world. Enter postbiotics.

### What are postbiotics?

A consensus statement by the International Scientific Association of Probiotics and Prebiotics (ISAPP) on the definition and scope of postbiotics defined postbiotic as a “preparation of inanimate microorganisms and/or their components that confers a health benefit on the host.” (Salminen et al., 2021). The review paper lists past proposed definitions of the term postbiotic which perhaps explains the confusion in the literature and with consumers on this concept. Weigh et al. (2019) define postbiotics as functional bioactive compounds, generated in a matrix during fermentation which may be used to promote health. The term postbiotics can be regarded as an umbrella term for all synonyms and related terms of these microbial fermentation compounds. Therefore, postbiotics can include many different constituents including metabolites, SCFAs, microbial cell fractions, functional proteins, extracellular polysaccharides (EPS), cell lysates, teichoic acid, peptidoglycan-derived muropeptides and pili-type structures. The concept suggests that the microbes produced by fermentation of fiber are not the important mechanisms. The byproducts of fiber fermentation, for example, SCFAs are more important.

The need for established clinical markers and microbial endpoints are still essential to determine the causal role of the GI microbiota in protecting health (Deehan et al., 2017). Few studies collect fecal samples and even when fecal samples are collected, there is little information provided on the dietary exposure and the kinds and amounts of dietary fiber that were consumed. Collection of fecal samples to measure the gut microbiota with the suggestion that we can predict health from such information is premature and potentially misleading.

### Links between dietary fiber intake and health outcomes

Intake of intrinsic fiber is linked to less risk of cardiovascular disease. Additionally, dietary fiber is accepted as an important piece in gut health and a first step in treating constipation and diarrhea. Fibers differ in their chemistry and there are some relationships between fiber chemistry and physiological effect. Other aspects of fiber, including fermentability, will also predict physiological effects.

Additional attributes of fiber, for example, viscosity, will determine the possibility that fiber will lower blood lipids or modulate blood glucose. Because of the inconsistency of fiber's effect on physiological parameters, the FDA now requires isolated fiber to show at least 1 physiological benefit before the fiber can list its content on the Nutrition Facts label.

### Fiber intake and recommendations—mind the gap

We have long appreciated the importance of dietary fiber in the diet and have promoted the need to consume adequate dietary fiber across the lifecycle. Additionally, the importance of dietary fiber in treating diseases such as constipation and high blood lipids is well accepted. Yet intakes of dietary fiber are inadequate across the globe and despite public health guidance to eat more plant foods and fiber, usual intake is about half of recommended levels. In the past, public health measures to add deficient nutrients to the diet in foods has been promoted to solve dietary deficiencies. As more fibers gain acceptance by the FDA as having a physiological benefit, it might be considered to add fiber to popular foods or beverages to increase consumption of dietary fiber to recommended levels. The large individual variability in response to dietary fiber and concerns with intestinal gas and bloating must be considered as those are often reported as the reasons that consumers are not willing to consume more dietary fiber.

### Conclusion

Even in 300 BC, Hippocrates said “wholemeal bread makes larger feces than refined bread.” The importance of dietary fiber in laxation and bowel health has long been appreciated. More recently prospective, cohort studies find that higher intakes of dietary fiber are linked to decreased risk of developing cardiovascular disease. Recommendations for intake of dietary fiber in North America are based on these epidemiologic studies that find that 14 g dietary fiber/1000 kcalories is associated with less cardiovascular risk. Thus, the Nutrition Facts panel recommends 28 g of dietary fiber for the average consumer of 2000 kcalories. Usual intake of dietary fiber is approximately half that amount which makes dietary fiber a nutrient of concern. Although dietary guidance supports consumption of foods concentrated in dietary fiber, whole grains, legumes, vegetables, nuts, and fruit, many consumers turn to fiber supplements to obtain their needed fiber intake.

Current research interest in the effect of dietary fiber on the gut microbiota has expanded the interest of fiber in disease prevention into fields such as immunology, brain health, and diabetes control. Fiber is active throughout the gastrointestinal tract, but much of the current interest is in the fermentation of dietary fiber in the gut. Although earlier thinking supported that certain microbiota were “healthy,” the prebiotic concept, more recent thinking is that the products of fiber’s fermentation are important players in fiber’s protective role in disease prevention. SCFAs from fiber fermentation help maintain the integrity of the colonic cells and are thought to trigger a cascade of additional health benefits.

We know that intake of dietary fiber is protective, but we also know that fibers cover a range of physiological benefits, solubility, fermentability, and viscosity, for example. Thus, public health guidance supports that consumers choose a variety of fiber-rich foods to obtain the Adequate Intake (AI) daily. Ideally, fiber should be provided by whole foods, but since dietary fiber intake continues to lag significantly behind dietary recommendations, isolated fibers with health benefits supported by research trials are also part of the solution to increasing dietary fiber intakes to recommended levels.

### Key points

- The doubly labeled water method has become the gold standard for determining energy requirements because it allows for measurement of energy requirements in individuals leading their usual daily lives.
- The major components of energy requirements are: basal metabolic rate, thermic effect of feeding, energy expenditure for physical activity, and (in children) energy needs for growth.
- The major factors influencing energy requirements are body size, level of physical activity, and age and sex; equations are presented that allow calculation of typical requirements based on these parameters.

### Glossary

**BMR, RMR, and REE** Basal Metabolic Rate is the rate of energy expenditure in the thermo-neutral state 12–18 h after last eating. This term is often used interchangeably with Resting Metabolic Rate and Resting Energy Expenditure, although the extended period of fasting required for a BMR measurement is not necessary for RMR and REE, which typically have overnight fasting that is not necessarily >12 h

**MET** The Metabolic Equivalent is a unit of energy expenditure expressed relative to resting energy expenditure that provides a simple index of the relative strenuousness of different activities

**PAL** Physical activity level: The ratio of the total energy expenditure to BMR or REE over an extended period, typically assessed as

**Doubly Labeled Water Method** The DLW method is a stable isotope method that estimates total energy expenditure over periods of 1–3 weeks by measurement of the differential rates of disappearance of two stable isotopes of water

### Introduction

The term energy requirement is the amount of metabolizable<sup>1</sup> energy from food needed to match the body's energy expenditure needed to maintaining all its functions and engage in all forms of physical activity, plus the additional energy needed for growth in children, for pregnancy and lactation, when recovering from some illnesses, and when exposed to cold. The amount of food energy needed by an individual depends on his/her size and several other factors. For example if the individual has overweight or obesity, the food needs to maintain the extra weight will be greater than if they are underweight for the same level of physical activity.

<sup>1</sup>Metabolizable energy is the amount of energy available to the body after obligatory losses in stool and urine. Typically, approximately 90% of the total energy in food is available as metabolizable energy.

## Estimated energy requirements determined using the doubly labeled water method

Measures of total energy expenditure estimated over 2–3 weeks can be obtained by the use of the double-labeled water technique (Speakman and Hambly, 2016), which relies on the difference in labeling of body water with two stable isotopes of water, deuterium and  $^{18}\text{O}$ . The differential dilution of deuterium and  $^{18}\text{O}$  in urinary water over time is monitored in urine during a 1–3-week period following a single oral dose of  $\text{D}_2^{18}\text{O}$ . The  $^{18}\text{O}$  concentration in urine decreases more rapidly than the deuterium because the oxygen in water exchanges rapidly with the body's bicarbonate pool, which is turning over rapidly as carbon dioxide is produced by tissue metabolism and excreted in expired air. Thus, the difference in rate constants for disappearance of  $^{18}\text{O}$  and deuterium provides a measure of the rate of carbon dioxide production. Carbon dioxide production can then be converted to a rate of energy expenditure with knowledge of the balance of macronutrients being oxidized, which can be estimated from food records. The technique is an important advance over previous methods for determining energy requirements, because it allows scientists to measure energy expenditure in the free living state while participants lead their usual daily lives.

The doubly labeled water method has been adopted as the gold standard for assessment of energy requirements both in the US and Europe (e.g. Institute of Medicine, Food and Nutrition Board, 2002). For individuals where weight stability is optimal, energy requirements are equal to total energy expenditure in the weight stable state. For children and pregnant and lactating mothers, additional allowance needs to be made for the cost of tissue deposition and milk excretion, but in humans this amount is usually a small fraction of total energy requirements. Thus, using doubly labeled water as the basis for energy requirements has allowed for more accurate determination of energy requirements than in the past, when methods such as activity diaries combined with minute-to-minute estimates of the energy costs of different physical activities were used. A limitation of using the doubly labeled water method to estimate energy requirements is that most of the available data was not obtained for the purpose of measuring energy requirements, but rather for other scientific purposes relating to energy expenditure, and thus the population group means may not be normative.

The US Institute of Medicine compiled all available doubly labeled water for a comprehensive reevaluation of energy requirements in 2002 (Institute of Medicine, Food and Nutrition Board, 2002), and are currently updating this information. The available equations from 2002 were generated from all available data at the time, with empirical approaches used to add energy needed for growth when relevant for different population groups. A summary of the equations obtained are summarized in Table 1. Ages from birth to old age are covered, and quartiles of energy expenditure were derived for individuals aged 3 years and above, allowing for estimated typical energy requirements to be derived for individuals with different lifestyles.

## The components of energy requirements

As noted above, total energy expenditure is the major component of energy requirements and has three main components: the BMR, postprandial thermogenesis, and energy expenditure for physical activity. BMR usually amounts to 50–70% of an individual's total energy expenditure. Postprandial thermogenesis amounts to approximately 10% of total energy expenditure, with this amount used for the metabolic cost of processing, i.e. eating, absorbing, transporting, and storing food. The remaining energy is used for physical activity and non-exercise activity thermogenesis. In addition to total energy expenditure, estimated energy requirements allow for energy deposition in tissue and milk production. These separate components of estimated energy requirements are summarized below.

## Basal metabolic rate

The rate at which the body burns its own stored fuels in the fasted, resting, and relaxed state, i.e. in the basal state in a thermoneutral environment, is called the basal metabolic rate (BMR). The process of oxidation of stored fuels involves a series of enzymatically controlled biochemical reactions leading eventually to the combination of oxygen with the carbon and hydrogen components of the body's fuels thereby yielding carbon dioxide and metabolically derived water. The incompletely oxidized nitrogen is excreted in urine primarily as urea, after synthesis by the liver. The intermediate steps in the metabolism of the body's fuels are linked biochemically to drive the generation of phosphate-containing organic molecules, such as adenosine triphosphate (ATP), which in turn serve as the direct energy sources for all the body's cell activities, including the synthesis of complex molecules, the maintenance of tightly controlled ionic gradients in the cell, and the excretion of ions and molecules outside the cell. Thus, the oxygen being taken up by the lungs reflects the tissue metabolism of the fuels needed to regenerate the ATP used up in either biochemical "internal" work or mechanical external work undertaken by the body's muscles.

BMR varies with the age of the individual, at least in part because of the varying sizes of metabolically very different organs at different ages. Thus, a child has a relatively large brain, liver, and intestine with a higher metabolic rate per kilogram of body weight than a more muscular adult. Body fat cells are metabolically active but contain a substantial amount of inert fat, so that the larger fat mass of a woman results in a lower BMR per unit body weight than a man. If energy expenditure is adjusted for the amount of fat-free mass and fat mass, then the metabolic rate of men and women is similar. As men and women age, they tend to lose fat free mass and store extra fat, and some organs including the brain can shrink, so the BMR on a weight basis falls with age.

**Table 1** Equations to estimate energy requirements by age-group and gender from US Institute of Medicine Dietary Reference Intakes, which were derived from doubly labeled water measures of energy expenditure (Institute of Medicine, Food and Nutrition Board, 2002).

**EER for boys and girls aged 0–3 years:**

$$\begin{aligned} 0-3 \text{ months} &= (89 \times \text{weight} - 100) + 175 \\ 4-6 \text{ months} &= (89 \times \text{weight} - 100) + 56 \\ 7-12 \text{ months} &= (89 \times \text{weight} - 100) + 22 \\ 13-36 \text{ months} &= (89 \times \text{weight} - 100) + 20 \end{aligned}$$

**EER for boys 3–18 years:**

$$\begin{aligned} \text{EER age 3-8} &= 88.5 - (61.9 \times \text{age}) + \text{PA} \times (26.7 \times \text{weight}) + (903 \times \text{height}) + 20 \\ \text{EER age 9-18} &= 88.5 - (61.9 \times \text{age}) + \text{PA} \times (26.7 \times \text{weight}) + (903 \times \text{height}) + 25 \end{aligned}$$

**Where ages is in years, weight in kg, height in m and PA is physical activity coefficient:**

$$\begin{aligned} \text{PA} &= 1.00 \text{ if PA is } 1.0 - <1.4 \text{ (sedentary)} \\ \text{PA} &= 1.13 \text{ if PA is } >1.4 - <1.6 \text{ (low active)} \\ \text{PA} &= 1.26 \text{ if PA is } >1.6 - <1.9 \text{ (active)} \\ \text{PA} &= 1.42 \text{ if PA is } >1.9 - <2.5 \text{ (very active)} \end{aligned}$$

**EER for girls 3–8 years:**

$$\begin{aligned} \text{EER age 3-8} &= 135.2 - (30.8 \times \text{age}) + \text{PA} \times (10.0 \times \text{weight}) + (934 \times \text{height}) + 20 \\ \text{EER age 9-18} &= 135.2 - (30.8 \times \text{age}) + \text{PA} \times (10.0 \times \text{weight}) + (934 \times \text{height}) + 25 \end{aligned}$$

**Where ages is in years, weight in kg, height in m and PA is physical activity coefficient:**

$$\begin{aligned} \text{PA} &= 1.00 \text{ if PA is } 1.0 - <1.4 \text{ (sedentary)} \\ \text{PA} &= 1.16 \text{ if PA is } >1.4 - <1.6 \text{ (low active)} \\ \text{PA} &= 1.31 \text{ if PA is } >1.6 - <1.9 \text{ (active)} \\ \text{PA} &= 1.56 \text{ if PA is } >1.9 - <2.5 \text{ (very active)} \end{aligned}$$

**EER for adult men 19 years and older (includes normal weight and individuals with overweight and obesity):**

$$\text{EER} = 864 - (9.72 \times \text{age}) + \text{PA} \times (14.2 \times \text{weight}) + 503 \times \text{height}$$

**Where ages is in years, weight in kg, height in m and PA is physical activity coefficient:**

$$\begin{aligned} \text{PA} &= 1.00 \text{ if PA is } 1.0 - <1.4 \text{ (sedentary)} \\ \text{PA} &= 1.11 \text{ if PA is } >1.4 - <1.6 \text{ (low active)} \\ \text{PA} &= 1.25 \text{ if PA is } >1.6 - <1.9 \text{ (active)} \\ \text{PA} &= 1.48 \text{ if PA is } >1.9 - <2.5 \text{ (very active)} \end{aligned}$$

**EER for adult women 19 years and older (includes normal weight and individuals with overweight and obesity):**

$$\text{EER} = 387 - (7.31 \times \text{age}) + \text{PA} \times (10.9 \times \text{weight}) + 660.7 \times \text{height}$$

**Where ages is in years, weight in kg, height in m and PA is physical activity coefficient:**

$$\begin{aligned} \text{PA} &= 1.00 \text{ if PA is } 1.0 - <1.4 \text{ (sedentary)} \\ \text{PA} &= 1.12 \text{ if PA is } >1.4 - <1.6 \text{ (low active)} \\ \text{PA} &= 1.27 \text{ if PA is } >1.6 - <1.9 \text{ (active)} \\ \text{PA} &= 1.45 \text{ if PA is } >1.9 - <2.5 \text{ (very active)} \end{aligned}$$

**EER for pregnancy aged 19–50 years**

$$\begin{aligned} \text{1st trimester:} & \text{adult EER} + 0 \text{ energy expended in pregnancy} + 0 \text{ energy deposition} \\ \text{2nd trimester:} & \text{adult EER} + 160 \text{ kcal/day energy expended in pregnancy} + 180 \text{ kcal/day energy deposition} \\ \text{3rd trimester:} & \text{adult EER} + 272 \text{ kcal/day energy expended in pregnancy} + 180 \text{ kcal/day energy deposition} \end{aligned}$$

**EER for lactation aged 19–50 years**

$$\begin{aligned} 0-6 \text{ months:} & \text{adult EER} + 500 \text{ kcal/day milk energy} - 170 \text{ kcal/day body fat loss} \\ 6-12 \text{ months:} & \text{adult EER} + 400 \text{ kcal/day milk energy} - 0 \text{ kcal/day body fat loss} \end{aligned}$$

If oxygen consumption and carbon dioxide production are measured using an “indirect” calorimeter system (so called because it does not measure energy expenditure directly), classic equations originally developed by J.S. de Weir can be used to calculate energy expenditure (de Weir, 1949). The conditions of the measurement are lying quietly and awake, fasting 12–18 h in a thermoneutral environment, BMR can be accurately calculated:

$$\text{RMR(kcal / day)} = 1440(3.941 \text{ VO}_2 + 1.106 \text{ VCO}_2)$$

where  $\text{VO}_2$  and  $\text{VCO}_2$  are measured in liters per minute.

Equations have also been developed to predict BMR from readily measured anthropometric variables, and Table 2 shows equations that can be used to calculate based on biological sex, weight, height and age (Henry, 2005). There is a range of BMR amounting to  $\pm 20\%$  of the mean value at each weight. Thus, in a young 25-year-old woman of 55 kg, the anticipated mean BMR is 1305 kcal/day but could vary under normal conditions from 1063 to 1547 kcal/day. The differences in BMR of different individuals of the same weight in part reflects differences in their proportion of lean to fat tissues. Approximately 40% of the BMR variation between sexes and the age of individuals may be explained by differences in the size of the body organs, for example, liver, intestine, and

**Table 2** BMR equations for different age groups and genders from Henry (2005).

Gender	Age (years)	BMR (kcal/day)		
		Coefficient weight (kg)	Coefficient height(m)	Constant
Males	<3	28.2	859	−371
	3–10	15.1	313	306
	10–18	15.6	266	299
	18–30	14.4	313	133
	30–60	11.4	541	−137
	>60	11.4	541	−256
Females	<3	30.4	703	−287
	3–10	15.9	210	349
	10–18	9.40	249	462
	18–30	10.4	615	−282
	30–60	8.18	502	−11.6
	>60	8.52	421	10.7

Reproduced from Department of Health, 1991. Dietary reference values for food energy and nutrients for the United Kingdom. Report on Health and Social Subjects, vol. 41. HMSO, London.

muscle, but there is a residual difference between individuals who seem to be explicable only in terms of differences in the rate at which different tissues metabolize fuel. This is controlled in part by the circulating concentration of thyroid hormones. Adults with an above-average level of circulating thyroid hormones tend to have a higher but still normal BMR. Smokers' BMRs are approximately 5% above normal, perhaps because of activation of the sympathetic nervous system.

Young women show a swing in BMR that is at its lowest in the late follicular phase of the menstrual cycle, just before ovulation. On ovulation, the basal body temperature rises rapidly by approximately 0.5 °C and the BMR immediately increases but rises further to a peak in the later luteal phase. This metabolic swing of  $\pm 5\%$  is independent of changes in food intake, but the recognized 5–10% fall in intake during the follicular phase with a similar rise in the luteal phase may accentuate the hormonally dependent swing in metabolism. The effects of contraceptives that inhibit ovulation and the subsequent rise in basal temperature are not well documented. The previous day's food intake may somewhat affect the BMR, especially if there has been substantial overeating or undereating. In addition, the mixture of fuels combusted during fasting is influenced by the proportion of the previous 3–4 days' intakes derived from carbohydrate; much of the glucose from glycogen is metabolized in the fasting state if carbohydrate intake was previously high. When glycogen stores in the liver near exhaustion, the body switches to using body fat with a small fall in carbon dioxide output; a carbohydrate-rich diet induces a slightly higher fasting metabolic rate probably because of a slight induction of thyroid metabolism by dietary carbohydrates.

The BMR falls by 2–5% when individuals transfer to live in a tropical warm environment; in uninsulated houses, seasonal BMR can increase 5–10% in winter as seen in Japan before World War II. The BMR formulas shown in Table 2 ignore any temperature effects. The observed lower BMR of some people living in the tropics may also reflect the effects of malnutrition. Poor nutrition can have both immediate and longer-term effects in lowering the BMR. After 4 days of semistarvation the BMR falls, and after 2 weeks the BMR is approximately 15% lower as the body's organs become more efficient. More prolonged or severe semistarvation induces a progressive loss of the body lean tissues as well as fat, and the BMR therefore continues to decline in proportion to the loss of lean tissues. Body weight can eventually stabilize at a new low level and, if the physical activity is also reduced, semistarved volunteers can come back into energy balance on as little as 50% of their initial intake. However, this requires a large loss of weight and marked lethargy if energy balance is to be preserved on such a low intake.

### Postprandial thermogenesis

The increase in oxygen uptake and carbon dioxide production after a meal, known as postprandial thermogenesis, has also been described as the specific dynamic action of food, dietary-induced thermogenesis, and the thermic effect of feeding (de Jonge and Bray, 1997). The maximum postprandial thermogenesis occurs after ingesting protein, and both glucose and fat have only a small effect, with a summary of postprandial thermogenesis studies indicating that 13.2% of protein metabolizable energy is lost to postprandial thermogenesis compared to 5.1% for fat and 5.4% for carbohydrate, while alcohol induces a variable 0–8% effect (Eisenstein et al., 2002). Nevertheless, the overall effect of protein on energy expenditure is relatively modest in diets of typical composition, in which protein is likely to be in the range 10–25% of energy. Some additional dietary components increase metabolism: caffeine equivalent to two cups of tea induces a 1–3% increase and spices, as in Indian curry, by up to 25% in some reports.

Differences in postprandial energy expenditure have been sought as an explanation for the propensity of some individuals to obesity but there is no strong evidence to support this thesis. A proportion of obese subjects have a reduced metabolic response to a meal; this effect may prove to depend on the degree of abdominal insulation because the response is reduced if volunteers are swathed in insulation to reduce the abdominal heat loss, thereby increasing the temperature of the blood entering and leaving the liver. Insulin resistance may also explain the difference. Lactating mothers (and pregnant women) also have a lower postprandial thermogenesis that returns to normal after they have stopped breast-feeding. Smoking and postprandial thermogenesis interact synergistically so the thermic output after a meal is enhanced. The small postprandial response during lactation is consistent with that observed in many species of animal in which brown adipose tissue is used as the organ for modulating heat production as a mechanism to maintain body temperature. However, this organ is normally not very active in humans although recent analyses with new scanning techniques have shown that its activity does continue in adults and small seasonal changes in BMR may reflect changes in brown fat metabolism. So postprandial thermogenesis as well as the response to cold in adults may involve brown adipose activity.

Prolonged overfeeding may produce an increase in postprandial response providing the intensity of overfeeding (especially with carbohydrate) is high. Thus, progressive overconsumption of 1500 kcal/day has been reported to lead to up to a 33% increase in BMR combined with postprandial thermogenesis. Nevertheless, this apparent mechanism for dissipating excess energy is limited because energy is stored, at least two-thirds as fat and the rest as lean tissue. The majority of the increased metabolism may be accounted for the cost of fat synthesis from carbohydrate, although the human capacity to transform carbohydrate into fat is relatively limited unless carbohydrate overfeeding is extreme, preference being given to the selective storage of the fat component of the ingested energy.

### Physical activity

The energy cost of physical activity can be measured with calorimetry systems that collect expired gasses. Based on these methods, typical costs of different physical activities have been generated. Weight-bearing movement and antigravitational moves, for example, walking up a hill with a load, are particularly energetic. The simplest way of estimating individual costs for specific tasks involves the use of extensive tables listing the energy cost of different movements expressed as metabolic equivalents or METs, as summarized in [Table 3A](#) ([Ainsworth et al., 2011](#)). For simplicity, METs are energy expenditure values expressed relative to energy expenditure in the resting state. METs for typical activities range from 1 to more than 10 depending on the amount of work being performed. Whole body calorimetry performed over 24 h can also measure energy expenditure for physical activity, as well as non-exercise activity thermogenesis, by correlating fluctuations in energy expenditure with motion sensors embedded in the chamber. There are also internationally recognized questionnaires for assessing individuals' physical activity patterns and sophisticated accelerometers and wrist-worn activity sensors worn by the individual, with a standardization of their energy equivalence from measures of oxygen uptake. Accelerometers, and commercial variants such as smart watches, are increasingly used to measure the pattern and energy equivalence of daily activities in population studies.

The ratio of the total daily energy expenditure to the BMR is designated the physical activity level (PAL). Physical activity is important to general health so it is desirable that the overall PAL of individuals should be high. However, very high minute-to-minute MET values cannot be sustained, with the consequence that the usual average daily PAL level is in the 1.0–2.0 range. Even very active individuals are unlikely to have a daily PAL value over 2.5. [Table 3B](#) also shows a common definition for activity level in relation to PAL level.

### Extra energy costs of growth, pregnancy and lactation

The cost of growth amounts to 2.5–6.0 kcal/g of new tissue deposited; the value being higher if fat with little lean tissue is laid down. A newborn has a high energy requirement of approximately 110 kcal/kg with a cost of weight gain amounting to 6 kcal/g, but by 1

**Table 3A** Typical energy expenditures and MET ratios (activity energy expenditure/resting energy expenditure) for some different activities from [Ainsworth et al. \(2011\)](#).

Activity	MET value
Inactivity, lying quietly; or sleeping	1.0
Inactivity, sitting or standing quietly	1.3
Walking, <2.0 mph	2.0
Walking, 2.8–3.2 mph, level firm ground	3.5
Walking, carrying 1–15 lb load	5.0
Running, 4 mph	6.0
Swimming, leisurely pace	6.0
Running, 10 mph (6 min mile)	14.5

**Table 3B** Classification system for level of physical activity in adults in relation to quartiles of physical activity level as defined in doubly labeled water studies ([Institute of Medicine, Food and Nutrition Board, 2002](#)).

<i>Activity level classification</i>	<i>PAL range</i>
Sedentary	1.0 – <1.4
Low active	>1.4 – <1.6
Active	>1.6 – <1.9
Very active	>1.9 – <2.5

year of age, the total daily requirement has fallen to approximately 80 kcal/kg as growth slows with growth now costing 2.5 kcal/g. Without sufficient energy, a child will fail to grow, but the causes of growth failure usually also correlate with deficiencies of protein and or vitamins and minerals or to infection, rather than only to a lack of dietary energy. Adolescents, particularly boys, who are physically very active, may have a high demand for energy. However, the actual cost of even rapid growth rates at this age is modest relative to total energy expenditure.

Traditionally, pregnancy is considered, incorrectly, a time of great demand for food. Good nutrition is extremely important and a weight gain in pregnancy of approximately 11–16 kg for a woman with a Body Mass Index in the healthy range (18.5–24.9 kg/m<sup>2</sup>), and 5–9 kg for mothers who have obesity when they become pregnant, is considered appropriate for reducing the risk of maternal and fetal complications and preterm and low birth weight babies ([Institute of Medicine, 2009](#)). With a weight gain of 12 kg for women with a healthy BMI, the net increase in energy requirements taking into account changes in BMR and tissue deposition is 0, 320 and 452 kcal/day, respectively, for first, second and third trimesters, in addition to energy requirements prior to pregnancy. Women who enter pregnancy with obesity are recommended to gain less weight, with a corresponding reduction in additional energy requirements to support weight gain and fetal growth.

In lactation the net extra energy needed to cover the energy in the milk and the cost of producing, taking into account fat mobilization from body stores of an average 170 kcal/day on average, is estimated at 330 kcal/day in the first 6 months of lactation. During later lactation, milk production typically falls and maternal body weight stabilizes, with an estimated increment in energy requirements for lactation of 400 kcal/day.

## Conclusion

With the widespread availability of the doubly labeled water method, nutrition science has an objective way to create estimated energy requirement equations for different population groups including adults of all ages, children, and pregnant and lactating mothers. This advance will increasingly have important consequences for next-generation dietary reference intakes for other nutrients, because energy requirements define the total amount of food energy that can be consumed, which in turn has implications for the types of foods that will ensure adequacy of macronutrients and micronutrients. Improving the scientific basis of nutritional requirements in this way will support public health initiatives to improve human health through healthy nutrition.

### Glossary

**Allele** Alternative form of a genetic locus; a single allele for each locus is inherited from each parent (e.g., at a locus for eye color the allele might result in blue or brown eyes).

**Gene** The fundamental physical and functional unit of heredity. A gene is an ordered sequence of nucleotides located in a particular position on a particular chromosome that encodes a specific functional product (i.e., a protein or RNA molecule).

**Gene expression** The process by which a gene's coded information is converted into the structures present and operating in the cell. Expressed genes include those that are transcribed into mRNA and then translated into protein and those that are transcribed into RNA but not translated into protein (e.g., transfer and ribosomal RNAs).

**Genetic polymorphism** Difference in DNA sequence among individuals, groups, or populations (e.g., genes for blue eyes versus brown eyes).

**Genotype** The genetic constitution of an organism, as distinguished from its physical appearance (its phenotype).

**Nutrigenetics** Refers to an individual's specific response to diet due to genetic variants or polymorphisms (i.e., individuals responding differently to the same diet by having different levels of, for example, serum cholesterol and blood pressure because of genetic variation).

**Nutrigenomics** Refers to the role of nutrients in gene expression (i.e., polyunsaturated fatty acids suppress fatty acid synthase (mRNA) gene expression).

**Polymorphism** Difference in DNA sequence among individuals that may underlie differences in health. Genetic variations occurring in more than 1% of a population would be considered useful polymorphisms for genetic linkage analysis.

## Introduction

Approximately 80 years ago (1929–1930) Burr and Burr were the first to discover the importance of linoleic acid (LA) 18:2 $\omega$ -6 and alpha-linolenic acid (ALA) 18:3 $\omega$ -3 in restoring the effects caused by the fat-free diet in deprived animals. They coined the term 'essential fatty acids' (EFA). Although healthy skin and successful growth, reproduction, and lactation were obtained in mammals fed with LA as the only source of EFA, ALA was found to permit growth, but was unable to prevent the skin lesions of EFA deficiency, or support reproduction. Omega-6 fatty acids are the predominant polyunsaturated fatty acids (PUFAs) in all diets, especially the US and other Western diets (Table 1). The major omega-6 fatty acid in Western diets is LA, representing approximately 90% of all the PUFA in North American Diets. Today we know that LA and ALA and their long fatty acid derivatives, arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) respectively are essential for normal growth and development of human beings, and in the prevention and management of chronic diseases.

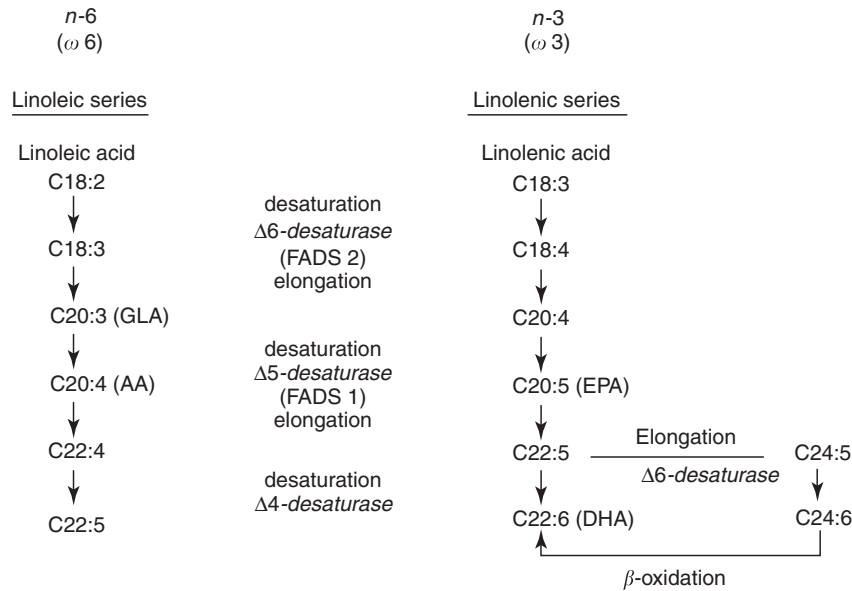

Over the past five years major advances have taken place in the understanding of mechanisms by which omega-6 and omega-3 fatty acids carry out their metabolic effects at the molecular level. Genetic variants in the LA and ALA metabolic pathways indicate the need to consider their genetic variants in the determination of estimating dietary requirements and in influencing gene expression. Genetic variants most likely account for the conflicting results of epidemiologic studies relative to the effects of omega-3 fatty acids in cardiovascular disease and cancer. Therefore this article focuses on Nutrigenetics – how genetic variation influences dietary response and on Nutrigenomics – how omega-6 and omega-3 fatty acids influence gene expression.

## Eicosanoid Metabolism and Biological Effects of Omega-6 and Omega-3 Fatty Acids

The two families of omega-6 (LA) and omega-3 (ALA) fatty acids are physiologically and metabolically distinct, they cannot be synthesized in the human body, and they must be obtained from the diet. Figure 1 shows the metabolism of LA and ALA into

**Table 1** *n*-6/*n*-3 ratio in various populations

Population	<i>n</i> -6/ <i>n</i> -3
Paleolithic	0.79
Greece before 1960	1.00–2.00
Current Japan	4.00
Current India, rural	5–6.1
Current UK and northern Europe	15.00
Current US	16.74
Current India, urban	38–50

**Figure 1** Desaturation and elongation of  $\omega$ 3 and  $\omega$ 6 fatty acids.

very-long-chain polyunsaturated fatty acids (LC-PUFA) through a series of desaturases and elongases. Both LA and ALA use the same enzymes (desaturases and elongases) and compete with each other for enzyme availability. During evolution there was a balance in the intake of LA and ALA with a ratio of  $\omega$ -6/ $\omega$ -3=1, whereas today in Western societies the ratio is approximately 16/1  $\omega$ -6/ $\omega$ -3 due to the high intake of vegetable oils-corn oil, sunflower, safflower, soybean, and linseed oil, which are high in LA (**Figure 2**). LA is found in high amounts in grains with the exception of flaxseed, perilla, rapeseed, and walnuts that are rich in ALA. The green leaves of plants, particularly wild plants are higher in ALA than LA. A low LA/ALA ratio, that is, an increase of ALA leads to higher EPA levels, which competes with AA, and increases the production of anti-inflammatory prostaglandins and leukotrienes.

The PUFA composition of phospholipids has been shown to be associated with normal growth and development, as well as in the outcome of chronic diseases such as coronary heart disease (CHD), hypertension, cancer, diabetes, mental health, neurodegenerative diseases, arthritis, allergies, and other autoimmune diseases, because both omega-6 and omega-3 PUFAs are processed to powerful promoters of eicosanoids such as prostaglandins and leukotrienes, influence gene expression, and telomere length. **Figure 1** shows the metabolic pathways of omega-6 and omega-3 fatty acids. The key enzymes in this pathway are the delta-5 and delta-6 desaturases, which are encoded by fatty acid desaturase (FADS) 1 and (FADS) 2, respectively. They are the rate limiting enzymes in the synthesis of the long chain PUFA, AA, EPA, and DHA from their dietary precursors LA and ALA.

**Figure 2** Hypothetical scheme of fat, fatty acid ( $\omega$ 6 and  $\omega$ 3, trans and total) intake (as percent of calories from fat) and intake of vitamins E and C ( $\text{mg day}^{-1}$ ).

**Table 2** Effects of ingestion of EPA and DHA from fish or fish oil

---

Decreased production of prostaglandin E <sub>2</sub> (PGE <sub>2</sub> ) metabolites
A decrease in thromboxane A <sub>2</sub> , a potent platelet aggregator and vasoconstrictor
A decrease in leukotriene B <sub>4</sub> formation, an inducer of inflammation, and a powerful inducer of leukocyte chemotaxis and adherence
An increase in thromboxane A <sub>3</sub> , a weak platelet aggregator and weak vasoconstrictor
An increase in prostacyclin PGI <sub>3</sub> , leading to an overall increase in total prostacyclin by increasing PGI <sub>3</sub> without a decrease in PGI <sub>2</sub> , both PGI <sub>2</sub> and PGI <sub>3</sub> are active vasodilators and inhibitors of platelet aggregation
An increase in leukotriene B <sub>5</sub> , a weak inducer of inflammation and a weak chemotactic agent

---

Competition between the omega-6 and omega-3 fatty acids occur in prostaglandin formation that are metabolically and physiologically distinct and have suppressing properties. EPA competes with AA, for prostaglandin and leukotriene synthesis at the cyclooxygenase and lipoxygenase level (**Figure 1**). **Table 2** shows the changes that occur when humans ingest fish or fish oil.

Omega-3 fatty acids modulate prostaglandin metabolism, decrease triglycerides, raise high-density lipoprotein (HDL), and in high doses lower cholesterol, and have antithrombotic and anti-inflammatory properties that account for decreasing the risk for CHD and other chronic conditions, i.e., cognition in the elderly (**Table 3**). Recent studies show that EPA and DHA attenuate the rate of decrease in telomere length, which may account for their beneficial effects on aging and CHD, whereas LA is the most potent nutrient in decreasing telomere length leading to cell apoptosis and aging, and increasing the risk for CHD. In the early phase of inflammation, excessive amounts of interleukins and lipid mediators are released and these play a crucial role. Proinflammatory eicosanoids of AA metabolism are released from membrane phospholipids in the course of inflammatory activation. EPA is released to compete with AA for enzymatic metabolism inducing the production of less inflammatory and chemotactic derivatives (**Table 2**). During the resolution phase of inflammation EPA produces Resolvins E1 and E2 and DHA produces Resolvins D1-D2 and neuroprotectin D1.

## Genetic Variation: Nutrigenetics

### Genetic Variants, FADS1 and FADS2 in Estimating Nutritional Requirements of Omega-3 and Omega-6 Fatty Acids

The FADS1 and FADS2 gene cluster involved in the metabolic pathway of LA and ALA as well as the enzymes involved in the production of eicosanoids, 5-LO, and cyclooxygenase from the AA and EPA, are polymorphic. Recent studies on their polymorphisms indicate that the minor alleles of the genetic variants in FADS1 and FADS2 are associated with higher LA and lower AA levels in red cell membrane and plasma phospholipids, which may influence the estimation of dietary requirements particularly during pregnancy and lactation as well as the infant's IQ whereas an increase in the activity of the desaturases increases the AA to LA ratio and the risk for CHD. Furthermore genetic variants in the 5-LO and COX-2 genes have been associated with increased risk for CHD and cancer.

The levels of LC-PUFA in plasma serum or red cell membrane phospholipids depend on dietary intake and endogenous metabolism (**Figure 1**). There have been many indications for considerable inter-individual variation in the capacity for endogenous formation of LC-PUFAs. For example, more than 20 years ago there was a rather close correlation of omega-6 and omega-3 fatty acids content in mature milk in human beings even though the main dietary sources were different. Thus it appears that some women have a higher ability to synthesize and secrete milk LC-PUFAs of both the omega-6 and omega-3 series, than others. In addition there was a tracking of plasma LC-PUFA levels in the absence of tracking of dietary intake patterns, suggesting that there is inter-individual variation in the ability to endogenously synthesize LC-PUFAs among children, which persists over time and could most likely be due to genetically determined differences in metabolic turnover. Changes in PUFA conversion have been shown with stable isotope studies.

### Genetic Variants of the FADS1 and FADS2 Gene Cluster Influence Omega-6 and Omega-3 Fatty Acids Composition in Both Plasma and Red Cell Membrane Phospholipids During Pregnancy and Lactation

AA, EPA, and DHA play central roles in infant growth, neural development, and immune function. The maternal status of AA, EPA, and DHA during gestation influences maternal to infant transfer via the placenta and breast milk provides fatty acids to infants after birth. FADS1 and FADS2 single nucleotide polymorphisms influence plasma phospholipid and erythrocyte ethanolamine phosphoglyceride (EPG) omega-6 and omega-3 fatty acids during pregnancy and their breast milk during lactation. Minor allele

**Table 3** Effects of *n*-3 fatty acids on factors involved in the pathophysiology of atherosclerosis, inflammation, and aging

Factor	Function	Effect of <i>n</i> -3 fatty acid
Arachidonic acid	Eicosanoid precursor; aggregates platelets; stimulates white blood cells	↓
Thromboxane A <sub>2</sub>	Platelet aggregation; vasoconstriction; increase of intracellular Ca <sup>2+</sup>	↓
Prostacyclin (PGI <sub>2/3</sub> )	Prevent platelet aggregation; vasodilation; increase cAMP	↑
Leukotriene (LTB <sub>4</sub> )	Neutrophil chemoattractant; increase of intracellular Ca <sup>2+</sup>	↓
Fibrinogen	A member of the acute phase response; and a blood clotting factor	↓
Tissue plasminogen activator	Increase endogenous fibrinolysis	↑
Platelet activating factor (PAF)	Activates platelets and white blood cells	↓
Platelet-derived growth factor (PDGF)	Chemoattractant and mitogen for smooth muscles and macrophages	↓
Oxygen free radicals	Cellular damage; enhance LDL uptake via scavenger pathway; stimulate arachidonic acid metabolism	↓
Lipid hydroperoxides	Stimulate eicosanoid formation	↓
Interleukin 1 and tumor necrosis factor	Stimulate neutrophil O <sub>2</sub> free radical formation; stimulate lymphocyte proliferation; stimulate PAF; express intercellular adhesion molecule-1 on endothelial cells; inhibit plasminogen activator, thus, procoagulants	↓
Interleukin-6	Stimulates the synthesis of all acute phase proteins involved in the inflammatory response: C-reactive protein (CRP); serum amyloid A; fibrinogen; α <sub>1</sub> -chymotrypsin; and haptoglobin	↓
CRP	An acute phase reactant and an independent risk factor for cardiovascular disease	↓
Endothelial-derived relaxation factor	Reduces arterial vasoconstrictor response	↑
Insulin sensitivity		↑
VLDL		↓
HDL	Decreases the risk for CHD	↑
Lp(a)	Lipoprotein(a) is a genetically determined protein that has atherogenic and thrombogenic properties	↓
Triglycerides and chylomicrons	Contribute to postprandial lipemia	↓
Telomeres	Have anti-aging effects whereas LA promotes shortening of telomeres and aging	↑
Resolvin E1–E2 (EPA)	Anti-inflammatory important in the resolution of inflammation	↑
Resolvin D1–D2 (DHA)	Anti-inflammatory important in the resolution of inflammation	↑
Neuroprotectin (DHA)	Protects brain; important in patients with strokes or trauma	↑
PPAR	Upregulates the expression of genes involved in lipid metabolism and downregulates the expression of genes involved in inflammation and suppresses NFκB	↑

VLDL: very-low-density lipoprotein.

homozygotes of rs 174553 (GG), rs 99780 (TT), and rs 174583 (TT) had lower AA but higher LA in plasma phospholipids and erythrocyte EPG and decreased omega-6 and omega-3 fatty acids product to precursor ratio at 16 and 36 weeks gestation  $P < 0.001$ . Breast milk fatty acids were influenced by genotype, with significantly lower 14:0, AA and EPA, but higher 20:2ω-6 in the minor allele homozygotes of rs 174553 (GG), rs 99780 (TT), and rs 174583 (TT) and lower AA, EPA, DPA 22:5ω-3, and DHA in the minor allele homozygotes GG of rs 174575. The results indicate a robust association between minor alleles of the 4 SNPs and lower AA and other omega-6 fatty acids relative to precursor LA. Similar results were found for the omega-3 series. Genetic variation in the FADS1 and FADS2 gene cluster is important for the composition of fatty acids provided to breastfed infants in mother's milk.

### Genetic Variants in Omega-6 and Omega-3 Fatty Acids Metabolism and IQ

Children's intellectual development is influenced by both genetic and environmental experiences. Breastfed children attain higher IQ scores than children not fed breast milk. Breastfeeding is thought to influence brain development through nutritional processes involving fatty acids. The predominant LC-PUFA present in human milk but not in cow's milk, are DHA and AA. Substantial

amounts of DHA and AA accumulate in the human brain during the first postnatal months and infants who are breastfed have higher concentrations of DHA and AA than infants fed unsupplemented formulas. Randomized controlled clinical trials comparing the neurodevelopment of infants fed DHA supplemented versus unsupplemented formula have produced inconsistent results. A search in the Kyoto Encyclopedia of Genes and Genomes (KEGG) database for genes involved in LC-PUFA metabolism that might moderate the effect of breastfeeding on IQ led to FADS2. FADS2 gene expression is regulated through end product inhibition and dietary LC-PUFA such as those available in breast milk. Two SNPs (rs 174575 and rs 1535) were selected as candidate biomarkers, to test the hypothesis that the cognitive advantage associated with breastfeeding in human beings is related to genetic differences in LC-PUFA metabolism, which was replicated in two birth cohorts. It was found that the difference in IQ test scores between breastfed and not breastfed to be 5.6 IQ points in one birth cohort and 6.3 IQ points in the other cohort. Analysis revealed that the rs 174575 interacted with breastfeeding to influence IQ in both cohorts. There was a dominant effect of the C allele in response to breastfeeding, with those carrying the C allele having a statistically significant 6.4-IQ-point advantage relative to children not breastfed. In contrast, GG homozygous neither gained an advantage from breastfeeding nor suffered a disadvantage from not being breastfed. The interaction between children's 174575 genotype and breastfeeding suggests that C carrying children benefit from breast milk more than GG homozygotes. There were no significant IQ differences among children fed breast milk as a function of maternal genotypes. Therefore these results suggest that the rs 174575 influence of breastfeeding effects on IQ involves genetic differences in children's LC-PUFA metabolism rather than rs 174575 differences among lactating women in their milk composition. Among GG homozygote children the IQ advantage associated with breastfeeding was nil. But children who were C-carriers the difference in IQ was 6.8 IQ points with C-carriers having the advantage. This advantage corresponds to a moderate effect size that is associated with many important life outcomes. This very important finding needs to be replicated in much larger cohorts and populations. The molecular mechanism by which rs 174575 may influence cognitive development is not known (Table 4). The rs 174575 C allele is linked with the major alleles of FADS1 and FADS2 SNPs, which are associated with more efficient fatty acid processing, possibly due to increased transcriptomal activity or a more active protein (Table 5).

#### Genetic Variants in FADS1 and FADS2 and CHD Risk

Desaturase activity is assayed in vitro or in animals by measurement of the rate of conversion of radiolabeled precursor fatty acids to their respective products, but ethical and practical reasons prevent this possibility in humans. Instead a product to precursor ratio (e.g., AA/LA or EPA/ALA) as a surrogate measure to estimate desaturase activity is well established. In an ongoing case-control study with or without angiographic evidence of coronary artery disease (CAD), both AA/LA and the ratio of EPA to ALA were higher in

**Table 4** Adequate intake (AI) for adults

<i>Fatty acid</i>	<i>Grams per day (2000 kcal diet)</i>	<i>% Energy</i>
LA	4.44	2.0
(upper limit) <sup>a</sup>	6.67	3.0
ALA	2.22	1.0
DHA+EPA	0.65	0.3
DHA to be at least <sup>b</sup>	0.22	0.1
EPA to be at least	0.22	0.1
TRANS-FA		
(upper limit) <sup>c</sup>	2.00	1.0
SAT		
(upper limit) <sup>d</sup>	—	<8.0
MONOs <sup>e</sup>	—	—

ALA,  $\alpha$ -linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; LA, linoleic acid; MONOs, monounsaturated fatty acids; SAT, saturated fatty acids; TRANS-FA, *trans*-fatty acids.

*Note:* If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an adequate intake is used instead of a recommended dietary allowance. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.

<sup>a</sup>Although the recommendation is for AI, the Working Group felt that there is enough scientific evidence to also state an upper limit (UL) for LA of 6.67 g day<sup>-1</sup> based on a 2000 kcal diet or of 3.0% of energy.

<sup>b</sup>For pregnant and lactating women, ensure 300 mg day<sup>-1</sup> of DHA.

<sup>c</sup>Except for dairy products, other foods under natural conditions do not contain *trans*-FA. Therefore, the Working Group does not recommend *trans*-FA to be in the food supply as a result of hydrogenation of unsaturated fatty acids or high-temperature cooking (reused frying oils).

<sup>d</sup>Saturated fats should not comprise more than 8% of energy.

<sup>e</sup>The Working Group recommended that the majority of fatty acids are obtained from monounsaturates. The total amount of fat in the diet is determined by the culture and dietary habits of people around the world (total fat ranges from 15% to 40% of energy) but with special attention to the importance of weight control and reduction of obesity.

**Table 5** Adequate intake (AI) for infant formula/diet

<i>Fatty acid</i>	<i>Percent of fatty acids</i>
LA <sup>a</sup>	10.00
ALA	1.50
AA <sup>b</sup>	0.50
DHA	0.35
EPA <sup>c</sup>	
(upper limit)	<0.10

AA, arachidonic acid; ALA,  $\alpha$ -linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; LA, linoleic acid; MONOs, monounsaturated fatty acids; SAT, saturated fatty acids; *TRANS-FA*, *trans*-fatty acids.

*Note:* If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an adequate intake is used instead of a recommended dietary allowance. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.

<sup>a</sup>The Working Group recognizes that in countries like Japan the breast milk content of LA is 6–10% of fatty acids and the DHA is higher, approximately 0.6%. The formula/diet composition described here is patterned on infant formula studies in Western countries.

<sup>b</sup>The Working Group endorsed the addition of the principal long chain polyunsaturates, AA and DHA, to all infant formulas.

<sup>c</sup>EPA is a natural constituent of breast milk, but in amounts more than 0.1% in infant formula may antagonize AA and interfere with infant growth.

participants with CAD than in those without CAD, but in a multiple logistic regression model only a higher AA/LA resulted as an independent risk factor for CAD. Concentrations of high sensitivity C-reactive protein (hs-CRP) increased progressively across tertiles of AA/LA. Graded increases in hs-CRP concentrations and CAD risk were related to the carriership of FADS haplotypes, including the alleles associated with a higher ratio of AA/LA.

A number of studies have shown that higher amounts of AA in adipose tissue are associated with higher risk of acute myocardial infarction. In populations eating a Western diet rich in omega-6 PUFA a high desaturase activity due to FADS1 and FADS2 polymorphism may promote an increased bioavailability of AA with prevailing synthesis of AA-derived proinflammatory eicosanoids leading to atherosclerosis and vascular damage. On the other hand, high desaturase activity in subjects on a diet rich in omega-3 fatty acids or receiving EPA and DHA supplementation could result in an opposite situation with a preferential synthesis of anti-inflammatory eicosanoids.

### Genetic Variants in the 5-LO, the Role of Omega-6 and Omega-3 Fatty Acids in CHD

Because atherosclerosis involves arterial inflammation, investigators determined 5-lipoxygenase (5-LO) genotypes, carotid artery intima-media thickness, markers of inflammation, CRP, interleukin-6 (IL-6), dietary AA, EPA, DHA, LA, and ALA with the use of six 24-hour recalls of food intake. The results showed that 5-LO variant genotypes were found in 6.0% of the cohort. Mean intima-media thickness adjusted for age, sex, height, and racial or ethnic group was increased among the carriers of two variant alleles as compared with the carrier of the common (wild-type) allele. In multivariate analysis, the increase in intima-media thickness among carriers of two variant alleles was similar in this cohort to that associated with diabetes, the strongest common cardiovascular risk factor. Increased dietary AA significantly enhanced the apparent atherogenic effect of genotype, whereas increased dietary intake of omega-3 fatty acids EPA and DHA blunted this effect. Furthermore, the plasma level of CRP of two variant alleles was increased by a factor of 2, as compared with that among carriers of the common allele. Thus, genetic variation of 5-LO identifies a subpopulation with increased risk for atherosclerosis. The diet-gene interaction further suggests that dietary omega-6 fatty acids LA and AA promote, whereas marine omega-3 fatty acids EPA and DHA inhibit leukotriene-mediated inflammation that leads to atherosclerosis in this subpopulation (Figure 1). The study constitutes evidence that genetic variation in an inflammatory pathway – in this case the leukotriene pathway – can trigger atherogenesis in humans. These findings could lead to new dietary and targeted molecular approaches for the prevention and treatment of cardiovascular disease according to genotype.

### Genetic Variants in the 5-LO, Omega-6 Fatty Acids, and Breast Cancer

A number of epidemiologic studies and animal experiments suggest that omega-6 fatty acids increase the risk of cancer and omega-3s decrease. However not all studies have produced consistent results. The 5-LO pathway has been implicated in carcinogenesis and tumor progression in many types of cancer; lung, colon, prostate, kidney, bladder. Earlier epidemiologic studies on dietary fat intake

and breast cancer did not find positive association between omega-6 and breast cancer risk. Those studies however did not take into account genetic predisposition related to omega-6 fatty acid metabolism. A recent study on genetic variants in the 5-LO gene (ALOX5) and 5-lipoxygenase-activating protein gene (ALOX5AP) in combination with dietary LA intake in a population-based multi-ethnic case-control study on breast cancer in Latin, African-American and White women in the San Francisco area, did not find significant main effects of ALOX5 and ALOX5AP genotypes on breast cancer risk that were consistent across race or ethnicity. There was a significant interaction between the ALOX5AP -4900 A>G polymorphisms and dietary LA intake among women consuming a diet high in LA (top quartile of intake  $>17.4$  g day<sup>-1</sup>), carrying the AA genotype. The AA genotype was associated with higher breast cancer risk, compared to genotype AG or GG. Among women consuming  $\leq 17.4$  g day<sup>-1</sup> of LA ALOX5AP -4900 genotype was not associated with breast cancer risk. These findings indicate that studies on dietary fat intake and cancer should take into consideration both type of fat and genetic variants. Furthermore, in the U.S. 17.4 g day<sup>-1</sup> is the intake that a significant portion of the population ingests.

### **Genetic Variants of Cyclooxygenase-2 (COX-2) and the Protective Effect of Long Chain Omega-3 Fatty Acids in Cancer of the Prostate**

Prostate cancer is one of the most common types of cancer in men. Increasing evidence points to chronic inflammation as one of the factors leading to cancer. Inflammation may result from bacterial or viral infections, intra-prostatic urine reflux, or diet. Dietary components that are potent anti-inflammatory agents are the omega-3 PUFAs. Studies have shown that genetic variants at the COX-2 gene modify prostate inflammation through the COX-2 enzymatic pathway. COX-2 is a key enzyme in fatty acid metabolism and inflammation. In a case-control study of 466 men diagnosed with aggressive prostate cancer and 478 age- and ethnicity-matched controls nine COX-2 tag SNPs were genotyped. Dietary history was assessed with a semiquantitatively food frequency questionnaire. Increasing omega-3 intake was associated with a decreased risk of aggressive prostate cancer, and this inverse association was even stronger among men with genetic variants rs 4648310 (+8897 A/G) flanking the 3' region of COX-2. The patient with the lowest intake of omega-3s and the genetic variant had the most aggressive tumor whereas the omega-3 PUFAs were protective and this effect was modified by the genetic variant. This gene by diet (omega-3s) interaction clearly shows that the main dietary effect was modified by the genetic variant whereas men with the variant genotype AG or GG and low intake of omega-3s had much higher risk than men with the variant genotype and high intake of omega-3s. A study in Swedish men found similar inverse association between consumption of fatty fish and prostate cancer risk, an effect also modified by rs 5275 (+6364 A>G) SNP in COX-2.

### **Nutrigenomics: The Role of Omega-6 and Omega-3 Fatty Acids in Gene Expression**

#### **Anti-Inflammatory Aspects: Omega-3 Fatty Acids Downregulate the Expression of Genes Involved in Inflammation and Obesity**

Animal experiments and human studies have shown that EPA and DHA have the ability to upregulate and downregulate genes in various tissues including adipose tissue and peripheral blood mononuclear cells (PBMCs) in humans. Clinical studies indicate that inflammation is at the base of many diseases including cardiovascular disease, aging, mental health, obesity, diabetes, and even cancer. EPA and DHA have been shown to have beneficial effects in these conditions but the exact mechanisms by which EPA and DHA suppress inflammation are still under investigation. Previous studies have focused on the ability of EPA and DHA to suppress interleukin-1 $\beta$  (IL1 $\beta$ ) and IL-6 cytokines and to play an important role in the resolution of inflammation as well as through the production of resolvins E1 and E2 from EPA, and D1 and D2 from DHA, and neuroprotectins D1 from DHA. EPA and DHA activate peroxisome proliferator-activated receptor alpha (PPAR $\alpha$ ), which upregulates the expression of genes involved in lipid metabolism and downregulates the expression of genes involved in inflammation by suppressing Nuclear factor-Kappa-B (NF- $\kappa$ B).

In studying the effect of fish oil on adipose tissue it was noted that 1.8 g of EPA and DHA decreased the total omega-6/omega-3 ratio in the plasma phospholipids from  $12.9 \pm 1.1$  to  $5.6 \pm 0.7$ . Total fat mass and subcutaneous adipocyte diameter were lower in the group receiving 1.8 g of EPA and DHA than in the placebo group. In addition, with EPA and DHA supplementation, significant correlations were found between the adipocyte markers (adipocyte diameter and whole fat mass) and the main adipokines—plasma leptin and adiponectin as well as plasma atherogenic factors (plasminogen activator inhibitor factor-1 (PAI-1), insulin, and triacylglycerol). There was no correlation between adipocyte diameter and plasma tumor necrosis factor-alpha (TNF- $\alpha$ ) or plasma IL-6. As expected adipocyte diameter and fat mass percentage were correlated with atherogenic (cysteine protease cathepsin S or CTSS) and inflammation related genes (the chemoattractant gene plasminogen activator urokinase receptor, or PLAVR), the macrophage surface marker CD11b, and the macrophage phagocytic activity marker CD68. There was no change in weight but there was significant loss in body fat mostly in the trunk and subcutaneous tissue, but not in visceral tissue. After fish oil treatment, PAI-1 was lower whereas leptin, IL-6, TNF- $\alpha$ , and serum amyloid A did not change significantly after 2 months with 1.8 g EPA and DHA supplementation. Epidemiologic studies have shown a correlation between adipocyte size and the omega-6 and omega-3 fatty acids content in subcutaneous abdominal adipose tissue, in a group of overweight patients who had undergone abdominal surgery, and metabolic studies indicate a beneficial role of EPA and DHA in lowering adiposity in humans.

Studies on the relationship between plasma omega-3 PUFA composition and weight status found that higher omega-3 PUFA intake was associated with a healthier BMI, waist circumference, and hip circumference. These findings suggest that omega-3 PUFA may play a role in weight status and abdominal adiposity in human beings. In earlier studies EPA and DHA supplementation

reduced body fat mass and stimulated lipid oxidation in healthy adults. Others subsequently concluded that omega-3 fatty acid intake by itself or along with exercise increases weight loss. Caloric restriction is recommended for weight loss. Of interest is the fact that caloric restriction affects gene expression in a manner similar to EPA and DHA supplementation.

## Summary and Conclusions

Fatty acid composition in red cell membranes and serum phospholipids plays an important role in cellular processes, and has been shown to be associated with the etiology of several complex diseases in humans. The metabolism of EFAs, LA, and ALA and their metabolic derivatives are controlled by enzymes encoded by polymorphic genes. Therefore the availability of PUFAs to various tissues is of major importance to health and depends on both dietary intake and endogenous production or metabolic turnover.

The genetic variants FADS1 and FADS2 lead to differences in the conversion of omega-6 and omega-3 fatty acids catalyzed by the delta-5 and delta-6 desaturases, which suggests that individuals may require different amounts of dietary PUFAs or LC-PUFAs to achieve comparable biological effects. Furthermore further studies addressing the biological effects of PUFAs and LC-PUFAs should include genotyping for FADS1 and FADS2 polymorphisms.

Variants in the human genes of delta-5 and delta-6 desaturase FADS1 and FADS2 that influence both serum and red cell membrane phospholipid levels of PUFA, have a frequency of 26% in the population. The minor alleles are associated with lower AA and higher LA and account for 28% of the variation in serum phospholipid AA and up to 12% of its precursor fatty acids. Smaller percentage values were found for omega-3 fatty acids. These findings suggest that individuals may require different amounts of dietary LA, ALA, or AA, EPA, and DHA, for both normal development and in the prevention and management of chronic diseases.

The interaction between dietary factors and genetic variants could explain the differences noted in association studies. Considering that a low omega-3 intake in the presence of certain genetic variants leads to a more aggressive disease, an increase in omega-3 intake and a decrease in omega-6 leading to a balanced omega-6/omega-3 ratio may be a sensible recommendation to reduce disease risk in the general population. Nutrigenetics/nutrigenomics will continue to provide data on mechanisms of nutrients and gene interactions in both health and disease.

### Glossary

**Arachidonic acid (20:4*n*-6)** A 20 carbon omega-6 fatty acid which is a precursor of eicosanoids.

**Eicosanoids** A family of signaling molecules made by oxidation of twenty-carbon essential fatty acids; they include the prostaglandins, thromboxanes, leukotrienes and epoxyeicosatrienoic acids.

**Essential fatty acids** Fatty acids that the body cannot manufacture and that may cause nutritional deficiency if not supplied through diet. The two essential fatty acids for humans are  $\alpha$ -linolenic acid and linoleic acid.

**Linoleic acid (18:2*n*-6)** The precursor fatty acid of the *n*-6 fatty acids, and the primary dietary *n*-6 fatty acid comprising greater than 97% of total *n*-6 fatty acid intake.

**Omega-3 (*n*-3) polyunsaturated fatty acid** A class of polyunsaturated fatty acids characterized by the presence of two or more *cis*-double bonds, with the position of the first double bond three carbon atoms from the methyl end of the molecule.

**Omega-6 (*n*-6) polyunsaturated fatty acid** A class of polyunsaturated fatty acids characterized by the presence of two or more *cis*-double bonds, with the position of the first double bond six carbon atoms from the methyl end of the molecule.

**Polyunsaturated fatty acids** Fatty acids in which more than one double bond exists within the molecule.

**$\alpha$ -Linolenic acid (18:3*n*-3)** The precursor fatty acid of the *n*-3 fatty acids.

### Abbreviations

AA	Arachidonic acid – 20:4 <i>n</i> -6
ALA	$\alpha$ -Linolenic acid – 18:3 <i>n</i> -3
COX-2	Cyclooxygenase-2
DGLA	Dihomo- $\gamma$ -linolenic acid – 20:3 <i>n</i> -6
DHA	Docosahexaenoic acid – 22:6 <i>n</i> -3
DiHETE	Dihydroxyeicosatetraenoic acid
DPA	Docosapentaenoic acid – 22:5 <i>n</i> -3
EET	Epoxyeicosatrienoic acids
EFA	Essential fatty acid
EPA	Eicosapentaenoic acid – 20:5 <i>n</i> -3

GLA	$\gamma$ -Linolenic acid – 18:3 $n$ -6
HDL	High-density lipoprotein
HETE	Hydroxyeicosatetraenoic acid
LA	Linoleic acid – 18:2 $n$ -6
LDL	Low-density lipoprotein
LT	Leukotriene
LXA <sub>4</sub>	Lipoxin A <sub>4</sub>
LXB <sub>4</sub>	Lipoxin B <sub>4</sub>
$n$ -6	Omega-6
$n$ -3	Omega-3
PG	Prostaglandin
PUFA	Polyunsaturated fatty acid
VLDL	Very low density lipoprotein

## Introduction

The omega-6 ( $n$ -6) fatty acids have the potential to influence a number of chronic diseases and disorders. This article focuses on the effects of  $n$ -6 fatty acids in relation to cardiovascular disease and atherosclerosis.

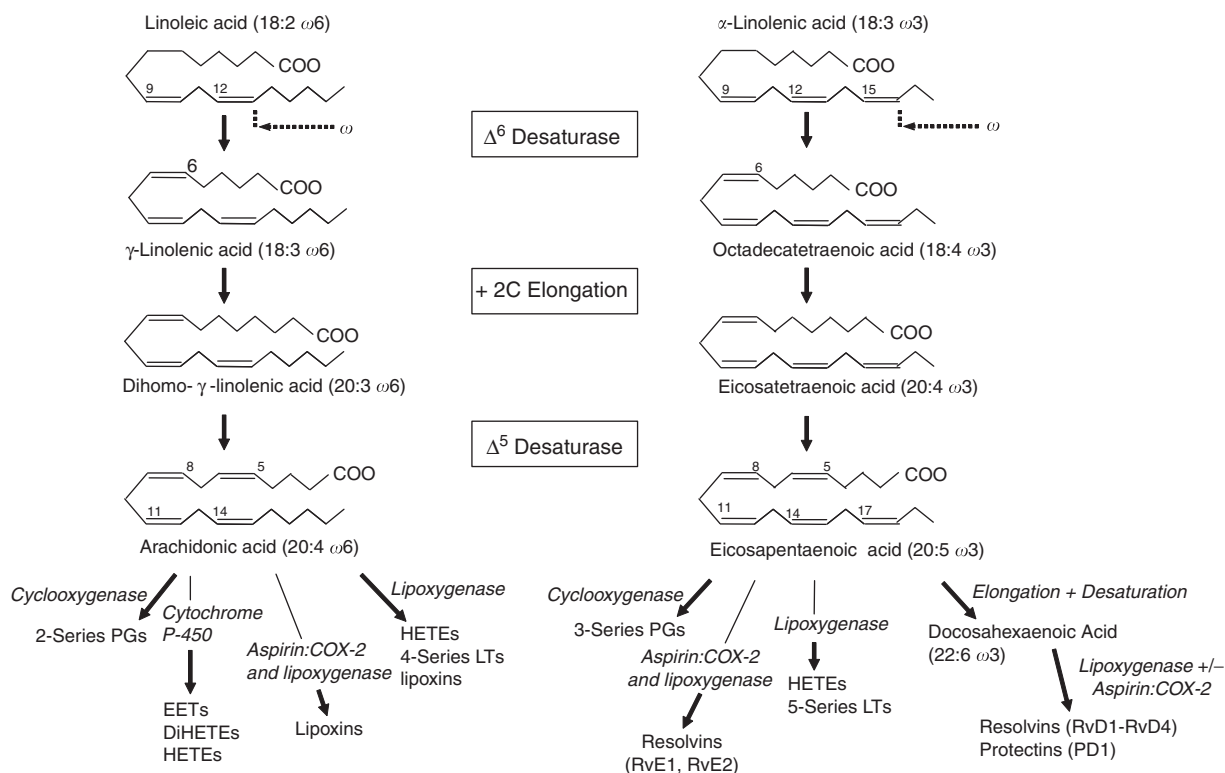

## Structure, Function, and Nutritional Requirements

The  $n$ -6 fatty acids are a class of polyunsaturated fatty acids (PUFAs) characterized by the presence of two or more *cis*-double bonds, with the position of the first double bond six carbon atoms from the methyl end of the molecule. The general formula of  $n$ -6 fatty acids is  $\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_x(\text{CH}_2)_y\text{COOH}$ . Linoleic acid [*cis*-9, *cis*-12-octadecadienoic acid, 18:2 $n$ -6, LA] and  $\alpha$ -linolenic acid [*cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid, 18:3 $n$ -3, ALA] are the precursor fatty acids of the  $n$ -6 and omega-3 ( $n$ -3) fatty acids, respectively.

LA is the primary dietary  $n$ -6 fatty acid comprising greater than 97% of total  $n$ -6 fatty acid intake. The average daily intake of LA for adults older than 19 years is approximately 11 g or 4.4% of energy in Australia, and 14.8 g and 6.7% of energy in the United States. In contrast, the average intake of ALA is approximately 1.1 g day<sup>-1</sup> or 0.6% of energy. LA and ALA cannot be made by mammals and are therefore termed essential fatty acids (EFAs). In addition, mammals are unable to interconvert LA and ALA, or any of the  $n$ -6 and  $n$ -3 fatty acids, because mammalian tissues do not contain the necessary desaturase enzyme. Plant tissues and plant oils are rich sources of LA. ALA is also present in plant sources such as green vegetables, flaxseed, canola, and some nuts. Once consumed in the diet, LA can be converted via chain elongation and desaturation to  $\gamma$ -linolenic acid (GLA, 18:3 $n$ -6), dihomogamma-linolenic acid (DGLA, 20:3 $n$ -6), and arachidonic acid (AA, 20:4 $n$ -6) (Figure 1). The same enzymes involved in elongation and desaturation of the  $n$ -6 fatty acids are common to the omega-3 ( $n$ -3) series of fatty acids (Figure 1). Thus, ALA can be converted to eicosapentaenoic acid (EPA, 20:5 $n$ -3) and docosahexaenoic acid (DHA, 22:6 $n$ -3). In humans, however, the conversion is relatively inefficient and gender dependent. The major source of dietary EPA and DHA is fish, seafood, and marine oils, although small quantities of  $n$ -3 fatty acids, particularly of docosapentaenoic acid (DPA, 22:5 $n$ -3), are derived from meat and poultry.

The  $n$ -6 and  $n$ -3 fatty acids are metabolically and functionally distinct and often have important opposing physiological functions. Indeed, the balance of EFA is important for good health and normal development. Historically, human beings evolved on a diet in which the ratio of  $n$ -6 to  $n$ -3 fatty acids was approximately 1:1. In contrast, Western diets have a ratio of approximately 15:1. Evidence for this change in diet through history comes from studies on the evolutionary aspects of diet, modern-day hunter-gatherers, and traditional diets. Modern agriculture has led to a substantial increase in  $n$ -6 fatty acids at the expense of  $n$ -3 fatty acids, which has resulted in excessive consumption of  $n$ -6 fatty acids by humans.

The  $n$ -6 EFAs have two main functions. First, they act as structural components of membranes forming the basis of the phospholipid component of the lipid bilayer of plasma membranes in every cell in the body, thus providing a membrane impermeable to most water-soluble molecules. The length and degree of saturation of the fatty acids determine how the phospholipid molecules pack together and consequently affect membrane fluidity, signal transduction, and the expression of cellular receptors. The second role of  $n$ -6 fatty acids is to act as precursors to the eicosanoids (Figure 1). The eicosanoids are a family of 'hormone-like' compounds including prostaglandins (PGs), leukotrienes (LTs), and hydroxy- (HETEs), dihydroxy- (DiHETEs), and epoxy- (EETs) fatty acids. Eicosanoids, however, are distinct from most hormones in that they act locally, near their sites of synthesis, and they are catabolized extremely rapidly. Thus, they are considered to be locally acting hormones. The eicosanoids modulate renal and pulmonary functions, vascular tone, and inflammatory responses. The enzymes involved in AA metabolism include the cyclooxygenases and lipoxygenases, which yield the two-series PGs and four-series LTs, respectively. Lipoxygenases also utilize AA for the formation of the hydroxyeicosatetraenoic acids (HETEs). A third pathway for the utilization of AA involves the cytochrome P-450 enzymes found in the liver, kidney, lung, intestines, heart, small blood vessels, and white blood cells. AA metabolized via cytochrome P-450 yields epoxyeicosatrienoic acids (EETs), dihydroxyeicosatetraenoic acids (DiHETEs), as well as HETEs. The cytochrome P-450 metabolites

**Figure 1** Essential fatty acid metabolism.

play an important role as paracrine factors and second messengers in the regulation of pulmonary, cardiac, renal, and vascular function and modulate inflammatory and growth responses. Finally, AA can be utilized by a pathway comprising the interaction of aspirin with cyclooxygenase-2 (COX-2) and lipoxygenase to generate a family of compounds called the lipoxins. COX-2 is an inducible form of the cyclooxygenase enzyme activated during inflammation. The lipoxins (LXA<sub>4</sub> and LXB<sub>4</sub>) are potent anti-inflammatory mediators. They can also be derived from the action of lipoxygenase in the absence of aspirin–COX-2 (Figure 1).

### Endothelial Function, Atherosclerosis, and Cardiovascular Disease

The vascular endothelium is the most important organ controlling vascular function and consists of a single layer of epithelial cells lining blood vessels. Its primary function is to regulate vascular tone, but it plays a critical role in modulating coagulation and fibrinolysis, inflammation, smooth muscle cell proliferation, and macrophage function. Many of these functions are regulated through the release of various mediators including eicosanoids. There is multiple and close interaction of the endothelial cells with circulating cells, smooth muscle cells, and macrophages. There is also evidence that endothelial dysfunction precedes clinically apparent atherosclerosis.

Atherosclerosis is an inflammatory disease involving multiple cellular and molecular responses that lead to an alteration in vascular function and structure, and the development and progression of cardiovascular disease. Atherosclerosis is characterized by degenerative changes, deposition of cholesterol, proliferation of smooth muscle cells, involvement of a range of circulating proinflammatory cells, and fibrosis. Resulting atheromatous plaques cause narrowing of arteries and increase the likelihood of thrombosis and occlusion. When this occurs in the coronary arteries, the outcome is myocardial infarction with possible death.

### Eicosanoids: Relevance to Endothelial Function, Thrombosis, Inflammation, and Atherosclerosis

In general, the eicosanoids derived from AA have potent prothrombotic and proinflammatory activity. In contrast, the eicosanoids derived from EPA have reduced biological activity and are less prothrombotic and proinflammatory. Eicosanoid production is generally tightly controlled through homeostatic mechanisms. However, eicosanoid production can be significantly altered in situations in which endothelial dysfunction, atherosclerosis, and plaque rupture, or various thrombotic or inflammatory conditions are present.

### Prostaglandins and Leukotrienes

Prostaglandins have a central role in the regulation of platelet aggregation and vascular tone. In this regard, two of the major prostaglandins derived from AA are thromboxane  $A_2$ , produced in platelets, and prostacyclin  $I_2$ , produced in endothelial cells. Thromboxane  $A_2$  promotes platelet aggregation and blood vessel constriction, whereas prostacyclin  $I_2$  has opposite effects. An increase in availability of EPA can decrease platelet thromboxane  $A_2$  and increase thromboxane  $A_3$ , the latter having considerably less physiological activity. EPA supplementation also stimulates formation of prostacyclin  $I_3$ , whereas prostacyclin  $I_2$  is unaffected. Prostacyclin  $I_3$  and prostacyclin  $I_2$  are equipotent in their biological activity. The net result following intake of  $n$ -3 fatty acids is a shift in the thromboxane/prostacyclin balance toward a reduced prothrombotic state.

Leukotriene  $B_4$  is a potent inflammatory mediator produced by neutrophils from 20:4 $n$ -6 at the site of injury. Leukotriene  $B_4$  is also a powerful chemotactic factor responsible for attracting neutrophils to the site of injury. Leukotriene  $B_5$ , which is produced from EPA, has significantly lower biological activity. Therefore, an increased availability of EPA has the potential to reduce inflammation.

### Fatty Acid Intake and Eicosanoids

The concentration of the eicosanoid precursor fatty acids both circulating and in tissues depends on dietary intake. DGLA and AA can be obtained from animal meat and fat, and by desaturation and chain elongation of LA. The major dietary source of EPA and DHA is fish and seafood. EPA can also be obtained indirectly from ALA, although desaturation and chain elongation of ALA appears to be a less important pathway in humans.

Only the free form of the fatty acid precursors of eicosanoids can be utilized by the enzymes for conversion to the biologically active metabolites. However, the amount of precursor free fatty acid in the cytoplasm and circulating is usually low and so too is basal eicosanoid formation. Furthermore, basal eicosanoid formation may depend on dietary and adipose tissue fatty acid composition. The amount of eicosanoid precursor free fatty acids is controlled to a large extent by incorporation and release from cellular phospholipids. Which eicosanoids are produced during stimulated synthesis may depend on membrane fatty acid composition as well as the cell type involved. Dietary fatty acid composition, therefore, has the potential to affect basal and stimulated synthesis of eicosanoids and influence endothelial function, and thrombotic and inflammatory responses.

### $n$ -6 Fatty Acids and Risk of Cardiovascular Disease

Evidence that differences in  $n$ -6 fatty acid intake can influence cardiovascular disease risk derives from several sources. Population studies may provide useful data for establishing optimal intakes of  $n$ -6 fatty acids. However, valuable information on the potential mechanisms and effects of these fatty acids is derived from randomized controlled studies focusing on their impact on thrombosis, inflammation, endothelial function, and other cardiovascular risk factors.

#### Cardiovascular Disease: Population Studies

The incidence of cardiovascular disease within populations with either very high or very low intakes of  $n$ -6 fatty acids may provide some indication for optimal intakes of  $n$ -6 fatty acids. Within populations with low  $n$ -6 fatty acid intakes ( $<3\%$ ), there would appear to be a benefit of having a higher  $n$ -6 fatty acid intake on cardiovascular disease risk reduction. These observations suggest that very low  $n$ -6 fatty acid intakes increase the risk for cardiovascular disease. The presence of EFA deficiency in a significant proportion of such populations may explain the increased risk. Several populations, including the Israelis, Taiwanese, and !Kung bushmen in the African Kalahari desert, have high to very high intakes of  $n$ -6 fatty acids. The contribution of  $n$ -6 fatty acids to total energy intake is approximately 10% in the Israelis and Taiwanese and approximately 30% in the !Kung bushmen. Rates of cardiovascular disease are low in the Taiwanese, where dietary  $n$ -6 fatty acids are obtained mainly from soybean oil, and estimated to be very low in the !Kung bushmen, where dietary  $n$ -6 fatty acids were obtained mainly from the monongo fruit and nut. In the Taiwanese, the soybean oil is refined but is accompanied by a diet rich in antioxidant polyphenols, notably from tea, fruits, and vegetables. In the !Kung bushmen, the oil is unrefined and is therefore likely to contain a range of phytochemicals. There is, however, a high prevalence of cardiovascular disease in the Israeli population, where  $n$ -6 PUFAs are obtained largely from refined sources. These observations suggest that a high  $n$ -6 fatty acid intake can be compatible with low risk of cardiovascular disease, but the dietary context may be very important. Given that  $n$ -6 fatty acids are susceptible to lipid peroxidation, high  $n$ -6 fatty acid intake may increase risk for cardiovascular disease when consumed against a background diet low in antioxidants. The potential impact on eicosanoid metabolism remains uncertain.

Several factors may need to be considered in the interpretation of the results of population studies. (1) The effect of LA on atherosclerosis and cardiovascular disease may depend on the background intake in the population being studied. (2) Any relationships observed may be confounded by intake of other foods from which LA derives. (3) LA may have differential effects on aspects of the etiology of cardiovascular disease, including endothelial function, thrombosis, arrhythmia, and atherosclerosis.

## Thrombosis

Dietary fatty acids influence thrombosis by altering the activity and function of endothelial cells, platelets, and other circulating cells: effects that can be mediated, in part, by alterations in eicosanoid metabolism. Replacement of dietary saturated fatty acids with unsaturated fatty acids, including *n*-6 fatty acids, generally lowers the risk of thrombosis and cardiovascular disease. Furthermore, studies have shown that an increase in *n*-3 fatty acid intake can increase vasodilation, attenuate platelet aggregation, and alter circulating concentrations of factors involved in coagulation and fibrinolysis. The net effect of increasing *n*-3 fatty acid intake is a tendency toward reduced risk for thrombosis. These findings are supported by population studies demonstrating that *n*-3 fatty acids may reduce the risk of thrombosis. It remains uncertain whether the major factor influencing these functions is the absolute increase in *n*-3 fatty acids, or the relative proportions of *n*-6 and *n*-3 fatty acids in the diet and cell membranes. There is evidence, however, that increased *n*-3 fatty acid intake may be more beneficial in populations consuming relatively small quantities of fish, which includes many Western populations.

Much of the evidence for a potential impact of *n*-6 fatty acids on thrombosis derives from research on platelet function. The role of platelets in thrombosis is established and the influence of fatty acid intake on platelet function has been assessed in many studies. Platelets play a part in thrombosis by adhering to, and aggregating at, the site of injury. Platelet reactivity and increased platelet activation may increase the risk of thrombosis. *In vitro* and *in vivo* studies assessing effects of *n*-6 fatty acids on platelet aggregation are inconsistent. To date there is little evidence that a high *n*-6 fatty acid diet in humans decreases platelet aggregation and some studies are suggestive of increased aggregation with high *n*-6 fatty acid diets, primarily in the form of LA. The effects of AA on platelet aggregation are also not clear. One of the main difficulties in interpreting these studies is the unresolved issue as to how the *in vitro* aggregation test reflects platelet function *in vivo*.

## Inflammation

Inflammation is involved in many human diseases including cardiovascular conditions such as thrombosis, stroke, and atherosclerosis. Conditions associated with increased inflammation, such as inflammatory arthritis, dermatological conditions such as psoriasis and atopic dermatitis, chronic inflammatory bowel disease, autoimmune diseases, and bronchial asthma, appear to be beneficially influenced to a greater extent by *n*-3 fatty acids than by *n*-6 fatty acids.

Whether increased intake of *n*-6 fatty acids can exacerbate inflammation *via* increased production of proinflammatory eicosanoids remains uncertain. Results of *in vitro* studies and intervention studies in humans are generally consistent with this theoretical potential of *n*-6 fatty acids to enhance inflammation, at least in comparison to *n*-3 fatty acids and probably omega-9 (*n*-9) mono-unsaturated fatty acids. The importance of absolute and relative intakes of *n*-6 fatty acids to inflammatory processes also remains unclear. The effects of changes in *n*-6 fatty acid intake on inflammatory processes may depend on the background dietary fatty acid intake, as well as proportional and absolute intake of *n*-3 fatty acids.

Resolution of inflammation involves the reduction or removal of inflammatory cells and debris from inflamed sites, enabling the return to homeostasis. This process, which was initially considered to be a passive process, is now known to be rapidly initiated after acute challenges by cellular pathways that lead to the synthesis of lipid mediators such as lipoxins, resolvins, and protectins. The lipoxins (LXA<sub>4</sub> and LXB<sub>4</sub>) are derived from AA and have anti-inflammatory and proresolution properties (Figure 1). They are biosynthesized by the sequential action of lipoxygenases or via interaction of aspirin with COX-2 and lipoxygenase. Recently, a novel family of lipid mediators, the resolvins and protectins, which are derived from EPA and DHA, has also been described and implicated in the resolution of inflammation (Figure 1). Resolvins and protectins are local mediators that are generated during spontaneous resolution of inflammation.

## Cholesterol and Lipoproteins

The major classes of circulating lipoproteins in human plasma are chylomicrons, very low density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). High fasting plasma concentrations of LDL cholesterol and triglycerides – predominantly circulating as part of VLDL – and low plasma concentrations of HDL cholesterol, are associated with increased risk of cardiovascular disease. Dietary fatty acids can influence lipoprotein metabolism and therefore have the potential to influence atherosclerosis and cardiovascular disease risk. Most studies examining the effects of *n*-6 PUFAs on cholesterol metabolism have focused on LA.

It is now established that LDL cholesterol lowering reduces the risk of cardiovascular disease. In the fasting state, LDL is the major cholesterol-carrying lipoprotein in human plasma. The mechanisms through which raised plasma LDL cholesterol concentrations increase cardiovascular disease risk are not entirely understood, but oxidative modification of LDL is thought to be involved. An increase in LA intake results in a lowering of plasma LDL cholesterol concentrations and therefore has the potential to reduce cardiovascular disease risk. These effects may not be linear over the entire range of LA intake and most of the benefits appear to be gained by moving from lower (<2% of energy) to moderate (~4–5% of energy) intakes. In addition, the effects of dietary *n*-6 PUFAs are less than half that of lowering dietary saturated fatty acids. Therefore, if total fat intake is maintained, the LDL cholesterol lowering effects of increasing *n*-6 PUFA intake are greatly enhanced if saturated fatty acid intake is also decreased.

HDL cholesterol is inversely associated with cardiovascular disease risk. The mechanism by which HDL reduces cardiovascular disease risk may involve reverse cholesterol transport and reductions in cholesterol accumulation in the arterial wall. Intakes of LA

within the normal ranges of intakes in most populations do not appear to alter HDL cholesterol concentrations. However, very high intakes – more than 12% of energy – can lower HDL cholesterol concentrations.

### Oxidative Stress

Several lines of evidence suggest that oxidatively modified LDL plays an important role in the development of atherosclerosis. Oxidative modification of LDL involves peroxidation of PUFAs. LDL particles enriched in PUFAs have been shown to be more susceptible to oxidative modification compared with LDL particles rich in monounsaturated fatty acids. Others have also suggested that a diet high in PUFAs may overwhelm the antioxidant defenses of cells. In particular, studies have shown that LA-enriched LDL is more prone to *in vitro* oxidation than oleic acid-enriched LDL. Concern also remains with respect to the potential for increased lipid peroxidation following *n*-3 fatty acids. However, much of the early literature relating to PUFAs and lipid peroxidation is based on indirect and nonspecific assays, including measurement of LDL oxidative susceptibility, which relies on the isolation of LDL from plasma. In this regard, the recent discovery of F<sub>2</sub>-isoprostanes, which are nonenzymatic prostaglandin-like products of free radical peroxidation of AA, has allowed for the direct assessment of *in vivo* lipid peroxidation. There is now good evidence that quantitation of F<sub>2</sub>-isoprostanes provides a reliable measure of *in vivo* oxidative stress. Using measurement of F<sub>2</sub>-isoprostanes, recent data have demonstrated that *n*-3 fatty acids decrease oxidative stress. It has also been suggested that the concentration of PUFAs may be a more important factor affecting lipid peroxidation than the degree of unsaturation. Further research using better markers of lipid peroxidation is required before definitive statements can be made relating to the effect of *n*-6 fatty acids and indeed PUFAs in general, on oxidative stress.

### Blood Pressure

The possible effects of dietary fatty acids on blood pressure have been explored in population studies and dietary intervention trials. Although a hypotensive influence of *n*-6 fatty acids was suggested in early clinical studies, this has not been confirmed in subsequent randomized controlled trials. In normotensive individuals, randomized controlled trials have shown no consistent effects on blood pressure with dietary modifications to change the intake of *n*-6 fatty acids. LA supplements have also produced either no change or reduction in blood pressure. Additionally, studies in hypertensives have shown no consistent effects of *n*-6 fatty acids on blood pressure. Current data suggest that *n*-6 fatty acids, when substituted for saturated fatty acids, may have some blood pressure lowering effect if part of complex dietary changes that include increases in fruit, nuts, and vegetable consumption and low-fat dairy products. These effects may also be enhanced by moderation of salt intake.

### Conclusions

Diets low in *n*-6 fatty acids, principally LA, appear to be associated with an increased risk of cardiovascular disease. The results of studies examining the effects of LA on risk factors for atherosclerosis and cardiovascular disease are consistent with this observation. An increase in *n*-6 PUFA intake from a low to a moderate intake level, in conjunction with decreases in total and saturated fat intake, may beneficially influence lipoprotein metabolism, lower blood pressure, and reduce cardiovascular disease risk. Observations in populations with high *n*-6 PUFA intake indicate that high intakes of *n*-6 fatty acids (>10%) can occur together with low rates of cardiovascular disease and possibly also cancer. However, where antioxidant composition of the diet is low, there is the potential for increased risk of cardiovascular disease. An increased susceptibility of PUFAs to oxidative damage, particularly in the presence of low concentrations of protective antioxidants, may be an important factor. The source of *n*-6 PUFAs in the diet, refined versus unrefined, and the composition of the background diet, may therefore be important determinants of whether high *n*-6 fatty acid intake increases or decreases the risk of cardiovascular disease. In addition, the quantity of *n*-6 to *n*-3 fatty acids in the diet may also play an important role in determining cardiovascular risk.

Available data suggest that the relative proportion of all the classes of dietary fatty acids may be more important and relevant to cardiovascular risk reduction than any single class of fatty acids. The importance of *n*-6 fatty acids in relation to cardiovascular risk was recently summarized in an American Heart Association statement, which concluded that consumption of at least 5–10% of energy from *n*-6 fatty acids in the context of other appropriate lifestyle and dietary behavior may reduce the risk of coronary heart disease relative to low intake.

## Key points

- Fiber is an essential component of a healthy diet
- Due to the various ways to quantify and define dietary fiber, reaching a consensus on recommended daily intake is challenging for both regulatory bodies and practitioners
- Recommended daily dietary fiber intakes across age groups and countries
- Overall, most age groups are unable to meet general fiber intake recommendations
- Fiber is associated with short term and long-term health benefits, both directly related to gut health as well as other physiological benefits
- Plant based diets will benefit not only planetary health but also human health through overall increased fiber intake

## Introduction

Fiber is an essential component of a healthy diet. As knowledge surrounding fiber has evolved, so too has understanding regarding its resulting physiological impacts. However, despite the consensus on its health benefits, the quantification methods and definitions vary greatly, making a universally agreed upon intake recommendation challenging across age groups. Consequently, international recommendations on total dietary fiber (TDF) intake vary by regulatory bodies, with most agreeing on an intake of greater than 25 g/day for the average adult and more diversity existing among recommendations for children. Working toward further collaboration on a fiber definition and recommendation will aid in international harmonization as it will be beneficial in being able to accurately measure intake as well as establish internationally accepted food labeling, conduct nutrition research, and accurately synthesize food composition tables.

Despite the consensus on fiber's beneficial health effects, fiber intake across the globe generally only meets half of the recommended amount. This is due to a number of barriers including the consumption of processed food due to a standard Western diet, and the unattainability of recommendations, especially for children. Potential solutions to this include the fortification of foods with dietary fiber, keeping the calorie content at an advisable level while helping individuals meet the recommendations, as well as the general move toward plant-based foods to mitigate climate change, thereby increasing overall fiber intake.

As fiber intake is linked to beneficial health outcomes, individuals consuming higher fiber diets will experience the beneficial and preventative role that appropriate fiber consumption can play in human health.

## Definition of dietary fiber

Fiber is classified in a variety of ways including source, such as cereal and legume fiber, chemistry, such as oligosaccharides (carbohydrates with degree of polymerization (DP) 3–9) and polysaccharides (carbohydrates with DP > 9), physiochemical properties, such as solubility and viscosity, and food matrix such as pre-processing like grinding and cooking. These numerous classifications translate into a variety of definitions from regulatory bodies. Prebiotics are an additional area related to dietary fiber with many qualifying as dietary fiber. They are described as substances selectively utilized by the host to benefit specific growth or activity of bacteria in the colon and therefore improving host health.

The Institute of Medicine (IOM), now titled the National Academy of Medicine (NAM) classifies fiber as plant derived, non-starch polysaccharides and lignin that are not digested or absorbed by the small intestine (Turner and Lupton, 2011). The UK based Scientific Advisory Committee on Nutrition (SCAN) extends this definition to including certain oligosaccharides as falling under the fiber definition (SACN Carbohydrates, 2015). The Codex Alimentarius Commission details perhaps the most comprehensive definition, describing dietary fiber as carbohydrates and lignin that are neither digested nor absorbed with three or more monomeric units (MU), including intact and intrinsic non-starch polysaccharides (NSP) (MU > 10), resistant oligosaccharides (RO) (MU 3–9), and resistant starch (RS) (MU > 10) (WHO/FAO, 2009). Countries who adhere to Codex guidelines can determine how much of this definition they align with and thus adhere to. Codex updated their definition in 2014 to include any substance as dietary fiber regardless of its source as long as it provides the stated physiological effect (Jones, 2014). This was with the goal of creating international harmonization around nutrition labeling, food composition tables, nutrition research and dietary recommendations for healthy people. However, there is still discrepancy between different regulatory bodies on the definition of fiber and therefore the recommendations, measured intake, and study exposure guidelines.

## Current fiber dietary guidelines (US, Europe, UK)

Historically, anecdotal evidence indicated fiber as beneficial due to an observed link between carbohydrate and fiber consumption in non-Western countries and stool size and transit time related to overall health. As scientific methods developed to analyze fiber and measure its intake against epidemiological observances, regulatory bodies in Western countries have developed recommended intakes of dietary fiber for their populations since the 1970s.

**Table 1** Fiber recommendations for children.

Country/region	Source	Year of publication	Daily fiber recommendation
USA	National Academy of Medicine	2017 ( <a href="#">Quagliani and Felt-Gunderson, 2016</a> )	Age 1–3 years: 19 g/day Age 4–8 years: 25 g/day Age 9–13 years: 31 g/day (M) 26 g/day (W) Age 14–19: 38 g/day (M) 26 g/day (W)
UK	UK Scientific Advisory Committee on Nutrition	2015 ( <a href="#">SACN Carbohydrates, 2015</a> )	Age 2–5 years: 15 g/day Age 5–11 years: 20 g/day Age 11–16 years: 25 g/day Age 16–18: 30 g/day
Europe	European Food Safety Authority	2010 ( <a href="#">Efsa Panel on Dietetic Products, 2010</a> )	Age 1–3 years: 10 g/day Age 4–6 years: 14 g/day Age 7–10 years: 16 g/day Age 11–14 years: 19 g/day Age 15–17 years: 21 g/day

For different nutrients, dietary reference intakes (DRIs) are established as reference ranges to set dietary guidelines and assess intakes. The DRIs for fiber include an adequate intake (AI), the nutrient amount required to meet the needs of an observed or experimental group of healthy people when an Estimated Average Requirement (EAR—the nutrient amount needed to meet the needs of half of the healthy individuals in a group) or the Recommended Dietary Allowance (RDA—a nutrient amount needed to meet the daily requirements of nearly all (97–98%) of healthy individuals in a group) cannot be set. Overall, countries make AI recommendations for adults, older adults, and children, aged 1–18 years old. There are no current recommendations for healthy infants age 0–6 months who are milk-fed as breast milk does not contain dietary fiber. Similarly, no recommendations exist for infants 7–12 months due to lack of data as well as low consensus of whole food intake overall.

The AI for TDF in US children and adults was informed by epidemiological studies examining cardiovascular disease (CVD) ([Tables 1 and 2](#)). European countries have a wide range of recommended intakes for TDF in children and adults, also informed by epidemiological studies examining its benefits for bowel function, blood lipids, glucose response, and protection from noncommunicable diseases ([Tables 1 and 2](#)). Similarly, SCAN established recommended intakes for TDF in children and adults based on epidemiological findings.

Overall, fiber recommendations are for TDF and do not specify the types of fiber. This is largely due to lack of consensus on how to quantify fiber. However, as different foods have different fiber types and these types vary in their physiological benefit, future guidelines could potentially begin to set intakes for specific fiber types to best serve their population health. For example, vegetables contain primarily non-starch polysaccharides (NSP) such as cellulose, pectic polysaccharides, and hemicelluloses, while legumes additionally contain resistant starch (RS) and resistant oligosaccharides (RO) such as alpha-Galactosides, beta-Fructo-oligosaccharides, resistant dextrins, and polydextrins.

## Food labeling

In the US, TDF is required to be listed on the nutrition facts label. Differentiating soluble and insoluble fiber was also historically required on the label but recently removed from the requirements due to inconsistent scientific findings on their previously understood physiological effects ([Medicine et al., 2001](#)). In 2016, the United States Food and Drug Administration (FDA) changed the dietary fiber Daily Value (DV) recommendation from 25 g/day to 28 g/day based on a 2000 calorie diet, requiring food manufacturers to update their labels and to reassess whether they would need to reformulate their product to keep in alignment with previously stated health claims.

**Table 2** Fiber recommendations for adults.

Country/region	Source	Year of publication	Daily fiber recommendation
USA	National Academy of Medicine	2017 ( <a href="#">Quagliani and Felt-Gunderson, 2016</a> )	Age 19–50: 38 g/day (M) 25 g/day (W) Age 50+: 30 g/day (M) 21 g/day (W)
UK	UK Scientific Advisory Committee on Nutrition	2015 ( <a href="#">SACN Carbohydrates, 2015</a> )	Adults: 30 g/day
Europe	European Food Safety Authority	2010 ( <a href="#">Efsa Panel on Dietetic Products, 2010</a> )	Adults: >25 g/day

## Fiber: food sources and functional fiber

Most fiber intake comes from plant foods, including fruit, vegetables, nuts, pulses, and whole grains. As fruit and vegetables have a high-water content, most only contain 1–3 g of fiber per serving (Slavin, 2008). As a result, whole grains are the primary source of fiber intake overall as they typically contain more grams of fiber per serving. Additionally, fortified high-fiber cereals are a good choice when it comes to obtaining a large amount of fiber in a food product serving. As these sources are whole food sources, they also contain vitamins, minerals, and other micronutrients that can provide additional benefit to the consumer.

Due to even most plant foods containing low amounts of fiber per serving, enriching foods with added fiber to increase the total amount or to aid in functional properties is a common approach in the food industry. Added or functional fiber is approved differently depending on the regulatory body. In the US, the NAM defines added or functional fiber as isolated non-digestible carbohydrates that confer a beneficial physiological response to the consumer. This isolated fiber can either be synthetically made or derived from nondigestible carbohydrates and is allowed on the nutrition facts panel if it analytically and physiologically behaves like fiber. As a result, while some functional fibers can count toward the TDF, others cannot if they have not yet been proven to demonstrate a beneficial physiological effect to the consumer. Physiological effects include lowering blood glucose and cholesterol levels, lowering blood pressure, improving laxation, increasing mineral absorption, and reducing energy intake. Trials that further examine various fibers' physiological effects will aid in developing and labeling products that better help consumers meet their daily requirements.

## Health claims

Claims related to fiber differ across countries. For a European health claim to state that a food is “high in” a particular fiber, the food must contain at least 6 g per 100 g or 3 g per 100 kcal of the fiber as defined by the EU commission (Stephen et al., 2017; Commission, 2006). Similarly, for a food to be a “source of fiber,” it must contain at least 3 g of fiber per 100 g or at least 1.5 g of fiber per 100 kcal. Specific to Europe, health claims indicate specific fibers and their demonstrated health benefits, such as pectin improving glycemic response or wheat bran fiber related to fecal bulk. In contrast, the US does not specify type of fiber, only the amount and the food source. For a food to be “high” in fiber in the US, the United States Food and Drug Administration (FDA) outlines that the food must contain greater than 20% of the DRV per reference amount customarily consumed (RACC), and between 10 and 19% to be considered a “good source of fiber” (Regulations, 2012a,b). While these claims have proven benefits in an experimental setting, the intake amount required to meet the health claim is often difficult for the average consumer to achieve outside of an experimental diet.

## Fiber intake: amount and sources

National food surveys and 24 h recalls are the preferred method for collecting population dietary intake. In the US, the National Health and Nutrition Examination Survey (NHANES) measures intakes via 24 h recalls every 2 years from age categories: 1–4, 4–12, 13–18, 18+, 18–39, 40–59, and 60 years old and over. The UK utilizes the National Diet and Nutrition Survey (NDNS) which assesses the diet, nutrient intake, and nutritional status of the UK population. Europe utilizes a variety of surveys based on the country of interest.

A review by Stephen et al. assessed 29 studies on fiber intake in Europe, the UK, and the US, and found that overall, fiber intake in adult males and females ranged from 15 to 25 g/day and 14–21 g/day respectively (Stephen et al., 2017). The authors noted that overall intake was higher in Europe as compared to North America. Intakes in children varied more widely and thus were less generalizable. Table 3 outlines the most recent data from NHANES and the NDNS for various age groups (Stephen et al., 2017).

**Table 3** Total dietary fiber intake for specific age groups as assessed by the National Health and Nutrition Examination Survey (NHANES) and the National Diet and Nutrition Survey (NDNS).

Country	Survey	Year of survey	Age	Total fiber intake (g/d)
USA	NHANES	2011–2012 (Agriculture, 2012)	20+	M: 19.1; F: 15.5
			60+	M: 19.6; F: 15.9
			13–18	M: 18.1; F: 12.5
			4–12	M: 15.4; F: 13.9
			0–4	12.1
UK	NDNS	2009–2012 (Agency, 2014)	0–4	8.2
			4–10	M: 11.5; F: 10.7
			11–18	M: 12.8; F: 10.7
			19–64	M: 14.7; F: 12.8
			65+	M: 14.9; F: 13.9

Stephen et al. also noted that grain products were the largest source of fiber in all countries for adults, while there was greater variance in fiber sources in children across and within countries.

## Health impacts of fiber

There are both short- and long-term benefits from consuming dietary fiber. These benefits are both directly related to gastrointestinal health as well as extend to other organs and systems. Short-term benefits include immune system support, increasing mineral absorption in the colon, and preventing or ameliorating autoimmune diseases. Long-term benefits include reducing the risk of non-communicable diseases and reducing bowel conditions such as constipation.

### Cardiovascular disease

Dietary fiber has long shown its ability to protect against cardiovascular disease (CVD) and this relationship is the main epidemiological finding by which the US sets their AI. A systematic review by Threapleton et al. assessing 22 prospective cohort studies found an inverse association between total dietary fiber intake and risk of CVD and coronary heart disease (Threapleton et al., 2013a,b). However, despite this well-established relationship, the mechanisms of action (MoA) are not well known. Some proposed MoA include fiber's ability to mitigate CVD risk factors such as soluble fiber's ability to decrease low density lipoprotein (LDL) cholesterol, thereby decreasing overall serum cholesterol, and attenuating CVD risk (Buttriss and Stokes, 2008). Additional studies have shown higher fiber diets' ability to decrease C-reactive protein, a marker of systemic inflammation, modulate postprandial glycemic response, decrease body fat through overall caloric intake modulation, and decrease hypertension, thereby protecting against CVD.

In the US, the FDA has allowed specific authorized health claims linking beta-glucan consumption from oats, barley, and psyllium husk to reduced risk of CVD. EFSA also allows similar function health claims, extending the food sources to oat, oat bran, barley, and barley bran.

### Metabolic health

Various trials have examined the impacts of high fiber diet on overall metabolic health, analyzing markers such as insulin sensitivity, HbA1C, lipid profiles, body weight, and C-reactive protein. An interventional trial examining 111 overweight adults with features of metabolic syndrome found that the adults supplemented with the high cereal fiber (HCF) diet had improved insulin sensitivity as compared to control, high protein (HP), and HCF/HP groups (Weickert et al., 2011a,b). An observational trial examining 190 Japanese adults without type 2 diabetes found that an increase of dietary fiber to carbohydrate ratio in the diet resulted in decreased HbA1C (Morimoto et al., 2018). A systematic review and meta-analysis also found that a high-fiber diet resulted in improved insulin sensitivity, HbA1C, lipid profile, body weight, and C-reactive protein (Reynolds et al., 2020).

Regarding body weight and abdominal adiposity, current evidence-based trials provide conflicting results, with some indicating that increased fiber diets result in lower body weights and decreased overall caloric intake and others indicating that changes in weight and intake were minor or nonsignificant. Most of these studies indicate the ability of dietary fiber intake to decrease overall caloric intake due to appetite suppression related to increase satiation. Future studies should further examine these links as well as design longer-term trials to better understand any potential linkages. Additionally, trials examining dietary fiber intake's effect on body weight maintenance would be of interest.

Two systematic reviews examining prospective cohort studies found that fiber intake (TDF) was associated with a decrease in the long-term risk of the development of type 2 diabetes mellitus (Threapleton et al., 2013a,b; Yao et al., 2014). Cereal fiber was the primary fiber responsible for reduced diabetes risk. Additional prospective cohort studies have also indicated that insoluble cereal dietary fiber and whole grains are those associated with decreased risk for type 2 diabetes mellitus (Schulze et al., 2007; de Munter et al., 2007). While the MoA for this association is not fully known, proposed mechanisms include fiber's ability to increase gastric distention and delay emptying, thereby decreasing overall caloric intake, soluble fiber's ability to modulate the absorption of glucose, and fiber's ability to increase the absorption of nutrients, and stimulate beneficial colonic bacteria which may impact the gut-brain axis and not yet known type 2 diabetes linkages.

### Gut microbiome

The gut microbiome and its interconnected and complex role in overall health is currently of great scientific and consumer interest. As of yet, most studies examining fiber's effect on the gut microbiome come from animal models, specifically rodent-based studies. One such study demonstrated the role of dietary fiber's role in protecting gnotobiotic rodents' colonic mucosal barrier from erosion and therefore overall gastrointestinal health (Desai et al., 2016). While these studies have not been conducted in humans, they point toward potentially similar benefits as well as trial designs to emulate.

Dietary fiber is known to improve overall microbiome health and metabolite production. However, a randomized control trial (RCT) ( $n = 69$ ) examining MoA for fiber's ability to improve insulin sensitivity found that among overweight adults, those who were supplemented with the high cereal fiber isocaloric diet had no alterations in short-chain fatty acid (SCFAs) production or gut microbiota ecology despite improved insulin sensitivity in this group (Weickert et al., 2011a,b). As cereal fibers tend to be both primarily insoluble and nonfermentable, perhaps their role in gut health is more related to their ability to increase stool bulk through microbial mass growth.

As a subset of fiber, prebiotics are also of great consumer interest as well as scientific exploration. While various studies exist pointing to their beneficial effects on various colonic bacterial strains, there are currently no prospective, cohort studies which link changes in the microbiota as a result of prebiotic exposure to health outcomes (Brownawell et al., 2012). As a result, for prebiotics to be listed as a dietary fiber, studies need to be designed to indicate a linkage between their consumption and a resulting health benefit. Standardization of health outcome quantification methods as well as prebiotic protocols in human studies are key to establishing this linkage.

### Gut health

Dietary fiber's beneficial effects on gastrointestinal health are well established. Fiber impacts the gut overall by increasing chewing and saliva production, increasing gastric distention and delaying emptying (potentially decreasing caloric intake), delaying nutrient absorption (thereby modulating glucose and insulin response), altering gut hormones such as GLP-1, PYY, and ghrelin (thereby modulating hunger cues), and aiding in colonic fermentation and the production of short chain fatty acids (SCFAs) (Dayib et al., 2020).

Due to differing physiochemical effects, different fibers will have differing effects on stool weight. Some fibers, such as pectin and inulin are extensively fermented (over 90%), while others are poorly fermented, such as purified cellulose (less than 10%). Overall, however, even fibers that are extensively fermented are able to increase stool weight since the fermentation process increases the bacterial mass, resulting in a greater water binding capacity.

Regarding gut motility, if transit time is already normal (2 days, 48 h), increasing fiber intake will not alter or improve this transit time (Marlett et al., 2000). However, if intake is low, fiber intake will normalize transit time to 2–4 days (Harvey et al., 1973). A review conducted in 2007 found that of 150 studies examining the effects of fiber intake on stool bulk, specific types of fiber such as raw wheat and fruit and vegetable fiber were more effective in increasing stool bulk as compared to soy, legume, and pectin fibers (Elia and Cummings, 2007). An additional meta-analysis found that dietary fiber intake as compared to placebo in constipated patients resulted in increased stool frequency (Yang et al., 2012). However, they noted that associations between fiber intake and improved stool consistency, treatment success, laxative use and painful defecation would need to be further explored.

### Barriers and solutions to meeting recommendations

As fiber is labeled a nutrient of concern in the US due to low intake, also reflected worldwide, it is important to assess the barriers to meeting dietary fiber intake recommendations and propose solutions.

Processed food has been touted both as a barrier to fiber intake as well as a way to increase fiber consumption. A typical Western diet often contains high amounts of ultra-processed foods which could either contain large amounts of refined grains and therefore lack fiber, or alternatively, could include ultra-processed foods that have been enriched or fortified to include fiber in the form of whole grains or functional fibers. As a result, a solution could be the development of standards around fiber benchmarks in ultra-processed foods to ensure that populations consuming these foods are able to meet the fiber intake recommendations and therefore confer the beneficial health effects.

Clean food labeling is proposed as a barrier in fiber intake as consumers are looking for labels that have five or less ingredients, specifically ingredients that they can pronounce and understand. As a result, if an enriched or fortified food contains a chemically based and described fiber ingredient, this subgroup of consumers may avoid the product, therefore decreasing their consumption of fiber. Additionally, as described above, these consumers also avoid ultra-processed foods due to the high number of ingredients, therefore also potentially missing food products that have a high source of fiber. Education and awareness around nutrition facts labels, ingredient descriptions, and the health benefits of ultra-processed foods could aid in increasing literacy and therefore consumption of high fiber food products.

Many sources note the unattainability of most fiber intake recommendations for both children and adults due to fiber intake also being linked to calorie intake. Enriching and fortifying foods products could aid in providing consumers with appropriate fiber amounts while keeping calorie intake at desirable level (Jones, 2014). Additionally, as a greater consensus is reached on the categorization of dietary fiber and the specific health benefits of each fiber type, perhaps more realistic and defined dietary fiber intake recommendations will be developed which will be both more realistic for the consumer and more precise for overall health.

Recent diet trends have tended to favor less fiber in the diet such as low carbohydrate diets, low gluten diets, the ketogenic diet, the paleo diet, and the low FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diet. Individuals participate in these diets for a range of reasons, including weight loss, specific health outcomes related to communicable and

noncommunicable diseases, and popular culture trends. While each of these diets have various trials indicating health outcomes, most are short-term in nature and fail to examine any negative consequences due to low fiber consumption. However, the recent plant-based movement could counter some of these effects. To mitigate climate change related to food production and thus meet sustainability targets established by organizations such as the Food Agriculture Organization (FAO), EAT-Lancet, and the World Health Organization (WHO) for planetary health, plant-based diets are encouraged across cultural and socioeconomic groups. As a result, fiber intake could be increasing overall as more individuals adopt plant-based diets and move away from the majority of calories coming from fiber-poor food sources.

## Conclusion/summary/outlook

Dietary fiber is an essential nutrient with many known and yet to be discovered health benefits. These benefits include both short and long-term health impacts such as immune system support, increasing mineral absorption in the colon, ameliorating autoimmune disease, and supporting colonic health. While countries recommend different dietary fiber amounts across populations and age groups, dietary intakes often fall short, averaging at less than half of recommended amounts. This is due to various barriers such as the consumption of processed food, low fiber diets, lofty intake recommendations, overall caloric intake considerations, and clean-label preferences. Fiber can also be added to the diet as a dietary supplement, bulk laxative, or be added to popular foods and drinks with functional fiber. Thus, processed foods can also be a solution to adding fiber into the food supply. As education surrounding the importance of fiber and its resulting health benefits continues, as well as overall adoption of plant-based diets to meet climate goals increase, overall fiber intake should better match recommended amounts with consequent health benefits for populations worldwide.

### Key points

- Folates are a class of B vitamins consisting of multiple interconvertible chemical forms that are essential for one-carbon metabolism-related biochemistry, including DNA and RNA synthesis, amino acid metabolism, methylation reactions, and formate metabolism.
- Consequences of folate deficiency include megaloblastic anemia, hyperhomocysteinemia, cancer initiation, neurological and cognitive impairment, depression, and neural tube defects and other negative birth outcomes.
- Folic acid is the synthetic, oxidized form of folate that is used as a supplement and as a fortificant in foods.
- Folic acid fortification of cereal and grain food products has significantly reduced the incidence of neural tube defects.
- Excess folic acid exposure due to supplementation and fortification may have additional effects on cancer rates, vascular disease, development, and the severity of B12 deficiency, but these effects are controversial and require further investigation.

### Introduction

In the 1930s, first Lucy Wills (Wills, 1931) and then Robert Stokstad (Stokstad and Manning, 1938) isolated a natural component of yeast (termed “Wills factor” and “factor U”, respectively) that prevented megaloblastic anemia of pregnancy and promoted growth in chickens. In the next decade, Herschell Mitchell, Esmond Snell, and Robert Williams (Mitchell et al., 1941) isolated a factor from spinach that could support the growth of lactic acid bacteria, *Streptococcus faecalis* and *Lactobacillus casei*. They named this factor “folic acid” based on *folium*, the Latin word for leaf. Shortly thereafter, Stokstad (Stokstad, 1943) isolated the pure crystalline form of the

vitamin, and it was recognized that the Wills factor, factor U, and folic acid were the same substance. Beginning in the 1950s and 1960s, the components and details of folic acid metabolism, and the metabolism of its many interconvertible reduced forms collectively known as “folates”, were elucidated. These included metabolic interrelationships with vitamin B<sub>12</sub> and methionine/homocysteine metabolism, roles in pyrimidine and purine synthesis, and the determination of the molecular basis for deficiency diseases. In subsequent decades, key discoveries included identification of polymorphic variants of folate metabolizing enzymes, interrelationships with formate metabolism, and characterization of subcellular compartmentalization of folate metabolism within the cytosol, the mitochondria and, most recently, the nucleus. In the late 1980s and 1990s, clinical interest in folates and folic acid heightened with the identification of elevated plasma homocysteine (hyperhomocysteinemia) as a risk factor for vascular disease, cognitive dysfunction, and dementia. During this time, it was also determined that periconceptual supplements of the vitamin were effective in reducing the risk of neural tube defects (NTDs). This led to wide-spread fortification of cereal and grain products with folic acid in the US and Canada beginning in the mid-to late-1990s. Today, more than 80 countries and territories have instituted folic acid fortification programs, which have been highly effective in reducing NTDs. There are, however, lingering questions regarding the safety of excess folic acid consumption.

## Chemistry and biochemical functions

### Chemical forms

Though used generically, the term “folic acid” refers specifically to the synthetic form of the vitamin, which is used in supplements and as a fortificant in foods. The term “folate” refers generally to all forms of the vitamin. As shown in **Fig. 1**, folic acid consists of a pterin moiety linked via a methylene group to a para-aminobenzoyl-glutamate moiety. Its metabolic activity requires reduction to the tetrahydrofolate (THF) derivative, addition of a chain of glutamate residues in  $\gamma$ -peptide linkage, and acquisition of one-carbon units. One-carbon units at various levels of oxidation are generated metabolically and are reactive only as moieties attached to the N5 or N10 positions of the folate molecule (**Table 1**). The range of oxidation states for folate one-carbon units extends from methanol to formate as methyl, methylene, methenyl, formyl, or formimino moieties. When one-carbon units are incorporated into folate derivatives, they may be converted from one oxidation state to another by the gain or loss of electrons.

### Overview of biochemical functions

The biochemical function of folate substrates is to transfer and use one-carbon units in a variety of essential reactions (**Fig. 2**), including *de novo* purine biosynthesis (formylation of glycinamide ribonucleotide and 5-amino-4-imidazole carboxamide ribonucleotide), pyrimidine nucleotide biosynthesis (methylation of deoxyuridylic acid to thymidylic acid), amino acid interconversions (interconversion of serine to glycine, catabolism of histidine to glutamic acid, and vitamin B<sub>12</sub>-dependent conversion of homocysteine to methionine), and the generation and use of formate.

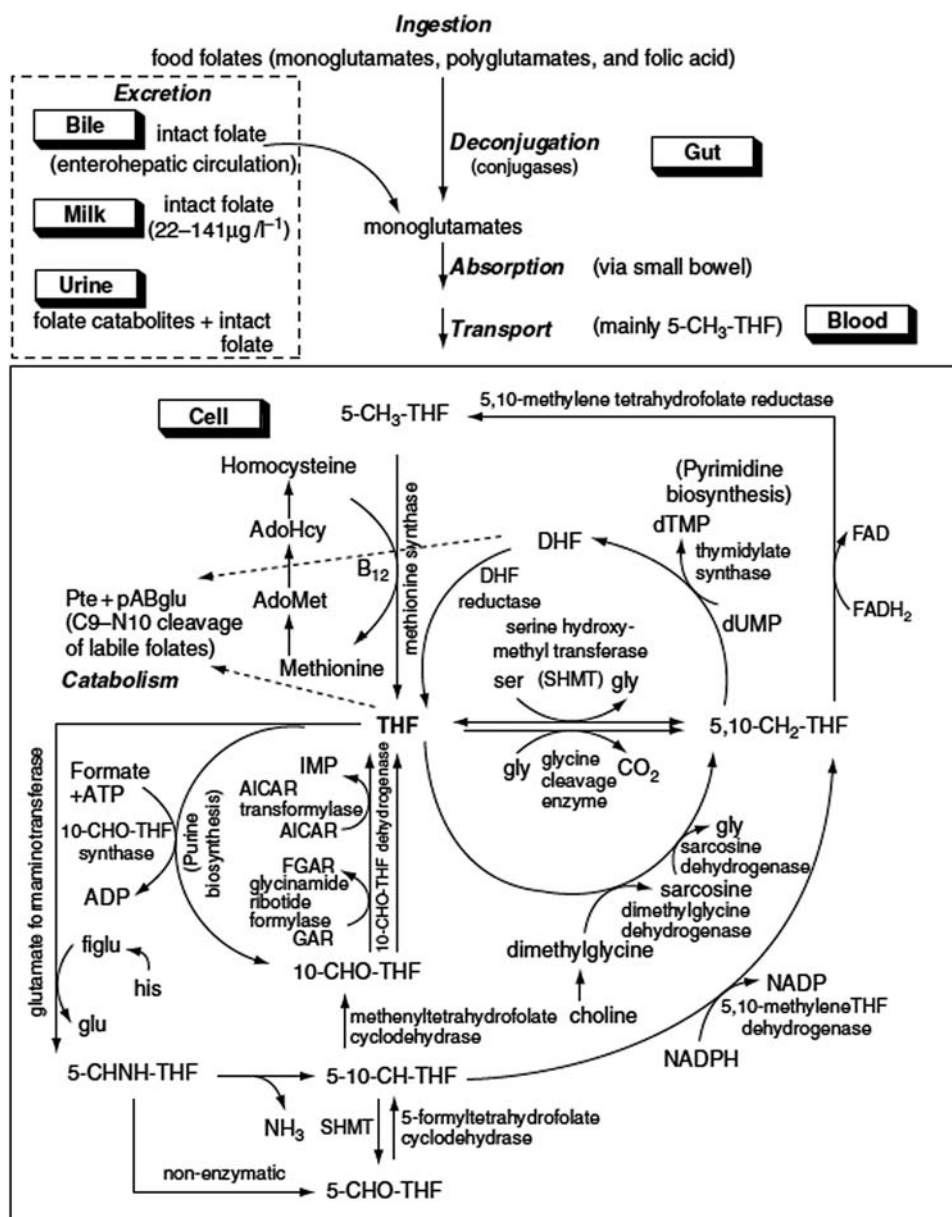

Many of the enzymes involved in these reactions are multifunctional and are capable of channeling substrates and one-carbon units from reaction to reaction within a protein matrix. Another feature of intracellular folate metabolism is the compartmentalization of folate coenzymes among the cytosol, the mitochondria, and the nucleus (**Fig. 3**). For instance, 5-methylTHF is associated with the cytosolic fraction of the cell, whereas most of 10-formylTHF is located in the mitochondria. Similarly, some

**Fig. 1** Structural formula of tetrahydrofolate (THF) compounds. In tetrahydrofolate R = H; other substituents are listed in **Table 1**. The asterisk indicates the site of attachment of extra glutamate residues; the hatched line and double asterisk indicates the N5 and/or N10 site of attachment of one-carbon units.

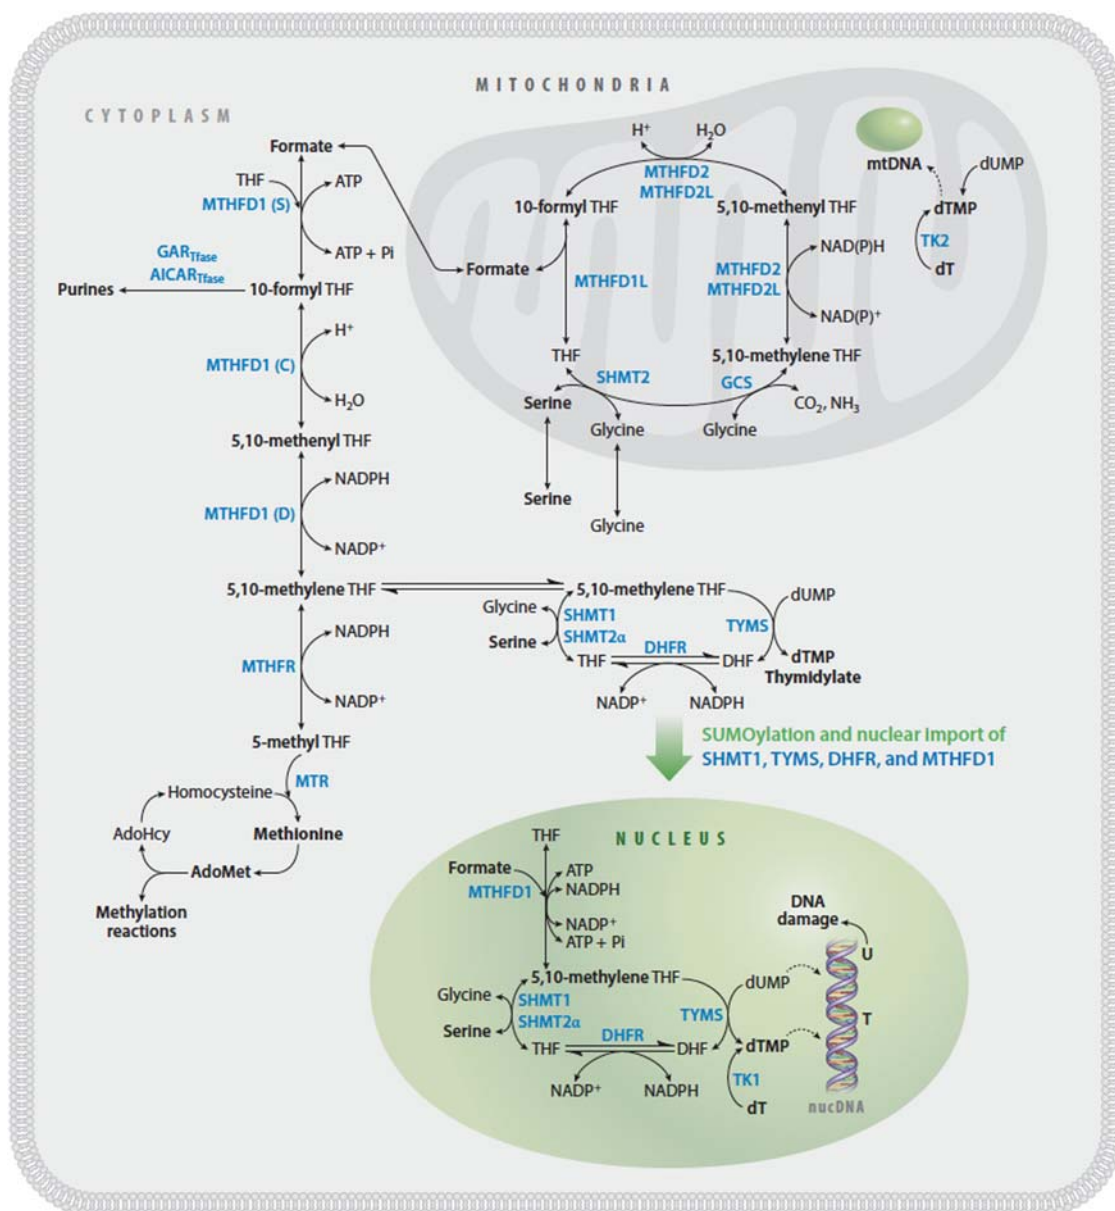

**Table 1** Structure and nomenclature of folate compounds.

<i>Compound</i>	<i>R-group</i>	<i>Oxidation state</i>
5-formylTHF	—CHO	Formate
10-formylTHF	—CHO	Formate
5-formiminoTHF	—CH=NH	Formate
5,10-methenylTHF	—CH=	Formate
5,10-methyleneTHF	—CH <sub>2</sub> —	Formaldehyde
5-methylTHF	—CH <sub>3</sub>	Methanol

**Fig. 2** Physiology and metabolism of folate. GAR, glycinamide ribonucleotide; FGAR, formylglycinamide ribonucleotide; AICAR, aminoimidazolecarboxamide ribonucleotide; FIGLU, formiminoglutamic acid; IMP, inosine monophosphate.

**Fig. 3** Subcellular compartmentalization of folate metabolism. AdoHcy, S-adenosylhomocysteine; AdoMet, S-adenosylmethionine; AICARTase, aminoimidazolecarboxamide ribonucleotide transformylase; DHFR, dihydrofolate reductase; dT, deoxythymidine; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; GARTase, glycinamide ribonucleotide transformylase; MTHFD1, methylenetetrahydrofolate dehydrogenase 1; MTHFR, methylenetetrahydrofolate reductase; MTR, methionine synthase; mtDNA, mitochondrial DNA; SHMT, serine hydroxymethyltransferase; SUMO, small ubiquitin-like modifier; THF, tetrahydrofolate; TK, thymidine kinase; TYMS, thymidylate synthase. Reprinted with permission from Field et al. (2018).

folate-dependent enzymes are associated with one or other compartment, though some are found in both. Metabolic products of folate-dependent reactions, such as serine and glycine, are readily transported between the two locations, but the folate coenzymes are not. In recent years, the existence and importance of nuclear folate metabolism, first suggested by reports from the 1960s and early 1980s, has come to be appreciated. This stems from the discovery that key cytosolic enzymes undergo small-ubiquitin-like modifier-dependent modification (a process called SUMOylation), which facilitates the nuclear import of these enzymes from the cytosol into the nucleus (Fig. 3) (Field et al., 2018).

### Source of one-carbon units

One-carbon units at the oxidation level of formate can enter directly into the folate pool as formic acid in a reaction catalyzed by 10-formylTHF synthase (EC 6.3.4.3) (Fig. 2). Entry at the formate level of oxidation can also take place via a catabolic product of

histidine, formiminoglutamic acid. The third mode of entry at the formate level of oxidation involves the formation of 5-formylTHF from 5,10-methenylTHF by the enzyme serine hydroxymethyltransferase (SHMT) (EC 2.1.2.1). The 5-formylTHF may be rapidly converted to other forms of folate.

The enzyme SHMT is also involved in the entry of one-carbon units at the formaldehyde level of oxidation by catalyzing the transfer of the  $\beta$ -carbon of serine to form glycine and 5,10-methyleneTHF. Other sources of one-carbon entry at this level of oxidation include the glycine cleavage system and the choline-dependent pathway; both enzyme systems generate 5,10-methyleneTHF in the mitochondria of the cell.

### Removal of one-carbon units

One-carbon units are removed from folate by a number of reactions. The enzyme 10-formylTHF dehydrogenase (EC 1.5.1.6) provides a mechanism for disposing of excess one-carbon units as carbon dioxide. (Folate administration to animals enhances the conversion of ingested methanol and formate to carbon dioxide, diminishing methanol toxicity.) Additionally, single-carbon units from 10-formylTHF are used for the biosynthesis of purines (Fig. 2).

The one-carbon unit of 5,10-methyleneTHF is transferred in two ways. Reversal of the SHMT reaction produces serine from glycine, but as serine is also produced from glycolysis via phosphoglycerate, this reaction is unlikely to be important. However, one-carbon transfer from 5,10-methyleneTHF to deoxyuridylate to form thymidylic acid, a precursor of deoxyribonucleic acid (DNA), is of crucial importance to the cell. Although the source of the one-carbon unit, namely 5,10-methyleneTHF, is at the formaldehyde level of oxidation, the one-carbon unit transferred to form thymidylic acid appears at the methanol level of oxidation. Electrons for this reduction come from THF itself to generate dihydrofolate as a product. The dihydrofolate must in turn be reduced back to THF in order to accept further one-carbon units.

A solitary transfer of one-carbon units takes place at the methanol level of oxidation. It involves the transfer of the methyl group from 5-methylTHF to homocysteine to form methionine and THF. This reaction is catalyzed by the enzyme methionine synthase (EC 2.1.1.13) and requires vitamin B<sub>12</sub> as a cofactor. The substance 5-methylTHF is the dominant folate in the body, and it remains metabolically inactive until it is demethylated to THF, whereupon polyglutamylation takes place to allow subsequent folate-dependent reactions to proceed efficiently. Methionine is activated by reaction with ATP to form S-adenosylmethionine (SAM). SAM serves as the universal methyl donor for a variety of essential methylation reactions, including those involving DNA, ribonucleic acid (RNA), histones, proteins, phospholipids, neurotransmitters, and creatine synthesis.

### Regulation of folate metabolism

The biochemical functions of folate can be divided into two general categories: (1) the synthesis of bases for incorporation into DNA and RNA, and (2) the metabolism of homocysteine to form methionine and subsequently SAM. Whether folate is utilized for the former or the latter purpose is controlled by biochemical feedback mechanisms that specifically affect the conversion of 5,10-methyleneTHF to 5-methylTHF by the enzyme, 5,10-methyleneTHF reductase (MTHFR) (EC 1.5.1.20). MTHFR is subject to allosteric inhibition by SAM. When intracellular SAM concentrations are low, MTHFR actively promotes the synthesis of 5-methylTHF for methionine and SAM synthesis. When SAM concentrations are high, inhibition of MTHFR by SAM reduces the synthesis of 5-methylTHF, methionine, and SAM, and promotes utilization of 5,10-methyleneTHF for thymidylate and purine synthesis (Selhub and Miller, 1992). Another important inhibitor of MTHFR is dihydrofolate. Accumulation of DHF as a product of thymidylate synthesis will inhibit MTHFR, thus conserving 5,10-methyleneTHF for further thymidylate synthesis. In this way, DHF may serve as a sensor of active DNA synthesis and cellular proliferation (Matthews and Daubner, 1982).

### Enzyme polymorphisms

Common polymorphisms have been identified in key enzymes involved in folate metabolism. The most well studied is the C677T single nucleotide polymorphism in the MTHFR gene, which encodes for either alanine (wild type) or valine (variant) at residue 222 within the amino acid sequence (Frosst et al., 1995). The variant form of the enzyme is thermolabile *in vitro* and has approximately 70% lower activity than the wild-type enzyme due to reduced affinity for its substrate (5,10-methyleneTHF) and its cofactor, flavin adenine dinucleotide (FAD) (Kang et al., 1988). Homozygosity for the variant form is found in 10–15% of Caucasians, with lower prevalence in blacks and higher in Hispanics. The lower activity of the variant MTHFR is associated with a variety of conditions, including hyperhomocysteinemia, greater risk of NTDs, and lower risk of some cancers. Hyperhomocysteinemia and NTD risk can be attenuated by increased dietary folate intake or folic acid supplements. Prevalent polymorphisms in several other folate metabolizing enzymes have been identified, including those within thymidylate synthase (EC 2.1.1.45), methionine synthase, methionine synthase reductase (EC 1.16.1.8), reduced folate carrier, and folylpoly- $\gamma$ -glutamate carboxypeptidase (EC 3.4.17.21), among others. The effects of these polymorphisms on enzyme activity and associated pathophysiological conditions range from none to weak or moderate, depending on the nature of the specific polymorphism.

## Nutritional aspects

### Dietary sources

Folate is synthesized by microorganisms and higher plants, but not by mammals, for which it is an essential vitamin. The most concentrated food folate sources include liver, yeast extract, green leafy vegetables, legumes, certain fruits (e.g., oranges and strawberries), and fortified cereal and grain products. Folate content is likely to depend on the maturity and variety of particular sources. Prolonged exposure to heat, air, or ultraviolet light is known to inactivate the vitamin; thus, food preparation and cooking can make a difference to the amount of folate ingested. Boiling, in particular, results in substantial food losses. The major source of folate loss from vegetables during boiling may be leaching as opposed to folate degradation. Broccoli and spinach are particularly susceptible to loss through leaching during boiling, compared with potatoes, because of their larger surface areas. The retention of folate during cooking depends on the food in question as well as the method of cooking. Foliates of animal origin are stable during cooking by frying or grilling. Steaming in preference to boiling is likely to double the amount of folate consumed from green vegetables. In countries with voluntary or mandatory fortification policies, folic acid from enriched cereal grain products, including bread, cereals, pasta, flour, and rice, may constitute the largest proportion of dietary intake of the vitamin.

### Bioavailability

The amount of folate that is absorbed and utilized physiologically varies among different food sources and among different chemical forms of the vitamin. Folic acid consumed as a supplement separate from food is the most highly bioavailable. The bioavailability of folic acid taken with a meal or as a food fortificant is approximately 85%, compared with folic acid consumed while fasting. Natural food folates are less bioavailable, at approximately 50% of the value for folic acid alone. Based on these differences in bioavailability, dietary folate equivalents (DFEs) have been defined as: 1 DFE = 1 µg food folate = 0.6 µg folic acid added to food = 0.5 µg folic acid taken without food (Institute of Medicine, 1998; Sutor and Bailey, 2000).

### Dietary reference intakes

The recommended dietary allowance (RDA) for males and nonpregnant and nonlactating females aged 15 years or older is 400 µg DFE day<sup>-1</sup> (Table 2) (Institute of Medicine, 1998). The RDA ranges from 65 to 300 µg DFE day<sup>-1</sup> for ages 0–14 years. The RDAs for pregnant and lactating women are, respectively, 600 and 500 µg DFE day<sup>-1</sup>, which accounts for the increased demands for folate of the growing fetus and breast-feeding infant. There is no upper tolerable intake level (UL) established for food folates. However, a UL for folic acid has been set at 1000 µg day<sup>-1</sup>. This is based not specifically on direct toxic effects of folic acid, but rather the possible masking of vitamin B<sub>12</sub> deficiency by high dose folic acid, which can correct hematological abnormalities but not the neuropathological manifestations of B<sub>12</sub> deficiency. In recent years, concerns have been raised that folic acid consumption exceeding the current UL may have other negative consequences related to cancer promotion, exacerbation (over and beyond masking) of the metabolic and clinical features of B<sub>12</sub> deficiency, impairment of immune function, and altered developmental programming. However, to date these concerns have not been considered in the establishment of the UL for folic acid (see the Section on Folic acid fortification beyond NTDs).

## Absorption, transport, and excretion

### Absorption

Food folates mainly consist of reduced polyglutamates, which are hydrolyzed to monoglutamates in the gut prior to absorption across the intestinal mucosa. The conjugase enzyme that hydrolyzes dietary folates, folylpoly-γ-glutamate carboxypeptidase, is found on the luminal brush border membrane in the human jejunum and has equal affinity for folate polyglutamates of various chain lengths. Uptake of folate monoglutamate into the intestinal cell is facilitated by two saturable carrier-mediated processes.

**Table 2** Recommended dietary allowances (RDA) for folate (US and Canada).

Category	Age	RDA (µg/day)
Infants	0–6 months	65
	6–12 months	80
	1–3 years	150
Children	4–6 years	200
	7–14 years	300
Adults	15+ years	400
Pregnancy		600
Lactation		500

These include the reduced folate carrier (RFC), a transporter protein that mediates the uptake of food folates, but has low affinity for folic acid, and folate binding protein (FBP), which mediates the uptake of both reduced and oxidized folates by receptor-mediated endocytosis. The luminal pH optimum for intestinal folate uptake is  $\sim 5.0$ – $6.0$ , and changes in luminal pH, as well as the presence of conjugase inhibitors, folate binders, or other food components can adversely affect the rate of hydrolysis and intestinal absorption. Such factors account for the wide variation in the bioavailability of the vitamin from foods of plant and animal origins. Some metabolism of the resultant monoglutamate, mainly to 5-methylTHF, appears to occur during the absorption process, though this may not be necessary for transport across the basolateral membrane of the intestinal mucosa into the portal circulation. The degree of metabolic conversion of supplemental folic acid depends on the dose; significant portions of pharmacological amounts are transported unaltered into the circulation.

### Transport and cellular uptake

Folate circulates in the blood predominantly as 5-methylTHF. A variable proportion circulates freely or is bound either to low-affinity protein binders such as albumin, which account for about 50% of bound folate, or to a high-affinity folate binder in serum, which carries less than 5% of circulating folate. The physiological importance of serum binders is unclear, but they may control folate distribution and excretion during deficiency.

Though most folate is initially taken up by the liver following absorption, it is delivered to a wide variety of tissues in which many types of folate transporters have been described. Because these transporters have affinities for folate in the micromolar range, they would not be saturated by normal ambient concentrations of folate. Therefore, folate uptake into tissues should be responsive to any increases in serum folate concentration arising from folate supplementation. An important determinant of folate uptake into cells is their mitotic activity, as would be expected given the dependence of DNA biosynthesis on folate coenzyme function. Folate accumulation is more rapid in actively dividing cells than in quiescent cells, a factor that is probably related to the induction and activity of folylpoly- $\gamma$ -glutamate synthase (EC 6.3.2.17). This enzyme catalyzes the addition of glutamate by  $\gamma$ -peptide linkage to the initial glutamate moiety of the folate molecule. Although polyglutamate derivatization may be considered a storage strategy, this elongation is the most efficient coenzyme form for normal one-carbon metabolism. The activity of folylpoly- $\gamma$ -glutamate synthase is highest in the liver, the folate stores of which account for half of the estimated 15–30 mg adult total body complement. Retention within the cell is facilitated by the high proportion of folate associated with proteins, and this is likely to be increased in folate deficiency.

The mobilization of liver and other stores of folate in the body is not well understood, particularly in deficiency states, though some accounts describe poor turnover rates in folate-depleted rats. Transport across cell membranes during redistribution requires deconjugation of the large negatively charged polyglutamates. Mammalian  $\gamma$ -glutamylhydrolases that hydrolyze glutamate moieties and transpeptidases that hydrolyze folylpolyglutamates directly to mono- or di-glutamate forms of the vitamin have been described for several tissues. Thus, mammalian cells possess two types of enzymes that can play a key role in folate homeostasis and regulation of one-carbon metabolism: folylpolyglutamate synthetase that catalyzes the synthesis of retentive and active folate, and a number of deconjugating enzymes that promote the release of folate from the cell. Polyglutamate forms released into the circulation either through cell death or by a possible exocytotic mechanism would be hydrolyzed rapidly by plasma  $\gamma$ -glutamyl-hydrolase to the monoglutamate form.

### Excretion

Folate is concentrated in bile and enterohepatic recirculation from the intestine accounts for considerable reabsorption and reuse of folate (about  $100 \mu\text{g day}^{-1}$ ). Fecal folates arise mainly through biosynthesis of the vitamin by the gut microflora, with only a small contribution from unabsorbed dietary folate. Urinary excretion of intact folates accounts for only a small fraction (1–2%) of ingested folate under normal physiological conditions. Free folates (i.e., non-protein bound) are filtered in the glomerulus and reabsorbed in the proximal tubules, which contain a high concentration of FBP. The greater amount of excretion in urine is accounted for by products that arise from cleavage of the folate molecule at the C9-N10 bond, consisting of one or more pteridines and *p*-acetamido-benzoylglutamate. The rate of scission of the folate molecule increases during rapid-mitotic conditions such as pregnancy and growth. Scission of folate is perhaps the major mechanism of folate turnover in the body.

## Deficiency and excess

### Megaloblastic anemia

Megaloblastic anemia (a form of macrocytic anemia) is characterized by larger than normal circulating red blood cells and hypersegmented neutrophils. Deficiencies of either folate or vitamin B<sub>12</sub> induce anemias that are clinically indistinguishable (Chanarin, 1979). The hematological effect in both cases is the result of intracellular concentration of 5,10-methyleneTHF that is inadequate to sustain thymidylate synthesis. In the case of folate deficiency, this is directly the result of a lack of dietary folate. In vitamin B<sub>12</sub> deficiency, this is due to what is known as the “methylfolate trap” (Scott and Weir, 1981). This occurs because the conversion of 5,10-methyleneTHF to 5-methylTHF by MTHFR is an irreversible reaction. When vitamin B<sub>12</sub> is deficient, the utilization of 5-methylTHF for methionine synthesis is inhibited. Consequently, the metabolism of 5-methylTHF cannot proceed forward or backward, and

thus the 5-methylTHF becomes metabolically trapped and a secondary folate deficiency occurs. Regardless of the cause of the folate deficiency, the resulting inhibition of DNA synthesis affects rapidly proliferating cells, in particular the blood cell precursors in the bone marrow. Inhibition of DNA synthesis leads to a block in cell replication, but not in cytoplasmic protein synthesis, which results ultimately in the release of megaloblastic or macrocytic red cells into the circulation. Other rapidly proliferating cells that are similarly affected by folate deficiency are the mucosal cells of the intestine. This leads to blunted intestinal villi and consequent reduced nutrient absorptive capacity.

It is important for the treatment of megaloblastic anemia to differentiate between folate and B<sub>12</sub> deficiencies as the cause in any given patient. High dose folic acid supplements correct hematological abnormalities, but not the neuropathological manifestations of B<sub>12</sub> deficiency. This occurs because folic acid is taken up into cells and is metabolized first to dihydrofolate and then THF by the enzyme, dihydrofolate reductase (EC 1.5.1.3) (Fig. 2). The THF can then be converted to 5,10-methyleneTHF and used for thymidylate synthesis. In this way, the folic acid bypasses the methylfolate trap, reverses the megaloblastic anemia, and essentially “masks” the B<sub>12</sub> deficiency. The patient nonetheless remains B<sub>12</sub> deficient and is susceptible to potentially irreversible neuronal damage if the B<sub>12</sub> deficiency continues untreated. Notably, there are clinical observations that have been interpreted to be evidence that folic acid supplementation in this context may actually exacerbate or accelerate the clinical manifestations of B<sub>12</sub> deficiency, particularly the neuropathology and its consequences, but this is controversial (Reynolds, 2002).

### Hyperhomocysteinemia

An important consequence of folate deficiency is the inability to remethylate homocysteine to form methionine (Fig. 2). Indeed, there is an inverse correlation between the concentration of folate and that of homocysteine in the blood (Jacques et al., 1999). Many clinical studies, beginning with the observations of children with homocystinuria presenting with vascular abnormalities and thromboembolism (McCully, 1969), have demonstrated an association between hyperhomocysteinemia and increased risk of premature atherosclerosis in the coronary, carotid, and peripheral vasculatures (Refsum et al., 1998). Even mild hyperhomocysteinemia is recognized to be an independent risk factor for cardiovascular disease. The risk of heart disease increases proportionately in most, but not all, studies, throughout the full of range of blood homocysteine concentration. An increase in plasma homocysteine of 5  $\mu\text{mol L}^{-1}$  has been associated with a combined odds ratio of 1.3 for cardiovascular disease (Boushey et al., 1995).

Metabolically, homocysteine may be disposed of by the methionine synthase reaction (dependent on folate and vitamin B<sub>12</sub>), the transsulfuration pathway (dependent on vitamin B<sub>6</sub>), or the choline degradation pathway (independent of folate, B<sub>12</sub>, and B<sub>6</sub>) (Selhub and Miller, 1992). Deficiencies of each of these three vitamins and choline are associated with hyperhomocysteinemia. Of the three vitamins, folate has been shown to be most effective in lowering homocysteine concentration in the blood. Evidence for the potential role of folate intake in the prevention of vascular disease has come from an observed significant inverse relationship between serum folate concentration and fatal coronary heart disease. In addition to homocysteine-lowering, proposed mechanisms by which folate may affect vascular disease risk include antioxidant actions and interactions with the enzyme, endothelial nitric oxide synthase (EC 1.14.14.47) (Psara et al., 2020). It is important to note that folic acid supplements, with or without concomitant vitamin B<sub>12</sub> and B<sub>6</sub> supplements, though effective in lowering plasma homocysteine, have not been proven to be particularly effective in reducing overall vascular disease risk (Clarke et al., 2010). There is some evidence, however, that homocysteine-lowering is effective in preventing stroke (Huo et al., 2015).

### Neurological and cognitive dysfunction

Folate deficiency is associated with a variety of neurological consequences, including neuropsychiatric manifestations (insomnia, irritability, fatigue, and forgetfulness), peripheral neuropathies (decreased or absent reflexes, diminished vibration sense, and restless leg syndrome), optic neuropathy, and progressive vision loss. Folate deficiency has also been associated with cognitive impairment and dementia (Clarke et al., 1998). Both cross-sectional and longitudinal studies have verified that low folate intake or status is a risk factor for poor scores on objective measures of cognitive function and Alzheimer's disease. In addition, some, but not all studies have demonstrated a beneficial effect of folic acid supplements in preventing cognitive decline in older adults (Clarke et al., 2014). The benefit of folic acid supplements may be limited to the period prior to the development or the early stages of cognitive impairment (before significant structural damage and dementia have occurred). Folate deficiency may also contribute to altered mood and depression, and may limit the efficacy of anti-depressant medications (Alpert and Fava, 1997).

Several potential mechanisms have been postulated to explain the effects of folate deficiency on neurological function (Smith and Refsum, 2016). Most attention has focused on hyperhomocysteinemia which, in addition to cardiovascular disease, is associated with atherosclerotic and thrombotic damage that acutely (i.e., stroke and infarction) or chronically limits blood flow to the brain. Homocysteine or products of its oxidative metabolism, including homocysteine sulfinic acid and homocysteic acid, may also induce excitotoxicity or oxidative stress within the brain, with resultant neurodegeneration. Alternatively, hyperhomocysteinemia may be a marker of altered intracellular concentrations of SAM and S-adenosylhomocysteine (SAH). Reduced SAM and increased SAH induced by folate deficiency may inhibit key methylation reactions in the central nervous system involving proteins, neurotransmitters, phospholipids, and DNA. Inhibition of these processes may in turn cause metabolic impairments and structural damage. In addition, depressive symptoms associated with folate deficiency may result from altered SAM concentration in the brain. Oral SAM supplements have been shown to have anti-depressant properties and folate deficiency may induce depressive symptoms

by reducing SAM in the brain. This may also be relevant to cognition because depressive symptoms are a strong determinant of cognitive impairment in older adults.

## Cancer

Folate has a complex relationship with cancer. Folate deficiency limits the synthesis of thymidylc acid and causes the accumulation of uridylic acid. This leads to misincorporation of uracil into DNA. Cellular repair mechanisms efficiently excise the misincorporated uracil. However, because thymidylc acid availability is reduced due to the folate deficiency, DNA strand breaks occur, which leaves DNA vulnerable to mutation. In this way, folate deficiency is a risk factor for the initiation of cancer, while folate sufficiency is protective. In contrast, proliferating cancer cells, like all mammalian cells, require folate for replication and proliferation. When folate is deficient, replication and proliferation are inhibited. Thus, after cancer is initiated, folate deficiency will actually retard its progression. This phenomenon, first explored by Sidney Farber in the treatment of pediatric acute lymphoblastic leukemia (Farber and Diamond, 1948), is the basis for several *anti*-folate cancer chemotherapeutic drugs, including methotrexate (an inhibitor of dihydrofolate reductase) and 5-fluorouracil (an inhibitor of thymidylate synthase), among others.

## Neural tube and other birth defects

In early vertebral development, the neural tube forms from the invagination of neural crest cells, which subsequently differentiate into the brain and spinal column. NTDs are malformations in which there is failure of the neural tube to close properly during the fourth week of embryonic life. Incomplete closure of the spinal cord results in spina bifida, while incomplete closure of the cranium results in anencephaly. Observations in both humans and animals in the 1960s and 1970s suggested that poor nutritional status and specifically low folate status was a cause of NTDs. In the 1980s and early 1990s, randomized controlled trials demonstrated that folic acid supplements prevent the recurrence and occurrence of NTDs, which led to government-mandated fortification of cereal and grain products with folic acid in the US and Canada in 1998 (Miller, 2011; Centers for Disease Control and Prevention, 1992; Food and Drug Administration, 1996). Today, more than 80 countries and territories have instituted mandatory folic acid fortification programs. Assessments of the efficacy of folic acid fortification in the US, Canada, Chile, Costa Rica, and South Africa, among others, show that NTD incidence has decreased between 19 and 78%, depending on the rate of NTDs and folate status within a population prior to the institution of fortification (Heseker et al., 2009). These data indicate that folic acid fortification, for its intended purpose, has been one of the most highly successful public health interventions ever devised.

International agencies have published folic acid recommendations for the prevention of NTDs. To prevent recurrence, 4 mg folic acid day<sup>-1</sup> is recommended, while 400 µg day<sup>-1</sup> is recommended to prevent occurrence. Because women do not usually become aware that they are pregnant until after neural tube closure has occurred in the developing fetus, it is essential that folic acid supplements be commenced prior to conception. For informed women and their doctors, this is typically achieved through folic acid supplements. However, for the general population, in which a high proportion of pregnancies are unplanned, fortification is the more effective strategy for prevention. The level of fortification mandated in the US is 140 µg of folic acid per 100 g of flour, calculated to increase individual consumption of folic acid by 100 µg day<sup>-1</sup> and to bring overall folate intake to the recommended 400 µg day<sup>-1</sup>. Measurement of the actual folic acid in fortified foods indicates that manufacturers have added an amount closer to 200 µg folic acid per 100 g flour, presumably to provide a margin of error in achieving the mandated amount (Choumenkovitch et al., 2002).

Folate deficiency and hyperhomocysteinemia have also been associated with other abnormal pregnancy outcomes. These include premature delivery, low birth weight, fetal growth retardation, *abruptio placentae* (placental infarction), preeclampsia, and congenital heart defects. Randomized controlled clinical trials are needed to determine if folic acid supplements can reduce the incidence of these abnormal outcomes.

## Folic acid fortification beyond NTDs

Because of the essential role of folate in one-carbon metabolism, other effects of folic acid fortification have been considered, including the possibility that excess intake may have negative consequences. With respect to cancer, it is postulated that high folic acid intake at the population level could have both preventive and promoting effects. Folic acid supplements increase the grade and multiplicity of colorectal adenomas in patients who previously had colonic polyps removed (Cole et al., 2007). In addition, ecological studies suggest that temporary increases in the incidence of colorectal cancer occurred in the US and Chile concurrent with the institution of folic acid fortification (Mason et al., 2007; Hirsch et al., 2009). In contrast, a reduction in the rate of pediatric neuroblastoma was observed after the start of fortification (French et al., 2003). With respect to breast cancer, conflicting studies have found that risk may be decreased or increased with folic acid supplements (Stolzenberg-Solomon et al., 2006; Maruti et al., 2009). It is possible that these contradictory findings are explained by the timing of folic acid exposure. If exposure occurs before neoplastic initiation, folic acid may reduce the risk of cancer. However, if exposure occurs after initiation, then folic acid may promote proliferation and accelerate progression to clinical disease. Notably, a meta-analysis of folic acid intervention trials including more than 49,000 participants found that the relative risk (95% confidence interval) for cancer of any kind was 1.06 (0.99, 1.13) ( $p = 0.10$ ) indicating that there was a nonsignificant estimated 6% increase in cancer risk associated with folic acid

supplementation ( $\geq 0.5$  mg day<sup>-1</sup>; mean follow up time of 5.2 years) (Vollset et al., 2013). This suggests that, at the population level, the risk associated with folic acid supplementation is relatively small.

One of the positive consequences of folic acid fortification has been a significant reduction in the prevalence of hyperhomocysteinemia in the general population. It is unclear if this has translated into reduced risk of cardiovascular disease. Meta-analysis of homocysteine-reduction intervention trials suggests that there is limited or no benefit on overall cardiovascular disease risk (Clarke et al., 2010). However, subgroup analyses in some trials found significant reductions in stroke risk associated with homocysteine-lowering interventions, particularly for individuals with specific characteristics, such as age less than 69 years, those with elevated homocysteine or cholesterol, those not taking anti-platelet or lipid-lowering drugs, and those not exposed to folic acid fortification (Smith and Refsum, 2021). In addition, reduced rates of stroke were observed in the US and Canada around the time fortification was initiated, but not in England and Wales, where fortification had not been initiated (Yang et al., 2006). These latter studies were ecological in design, however, and the strength of this type of evidence is limited. Taken together, whether homocysteine-lowering with folic acid supplementation or fortification reduces cardiovascular disease risk may depend on the characteristics of the individual and may be limited to stroke and not other manifestations of cardiovascular disease (Smith and Refsum, 2021).

One of the primary concerns with folic acid fortification was the possible masking of vitamin B<sub>12</sub> deficiency, as described above. Further, observational studies suggest that excess folic acid intake, particularly in folic acid supplement users also exposed to folic acid fortification, may actually exacerbate both the neurological and hematological consequences of vitamin B<sub>12</sub> deficiency (Morris et al., 2007). Older adults with a combination of low serum vitamin B<sub>12</sub> and high serum folate concentrations were found to be at higher risk of cognitive impairment and anemia than adults of similar age who had both low vitamin B<sub>12</sub> and low folate. The combination of low vitamin B<sub>12</sub> and high folate was also associated with higher circulating homocysteine and methylmalonic acid and lower holotranscobalamin concentrations (metabolic indicators of functional vitamin B<sub>12</sub> deficiency) than the combination of low vitamin B<sub>12</sub> and low folate (Selhub et al., 2007; Miller et al., 2009). These findings are consistent with clinical observations from several decades ago, where patients with pernicious anemia (severe vitamin B<sub>12</sub> deficiency caused by autoimmune-induced vitamin B<sub>12</sub> malabsorption) exhibited further reduction in circulating vitamin B<sub>12</sub> concentration after being treated with high-dose folic acid (Lear and Castle, 1956; Bok et al., 1958). Recently, a hypothesis to explain this putative effect of folic acid on serum biomarkers of vitamin B<sub>12</sub> status has been put forward. The hypothesis states that in individuals with already low vitamin B<sub>12</sub> status, excess folic acid causes increased mobilization of circulating holotranscobalamin to the bone marrow to support reticulocyte formation and/or increased excretion of holotranscobalamin in the urine. This reduces the availability of B<sub>12</sub> to other organs and, thus, exacerbates manifestations of vitamin B<sub>12</sub> deficiency, including elevations of homocysteine and methylmalonic acid in the blood and neurological outcomes (Selhub et al., 2022). This hypothesis has not yet been systematically tested, and the conclusion that excess folic acid exacerbates vitamin B<sub>12</sub> deficiency remains controversial.

## Biomarkers and status assessment

The main clinical indicator of folate deficiency is megaloblastic anemia, as described above. The primary screening measurements for assessing folate status are serum and red blood cell folate concentrations. The gold-standard for folate measurement is a microbiological assay utilizing *L. casei*. Radioactive competitive binding and automated chemiluminescence assays are commonly used for research and clinical purposes, respectively. Mass spectrometry methods have also been devised. Though there is usually a high correlation between serum and red cell folate concentrations, serum folate typically reflects recent folate intake and short-term status, while red cell folate reflects long-term status, over the 120 days lifespan of the red cell. Common cut-off values used to define folate deficiency are  $<3$  ng mL<sup>-1</sup> ( $<7$  nmol L<sup>-1</sup>) in serum and  $<140$  ng mL<sup>-1</sup> ( $<305$  nmol L<sup>-1</sup>) in red cells. Elevated plasma homocysteine ( $>10$   $\mu$ mol L<sup>-1</sup>) is another indicator of folate deficiency. However, hyperhomocysteinemia has several potential causes, including vitamin B<sub>12</sub> and vitamin B<sub>6</sub> deficiencies, renal disease, and hypothyroidism; thus homocysteine is a sensitive, but not specific, indicator of folate status. Another biomarker sensitive to low folate status is global DNA methylation, as a consequence of the role of folate in the synthesis of SAM used for DNA methylation reactions.

## Summary

Folates, through their participation in one-carbon metabolism, play key biochemical roles in the synthesis of nucleotides for DNA and RNA synthesis, amino acid interconversions (i.e., serine to glycine and homocysteine to methionine), production of the universal methyl donor SAM, and formate metabolism. Predictably, folate deficiency leads to impairment of one-carbon metabolism, which underlies a variety of pathophysiological outcomes, including: megaloblastic anemia due to impaired nucleotide synthesis; increased risk of vascular disease related to hyperhomocysteinemia (particularly stroke); increased risk of cancer resulting from uracil misincorporation, DNA strand breaks, and increased susceptibility to mutation; increased risk of neurological/cognitive deficits and depression possibly related to hyperhomocysteinemia, oxidative stress, or impaired methylation reactions in the brain; and neural tube and other birth defects. Folic acid fortification in more than 80 countries around the world has significantly reduced the incidence of neural tube defects and represents one of the most successful public health interventions for its intended purpose ever implemented. In addition, to preventing neural tube defects, folic acid fortification may reduce risk of cardiovascular disease

and cancer. However, there is lingering concern that excess consumption of folic acid may exacerbate biochemical and pathophysiological manifestations of B12 deficiency. Additional basic and translational research is needed to address this issue.

## Key Points

- Homocysteine is a sulfur amino acid and product of methionine metabolism.
- Homocysteine metabolism requires several B-vitamins, including folate, B12, B6, and riboflavin.
- Hyperhomocysteinemia is caused by B vitamin deficiencies, genetic defects, and other pathophysiological conditions, including renal disease and hypothyroidism.
- Hyperhomocysteinemia is a risk factor for vascular disease, and neurodegenerative disease.
- B-vitamin supplementation lowers blood homocysteine concentrations.
- It is unclear if B-vitamin supplementation reduces the risk of vascular disease and neurodegenerative disease.

## Introduction

Homocysteine is a sulfur amino acid and an intermediate in the biochemical conversion of methionine to cysteine, a process called transsulfuration. The biochemistry of homocysteine was elucidated by Nobel Laureate Vincent Du Vigneaud and colleagues from the 1930s to the 1950s (Finkelstein, 2000). In the early 1960s, the description and characterization of the inborn error of metabolism, homocystinuria (Mudd et al., 1995), initiated a 60-year (and continuing) period of investigation that has revealed elevated blood homocysteine (hyperhomocysteinemia) as an independent risk factor for over 100 conditions, with most attention focused on vascular and neurodegenerative diseases (Smith and Refsum, 2021). Randomized controlled trials of B vitamins (folic acid with or without vitamin B12 and vitamin B6) effectively lower blood homocysteine concentration, but have been mostly ineffective in demonstrating significant effects on cardiovascular disease incidence (Clarke et al., 2010) or risk of age-related cognitive decline and dementia/Alzheimer's disease (Clarke et al., 2014). This has led many to the conclusion that hyperhomocysteinemia is a risk marker, but not a causative factor, in the pathogenesis of cardiovascular and neurodegenerative diseases. However, there have been several clinical trials with compelling evidence that homocysteine-lowering with B vitamins may be specifically effective in preventing stroke and slowing brain atrophy and cognitive decline in older adults with mild cognitive impairment (Smith and Refsum, 2021).

## Structure and forms

The most prominent features of homocysteine and cysteine are the free sulfhydryl groups located at the end of the side chains of both amino acids (Table 1). These sulfhydryl groups are highly susceptible to oxidation and the formation of disulfide linkages with other sulfhydryl compounds. The primary forms of homocysteine found in the blood (Table 1) consist of homocysteine in disulfide linkage with (1) cysteine residues within the primary sequences of albumin and other plasma proteins (protein-bound form), (2) free cysteines or cysteine containing peptides such as glutathione (mixed disulfides), and (3) other homocysteine molecules (homocystine). Only approximately 1% of homocysteine in the blood is in the free-reduced form. Methionine, in contrast, does not have a free sulfhydryl group, and therefore, does not form disulfide compounds.

## Biosynthesis and metabolism

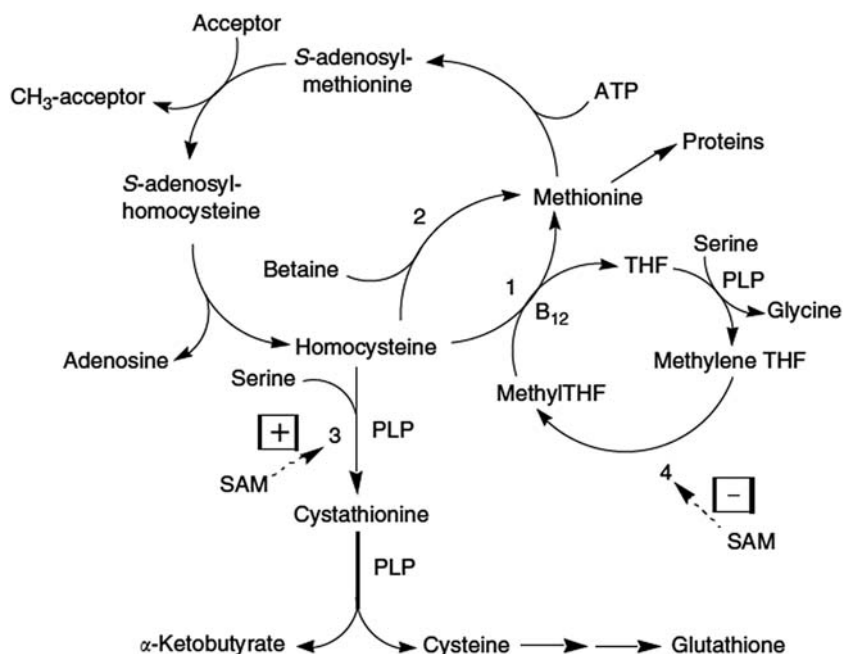

The ultimate source of homocysteine is dietary methionine (Fig. 1) (Selhub and Miller, 1992). Methionine is first activated by addition of an adenosyl group (from adenosine triphosphate) to form S-adenosylmethionine (SAM). SAM is an important intermediate known as the universal methyl donor for its role as the methylating agent in a variety of essential reactions, including those involving DNA, RNA, proteins, membrane phospholipids, neurotransmitters, and the synthesis of creatine. A product of all SAM-dependent methylation reactions is S-adenosylhomocysteine (SAH) which, in turn, is metabolized to form adenosine and homocysteine. Homocysteine is then at a metabolic intersection: It can be remethylated to form methionine or catabolized through cystathionine synthesis.

In remethylation, homocysteine reacquires a methyl group in a reaction catalyzed by the zinc-dependent enzyme, methionine synthase (5-methyltetrahydrofolate-homocysteine methyltransferase, EC 2.1.1.13), with methyltetrahydrofolate serving as the methyl donor and vitamin B12 serving as a cofactor. This reaction occurs in all mammalian cells. Alternatively, homocysteine can be remethylated in a folate- and vitamin B12-independent reaction using betaine as the methyl donor and catalyzed by betaine-homocysteine methyltransferase (EC 2.1.1.5). This reaction occurs primarily in the liver, to a lesser extent in the kidney, and possibly the brain.

**Table 1** Structures and forms of homocysteine and related amino acids.

	Structures		Forms of homocysteine in blood
Homocysteine	$\begin{array}{c} \text{NH}_3^+ \\   \\ \text{H}-\text{C}-\text{CH}_2-\text{CH}_2-\text{S}-\text{H} \end{array}$	Protein-bound	HCY-S-S-CYS-albumin
Cysteine	$\begin{array}{c} \text{COOH} \\   \\ \text{NH}_3^+ \\   \\ \text{H}-\text{C}-\text{CH}_2-\text{SH} \end{array}$	Mixed disulfide Homocystine	HCY-S-S-CYS HCY-S-S-HCY
Methionine	$\begin{array}{c} \text{COOH} \\   \\ \text{NH}_3^+ \\   \\ \text{H}-\text{C}-\text{CH}_2-\text{CH}_2-\text{S}-\text{CH}_3 \\   \\ \text{COOH} \end{array}$	Free reduced	HCY-SH

Abbreviations: HCY, homocysteine; CYS, cysteine.

**Fig. 1** The biosynthesis and metabolism of homocysteine. Reactions that are regulated by S-adenosylmethionine (SAM) are indicated by positive and negative signs. Key enzymes: (1) methyltetrahydrofolate-homocysteine methyltransferase or methionine synthase; (2) betaine-homocysteine methyltransferase; (3) cystathionine  $\beta$ -synthase; (4) methylenetetrahydrofolate reductase. Abbreviations: THF, tetrahydrofolate; PLP, pyridoxal-5'-phosphate (vitamin B6).

Homocysteine catabolism occurs through cystathionine synthesis in a condensation reaction with serine. This reaction is catalyzed by cystathionine  $\beta$ -synthase (EC 4.2.1.22), which requires vitamin B6 in the form of pyridoxal-5'-phosphate (PLP) as a cofactor. Cystathionine is then cleaved to form  $\alpha$ -ketobutyrate and cysteine in a second PLP-dependent reaction catalyzed by cystathionine  $\gamma$ -lyase (EC 4.4.1.1). Further metabolism of cysteine leads to the formation of glutathione or inorganic sulfate.

## Regulation of metabolism

An important aspect of homocysteine metabolism is that it is subject to allosteric control (Selhub and Miller, 1992). In addition to serving as the universal methyl donor, SAM is also an activator of cystathionine  $\beta$ -synthase and an inhibitor of methylenetetrahydrofolate reductase (MTHFR) (EC 1.7.99.5), the enzyme responsible for the synthesis of methyltetrahydrofolate (Fig. 1). These allosteric functions serve to control whether homocysteine is recycled to form methionine or catabolized to form cystathionine. When dietary supply of methionine is high, such as after a protein meal, intracellular SAM concentration increases. High SAM activates cystathionine  $\beta$ -synthase and inhibits MTHFR, thereby promoting homocysteine catabolism and limiting homocysteine remethylation. This serves to reduce the recycling of homocysteine when there is an adequate dietary supply of methionine. Conversely, under fasting conditions when there is no dietary influx of methionine, intracellular SAM concentration decreases. Cystathionine  $\beta$ -synthase is then not activated and the inhibition of MTHFR is relieved, thus promoting homocysteine remethylation over catabolism. Consequently, this maintains intracellular methionine concentration during times of limited dietary supply.

An additional level of control on homocysteine metabolism is exerted by oxidative stress, which reduces methionine synthase activity. This may occur by oxidative inactivation of the vitamin B12 cofactor or by oxidation of cysteine residues that are important for zinc binding. By inhibiting methionine synthase, oxidative stress tends to divert homocysteine toward cystathionine synthesis away from methionine synthesis. This serves to increase synthesis of glutathione, an important intracellular antioxidant.

As discussed in the following Section (Hyperhomocysteinemia – Other Causes of Hyperhomocysteinemia), alterations in homocysteine metabolism also occur after menopause, in diabetes, and in hypothyroidism. These observations suggest that hormones, including estrogen, insulin, thyroxine, and thyroid-stimulating hormone, may directly or indirectly affect homocysteine metabolism. The mechanisms by which these hormones affect homocysteine metabolism are poorly understood.

## Hyperhomocysteinemia

Under conditions of maximal metabolic efficiency, plasma homocysteine ranges from 4 to 10  $\mu\text{mol L}^{-1}$  (Refsum et al., 2004). Metabolic blocks in homocysteine metabolism lead to accumulation of intracellular homocysteine with subsequent export into the blood. Depending on the magnitude of the metabolic impairment, plasma homocysteine concentration can rise to varying degrees, as defined in Table 2.

**Genetic defects.** Severe elevations in plasma homocysteine (concentrations as high as several hundred micromoles per liter) are observed in individuals with homozygous genetic defects affecting cystathionine  $\beta$ -synthase, MTHFR, or any of several enzymes responsible for the conversion of vitamin B12 to its methionine synthase-associated cofactor form (Blom et al., 1998). These autosomal recessive genetic disorders, collectively termed homocystinuria because homocysteine accumulates in the urine as well as the blood, are associated with severe premature vascular disease, including thrombosis and atherosclerosis, mental retardation, dislocation of the eye lens (*ectopia lentis*), and skeletal malformations. Premature death (often in childhood) usually results from a major thrombotic or embolic event. Notably, one of the genetic defects that afflicts a significant proportion of homocystinuria patients reduces the affinity of cystathionine  $\beta$ -synthase for its vitamin B6 cofactor, PLP. For these patients, the metabolic defect can be overcome, to some extent, with high dose vitamin B6 supplements, which significantly lower plasma homocysteine, reduce morbidity, and increase life expectancy. Interestingly, for other genetic defects involving cystathionine  $\beta$ -synthase that cause homocystinuria independent of the affinity of the enzyme for PLP, high dose vitamin B6 supplements also have a therapeutic effect, despite having little or no influence on plasma homocysteine concentration.

**B-vitamin deficiencies.** Hyperhomocysteinemia is also caused by B-vitamin deficiencies (Selhub et al., 1993). Deficiencies of folate and vitamin B12 lead to impaired remethylation of homocysteine causing mild, moderate, or severe elevations in plasma homocysteine, depending on the severity of the deficiency, as well as coexistence of genetic or other factors that interfere with homocysteine metabolism (see below, in this Section). Because riboflavin is required for synthesis of flavin adenine dinucleotide (FAD), and because FAD serves as a cofactor for MTHFR, riboflavin deficiency can also affect homocysteine remethylation, and, therefore,

**Table 2** Degrees of hyperhomocysteinemia.

Total plasma homocysteine	Designation
4–10 $\mu\text{mol L}^{-1}$	Normal
11–25 $\mu\text{mol L}^{-1}$	Mild to moderate
26–50 $\mu\text{mol L}^{-1}$	Intermediate
>50 $\mu\text{mol L}^{-1}$	Severe

contribute to elevation in plasma homocysteine. Vitamin B6 deficiency leads to impairment of homocysteine catabolism and, thus, also causes hyperhomocysteinemia. However, the nature of hyperhomocysteinemia caused by vitamin B6 deficiency differs from that caused by folate and vitamin B12 deficiencies: In vitamin B6 deficiency, fasting blood homocysteine is usually not elevated or is only slightly elevated. Only after a protein meal, or after consumption of an oral methionine load (see the Section on Measurement of Blood Concentrations), does plasma homocysteine become abnormally elevated in vitamin B6-deficient patients. In contrast, plasma homocysteine tends to be elevated regardless of prandial state in patients with folate or vitamin B12 deficiency. The basis for these different manifestations is likely due to differential effects of the vitamin deficiencies on intracellular SAM and consequent disruption of the allosteric control of homocysteine metabolism (Selhub and Miller, 1992).

Over the last two decades, there has been growing interest in nutritional genomics. This refers to genetic variability among individuals and its effect on nutritional requirements. A prime example of this concept is a common polymorphism in MTHFR (677C→T) in which an alanine is replaced by valine at codon 222 in the primary sequence of the enzyme (Frosst et al., 1995). Individuals with the homozygous variant (677 TT) of this gene (10–15% of the general population, lower in blacks, higher in Latinos and in some parts of Europe, e.g. Southern Italy) have an enzyme that is thermolabile, with reduced affinity for its substrate (methylenetetrahydrofolate) and its cofactor (FAD). Consequently, 677 TT individuals require a higher intake of folate and riboflavin to maintain optimal enzyme activity than those with the wild-type isoform of the enzyme (677 CC). This is reflected by the fact that blood homocysteine is higher in people with the 677 TT isoform than in those with the 677 CC isoform, but only when overall folate and riboflavin status is low. When overall folate and riboflavin status is high, no difference in homocysteine is observed between the isoforms.

The clinical and public health importance of the MTHFR polymorphism is reflected by two observations: First, women with the 677 TT isoform are at increased risk of having a child with a neural tube defect (e.g., *spina bifida* and anencephaly) (Reilly et al., 2014). This risk can be reduced by folic acid supplements, an observation that underlies the decision by the US and Canadian governments to mandate folic acid fortification of grain products in 1998 (Miller, 2011). This program has been highly successful, having reduced the prevalence of folate deficiency from over 20% to approximately 1%, the prevalence of hyperhomocysteinemia by approximately 50%, and the incidence of neural tube defects by at least 20%. The success of the folic acid fortification program in the USA and Canada has spawned similar programs in more than 80 countries and territories throughout the world. Notable exceptions are the countries of the European Union, which have been slow to adopt this intervention strategy. This is due to concern about the feasibility of fortification, hesitancy to impose mandatory fortification on the population, and lingering concern about masking B12 deficiency and the possibility of other unrecognized health consequences associated with excess folic acid intake.

Individuals homozygous for the 677 TT isoform of MTHFR have been found to have elevated blood pressure, compared with wild-type (677 CC) and heterozygous (677 CT) individuals (Psara et al., 2020). Notably, supplementation of 677 TT individuals with riboflavin, the vitamin precursor of the MTHFR cofactor, FAD, effectively lowers blood homocysteine and both diastolic and systolic blood pressure to levels similar to wild-type and heterozygous individuals. The influence of these effects of riboflavin supplements on homocysteine and blood pressure on risk of stroke and other vascular disease outcomes remains to be determined.

Other polymorphisms in MTHFR and other enzymes involved in homocysteine metabolism [e.g. methionine synthase, methionine synthase reductase (EC 1.16.1.8), cystathionine  $\beta$ -synthase] have been identified and their overall influence on homocysteine metabolism, B vitamin requirements, and disease risk have been, and continue to be, evaluated.

**Other causes of hyperhomocysteinemia.** Other pathophysiological causes of hyperhomocysteinemia include renal dysfunction and hypothyroidism. The kidney is a major site of homocysteine metabolism and renal disease leads to a significant reduction in the body's overall capacity to metabolize this amino acid (Bostom and Lathrop, 1997). The resulting moderate to severe hyperhomocysteinemia can be attenuated, in part, by high dose B-vitamin supplements, which putatively maximize the residual renal metabolism, as well as the metabolic capacities of the extrarenal organs. Mild elevation in homocysteine occurs in patients with hypothyroidism, which resolves to normal with thyroid replacement therapy (Hussein et al., 1999). This observation implies that thyroxine and thyroid-stimulating hormone influence homocysteine metabolism directly, perhaps through up- or downregulation of key homocysteine-metabolizing enzymes. Alternatively, homocysteine may become elevated in hypothyroid patients secondary to mild impairment of renal function that may accompany the disorder.

Patients with diabetes (both insulin-dependent and insulin-independent) tend to have mild hyperhomocysteinemia (Wijekoon et al., 2007). However, this seems to be confined to those patients whose diabetes condition has progressed to involve renal insufficiency. Notably, in the absence of renal involvement, homocysteine concentration in diabetes patients tends to be lower than normal. Insulin has been shown to inhibit homocysteine catabolism through cystathionine synthesis. Therefore, reduced insulin in diabetes patients may actually promote homocysteine catabolism, thus leading to lower plasma concentration.

Premenopausal women tend to have lower plasma homocysteine than men of similar age, and homocysteine tends to rise in women after menopause. Hormone replacement therapy reduces homocysteine back to premenopausal concentration. Moreover, homocysteine decreases in male to female transsexuals, and increases in female to male transsexuals, effects primarily related to the estrogen and androgen regimens that such individuals follow. Taken together, these observations suggest an influence of sex hormones on homocysteine metabolism, though the mechanisms are not well understood.

Drugs can also affect homocysteine metabolism and lead to elevations of homocysteine in the blood. Certain anti-cancer drugs, such as methotrexate, and anti-epilepsy medications, such as valproate and carbamazepine, are inhibitors of folate metabolism. Resulting functional folate deficiency leads to hyperhomocysteinemia. The anti-Parkinsonian drug, levodopa or L-dopa, causes elevation in blood homocysteine by a different mechanism: A significant proportion of an oral dose of L-dopa is methylated by SAM, leading to increased intracellular synthesis of SAH and homocysteine. The excess synthesis of homocysteine can overwhelm

the capacities of the homocysteine metabolic pathways, particularly when B vitamin status is suboptimal, leading to hyperhomocysteinemia (Miller et al., 2003).

## Homocysteine and clinical outcomes

**Homocysteine and vascular disease.** The continuing interest in homocysteine is primarily related to its recognized status as an independent risk factor for cardiovascular, cerebrovascular, and peripheral vascular disease. This homocysteine theory of vascular disease is directly descendant from a seminal observation made by Kilmer McCully (McCully, 1969). In the early to mid-1960s, it was recognized that a prominent characteristic of patients with homocystinuria caused by defects in cystathionine  $\beta$ -synthase were very high elevations of both homocysteine and methionine in the blood. Therefore, it was not clear whether the vascular complications of this disorder were the consequence of hyperhomocysteinemia or hypermethioninemia. McCully observed that a patient with homocystinuria caused by a defect in a B12-metabolizing enzyme had hyperhomocysteinemia, but not hypermethioninemia. Nonetheless, this patient had similar (although not identical) vascular pathology to that observed in patients with homocystinuria caused by cystathionine  $\beta$ -synthase deficiency. From this, McCully concluded that the vascular culprit was homocysteine, and not methionine.

McCully's hypothesis was not immediately embraced. The prevailing theory of atherosclerosis at the time centered on cholesterol, and it proved difficult for McCully to convince his peers and national funding agencies of the potential importance of this new and competing hypothesis. Contributing to this was a lack of reproducible animal models of homocysteine-induced vascular disease, or a sensitive method to measure homocysteine in the blood. Consequently, McCully's hypothesis went into temporary obscurity.

In the mid-1970s, David and Bridget Wilcken reinvigorated McCully's hypothesis with their observation that a subset of patients with premature coronary artery disease had reduced ability to metabolize homocysteine (Wilcken and Wilcken, 1976). Notably, this association was observed in individuals who did not have any of the severe genetic defects that underlie homocystinuria, suggesting that less severe or modest impairment of homocysteine metabolism may contribute to vascular disease risk. Subsequently, the advent of reliable, high-throughput assays for total plasma or serum homocysteine in the 1980s (see the Section on Measurement of Blood Levels) allowed for large-scale epidemiological assessment of associations between homocysteine and vascular (and other) diseases, both cross-sectionally and longitudinally. Through the 1990s, an explosion of population and case-control studies established that hyperhomocysteinemia is, indeed, a risk factor for heart attack, stroke, thrombosis, and peripheral atherosclerotic disease. Moreover, the risk associated with hyperhomocysteinemia is independent of other prominent risk factors, such as hypertension, hypercholesterolemia, hyperlipidemia, smoking, male gender, and others. Further indication of the importance of homocysteine with respect to vascular disease is the estimate that the relative risk of coronary artery disease associated with hyperhomocysteinemia is about equivalent to that associated with hypercholesterolemia (Boushey et al., 1995). As the evidence mounted, McCully was vindicated and his contribution became widely recognized.

**Homocysteine, Cognitive Function, and Dementia.** As the relationship between homocysteine and vascular disease became more and more apparent, researchers also addressed the hypothesis that hyperhomocysteinemia may affect cognitive function and the risk of dementia in older adults. This was based primarily not only on the recognized association between homocysteine and cerebrovascular disease, but also the observation that homocysteine and its metabolite, homocysteic acid, can induce excitotoxicity in neurons. Throughout the 1990s and into the new century, many cohort studies revealed significant inverse correlations between plasma homocysteine concentration and performance on a variety of cognitive function tests. Moreover, individuals with Alzheimer's disease were found to have higher plasma homocysteine than age and sex-matched controls (Clarke et al., 1998), whereas baseline homocysteine predicted risk of incident dementia (Seshadri et al., 2002). Baseline homocysteine also predicted the rate of brain atrophy in older adults with mild cognitive impairment, and lowering of homocysteine with B vitamin supplements was shown to slow the rate of atrophy (Smith et al., 2010).

**Homocysteine and Pregnancy Outcomes.** Hyperhomocysteinemia has also been suspected as a risk factor for pregnancy complications and birth defects. Elevated plasma homocysteine has been associated with placental vasculopathy, pre-eclampsia, and placental infarction, as well as recurrent premature delivery, low birth weight, and spontaneous abortion. Birth defects associated with hyperhomocysteinemia in the mother include neural tube defects, orofacial clefts, clubfoot, and Down's syndrome. The protective effect of folic acid supplementation and fortification against neural tube defects, and perhaps the other abnormal birth outcomes cited, may be related to reduced homocysteine concentration.

**Mechanisms.** In parallel with epidemiological studies, a significant amount of basic research has focused on the mechanism(s) by which homocysteine may induce atherosclerosis and thrombosis. A definitive answer has proven elusive. Potential mechanisms with significant experimental support include, but are not limited to, the following: (1) modification of the endothelial cell surface, (2) S- or N-homocysteinylolation of plasma and cellular proteins, (3) activation of platelets, (4) modification of monocyte functions, (5) increased expression or activity of vascular adhesion molecules, and (6) oxidative damage induced by peroxides formed during disulfide bond formation.

A sixth potential mechanism relates to a known quirk of homocysteine synthesis and metabolism. The equilibrium of the interconversion between SAH and homocysteine (catalyzed by SAH hydrolase, EC 3.3.1.1) actually favors SAH synthesis (Fig. 1). *In vivo*, this reaction proceeds toward homocysteine synthesis because of product removal, i.e., the efficient metabolism of homocysteine back to methionine or through cystathionine synthesis. However, when there is a block in homocysteine metabolism, as occurs in the genetic defects, B-vitamin deficiencies, and other causes delineated previously (see Section on Hyperhomocysteinemia above),

homocysteine accumulates intracellularly. Consequently, SAH also accumulates within cells. The significance of this phenomenon is that SAH is a feedback inhibitor of all SAM-dependent methylation reactions. Therefore, hyperhomocysteinemia may cause or contribute to vascular disease through SAH-mediated inhibition of methylation.

Another area that has received attention is the relationship between homocysteine, nitric oxide, and endothelial function. One of the roles of nitric oxide is as a vasodilator. Homocysteine has been shown to be an inhibitor of nitric oxide synthesis, and thus can inhibit vasodilatation. This has led to the hypothesis that hyperhomocysteinemia, by inhibiting nitric oxide synthesis, impairs the ability of the vascular endothelium to maintain homeostasis of vascular tone. This in turn may directly or indirectly increase susceptibility to vascular insults, thus promoting atherosclerosis and thrombosis. This may underlie the aforementioned association between the MTHFR 677C→T polymorphism and blood pressure (Psara et al., 2020). Alternatively, elevated homocysteine may reflect reduced intracellular production of the product of the MTHFR reaction, 5-methyltetrahydrofolate, which is both a required substrate for the folate- and B12-dependent conversion of homocysteine to methionine and a putative antioxidant that protects nitric oxide synthesis from uncoupling by superoxide radicals.

An array of possible mechanisms by which homocysteine contributes to neurodegenerative disease also have been postulated. Those that have compelling experimental support include: (1) promotion of cerebrovascular disease by one or more of the mechanisms described above in this Section, (2) hyperphosphorylation of tau through activation of tau kinases leading to the formation of neurofibrillary tangles, and (3) inhibition of SAM-dependent methylation reactions leading to deposition of  $\beta$ -amyloid in the brain, reduced activity of protein phosphatase-2A (responsible for dephosphorylating tau), and impaired formation of phosphatidylcholine enriched in omega-3 fatty acids (Smith and Refsum, 2016).

The search for the definitive pathogenetic mechanism implicating homocysteine as a cause of vascular and neurodegenerative diseases continues, and it is recognized that several mechanisms may contribute synergistically. However, some have questioned whether homocysteine is a cause of vascular disease, or simply a consequence.

**Cause or effect?** Although there is considerable evidence, both epidemiological and experimental, that homocysteine is a causative factor in vascular disease, there are data that contradict this conclusion (Brattstrom and Wilcken, 2000). First, although cross-sectional and case-control studies fairly consistently demonstrate that hyperhomocysteinemia is associated with vascular disease, some prospective studies have found no relationship between baseline homocysteine and risk of incident vascular events. Second, several studies have found no relationship between the MTHFR 677C→T polymorphism and venous thrombosis, despite the association of this polymorphism with elevated plasma homocysteine.

In the late 1990s, several large-scale intervention trials were initiated to determine if folic acid supplements with or without vitamin B12 and vitamin B6, which effectively lower blood homocysteine, reduce vascular outcomes and mortality in individuals at increased risk of cardiovascular disease (Table 3). A meta-analysis evaluated the results of these studies. Overall, folic acid with or without vitamin B12 or vitamin B6, was effective in lowering homocysteine (an average of 25% across all the studies). However, over a median follow-up of 5 years, no significant reductions in major vascular events, major coronary events, stroke, or vascular mortality were observed. These findings suggest that lowering homocysteine with B vitamins is not an effective strategy for preventing major vascular outcomes (Clarke et al., 2010). A similar conclusion was made regarding homocysteine-lowering via B-vitamin supplements for the prevention of age-associated cognitive decline and risk of Alzheimer's disease/dementia. In the 2000s and early 2010s, a series of B-vitamin supplementation trials were conducted in older adults, and the results pooled and analyzed by meta-analysis. While, again, supplementation effectively lowered homocysteine (approximately 26–28%), no significant effects on global cognitive function or specific cognitive domains were found (Clarke et al., 2014).

Based on these analyses, some have concluded that there is no benefit of B-vitamin supplementation and homocysteine-lowering with respect to vascular and neurodegenerative disease risk. However, these conclusions have been challenged. *Post-hoc* reviews of the conditions and protocols of intervention trials, the characteristics of study participants, and sub-group analyses reveal that homocysteine-lowering may be beneficial for specific conditions under specific circumstances (Smith and Refsum, 2021). These include the following:

- Homocysteine-lowering may be more effective in preventing stroke than myocardial infarction and other major cardiovascular events.
- The effect of homocysteine-lowering on the risk of stroke may be modified by age of at-risk individuals, exposure to folic acid fortification, baseline homocysteine and cholesterol concentrations, and treatment with anti-platelet or lipid-lowering drugs.
- Homocysteine-lowering may be more effective in primary stroke prevention rather than recurrence.
- The effect of homocysteine-lowering on age-associated cognitive decline and risk of neurodegenerative disease may be modified by baseline homocysteine, as well as treatment with aspirin and omega-3 fatty acid status.
- The effect of homocysteine-lowering on age-associated cognitive decline may be most likely to be observed in older adults who are already experiencing cognitive decline, but who have not yet progressed to clinical dementia, that is, those with mild cognitive impairment.

Consensus on these issues has not yet been achieved. The uncertain relationship between hyperhomocysteinemia, B vitamins, and vascular disease/neurodegenerative disease is summarized in Fig. 2. If homocysteine is not a direct causative factor, it may still serve as a biomarker of both disease and the efficacy of B vitamin supplementation.

**Table 3** Intervention trials to determine the effect of B vitamin supplements on homocysteine and the risk of vascular events and mortality.

Study	Location	Trial Period	Intervention	Outcomes
Cambridge Heart Antioxidant Study 2 (CHAOS-2)	UK	1998–2002	FA (5.0 mg)	HCY reduced 11%; No effect on major Vascular events
Heart Outcomes Prevention Evaluation 2 (HOPE-2)	Canada	2000–2006	FA (2.5 mg) B12 (1.0 mg) B6 (50 mg)	HCY reduced 24%; No effect on death from cardiovascular events, MI, or stroke
Homocysteinemia in Kidney and End Stage Renal Disease (HOST)	USA	2000–2007	FA (40 mg) B12 (2 mg) B6 (100 mg)	HCY reduced 25%; No effect on all cause mortality, MI, or stroke
Norwegian Multi-Center B-Vitamin Intervention Study (NORVIT)	Norway	1999–2006	FA (0.8 mg) B12 (0.4 mg) B6 (40 mg)	HCY reduced 28%; No effect on MI, stroke, or sudden death due to coronary artery disease
Study of Effectiveness of Additional Reductions in Cholesterol and Homocysteine (SEARCH)	UK	1999–2008	FA (2.0 mg) B12 (1.0 mg)	HCY reduced 27%; No effect on major coronary events, stroke, non-coronary revascularization, or death due to vascular disease
Vitamins in Stroke Prevention (VISP)	USA	1996–2003	FA (2.5 mg) B12 (0.4 mg) B6 (25 mg)	HCY reduced 17%; No effect on stroke
Western Norway B-Vitamin Intervention Trial (WENBIT)	Norway	1999–2006	FA (0.8 mg) B12 (0.4 mg) B6 (40 mg)	HCY reduced 26%; No effect on MI, stroke, or hospitalization for angina pectoris
Women's Antioxidant and Folic Acid Cardiovascular Study (WAFACS)	USA	1998–2006	FA (2.5 mg) B12 (1.0 mg) B6 (50 mg)	HCY reduced 18%; No effect on MI, stroke, coronary revascularization, or cardiovascular mortality
B-Vitamin Treatment Trialists' Collaboration - Meta-Analysis	Multiple	–	–	HCY reduced 25% (mean of all studies); No overall effect on major vascular events, including cardiovascular events, stroke, and revascularization

Abbreviations: FA, folic acid; B12, vitamin B12; B6, vitamin B6; HCY, homocysteine; MI, myocardial infarction.

**Fig. 2** Hyperhomocysteinemia, B vitamins, and vascular disease/neurodegenerative disease. There is still some question whether elevated plasma homocysteine is a cause or consequence of vascular disease and neurodegenerative disease, and whether there are influences of B vitamins on disease risk that are independent of homocysteine.

## Measurement of blood concentrations

A variety of assays have been developed to quantify blood homocysteine, with those employing high-pressure liquid chromatography the most common (Refsum et al., 2004). These assays have proven to be relatively accurate and precise (coefficients of variation < 10%) and are relatively simple and rapid to perform. The development of such assays in the 1980s was the technological breakthrough that spurred the exponential increase in homocysteine-related research over the last 40 years, leading to the establishment of hyperhomocysteinemia as an independent risk factor for vascular disease, neurodegenerative disease, and other conditions.

As described above (in the Section Structure and Forms), homocysteine exists in several forms in the blood, including the protein-bound form, mixed disulfides, homocystine, and the free-reduced form. Assays for homocysteine usually measure the sum total of all these forms, i.e., total homocysteine. To accomplish this, the first procedure in homocysteine assays is a reduction step to break all disulfide bonds, thus converting all homocysteine to the free-reduced form. The free-reduced form is then quantified by one of various methods.

Blood sample collection and processing are critical factors in the determination of homocysteine concentration. Typically, blood samples for homocysteine analysis are collected in tubes containing an anticoagulant (e.g., ethylenediaminetetraacetic acid, heparin). Prompt separation of plasma from the blood cells after centrifugation is required to avoid excess release of intracellular homocysteine into the plasma or removal of homocysteine from the plasma by metabolically active leukocytes after blood withdrawal. Keeping the blood sample cold until centrifugation and separation (ideally within 4 h of blood withdrawal) minimizes

this problem. Serum homocysteine concentration typically exceeds plasma concentration by 20%. This is likely due to the fact that blood collected to isolate serum (i.e., without an anticoagulant) must clot at room temperature for 30–60 min before centrifugation and separation. Therefore, plasma is preferred for measurement of homocysteine. Once separated from blood cells, the concentration of homocysteine in plasma or serum remains stable for years when stored frozen.

Another important issue in the measurement of homocysteine is the prandial state of the individual. For individuals with adequate B-vitamin status, no genetic abnormalities, and no pathophysiological conditions that affect homocysteine metabolism, plasma homocysteine concentration after an overnight fast is similar to that after a meal (even high protein meals containing methionine). However, for individuals with low B6 status or heterozygous genetic defects in cystathionine  $\beta$ -synthase, post-prandial homocysteine can be significantly higher than fasting concentration. Because of the nutritional or genetic block in the conversion of homocysteine to cystathionine, there is decreased capacity to metabolize the influx of homocysteine synthesized from dietary methionine. This is the basis for the methionine load test for detection of impaired cystathionine  $\beta$ -synthase activity. In this test, baseline blood is drawn after an overnight fast, and then again 4 h after consumption of a large dose of methionine dissolved in orange juice (100 mg methionine per kilogram body weight). Plasma homocysteine increases to a greater extent in individuals with low vitamin B6 status or heterozygous genetic defects in cystathionine  $\beta$ -synthase than in individuals without these problems. Importantly, individuals with elevated fasting homocysteine and those with normal fasting, but elevated post-methionine load concentrations, are both at increased risk of vascular disease.

## Summary

Homocysteine is an important intermediate in the interconversion of methionine to cysteine (transsulfuration) and in folate/one-carbon metabolism. Elevation of homocysteine in the blood (hyperhomocysteinemia) primarily results from impaired metabolism due to B-vitamin deficiencies, genetic defects, and pathophysiological conditions such as renal disease and hypothyroidism. Hyperhomocysteinemia has been clearly established as a risk marker for many diseases and conditions, most prominently vascular disease, age-related cognitive decline and Alzheimer's disease/dementia. Whether lowering blood homocysteine concentration with B-vitamin supplements reduces the risk of vascular disease and neurodegenerative disease remains an open question. *Post hoc* review of clinical trials suggests that B-vitamin supplementation and homocysteine-lowering may be particularly beneficial for prevention of stroke and the slowing of cognitive decline and brain atrophy in older adults with mild cognitive impairment. Additional randomized control trials are needed to provide more definitive answers.

## Key points

- Iodine deficiency has multiple adverse effects on growth and development in humans; these are collectively termed the iodine deficiency disorders
- In nearly all regions affected by iodine deficiency, the most effective way to control iodine deficiency is through salt iodization

## Glossary

**Cretinism** A congenital condition caused by a deficiency of thyroid hormone during prenatal development and characterized in childhood by dwarfed stature and mental retardation

**Goiter** A noncancerous enlargement of the thyroid gland, visible as a swelling at the front of the neck, that is often associated with iodine deficiency

**Hypothyroidism** A physiological state characterized by insufficient production and/or action of thyroid hormone, which can result in a decreased basal metabolic rate, causing weight gain and fatigue

**Iodine deficiency disorders** The collective term for the multiple adverse effects on growth and development in animals and humans caused by iodine deficiency and the resulting inadequate thyroid hormone production

**Thyroglobulin** A thyroid protein that is the precursor to iodine-containing hormones and is typically present in the colloid of thyroid gland follicles

## Introduction

Bernard Courtois, a French chemist, discovered iodine (atomic weight 126.9) in 1811. In 1819, Jean-François Coindet, in Geneva, reported treating goiter with tincture of iodine. The connections between goiter, hypothyroidism and iodine were established in 1896, when Baumann and Roos discovered iodine in the thyroid. In the early 20th century, ground-breaking studies by Swiss and American scientists showed the efficacy of iodine prophylaxis in the prevention of goiter and cretinism.

## Dietary sources, absorption, and metabolism

Iodine (as iodide) is widely but unevenly distributed in the Earth's environment. In many regions, leaching from glaciation, flooding, and erosion have depleted surface soils of iodide, and most iodide is found in the oceans. Iodide ions in seawater are oxidized to elemental iodine, which volatilizes into the atmosphere and is returned to the soil by rain, completing the cycle. However, iodine cycles in many regions are slow and incomplete, leaving soils and drinking water iodine depleted. Crops grown in these soils will be low in iodine, and humans and animals consuming food grown in these soils become iodine deficient. Iodine-deficient soils are common in mountainous areas (e.g., the Alps, Andes, Atlas, and Himalaya ranges) and areas of frequent flooding, especially in

South and Southeast Asia (for example, the Ganges River plain of northeastern India). Many inland areas, including central Asia and Africa, and central and eastern Europe are iodine deficient. Iodine deficiency in populations residing in these areas will persist until iodine enters the food chain through addition of iodine to foods (e.g., iodization of salt) or dietary diversification introduces foods produced outside the iodine-deficient area.

The native iodine content of most foods and beverages is low. In general, commonly consumed foods provide 3–80 µg per serving. Foods of marine origin have higher iodine content because marine plants and animals concentrate iodine from seawater. Major dietary sources of iodine in the US are bread and milk. In Switzerland, based on direct food analysis, mean intake of dietary iodine is ~140 µg day<sup>-1</sup>, mainly from bread and dairy products. Much of the iodine content of dairy products is added during processing, for example, through the use of iodine-containing disinfectants. In many countries, use of iodized salt in households for cooking and at the table provides additional iodine. Dietary supplements often contain iodine. Based on data from the US Third National Health and Nutrition Examination Survey, 12% of men and 15% of nonpregnant women took a supplement that contained iodine, and the median intake of iodine from supplements was ~140 µg day<sup>-1</sup> for adults.

Iodine is ingested in several chemical forms. Iodide is rapidly and nearly completely absorbed in the stomach and duodenum. Iodate, widely used in salt iodization, is reduced in the gut and absorbed as iodide. In healthy adults, the absorption of iodide is >90%. Iodine is cleared from the circulation mainly by the thyroid and kidney, and although renal iodine clearance is fairly constant, thyroid clearance varies with iodine intake. In conditions of adequate iodine supply, ≤10% of absorbed iodine is taken up by the thyroid. In chronic iodine deficiency, this fraction can exceed 80%. During lactation, the mammary gland concentrates iodine and secretes it into breast milk to provide for the newborn.

The body of a healthy adult contains up to 20 mg of iodine, of which 70–80% is in the thyroid. In chronic iodine deficiency, the iodine content of the thyroid may fall to <20 µg. In iodine-sufficient areas, the adult thyroid traps about 60 µg of iodine/day, either from dietary iodine or from iodine released during thyroid hormone turnover, to balance losses and maintain thyroid hormone synthesis. Thyroglobulin (Tg), a large glycoprotein (molecular weight 660,000), is the carrier of iodine in the follicles of the thyroid. Thyrocytes produce and secrete the two thyroid hormones from Tg, thyroxine (T4) (the major form) and triiodothyronine (T3) (Yen, 2001). In the circulation, thyroid hormones are bound noncovalently to carrier proteins, mainly thyroxine-binding globulin. In target tissues, including liver, kidney, heart, muscle, pituitary, and the developing brain, T4 is converted to T3. T3 is the main physiologically active form of thyroid hormone and binds to nuclear receptors.

Thyroid hormone regulates a variety of physiologic processes, including reproductive function, growth and development, as well as the basal metabolic rate. During pregnancy, thyroid hormone crosses the placenta to the fetus early in the first trimester, before the fetal thyroid is functioning. In the developing brain, it influences cell growth and migration. It also promotes growth and maturation of peripheral tissues and the skeleton. Thyroid hormone increases energy metabolism in most tissues. It also increases the basal metabolic rate.

Both T4 and T3 are degraded through a complex series of pathways, and their turnover is relatively slow: the half-life of T4 is ~5 days and for T3, 1.5–3 days. The released iodine enters the plasma iodine pool and can be taken up again by the thyroid or excreted by the kidney. More than 90% of ingested iodine is ultimately excreted in the urine, with only a small amount appearing in the feces.

## Iodine deficiency disorders

Iodine deficiency has multiple adverse effects on growth and development in animals and humans (Zimmermann, 2009). These are collectively termed the iodine deficiency disorders (IDD) (Table 1), and are one of the most important and common human diseases. They result from inadequate thyroid hormone production due to lack of sufficient iodine.

**Table 1** Iodine deficiency disorders, by age group.

Age groups	Health consequences of iodine deficiency
All ages	Goiter Increased susceptibility of the thyroid gland to nuclear radiation
Fetus	Abortion Stillbirth Congenital anomalies
Neonate	Perinatal mortality Infant mortality Endemic cretinism
Child and adolescent	Impaired mental function Delayed physical development
Adults	Reduced work productivity Toxic nodular goiter; iodine-induced hyperthyroidism Hypothyroidism in moderate-to-severe iodine deficiency

Thyroid enlargement (goiter) is the classic sign of iodine deficiency. It is a physiologic adaptation to chronic iodine deficiency. As iodine intake falls, the ratio of T4 to T3 produced by the gland decreases, secretion of TSH increases in an effort to maximize uptake of available iodine, and thyroid-stimulating hormone (TSH) stimulates thyroid hypertrophy and hyperplasia. Large goiters may be cosmetically unattractive, can obstruct the trachea and esophagus, and may damage the recurrent laryngeal nerves and cause hoarseness.

Although goiter is the most visible effect of iodine deficiency, the most serious adverse effect is damage to reproduction and fetal development (Gowachirapant, 2017). Severe iodine deficiency during pregnancy is associated with a greater incidence of stillbirths, abortions, and congenital abnormalities. The fetal brain is particularly vulnerable to iodine deficiency. Normal levels of thyroid hormones are required for neuronal migration and myelination of the central nervous system (Morreale de Escobar, 2004). The most severe form of neurological damage from fetal hypothyroidism is termed cretinism. It is characterized by gross mental retardation along with varying degrees of short stature, deaf mutism, and spasticity. Up to 10% of populations with severe iodine deficiency may be cretinous. Iodine prophylaxis has completely eliminated the appearance of new cases of cretinism in previously iodine-deficient Switzerland and other countries.

Although new cases of cretinism are now rare, iodine deficiency still affects up to 30% of the global population (see below), and can impair cognitive development. A meta-analysis of 18 studies concluded that moderate-to-severe iodine deficiency reduces mean IQ scores by 13.5 points. Iodine deficiency is thus considered one of the most common causes of preventable mental retardation worldwide. Even in areas of mild-to-moderate iodine deficiency, cognitive impairment in school-aged children is at least partially reversible by administration of iodine. Overall, iodine deficiency produces widespread adverse effects in a population, including decreased educability and productivity, resulting in impaired social and economic development.

Only a few countries, including Switzerland, the Scandinavian countries, Australia, the US, and Canada, were completely iodine sufficient before 1990, due to iodized salt programs and adventitious iodine added during processing of foods. Since then, widespread introduction of iodized salt has produced dramatic reductions in iodine deficiency. The Global Scorecard of Iodine Nutrition, published by the Iodine Global Network, is based on the most recent available median urinary iodine concentration data from 194 World Health Organization Member States. In 2020, only 21 countries have insufficient iodine intake, while 118 countries have adequate iodine intake and 13 have excessive iodine intake (Zimmermann and Andersson, 2021).

## Iodine requirements

The US Food and Nutrition Board of the National Academy of Sciences has set an Adequate Intake (AI) for iodine in infancy and a Recommended Dietary Allowance (RDA) for children, adults, and pregnant and lactating women (Institute of Medicine, Academy of Sciences, 2001) (Table 2). The WHO has established recommended nutrient intakes for iodine (World Health Organization et al., 2007) (Table 2).

## Assessment of iodine status

Several methods are available for assessment of iodine nutrition. The most commonly used are measurement of thyroid size, concentration of urinary iodine (UI), and serum or dried blood spot thyroglobulin. As discussed below, UI is a sensitive indicator of recent iodine intake (days) and serum Tg shows an intermediate response (weeks to months), whereas changes in the goiter rate reflect long-term iodine nutrition (months to years) (Zimmermann, 2009).

Two methods are available for measuring goiter: neck inspection and palpation, and thyroid ultrasonography. Goiter surveys are usually done in school-aged children. By palpation, a thyroid is considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the subject being examined. In areas of mild-to-moderate iodine deficiency, where goiters are small, measurement of thyroid size by ultrasonography is a more objective and precise method, and is preferable to

**Table 2** Recommendations for iodine intake ( $\mu\text{g day}^{-1}$ ) by age or population group.

Age or population group	US Institute of Medicine		Age or population group	World Health Organization
	EAR	AI or RDA		RNI
Infants 0–12 months	–	110–130	Children 0–5 years	90
Children 1–8 years	65	90	Children 6–12 years	120
Children 9–13 years	73	120		
Adults $\geq 14$ years	95	150	Adults $> 12$ years	150
Pregnancy	160	220	Pregnancy	250
Lactation	209	290	Lactation	250

Abbreviations: AI, adequate intake; EAR, estimated average requirement; RDA, recommended daily allowance; RNI, recommended nutrient intake.

**Table 3** Epidemiological criteria from the World Health Organization for assessment of iodine nutrition in a population based on median urinary iodine concentrations (World Health Organization et al., 2007).

Urinary iodine concentrations ( $\mu\text{g L}^{-1}$ )	Iodine intake	Iodine nutrition
<b>School-aged children</b>		
<20	Insufficient	Severe iodine deficiency
20–49	Insufficient	Moderate iodine deficiency
50–99	Insufficient	Mild iodine deficiency
100–199	Adequate	Optimum
200–299	More than adequate	Risk of iodine-induced hyperthyroidism in susceptible groups
>300	Excessive	Risk of adverse health consequences (iodine-induced hyperthyroidism, autoimmune thyroid disease)
<b>Pregnant women</b>		
<150	Insufficient	
150–249	Adequate	
250–499	More than adequate	
$\geq 500^a$	Excessive	
<b>Lactating women<sup>b</sup></b>		
<100	Insufficient	
$\geq 100$	Adequate	
<b>Children less than 2 years of age</b>		
<100	Insufficient	
$\geq 100$	Adequate	

palpation. Portable ultrasound equipment can be used in the field, and goiter classified according to international reference criteria for iodine-sufficient children by age, gender, and body surface area. The total goiter rate is used to define severity using the following criteria: <5%, iodine sufficiency; 5.0–19.9%, mild deficiency; 20.0–29.9%, moderate deficiency; and >30%, severe deficiency (World Health Organization et al., 2007).

Because >90% of ingested iodine is excreted in the urine, UI is an excellent indicator of recent iodine intake. Most methods of measuring UI are based on the Sandell–Kolthoff reaction, in which iodide catalyzes the reduction of yellow ceric ammonium sulfate to the colorless cerous form, in the presence of arsenious acid. For populations, because it is impractical to collect 24 h samples in field studies, UI can be measured in spot urine specimens from a representative sample of the target group, and expressed as the median, in  $\mu\text{g L}^{-1}$  (Table 3). Spot UI measurements from populations are often misinterpreted; it is a common mistake to assume that all subjects with a spot UI < 100  $\mu\text{g L}^{-1}$  are iodine deficient, but even in iodine sufficient regions, individual spot UI concentrations are highly variable from day-to-day.

Tg is synthesized only in the thyroid, and is the most abundant intrathyroidal protein. In iodine sufficiency, small amounts of Tg are secreted into the circulation, and serum Tg is normally <10  $\mu\text{g L}^{-1}$ . In areas of endemic goiter, serum Tg increases due to greater thyroid cell mass and TSH stimulation. Serum Tg is well correlated with the severity of iodine deficiency as measured by UI, and is a sensitive indicator of iodine repletion. Tg can also be assayed on dried blood spots taken by a finger prick, simplifying collection and transport. A reference range for Tg on dried blood spots in school-aged children has recently been published, and Tg is now recommended to assess iodine status.

### Prophylaxis and treatment of iodine deficiency

There are two methods commonly used to correct iodine deficiency in a population: iodized oil and iodized salt (Zimmermann, 2009). In nearly all regions affected by iodine deficiency, the most effective way to control iodine deficiency is through salt iodization. All salt for human consumption, including salt used in the food industry, should be continuously iodized. Iodine can be added to salt in the form of potassium iodide (KI) or potassium iodate ( $\text{KIO}_3$ ). Because  $\text{KIO}_3$  has higher stability in the presence of salt impurities, humidity, and porous packaging, it is the recommended form. Iodine is usually added at a level of 20–40 mg iodine/kg salt, depending on local salt intake.

However, in industrialized countries, because about 90% of salt consumption is from purchased processed foods, if only household salt is iodized it will not supply adequate iodine. Thus, it is critical that the food industry uses iodized salt. The current push to reduce salt consumption to prevent chronic diseases and the policy of salt iodization to eliminate iodine deficiency do not conflict: iodization methods can fortify salt to provide recommended iodine intakes even if per capita salt intakes are reduced to <5 g day<sup>-1</sup>.

In some regions, iodization of salt may not be practical for control of iodine deficiency, at least in the short term. This may occur in remote areas where communications are poor or where there are numerous small-scale salt producers. In these areas, other options for correction of iodine deficiency should be considered, such as iodized oil (Zimmermann, 2009). Iodized oil is prepared from unsaturated fatty acids in seed or vegetable oils, by addition of iodine to the double bonds. It can be given orally or by

intramuscular injection. The intramuscular route has a longer duration of action (up to 2 years), but oral administration is more common because it is simpler.

Iodized oil is recommended for populations with moderate-to-severe iodine deficiency that do not have access to iodized salt, and may be targeted toward women of child-bearing age, pregnant women, and children. The recommended dose is 400 mg of iodine per year for women and 200 mg of iodine per year for children 7–24 months of age. Iodine can also be given as potassium iodide or iodate as drops or tablets, and in drinking or irrigation water. Iodine supplements ( $\sim 150 \mu\text{g day}^{-1}$ ) are recommended for pregnant and lactating women residing in areas of mild-to-moderate iodine deficiency.

### Iodine excess and toxicity

Ingestion of excess amount of iodine leads to acute iodine poisoning, which causes gastrointestinal irritation, abdominal pain, nausea, vomiting, and diarrhea, as well as cardiovascular symptoms, coma, and cyanosis. Most people are remarkably tolerant to high dietary intakes of iodine (Farebrother et al., 2019). The US Food and Nutrition Board of the National Academy of Sciences has set a Tolerable Upper Intake Level (UL) for iodine. The UL is the highest level of daily intake that is likely to pose no risk of adverse health effects in almost all individuals. The UL is  $200 \mu\text{g day}^{-1}$  for ages 1–3 years,  $300 \mu\text{g day}^{-1}$  for ages 4–8 years,  $600 \mu\text{g day}^{-1}$  for ages 9–13 years,  $900 \mu\text{g day}^{-1}$  for ages 14–18 years, and  $1100 \mu\text{g day}^{-1}$  thereafter (Institute of Medicine, Academy of Sciences, 2001). Individuals with autoimmune thyroid disease or chronic iodine deficiency may respond adversely to intakes lower than these.

A rapid increase in iodine intake in populations with chronic iodine deficiency may precipitate iodine-induced hyperthyroidism (IIH). This is more likely to occur if the iodine is given in excess, for example, if the iodine content of iodized salt is too high, or when iodine-containing medication is given. IIH occurs mainly in older people with nodular goiter. Thyrocytes in nodules often become insensitive to TSH control, and if iodine supply is suddenly increased, these autonomous nodules may overproduce thyroid hormone (Zimmermann and Boelaert, 2015). Symptoms of IIH include weight loss, tachycardia, and muscle weakness. It is dangerous when superimposed on underlying heart disease, and may be lethal. To reduce risk for IIH, the iodine level in salt should be monitored and reduced if too high.

### Conclusions

Because the native iodine content of most foods and beverages is low, the populations of many countries are at risk of iodine deficiency. It is critical to ensure adequate iodine intake in humans, because iodine deficiency has multiple adverse effects on growth and development. In most countries, the most effective and sustainable way to control iodine deficiency is through salt iodization. But salt iodization programs need to be carefully monitored to avoid both iodine deficiency and iodine excess.

## Key points

- Iodine is essential for the synthesis of thyroid hormone, which regulates growth, development, and metabolism.
- Multiple homeostatic mechanisms help to maintain stable thyroid hormone synthesis, but prolonged exposure to iodine deficiency or excess can lead to thyroid dysfunction.
- Pregnant and lactating women and young children are the groups most vulnerable to the effects of iodine deficiency.
- In addition to iodized salt, the primary means for prevention of iodine deficiency disorders, important dietary iodine sources include seafood and dairy products.
- Iodine deficiency may be exacerbated by concomitant micronutrient deficiencies and by exposure to environmental goitrogens.
- The iodine status of populations can be assessed based on median urinary iodine concentrations, blood thyroglobulin levels, and on prevalence of goiter.

## Glossary

**Goiter** Abnormally enlarged thyroid gland; often resulting from underproduction or overproduction of thyroid hormones or from iodine deficiency

**Goitrogens** Dietary substances that interfere with thyroid metabolism and aggravate the effects of iodine deficiency

**Iodine** An essential element in the diet needed by the thyroid gland for the synthesis of thyroid hormones

**Thyroglobulin** A protein that is the precursor to iodine-containing hormones and is typically present in the colloid of the thyroid gland. Abbreviated as Tg

**Thyroid stimulating hormone** Anterior pituitary hormone that stimulates the thyroid gland to produce thyroid hormones. Abbreviated as TSH

**Thyroxine** Hormone containing four atoms of iodine produced by the thyroid gland. Abbreviated as T4

**Triiodothyronine** Bioactive thyroid hormone with one less iodine atom per molecule than thyroxine. Abbreviated as T3

## Introduction

Iodine is an essential component of the hormones produced by the thyroid gland. Inadequate intake of iodine impairs thyroid function and results in a spectrum of disorders, including goiter, adverse obstetric outcomes, impaired cognitive development, and congenital abnormalities, collectively referred to as iodine deficiency disorders (IDDs). One billion people worldwide are at risk of iodine deficiency, with the highest risks in South Asia and sub-Saharan Africa (Zimmermann and Andersson, 2021). In nearly all countries the best strategy to control iodine deficiency is iodization of salt (Corstein et al., 2020).

## Ecology of iodine

Although iodine is widely present in the environment, it is distributed unevenly. The median concentration of iodine in soils worldwide is  $5 \mu\text{g g}^{-1}$  but can range from 1 to  $150 \mu\text{g g}^{-1}$  (Steinnes, 2009). The highest amounts are found in soils rich in organic components and located near the coast. Iodine was present during the primordial development of the Earth, but large amounts were leached from the surface soil by glaciation, snow, or rain and were carried by rivers and floods to the ocean. Thus, most of the world's iodine resides in the ocean. The major mechanism of iodine transfer from the ocean to land is based on volatilization of seawater iodine into the atmosphere (Carpenter et al., 2021). Another major source seems to be the release of volatile methyl iodide by marine organisms. However, the return of iodine to soil is insufficient compared to the original loss, leaving soils and drinking water iodine depleted. Iodine-deficient soils are common in mountainous areas (e.g., the Alps, Andes, Atlas, and Himalayan ranges) and areas of frequent flooding, especially in South and Southeast Asia (Zimmermann, 2009). Many inland regions in central Asia and Africa and central and eastern Europe are also affected by iodine-deficient soils. Populations in these areas that depend on locally grown food, consequently, become iodine deficient unless additional iodine is provided through imported iodine-rich foods, iodine fortification, or supplementation.

## Absorption and metabolism

Iodine is present in food in different chemical forms. Most ingested iodine is reduced to iodide in the gut and is absorbed almost completely in the duodenum (Alexander et al., 1967). Iodide is cleared from the circulation mainly by the thyroid and kidney. The thyroid adjusts the amount of iodide uptake to amounts required for adequate thyroid hormone synthesis. In conditions of adequate iodine supply, no more than 10% of the absorbed iodine is taken up by the thyroid. In chronic iodine deficiency, this fraction can exceed 80% (DeGroot, 1966). Similarly, during lactation, the mammary gland regulates iodine uptake for secretion in breast milk (Andersson and Braegger, 2021). Several other tissues can also concentrate iodine, including the salivary glands, choroid plexus, and gastric mucosa, but these are minor pathways of uncertain significance. Once the thyroidal iodine requirement has been met, excess iodine is excreted by the kidney.

The body of a healthy adult contains 15–20 mg of iodine, of which 70–80% is in the thyroid (Fisher and Oddie, 1969). In chronic iodine deficiency, the iodine content of the thyroid can fall below  $20 \mu\text{g}$ . In iodine-sufficient areas, the adult thyroid traps approximately  $60 \mu\text{g}$  of iodine per day to balance losses and maintain thyroid hormone synthesis. A transmembrane protein, the sodium/iodide symporter (NIS), mediates the first and key step in the process of supplying iodide to the gland. This protein transfers iodide into the cytoplasm of the follicular cells at a concentration gradient 20–50 times that of serum (Eskandari et al., 1997). Iodine in the thyroid gland then participates in a complex series of reactions to produce thyroid hormones. Iodide must first be oxidized to a higher oxidation state before it can act as an effective iodinating agent. Only  $\text{H}_2\text{O}_2$  is sufficiently potent to oxidize iodide. At the apical membrane, thyroid peroxidase (TPO) catalyzes the iodination of tyrosyl residues of thyroglobulin (Tg) producing either moniodotyrosine (MIT) or diiodotyrosine (DIT), the precursors of thyroid hormones (Dunn, 1995). TPO then catalyzes the coupling of the phenyl groups of the iodotyrosines through a diether bridge to form the thyroid hormones. Two residues of DIT couple within Tg to form thyroxine ( $\text{T}_4$ ), or one DIT and one MIT to form triiodothyronine ( $\text{T}_3$ ). In the thyroid, mature Tg, containing 0.1–1.0% of its weight as iodine, is stored extracellularly in the luminal colloid of the thyroid follicle. Approximately one-third of Tg's iodine is in  $\text{T}_4$  and  $\text{T}_3$ , the remainder being stored in the inactive precursors DIT and MIT. The iodine in the inactive precursors is not released into circulation, but instead is removed from the tyrosine moiety by a specific deiodinase and then recycled within the thyroid gland. This process is particularly important for iodine conservation in situations of iodine deprivation (Fig. 1).

Before secretion from the thyroid,  $\text{T}_4$  and  $\text{T}_3$  must be released from peptide linkage within Tg. Tg retrieved by micropinocytosis passes first through the endosomal system, where proteolysis and hormone release is initiated, then into lysosomes, where the process is completed and  $\text{T}_4$  and  $\text{T}_3$  are released into the circulation.  $\text{T}_4$  is secreted in higher quantities from the thyroid compared with  $\text{T}_3$ . Once in the circulation,  $\text{T}_4$  and  $\text{T}_3$  rapidly attach to several binding proteins synthesized in the liver, including thyroxine-binding globulin, transthyretin, and albumin. The bound hormone then migrates to target tissues where  $\text{T}_4$  is deiodinated to  $\text{T}_3$ , the metabolically active form.

$\text{T}_3$  is essential for the development and differentiation of all cells of the human body. It acts mostly through nuclear receptors regulating gene expression, although other mechanisms have also been described (Mendoza and Hollenberg, 2017).  $\text{T}_3$  plays a key role in normal skeletal development, linear growth, and the acquisition and maintenance of bone mass.  $\text{T}_3$  also has a critical role in

**Fig. 1** Iodine pathway in the thyroid cell. Iodide ( $I^-$ ) is transported into the thyrocyte by the sodium/iodide symporter (NIS) at the basal membrane and migrates to the apical membrane.  $I^-$  is oxidized by the enzymes thyroid peroxidase (TPO) and hydrogen peroxide ( $H_2O_2$ ) and attached to tyrosyl residues in thyroglobulin (Tg) to produce the hormone precursors monoiodotyrosine (MIT) and diiodotyrosine (DIT). Residues then couple to form thyroxine (T4) and triiodothyronine (T3) within the Tg molecule in the follicular lumen. Tg enters the cell by endocytosis and is digested. T4 and T3 are released into the circulation, and iodine on MIT and DIT is recycled within the thyrocyte. Reprinted with permission from Zimmermann, M.B., Jooste, P.L., Pandav, C.S., 2008. Iodine-deficiency disorders. *Lancet* 372: 1251–1262.

the development and function of the human central nervous system. Moreover, thyroid hormones are the major endocrine regulators of basal metabolic rate. Hypothyroidism results from insufficient production of thyroid hormones, whereas hyperthyroidism is due to excessive synthesis and secretion of thyroid hormones.

### Adaptations of thyroid metabolism to iodine deficiency

When dietary iodine intake is low, the thyroid may still achieve adequate secretion of thyroid hormones by modifications of metabolism. Thyroid stimulating hormone (TSH) is the primary factor that regulates the function of thyroid follicular cells and, ultimately, thyroid hormone secretion. In a classic negative feedback system, thyroid hormone inhibits the synthesis of TSH directly at the pituitary level and indirectly at the hypothalamic level by reducing the secretion of thyrotropin-releasing hormone (TRH). TSH stimulates the trapping of iodine into the thyroid, the breakdown of Tg, and an increase in the ratio of T3 to T4 synthesized and released into the blood (Abrams and Larsen, 1973). As a greater fraction of circulating iodine enters the thyroid, renal iodide excretion is reduced. As long as the iodine intake remains above approximately  $50 \mu g \text{ day}^{-1}$ , the absolute uptake of iodide by the thyroid remains normal and the iodine content of the thyroid will remain stable at about 15–20 mg, despite the decrease in serum iodine concentration (Zimmermann, 2009). Below this threshold, there is an increased risk of iodine depletion in the thyroid, and individuals may develop goiter.

The basic process in the transformation of the normal thyroid to a goiter is the generation of new thyrocytes and follicles (hyperplasia) in addition to increasing cell volume (hypertrophy). The optimal thyroid response to iodine deficiency would be an increase in thyroid blood flow, in iodide trapping capacity, and in iodination rate, and a low Tg content in a much reduced colloid space. However, the goitrous thyroid is often large and filled with colloid. The low iodine and high Tg concentration lead to a lesser iodination of Tg, thus reducing the efficiency of thyroid hormone synthesis (Dumont et al., 1995). Iodine deficiency-induced goiter typically is initially diffuse, but over time somatic mutations may lead to the development of nodularity and then to autonomously-functioning nodules (Krohn et al., 2005). In areas of moderate-to-severe iodine deficiency the characteristic pattern of circulating thyroid hormones is a variably elevated TSH, a low serum T4, and a normal or mildly increased T3 concentration. Overt hypothyroidism (elevated serum TSH and low T4) and cretinism usually develop only in regions of chronic, severe iodine deficiency. The effects of iodine deficiency on the development of goiter and thyroid function are extremely variable among

populations and individuals, even in endemic areas. The dietary, environmental, and genetic factors that account for this variability remain largely unknown.

### Adaptations of thyroid metabolism to iodine excess

Intakes up to 600  $\mu\text{g day}^{-1}$  in the European Union and 1100  $\mu\text{g day}^{-1}$  in the United States are defined as safe for adults (European Food Safety Authority Scientific Committee on Food, 2002; US Institute of Medicine, 2001). Nevertheless, most individuals tolerate higher intakes, whereas a few may have untoward effects at lower intakes. The NIS is key in maintaining normal thyroid hormone concentration as it reduces the transport of iodide into the thyroid cells under conditions of excessive iodine intake. Even before NIS reacts, a sudden iodine overload paradoxically blocks the second step of hormone synthesis, the organification of iodide. This so-called acute Wolff–Chaikoff effect requires a high ( $\geq 10^{-3}$  M) intracellular concentration of iodide and provides a short-term block against further thyroidal iodine uptake (Wolff and Chaikoff, 1948). After a few days of continued exposure to high iodine levels there is an escape from the acute Wolff–Chaikoff effect mediated by downregulation of NIS which lowers intrathyroidal iodine content and allows normal thyroid hormone synthesis to resume (Eng et al., 1999). Another response to iodine excess occurs in the first step of thyroid hormone synthesis (Taurog and Nakashima, 1978). When iodine is abundant, DIT predominates over MIT in favor of T4 biosynthesis, which is less active than T3. Thus, a euthyroid state is maintained despite an increased amount of iodine taken up by the gland.

There are no clinical symptoms specific to these adaptations of excessive intake. Although most individuals suffer no disturbance from iodine excess, some persons develop thyroid dysfunction despite the multiple control systems (Leung and Braverman, 2014). Iodine excess may cause hyperthyroidism (from a failure of the acute Wolff–Chaikoff effect), hypothyroidism (from a failure of the escape from the acute Wolff–Chaikoff effect), euthyroid goiter, or thyroid autoimmunity. Factors responsible for this variety of responses are mostly unknown.

### Impact of other micronutrients on thyroid and iodine metabolism

Besides iodine, other highly prevalent micronutrient deficiencies, such as deficiencies of iron, selenium, and vitamin A, adversely affect thyroid function. Although there is little information on the prevalence of concomitant iodine deficiency with iron, selenium, or vitamin A deficiency, in view of the high prevalence of these individual micronutrient deficiencies in low- and middle-income countries, it is highly likely that a substantial number of individuals may be affected by multiple micronutrient deficiencies.

Numerous studies in animals have shown that iron deficiency anemia impairs thyroid metabolism (Zimmermann, 2006). Iron deficiency anemia may influence thyroid metabolism by altering the central nervous system control and reducing TPO activity. Iron deficiency anemia could also impair thyroid metabolism through lowered oxygen transport. It is likely that these mechanisms jointly contribute to the impairment of thyroid function in iron deficiency. There is strong evidence for such an interaction between iron and iodine and thyroid metabolism from randomized, controlled intervention trials in humans, which have repeatedly shown that providing iron along with iodine, either as an iron supplement or as dual-fortified salt, results in significantly greater improvements of thyroid metabolism (Zimmermann et al., 2002; Eftekhari et al., 2006).

Selenium is an integral component of two important enzymes—iodothyronine deiodinase and glutathione peroxidase (GPX)—that are present in many tissues, including the thyroid gland. Briefly, there are three types of deiodinases. Two 5'-deiodinases (DIO1 and DIO2) catalyze the activation of the prohormone T4 to the active thyroid hormone T3. DIO1 is also involved in the degradation to the inactive hormone reverse T3 (Bianco and da Conceição, 2018). The third selenocysteine-containing deiodinase (DIO3) inactivates thyroid hormones, both the prohormone T4 and its active metabolites such as T3 and 3,5-T<sub>2</sub>. GPX and thioredoxin reductase are expressed in thyroid tissue and protect the thyroid gland from hydrogen peroxide produced during the synthesis of thyroid hormone, thereby protecting against oxidative damage (Duntas, 2010). In conditions of inadequate supply of both iodide and selenium, complex rearrangements of thyroid hormone metabolism enable adaptation by increasing retention of selenium in the brain, endocrine tissues, and especially in the thyroid gland. However, to date, most controlled intervention trials in humans have failed to confirm an effect of selenium supplementation on thyroid metabolism (Winther et al., 2020).

Vitamin A deficiency has multiple effects on the pituitary–thyroid axis. Vitamin A modulates thyroid hormone metabolism in the thyroid gland and the periphery, and the production of TSH by the pituitary. Similarly to iron, but with slightly less evidence from randomized clinical trials in children, vitamin A supplementation may provide a beneficial impact on thyroid metabolism, either when given alone or in combination with iodized salt (Hess, 2010).

### Requirements and dietary sources of iodine

Recommendations for iodine intake by age and population group, as defined by the US Institute of Medicine (IOM) and the World Health Organization (WHO), are shown in Table 1 (US Institute of Medicine, 2001; World Health Organization, United Nations Children's Fund and International Council for the Control of Iodine Deficiency, 2007). Infants are born with minimal intrathyroidal

**Table 1** Recommendations for iodine intake ( $\mu\text{g day}^{-1}$ ) by age and population group.

Age or population group	U.S. Institute of Medicine <sup>a</sup> ( $\mu\text{g day}^{-1}$ )	Age or population group	World Health Organization <sup>b</sup> ( $\mu\text{g day}^{-1}$ )
Infants 0–12 months	110–130	Children 0–5 years	90
Children 1–8 years	90	Children 6–12 years	120
Children 9–13 years	120		
Adults $\geq 14$ years	150	Adults $\geq 12$ years	150
Pregnant women	220	Pregnant women	250
Lactating women	290	Lactating women	250

<sup>a</sup>Adequate intake for infants  $\leq 12$  months; recommended daily allowance for individuals  $> 1$  year.

<sup>b</sup>Recommended nutrient intake.

Assessment of Iodine Deficiency Disorders and Monitoring Their Elimination. A Guide for Program Managers. Geneva: World Health Organization.

iodine stores and require daily iodine intakes of about 80  $\mu\text{g}$  to sustain a high rate of thyroid hormone synthesis (Dold et al., 2016). Compared to nonpregnant adults, pregnant women need increased iodine intakes because of a physiologic 50% increase in thyroid hormone synthesis starting in early gestation, transfer of some iodine to the fetus in the second half of gestation, when the fetal thyroid gland is functional, and because of increased renal iodine losses (Rodriguez-Diaz and Pearce, 2020). During lactation, as described above, iodine is actively secreted into breast milk, leading to increased daily iodine requirements to support the nutritional needs of both the mother and the breastfed infant. The most vulnerable population groups for iodine deficiency are young children and pregnant/lactating women due to their increased physiological needs and due to the importance of adequate iodine for neurodevelopment *in utero* and in early life.

The native iodine content of most foods and beverages is low. Most foods consumed contain 3–80  $\mu\text{g}$  per serving (Zimmermann, 2009). Although plant-based foods are generally low in iodine, iodine content is affected by the iodine in soil and irrigation water, and by the use of fertilizers (Ershow et al., 2018). Seafood and seaweed are generally rich sources of iodine. However, the iodine content of fish varies greatly depending on the water they inhabit. In countries such as Japan and Iceland, where there is a high consumption of seafood, some population groups have been found to consume excessive amounts of iodine (Laurberg et al., 1991; Fuse et al., 2021). In some regions of China excessive iodine levels occur naturally in drinking water (Zhao et al., 1998). Due to iodine in cattle feed and the use of iodophor cleansers by the dairy industry, cows' milk may be high in iodine and in many parts of the world dairy products are an important dietary source (van der Reijden et al., 2017).

The most important source of dietary iodine in most countries is iodized salt. The addition of iodine to salt is the most effective way to control iodine deficiency, and WHO, the United Nations Children's Fund (UNICEF), and the Iodine Global Network (IGN) recommend that salt in regions of iodine deficiency should be fortified at a concentration of 20–40 mg iodine per kg salt, depending on local salt intake (World Health Organization, United Nation Children's Fund and International Council for the Control of Iodine Deficiency, 2007). Since 1990, the proportion of households worldwide using iodized salt has risen from less than 20%–88%, thereby markedly reducing the problem of iodine deficiency (Zimmermann and Andersson, 2021).

The iodine content of breast milk varies depending on maternal iodine status and dietary intake (Andersson and Braegger, 2021). Colostrum contains the greatest amount of iodine, with concentrations as high as 200–400  $\mu\text{g L}^{-1}$ . In mature breast milk, median iodine concentrations of 100–200  $\mu\text{g L}^{-1}$  are consistent with adequate maternal iodine status.

Non-food sources of iodine include topical antiseptics (povidone-iodine), iodinated contrast media used for computed tomography scans and other imaging, and the antiarrhythmic medication amiodarone (Leung and Braverman, 2014). Annual dosing with 400  $\mu\text{g}$  iodized oil supplements may occasionally be employed for vulnerable populations in regions of severe iodine deficiency (World Health Organization, United Nation Children's Fund and International Council for the Control of Iodine Deficiency, 2007). Lower-dose daily oral iodine supplements are also available in many regions (Rodriguez-Diaz and Pearce, 2020).

### Dietary and environmental factors that affect iodine requirements

Goitrogens are dietary substances that interfere with thyroid metabolism and can aggravate the effect of iodine deficiency. Most goitrogens do not have a major clinical effect unless they are consumed at high levels and iodine deficiency is present. Vegetables of the Brassica family (i.e., broccoli, cabbage, cauliflower, kale, turnips, rapeseed) contain glucosinolates, which are potent goitrogenic substances (Felker et al., 2016). The metabolites of glucosinolates compete with iodine for thyroidal uptake. More important, however, are the naturally occurring goitrogens cyanoglucosides in several staple foods, such as cassava, maize, bamboo shoots, sweet potatoes, and lima beans (Ermans et al., 1972). Cyanoglucosides are metabolized to thiocyanates which are anions that compete with iodine in thyroid hormone synthesis. Flavonoids in millet and soy may impair TPO activity, which has raised

concerns about potential adverse effects of soy-based infant formulas on thyroid function of young children. However, evidence from clinical trials on soy consumption remains inconclusive (Otun et al., 2019).

Some substances that are commonly found in the environment may also affect thyroid function (Pearce and Braverman, 2009). The anions perchlorate, thiocyanate, and nitrate are competitive inhibitors of NIS at pharmacological doses. When present in high amounts, these substances can decrease the active transport of iodine into the thyroid and thereby reduce thyroid hormone synthesis. The most vulnerable population groups are the developing fetus and the newborn, as sufficient iodine is essential for their normal thyroid function at this crucial time of neurodevelopment. A low level of perchlorate exposure appears to be ubiquitous. However, the potential effects of environmental perchlorate exposure on thyroid function remain controversial, and more research is needed. Cigarette smoke contains cyanide that is metabolized to thiocyanate. Smoking has been shown to adversely affect thyroid hormone status and iodine concentration in breast milk (Laurberg et al., 2004). Nitrates occur naturally in soil, groundwater, and plants, and sodium nitrite is used as a preservative in cured meats and other foods. Studies in areas of very high nitrate contamination of water have found an increased risk of goiter or hypothyroidism (García Torres et al., 2020). Multiple other environmental substances are known to have adverse effects on thyroid hormone synthesis, metabolism, and action and may worsen the effects of iodine deficiency (Köhrle and Frädrich, 2021). Continued monitoring of chemical exposures is important to detect potential thyroidal inhibitors as industrial practices and governmental regulations change over time.

## Assessment of iodine status

The assessment of population iodine status is important to instigate salt iodization programs, guide program modifications, and contribute to greater safety of these programs (Brown et al., 2021). Four indicators are generally recommended for assessment of iodine status: thyroid volume, urinary iodine, serum TSH, and serum Tg concentrations. Thyroid volume reflects long-term iodine nutrition. Urinary iodine concentration is an indicator of recent and Tg concentration of medium-term iodine intake. More details are provided in the following sections.

### Thyroid volume

As described in the section on Adaptations of Thyroid Metabolism to Iodine Deficiency above, increased thyroid volume is a common consequence of long-term iodine deficiency. Thyroid volume can be determined by neck inspection and palpation or by ultrasonography. Goiter surveys are usually done in school-aged children. By palpation, a thyroid is considered goitrous when each lateral lobe has a volume greater than the terminal phalanx of the thumbs of the individual being examined. Because palpation has poor sensitivity and specificity in areas of mild iodine deficiency, measurements of thyroid volume by ultrasound is preferable. Thyroid ultrasound is non-invasive, quick, and feasible even in remote areas using portable equipment. Thyroid volume can be classified as goiter according to international reference criteria (Zimmermann et al., 2014). Although thyroid size decreases in children in response to iodine repletion, thyroid size may not return to normal values for months or years, if at all, after correction of iodine deficiency. Therefore, because of the lack of sensitivity to acute changes in iodine intake, this method is of limited usefulness in assessing the impact of salt iodization programs (United Nations Children's Fund, 2018).

### Urinary iodine concentration

Because the absorption of dietary iodine is high and approximately 90% of iodine consumed is excreted in urine, the urinary iodine concentration serves as a good reflection of iodine nutrition (Rohner et al., 2014). Urinary iodine concentration can be measured in spot urine specimens from a representative sample of the target group, and expressed as the median, in  $\mu\text{g L}^{-1}$ . Because there is substantial day-to-day and hour-to-hour variability in urinary iodine excretion, urinary iodine concentrations cannot be used as a biomarker for the iodine status of individuals (König et al., 2011). For program evaluation, urinary iodine concentration is the most useful indicator because it reflects the current dietary iodine intake, and WHO and UNICEF have proposed cut-off points for classifying population iodine nutrition into different degrees of public health significance (Table 2) (World Health Organization, United Nations Children's Fund and International Council for the Control of Iodine Deficiency, 2007; United Nations Children's Fund, 2018). Surveys to assess iodine deficiency have often relied on school-aged children because of their vulnerability and easy access in schools. However, children's iodine status does not always reflect iodine status in pregnant women and thus may result in underestimating the risk of iodine deficiency in the most vulnerable populations (Wong et al., 2011). In lactating women, although the WHO has provided thresholds for median urinary iodine, iodine status cannot be understood without also assessing breast milk iodine content (Dold et al., 2017).

### Thyroid hormone and thyroglobulin concentrations

Thyroid hormone concentrations are poor indicators of iodine status due to the strong regulatory adaptations of thyroid metabolism. In iodine-deficient populations, serum T3 increases or remains unchanged, and serum T4 usually decreases. However, these values are often within the normal range and overlap with iodine-sufficient populations (Rohner et al., 2014). The use of blood TSH concentration is not recommended as a biomarker for iodine status in school-age children or adults (Pearce and Caldwell, 2016).

**Table 2** Epidemiological criteria for assessing population iodine nutrition based on median urinary iodine concentrations in different population groups.

Median urinary iodine ( $\mu\text{g L}^{-1}$ )	Iodine intake	Iodine status
<b>School-aged children</b>		
<20	Insufficient	Severe iodine deficiency
20–49	Insufficient	Moderate iodine deficiency
50–99	Insufficient	Mild iodine deficiency
100–299	Adequate	Adequate iodine nutrition
$\geq 300$	Excessive	Risk of adverse health consequences
<b>Pregnant women</b>		
<150	Insufficient	
150–249	Adequate	
250–499	Above requirements	
$\geq 500$	Excessive	
<b>Lactating women<sup>a</sup></b>		
<100	Insufficient	
$\geq 100$	Adequate	

<sup>a</sup>In lactating women, the cut-offs for median urinary iodine concentrations are lower than the iodine requirement because of the iodine excretion in breastmilk. Breast milk as well as urinary iodine concentration measurements may be needed to assess the iodine status of lactating women.

Data sources: World Health Organization, United Nation Children's Fund, International Council for the Control of Iodine Deficiency Disorders, 2007. Assessment of Iodine Deficiency Disorders and Monitoring Their Elimination. A Guide for Program Managers. Geneva: World Health Organization; United Nations Children's Fund, 2018. Guidance on the Monitoring of Salt Iodization Programs and Determination of Population Iodine Status. <https://www.unicef.org/nutrition/files/Monitoring-of-Salt-Iodization.pdf>.

Although serum TSH increases slightly in iodine deficiency, the concentrations often stay within the normal range. In contrast, neonatal TSH concentration reflects iodine nutrition more accurately. TSH increases when the supply of thyroid hormone and iodine from the maternal circulation to the fetus has been compromised. WHO suggests that when a sensitive assay is used on samples collected during the first few days of life, a <3% frequency of TSH concentrations  $>5 \text{ mIU L}^{-1}$  indicates iodine sufficiency in a population (World Health Organization, United Nation Children's Fund and International Council for the Control of Iodine Deficiency, 2007).

When iodine intake is adequate, small amounts of Tg are secreted into the circulation. In iodine deficiency, thyroid hyperplasia and goiter increase serum Tg levels. Serum Tg levels are also increased in the setting of excessive iodine intake. Tg has been found to be a good indicator of iodine status reflecting iodine nutrition over months or years. Tg can be assessed in serum or whole blood stored on filter paper (Stinca et al., 2015; Zimmermann et al., 2013). Median thyroglobulin values  $<13 \mu\text{g L}^{-1}$  with <3% of thyroglobulin values  $>40 \mu\text{g L}^{-1}$  indicate optimal iodine nutrition in school-aged children.

## Conclusions

Adequate iodine intake is essential for the synthesis of thyroid hormone. Although multiple homeostatic mechanisms help to maintain stable thyroid hormone synthesis, prolonged exposure to either iodine deficiency or excess can lead to thyroid dysfunction. The most vulnerable population groups for iodine deficiency are young children and pregnant and lactating women due to their increased physiological needs and the importance of iodine for normal brain development. Iodized salt is the primary strategy to prevent iodine deficiency disorders, and seafood and dairy products are important dietary sources of iodine. Iodine deficiency may be exacerbated by concomitant micronutrient deficiencies and by exposure to environmental goitrogens. There is currently no validated biomarker for the iodine status of individual patients. The iodine status of populations is most frequently assessed based on median urinary iodine concentrations and blood thyroglobulin levels.

## Iron Chemistry and Physiology

### Body Content, Forms, and Function

Iron, the 26th element of the periodic table, has an atomic weight of 55.85. Two common aqueous oxidation states, ferrous ( $\text{Fe}^{2+}$ ) and ferric ( $\text{Fe}^{3+}$ ), enable iron to participate in oxidation/reduction reactions that are essential to energy metabolism by accepting or donating electrons. However, this property also enables free iron to catalyze oxidative reactions, resulting in reactive and damaging free radicals. Accordingly, body iron must be chemically bound to facilitate appropriate physiological function, transport, and storage, with minimal opportunity for free ionic iron to catalyze harmful oxidative reactions.

Most of the body's iron functions in heme protein complexes that transport oxygen as hemoglobin and myoglobin. Approximately two-thirds of the body iron is in hemoglobin, a 68 000 MW structure containing four subunits of heme, a protoporphyrin ring with iron in the center (**Figure 1**), and four polypeptide chains (two chains each of  $\alpha$ - and  $\beta$ -globin). For transport by hemoglobin, oxygen bonds directly to the iron atom, stabilized in an  $\text{Fe}^{2+}$  oxidation state surrounded by the protoporphyrin ring and histidine residues. Hemoglobin iron easily binds and releases oxygen, circulating in blood erythrocytes. Myoglobin, consisting of a single heme molecule and globin, enables oxygen transfer from erythrocytes to the mitochondria in muscle cells.

Smaller quantities of iron in the heme form function in mitochondrial cytochromes involved in electron transfer, oxygen utilization, and the production of ATP. A small fraction of body iron functions in heme-containing hydrogen peroxidases such as catalase that protect against excessive hydrogen peroxide accumulation by catalyzing its conversion to hydrogen and oxygen.

Iron also functions in nonheme proteins that contain an iron–sulfur complex, a cubical arrangement of four iron and four sulfur atoms. This is the principal form of iron in the mitochondria, functioning in enzymes of energy metabolism such as aconitase, NADH dehydrogenase, and succinate dehydrogenase. In both mitochondria and cytosol, aconitase is sensitive to iron concentrations. When iron is abundant, the aconitase enzyme assumes the full iron–sulfur cubic structure that is associated with carbohydrate metabolism. However, when intracellular iron concentrations are reduced, the protein loses aconitase activity and functions as an

**Figure 1** Heme (ferroprotoporphyrin).

iron-binding protein (IRP). IRPs interact with iron response elements (IREs) located in the mRNA to regulate the synthesis of proteins involved in iron transport, storage, and use, in response to changes in cellular iron concentrations.

### Absorption, Excretion, Transport, and Storage

#### Absorption

Both heme and nonheme (inorganic) iron are absorbed in an inverse proportion to body iron stores (indicated by serum ferritin; **Figure 2**). Heme iron is absorbed more efficiently than the nonheme form. Nonheme iron absorption can vary from 0.1% to >35% and that of heme iron from 20% to 50%, depending on body iron status (stores, erythropoiesis, and hypoxia) and bioavailability

**Figure 2** Heme and nonheme iron absorption as influenced by body iron stores and dietary bioavailability. HBV and LBV indicate high and low dietary bioavailability, respectively.

from the diet. These ranges indicate greater control of nonheme compared with heme iron absorption. When iron stores are high, absorption of nonheme iron can be minimized more completely, and when iron stores are low, nonheme iron is absorbed nearly as efficiently as heme iron. Because there is considerably more nonheme iron in the diet (usually ~85–100%), this form of iron contributes most to the physiological control of iron absorption in relation to iron needs.

The upper portion of the duodenum, with its low pH luminal conditions, is the primary site for both heme and nonheme iron absorption (Figure 3). Nonheme iron absorption is better understood than heme iron absorption, but a heme-carrying protein that may be responsible for mucosal uptake of heme iron has been identified. The globin proteins of hemoglobin are proteolytically digested in the intestinal lumen, producing peptide remnants that may enhance the absorption of the heme molecule by preventing heme polymerization. The heme molecule is absorbed as an intact porphyrin structure, most likely *via* a heme-carrying protein (HCP1), possibly involving endocytosis. In the mucosal cell, heme iron is split into ferrous iron and bilirubin by heme oxygenase, adding to a common pool of cellular iron for transport into plasma or intracellular storage and exfoliation.

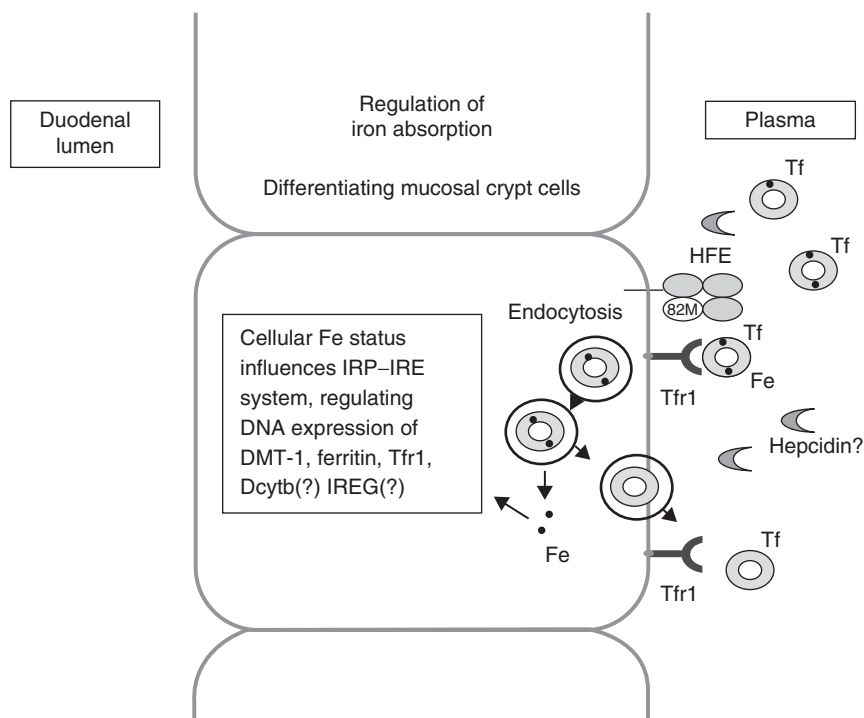

Nonheme iron is best absorbed if presented to the intestinal villi as soluble ions (preferably reduced, ferrous ions) or as low-affinity, low-molecular-weight iron ligands. Gastric acid facilitates these conditions. Ascorbic acid concurrently ingested with iron helps to maintain the iron in a soluble, reduced, low-molecular ligand form in the intestinal lumen.

Proteins involved in mucosal uptake and transfer of nonheme iron and possible regulatory molecules have been identified (Figures 3 and 4). These include duodenal cytochrome *b* (Dcytb), which converts ferric to ferrous iron at the apical mucosal surface. A divalent metal transporter (DMT-1) transfers ferrous iron into the mucosal cell. Mutations in DMT-1 impair iron absorption and produce microcytic anemia in rodents. Ferrous iron has the highest affinity for DMT-1, but it can also transport other divalent ions, such as manganese, lead, cadmium, zinc, and copper. This may contribute to competitive inhibition observed in the absorption of these metals. Iron transported into the enterocyte may be further transported to the body at the basolateral membrane, completing absorption, or may be held and returned to the intestinal lumen with cellular desquamation. Ferroportin, or Ireg-1, is involved in efflux of iron from the mucosal cell at the basolateral membrane. A mutation in ferroportin results in an uncommon form of hemochromatosis, an iron storage disorder. The mRNA for both DMT-1 and ferroportin contains an IRE, enabling the regulation of mRNA translation by intracellular iron concentrations. Dcytb, DMT-1, and ferroportin are all upregulated in iron deficiency. Intestinal transfer of iron to the circulation also involves hephaestin, an intestinal ferroxidase with a protein sequence similar to that of ceruloplasmin (a copper-containing ferroxidase in serum). A defective hephaestin gene in mice results in anemia and accumulation of iron in intestinal cells.

Iron absorption is responsive to recent iron intake, iron stores, erythropoiesis, hypoxia, pregnancy, and inflammation. A newly identified peptide, hepcidin, is related to several of these stimuli of regulatory control. Hepcidin is an antimicrobial peptide found in human blood and urine that serves as a signal for limiting iron absorption. Some control of absorption also likely involves the HFE protein located in the basolateral membrane of intestinal crypt cells. A specific point mutation in the HFE gene is associated

**Figure 3** Absorption of iron in the intestinal mucosa.

**Figure 4** Regulation of iron absorption in the mucosal crypt cells before differentiation and development into actively absorbing intestinal villi cells.

with the most common form of hemochromatosis, a disorder involving excessive iron absorption and accumulation. The HFE protein interacts with  $\beta_2$ -microglobulin (B2M) and transferrin receptor, apparently influencing iron uptake from serum transferrin, the primary protein involved in serum iron transport (**Figure 4**). Knowledge of the control of iron absorption is growing rapidly.

### Transport

Transferrin transports essentially all of the 3 or 4 mg of iron in serum, including dietary iron absorbed from the duodenum and iron from macrophages after the degradation of hemoglobin. Each transferrin molecule binds two ferric ions; the transferrin in serum is normally approximately one-third saturated with iron. The amount of iron that can be bound by transferrin is measured as the total iron-binding capacity (TIBC). In iron deficiency, serum iron is reduced, and TIBC is elevated; expressing serum iron as a fraction of the TIBC defines the transferrin saturation, which is reduced in iron deficiency. As iron deficiency develops, these measures of iron transport signal iron deficiency before the functional pool of circulating hemoglobin is reduced (**Figure 5**).

Membrane transferrin receptors enable the cellular uptake of iron. Transferrin receptors complex with transferrin, the complex is internalized by endocytosis, and the iron is released from transferrin inside the cell on vesicular acidification (**Figure 4**). Transferrin receptors are abundant in erythrocyte precursors, placenta, and liver, and the number of receptors changes inversely with cellular iron status. Serum transferrin receptors are soluble, truncated forms of the cellular receptors, present in proportion to the cellular receptors, which serve as a clinical indicator of cellular iron status that is useful in distinguishing between iron deficiency and other causes of anemia.

Other proteins involved in iron transport include lactoferrin, which is the major IRP in human milk. Haptoglobin and hemo-pexin proteins clear hemoglobin and heme, respectively, from circulation as they are released from senescent red blood cells or by disease.

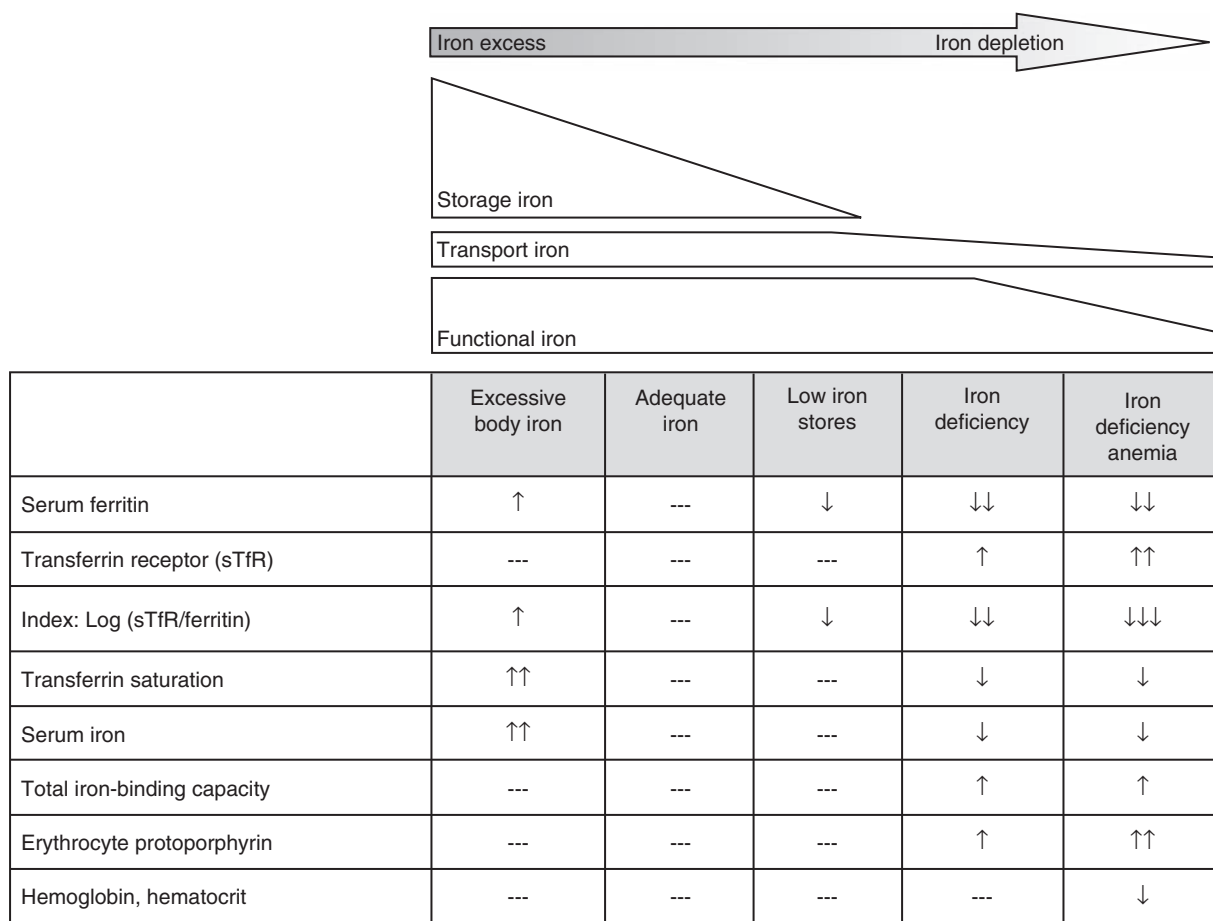

### Storage

Iron is primarily stored in the liver, spleen, and bone marrow in the form of ferritin or hemosiderin. Ferritin is a water-soluble protein complex of 24 polypeptide subunits in a spherical cluster with a hollow center that contains up to 25% iron by weight or 4000 atoms of iron per molecule. Hemosiderin is a water-insoluble complex, immunologically similar to ferritin, containing up to 35% iron. Ferritin and hemosiderin each account for approximately half of the storage iron in the liver.

### Excretion

The approximately 1 mg of iron lost daily by men and postmenopausal women represents mainly obligatory fecal losses from exfoliated mucosal cells, bile, and extravasated red cells, with minor additional amounts in desquamated skin cells and sweat. Urine contains minimal amounts of iron.

**Figure 5** Clinical indicators of body iron status.

Adolescent girls and premenopausal women lose considerable amounts of iron through menstruation. Menstrual losses of individual women vary considerably; half of women lose less than 14 mg of iron per menstrual period, but the distribution is skewed, and 5% lose 50 mg or more. Iron deficiency among women in affluent countries is commonly attributable to these high iron losses rather than to differences in dietary intakes.

### Body Iron Balance

The adult human has 2–4 g of total iron, or approximately 50 mg kg<sup>-1</sup> in men and 40 mg kg<sup>-1</sup> in women. Red blood cells contain approximately two-thirds of body iron and have an average life span of 120 days; consequently, approximately 20 mg of iron daily is efficiently recycled from senescent to newly formed erythrocytes through the reticuloendothelial system.

In contrast to other nutrients, controlled through both absorption and excretion, body iron balance is controlled almost exclusively by absorption. Adults consume approximately 10–20 mg iron daily from food. The average absorption and excretion of iron for adult men or postmenopausal women is approximately 1 mg daily. Menstruation can more than double iron losses in women of child-bearing age, increasing their requirement for absorbed iron. Pregnancy also increases the iron requirements considerably. Total body iron in fetuses and newborns is approximately 75 mg kg<sup>-1</sup> translating into an iron accretion rate of 1–1.5 mg kg<sup>-1</sup> per day, which, however, does not apply to newborn infants because the normal decline in hemoglobin concentration after birth causes significantly increased iron stores. Therefore, a healthy, term infant is initially independent of external iron and can double its birth weight before iron stores are depleted. Breast milk is low in iron (0.2–0.4 mg l<sup>-1</sup>), and even though this iron is well utilized, infants breastfed for longer than 4–6 months without receiving iron supplements or iron-fortified complementary foods are at a risk of developing iron deficiency anemia. After that age and through the first years of life, when the growth rate continues to be high, the iron requirements are higher than during any period later in life. Therefore, the introduction of iron-rich complementary food is essential to prevent iron deficiency. Compared to term infants, preterm infants have lower body iron and hemoglobin contents at birth, as well as serum and storage iron. Iron stores may be depleted already during the first months of life, coinciding with the onset of erythropoiesis and catch-up growth. In very low birth weight infants, iron losses due to phlebotomy can amount to 6 mg kg<sup>-1</sup> per week. Therefore, in contrast to term infants, in whom iron deficiency typically develops after the first half of infancy, preterm infants are at a risk of iron deficiency already during the first half of infancy. Preterm infants of short gestational age or of lower birth weight

are at a particular risk of developing iron deficiency as are preterm infants in low-income countries and those exclusively breastfed without iron supplementation. Maternal iron deficiency does not appear to compromise the iron endowment of their infants, but severe iron deficiency, i.e., iron deficiency anemia, does have an adverse effect on iron status of the newborn. Infants of moderately and severely anemic mothers have lower iron stores and a threefold increased risk of low birth weight, placing them at a higher risk of iron deficiency at an early age. The timing of umbilical cord clamping also affects the iron endowment of the newborn. Early cord clamping decreases iron transfer to the infant, whereas delayed cord clamping increases the red cell volume in the infants and, in turn, increases the iron endowment.

### Clinical Assessment of Iron Status

With adequate iron status, there is sufficient iron to meet all of iron's functional roles and a small reserve of storage iron that can be mobilized when needed (Figure 5). Excessive body iron, stored in the liver and bone marrow, is marked by elevated serum ferritin and also serum iron and transferrin saturation. Ferritin in plasma corresponds well with body iron stores, but its use as an indicator is limited under inflammatory conditions, which increase circulating ferritin concentrations. Iron deficiency occurs when iron stores are depleted and the iron transported for physiological function is reduced. Iron deficiency without anemia is commonly detected by abnormal values for two out of three blood indices, usually serum ferritin, transferrin saturation, and free erythrocyte protoporphyrin. The ratio of serum transferrin receptor to serum ferritin is considered a single, sensitive indicator of iron status across the full range of body iron status, except under conditions of inflammatory stress and during infancy (Figure 5). As iron deficiency becomes more severe, iron deficiency anemia results, with small, pale erythrocytes and reduced blood hemoglobin and hematocrit. The cut-off values used for different age groups when defining anemia and iron deficiency, respectively, may need some further consideration. A study on Swedish adolescents has pointed out how the cut-off values chosen to define anemia (hemoglobin) and iron deficiency (serum ferritin) affect the prevalence of these conditions. This dilemma is even more pronounced in infants and young children for whom appropriate reference values largely are missing and few attempts have been made to establish the appropriate cut-off values. Attempts have recently been made to establish age-appropriate cut-off values for infants with the conclusion that the prevalences of iron deficiency and iron deficiency anemia may have been overestimated.

## Iron Nutrition

### Iron Deficiency

Iron deficiency is the most common nutrient deficiency, affecting as many as two-thirds of all children and women of child-bearing age worldwide. It has been estimated that iron deficiency severe enough to cause anemia affects 20–25% of infants and as many as 40% of women and 25% of men. Iron deficiency occurs in industrially developed and developing countries. In the United States, 9–11% of toddlers, adolescent girls, and women of child-bearing age have iron deficiency, and 2–4% have iron deficiency anemia. The prevalence of iron deficiency is approximately doubled in US black and Hispanic women. The magnitude of this problem, however, is related not only to the socio-economic status of the population studied, but also how iron deficiency and anemia are defined (see Section on Clinical Assessment of Iron Status). UNICEF estimated that 40–50% of children below 5 years of age in low-income countries suffer from iron deficiency. Some estimates indicate that even in affluent societies it can be as high as 30% or as low as 5%, or less.

### Consequences of Iron Deficiency

Iron deficiency adversely affects pregnancy, impairs early childhood development, and cognitive function, and reduces the ability to do physical work. These serious problems are almost exclusively associated with iron deficiency severe enough to cause anemia; however, small reductions in exercise capacity, detectable in a laboratory setting, are also detectable in women with low iron stores and no anemia.

### Physical Work Capacity

Iron deficiency anemia adversely affects physical work capacity, reflecting the element's key role in oxygen and energy utilization. Maximal oxygen consumption during exercise is reduced, in association with decreased muscle myoglobin and other iron-containing enzymes. Iron supplementation has improved productivity among Guatemalan sugar and coffee plantation workers, Indian tea pickers, and Indonesian road construction workers and rubber tappers. Iron supplementation programs are clearly cost-effective in addition to providing a positive impact on human health and well-being.

### Cognitive Development

In infants, iron deficiency anemia has been associated with reduced mental and motor test scores and behavioral changes. This impaired mental and motor functioning appears to persist after treatment with iron, emphasizing the need for early detection and treatment and preferably prevention of iron deficiency during early development. However, it should be noted that iron deficiency in children is associated with a large number of psychosocial and economic disadvantages, which could account for some or all of the children's functional deficits. There are relatively few double-blind randomized-controlled trials of iron supplementation

with adequate power, but there is considerable evidence showing that children with iron deficiency anemia usually have poor cognitive and motor development and that iron supplementation usually has beneficial effects on motor development in children with iron deficiency anemia under 3 years of age and on cognition in iron-deficient anemic school-aged children.

### **Reproduction**

Iron deficiency anemia has been associated with premature birth and low birth weight. Iron supplementation during pregnancy is not always completely effective in preventing maternal anemia in women with low iron stores early in gestation, leading to suggestions for promoting adequate iron stores in all women of child-bearing age before conception.

### **Other**

Iron deficiency increases the susceptibility to lead poisoning. It may also impair resistance to infection and regulation of body temperature. Iron deficiency has been associated with the eating of nonfood material (pica) or ice (pagophagia). Clinical signs may include spoon-shaped fingernails and abnormalities of the mucosa of the mouth and gastrointestinal tract.

### **Recommended Dietary Intakes**

The US and Canadian recommended iron intakes are intended to meet the requirements of 97.5% of the healthy population, replacing excreted iron and maintaining essential iron functions with a minimal supply of body iron stores. They also assume a relatively high bioavailability of the dietary iron. The recommended 8 mg daily for adult men and postmenopausal women can easily be met with varied Western-style diets. More careful food choices are needed to obtain the 18 mg recommended to meet requirements for 97.5% of adult menstruating women. This higher recommendation reflects the high menstrual iron losses of some women; the median iron requirement is 8.1 mg for menstruating women.

During pregnancy, dietary iron recommendations are increased to 27 mg daily, based on the iron content of the fetus and placenta (approximately 320 mg) and the expanded blood volume associated with a healthy pregnancy. Meeting this recommendation generally requires iron supplementation. Supplementation with 30–60 mg daily is commonly recommended. Lactation has minimal impact on maternal iron balance and recommendations, largely due to lactational amenorrhea.

The high iron requirements of early growth put infants and toddlers at a risk of iron deficiency. Breast-feeding is recommended for the first year of life. Although iron in breast milk is relatively low ( $0.35 \text{ mg l}^{-1}$ , or 0.27 mg daily), it is well absorbed, possibly mediated by lactoferrin. Breast milk alone is assumed to be adequate for the first 6 months of infancy, with the addition of iron-rich foods in the next 6 months. When infant formula is used, iron fortification of the formula is recommended. Most infant formulas contain 4–12 mg of iron per liter, which is at least 10–30 times higher than the level of iron in breast milk. It may be questioned whether infant formula used during the first 6 months of life should contain a vast excess of iron, which provides no benefit in order to cover perceived increased iron requirements during 6–12 months of age. In areas where the same type of infant formula is used during the first 12 months of age, increasing the level of iron fortification in complementary foods may be an alternative possibility, whereas in areas where different types of infant formulas are used between 0–6 and 6–12 months of age, the follow-on formula may have a higher level of iron fortification. Reflecting the high but decreasing growth rate, the recommended daily intake of iron is 11 mg for infants 7–12 months, 7 mg for children between 1 and 3 years, and 10 mg for children between 4 and 8 years of age. There is no recommended intake for infants 0–6 months old, only an adequate intake (AI), which is  $0.27 \text{ mg day}^{-1}$  and based on the mean iron intake of exclusively breastfed infants. Iron stores are low in preterm infants as they are built during the last trimester of pregnancy. Iron supplementation and blood transfusion are therefore routinely used to prevent iron deficiency anemia in this population. The proper level and timing of iron supplementation is still controversial, but the ESPGHAN Committee on Nutrition recommends an intake of  $2\text{--}3 \text{ mg kg}^{-1}$  per day, corresponding to 1.8–2.7 mg per 100 kcal, and that prophylactic enteral iron should be started at 2–6 weeks of age (2–4 weeks in extremely low birth weight infants).

Western dietary recommendations have been based on mixed diets with a relatively high bioavailability of iron and may need to be increased twofold or more for low-meat, plant-based diets with greater phytic acid content (see section Bioavailability). Other factors that may increase dietary requirements include achlorhydria, which decreases iron absorption, hookworm, or other parasites that increase gastrointestinal blood loss, or intrauterine contraceptive devices that may increase menstrual losses by 30–50%. In contrast, hormonal contraceptives reduce iron requirements by reducing menstrual losses by approximately 50%.

## **Dietary Iron**

### **Food Sources**

Typical Western diets contain approximately 6 mg iron per 1000 kcal. Men and women consume approximately 16–18 and 12–14 mg daily, respectively. In the United States, 24% of dietary iron is supplied by breads, pasta, and bakery products. An additional 21% comes from (mostly fortified) cereal products. Other abundant dietary sources are red meats (9% from beef), poultry, legumes, and lentils. In countries such as the United States, fortification practices increase the influence of grain and cereal products as sources of iron. In countries without fortification to at least replace the iron lost during milling, the refinement of grain products considerably reduces dietary iron content. The populations of developing countries that eat little meat and do not include legumes or lentils as a dietary staple are at an increased risk of inadequate iron intake.

### Bioavailability

In underdeveloped countries, diets may be inadequate in both iron content and bioavailability (the amount that is absorbed and utilized by the body). However, the bioavailability of iron can be more important than the iron content in determining the amount of iron absorbed from food. Diets with similar total iron contents can differ 8–10-fold in the amount of absorbable iron. Dietary iron bioavailability is high from refined Western diets containing meat, poultry, and fish and abundant sources of ascorbic acid with low consumption of phytic acid from whole grains and legumes and limited drinking of coffee and tea with meals. On average, men absorb 1 mg daily from such diets, and women, with their lower iron stores, absorb approximately 2 mg. Individuals may absorb considerably more or less, depending on their body iron stores (Figure 2). It has been shown in adults that iron status is the strongest regulator of iron absorption. However, iron homeostasis in infants may not be fully developed.

It has been shown that iron absorption was similar in iron-supplemented and unsupplemented 6-month-old healthy, exclusively breast-fed infants born at term, whereas at 9 months of age, unsupplemented infants had considerably higher iron absorption. This strongly suggests that homeostatic regulation of iron absorption is absent in young infants but matures and is present at 9 months of age.

### Heme Iron

Approximately 10%, or 1–2 mg, of the iron in a mixed, Western diet is in the well-absorbed heme form. Heme iron accounts for approximately 40% of the iron in meat, poultry, or fish flesh. There is little to no heme iron in dairy products, or foods of plant origin. Heme iron is absorbed as an intact porphyrin structure. Heme iron absorption is enhanced by meat, poultry, or fish but it is not influenced by the other enhancers and inhibitors of nonheme iron absorption. Meat can be a significant source of heme iron for older infants and children and has a positive effect on iron status.

### Nonheme Iron

Nonheme iron usually accounts for 85–100% of dietary iron. In contrast to heme iron, the absorption of nonheme iron is substantially influenced by dietary enhancers and inhibitors consumed concurrently. These factors appear to affect the solubility of a single exchangeable pool of nonheme iron absorbed from the intestinal digesta.

Absorption of nonheme iron is enhanced by ascorbic acid, which reduces ferric iron to ferrous iron, resulting in a soluble iron–ascorbic acid complex. Enhanced absorption has been demonstrated with synthetic and several food sources of ascorbic acid. The enhancement increases logarithmically with the dose, approximately doubling absorption with as little as 25 mg of ascorbic acid and increasing absorption by nearly 10-fold with 1000 mg of ascorbic acid.

Nonheme iron absorption is also enhanced by concurrently consuming meat, poultry, or fish. Despite intensive study, the factor responsible for this enhancement by animal flesh has not been identified and may involve the general matrix of low-molecular-weight peptides released during digestion.

Nonheme iron absorption is reduced by phytic acid (inositol hexaphosphate), present in legumes, rice, and grains, that binds iron and makes it insoluble. Both phytate and iron are concentrated in the aleurone layer and germ of grains, and they are reduced with milling, which increases the bioavailability of the remaining iron. An additional unidentified factor in soy beans, independent of the phytic acid, also impairs iron absorption. Polyphenols in grains, fruits, and vegetables, and including the tannins in tea and coffee, also inhibit nonheme iron absorption. Ascorbic acid consumed concurrently can partially reduce the inhibition of nonheme iron absorption by both phytic acid and polyphenols. Calcium in supplemental quantities has been shown to inhibit both heme and nonheme iron absorption from foods in short term studies but shows no effect on long-term iron status.

### Supplementation and Fortification

The serious international problem of iron deficiency has been met with limited success by supplementation and fortification efforts. Both approaches suffer from difficulties in delivery and acceptance. Supplements that readily ionize into the ferrous form, such as ferrous sulfate, ferrous fumarate, or ferrous gluconate, are highly bioavailable but may cause gastrointestinal discomfort. Iron injections are poorly tolerated and can result in serious infections. Because daily supplementation reduces the physiological efficiency of iron absorption, routine weekly iron supplementation with 60 mg iron has been suggested in developing countries for women of child-bearing age, beginning in adolescence. Menstruating women in more affluent countries are advised to undergo an assessment from a health professional before taking iron supplements in excess of 20 mg daily.

Fortification of staple foods with 3–10 mg iron daily, depending on the needs of the population, is a long-term preventative strategy. In the United States, bread and cereal products are routinely fortified with 20 mg iron per pound (460 g) of flour, and additional fortification at the option of food suppliers is common. However, fortification is difficult when food processing is decentralized, as is common in low-income countries. Food fortification carries the additional challenge that the chemical forms of iron most bioavailable also tend to be the most reactive with the food fortified, resulting in adverse changes in flavor, color, and shelf-life. Promising approaches include the fortification of food sauces with iron chemically bound with amino acids or with EDTA (sodium iron ethylenediaminetetraacetic acid), from which it is well absorbed even in the presence of phytic acid. Elemental iron powders, commonly referred to as carbonyl, electrolytic, and reduced forms of iron, are relatively inert in foods and inexpensive, but their bioavailability may be 30–80% less than iron from ferrous sulfate, depending on the dissolution in the gastrointestinal tract. Ferric orthophosphate and ferric pyrophosphate do not adversely affect foods but are poorly bioavailable; however, efforts are under way

to enhance their bioavailability by reducing the particle size and encapsulating the particles with various lipids or carbohydrates to prevent agglomeration.

The form of iron given to infants may affect indicators of iron status differently. It has been shown that infants provided iron-fortified cereals between 6 and 9 months of age had significantly higher hemoglobin concentrations than infants given the same amount of iron daily in the form of iron drops. Similarly, it has been found that the addition of meat at 8 months of age had a positive effect on hemoglobin but not on serum ferritin. In contrast, infants given iron drops had significantly higher serum ferritin concentrations than those fed iron-fortified cereals. This suggests that dietary iron and iron from supplements are metabolized differently, with the latter preferentially being deposited in stores, whereas iron in meat and fortified foods is incorporated into erythrocytes. Further studies are needed to elucidate the mechanisms behind these observations.

### Excessive Intakes

An extensive biological control system limits the occurrence of free ionic iron that can readily participate in toxic, free radical-producing reactions. Large quantities of ingested iron are acutely toxic, and accidental ingestion of medicinal iron preparations is a cause of poisoning deaths in young children. Iron supplementation is also associated with gastrointestinal irritation. Iron supplements also adversely affect absorption of zinc. Iron absorption is well controlled, but iron overload can result from excessive parenteral iron administration or blood transfusions. Dietary iron overload, possibly exacerbated by genetic factors, occurs in sub-Saharan tribes that consume a high-iron traditional beer prepared and stored in iron containers. Genetic factors can substantially influence body iron retention, as indicated by hemochromatosis, a relatively frequent iron storage disorder of northern European descendants characterized by excessive iron absorption and leading to life-threatening iron damage of organs in adulthood. The possible association of high iron stores with increased risk of diseases related to oxidative stress, including cardiovascular disease, diabetes, and cancer, is an area of epidemiological investigation.

Iron overload as such has not been recognized in term human infants, and is only implicated in premature infants with a known, or feared, consequence of increased iron-associated oxidative damage. Indications of excessive iron intakes by infants have recently been observed in some studies. An adverse effect of iron supplements on linear growth has been shown in iron-replete infants in both affluent and developing countries. Other studies have shown negative effects of iron supplements on weight gain. However, the nutritional status of the infants in those studies was compromised overall, which is known to decrease linear growth and cause stunting. Thus, when linear growth is compromised, it is possible that the adverse effect of excess iron is manifested differently and instead impairs weight gain. The mechanism(s) behind the adverse effect of excess iron is still not known, but may involve the pro-oxidative effects of excess iron or, possibly, an interaction between iron and nutrients involved in growth, such as zinc.

### Key points

- Discuss the types of lipids found in foods and the human body.
- Summarize the fatty acid profile in different types of common dietary fats.
- Discuss the major contributors of different types of lipids to the diet.
- Review the relation between dietary lipids and cardiovascular disease; amount and types
- Summarize current dietary guidance with respect to dietary fat for the prevention and treatment of cardiovascular disease.

### Glossary

**$\omega$ -3 Fatty acid** Polyunsaturated fatty acids in which the first double bond in the acyl chain is three carbons from the methyl end. Of the common dietary  $\omega$ -3 fatty acids, carbon chain lengths range from 18 to 22 carbons. Soybean and canola oils contain  $\alpha$ -linolenic acid (ALA, 18:3); fish, seafood and algae contain eicosapentaenoic acid (EPA, 20:5) and docosaheptaenoic acid (DHA, 22:6)

**Atherosclerotic plaque** Accumulation of cholesterol in blood vessel walls forming atherosclerotic plaques. Atherosclerotic plaques can narrow the vessel lumen and impede blood flow, and/or trigger formation of blood clots that can subsequently occlude blood flow, resulting in angina, heart attack, stroke or phlebitis

**Dietary cholesterol** Fat-soluble compound found in animal fats, and is particularly high in eggs. It is a critical component of cell membranes, maintaining fluidity, and lipoproteins, maintaining structure. Cholesterol serves as a substrate for steroid hormones, bile acids, and vitamin D synthesis. In cholesterol-sensitive individuals, high intake of dietary cholesterol is associated with elevated plasma low density lipoprotein (LDL) cholesterol concentrations and cardiovascular disease risk

**Dietary fat** Macronutrient which provides 9 kcal g<sup>-1</sup>. Hydrophobic component of food. Primarily in the form of triglyceride. Also includes cholesterol, fat soluble vitamins and phospholipids

**Lipoproteins** Spherical particles with a hydrophilic surface composed primarily of phospholipid, apoproteins and unesterified cholesterol, and hydrophobic core composed primarily of triacylglycerol (triglyceride) and cholesteryl ester. Particles facilitate the transport of lipid in the aqueous milieu of the blood stream to peripheral tissue for subsequent metabolism or storage

**Monounsaturated fatty acid** Fatty acid containing a single double bond in the acyl chain. Oils rich in monounsaturated fatty acids are usually liquid at room temperature and semi-solid at refrigerator temperature. When fats rich in monounsaturated

fatty acids replace fats rich in saturated fatty acids in the diet, cardiovascular disease risk is lowered. Common dietary sources are canola and olive oils

**Polyunsaturated fatty acid** Fatty acid containing two or more double bonds in the acyl chain. Oils rich in polyunsaturated fatty acids are liquid at room and refrigerator temperatures. When fats rich in polyunsaturated fatty acids replace fats rich in saturated fatty acids in the diet, cardiovascular disease risk is lowered. Common dietary sources include soybean, corn, and unmodified safflower and sunflower oils

**Saturated fatty acid** Fatty acid containing no double bonds in the acyl chain. Fats rich in saturated fatty acids are usually solid at room and refrigerator temperatures. Diets high in saturated fatty acids and low in monounsaturated and polyunsaturated fatty acids are associated with elevated cardiovascular disease risk. Common dietary sources include fatty cuts of meat and full fat dairy products

**Trans fatty acid** Monounsaturated or polyunsaturated fatty acid in which at least one double bond is in the *trans*, rather than *cis*, configuration. There are two main sources of dietary *trans* fatty acids: animal fat and partially-hydrogenated fat. Recently, due to regulatory changes in Nutrient Facts labels and the FDA's Generally Recognized as Safe (GRAS) list, the latter has been a dramatic decrease in the food supply. Dietary *trans* fatty acids are associated with elevated cardiovascular disease risk

**Triacylglycerol (triglyceride)** Triacylglycerol is the major form of dietary lipid in fats and oils, whether derived from plants or animals, and the major form of lipid in the body. Triacylglycerol is composed of three fatty acids esterified to a glycerol molecule

Dietary fat is a macronutrient that has historically engendered considerable controversy and continues to do so. Contentious areas include optimal amount and type for cardiovascular disease risk reduction, and role in body weight regulation.

## Dietary fats and oils—the good, bad, and ugly

### Introduction

Dietary fats and oils are unique in modern times because they encompass good, bad, and ugly characteristics. The aspects of dietary fat that are classified as good include serving as a carrier of fat soluble vitamins (vitamins A, D, E, and K), enhancing the bioavailability of fat-soluble bioactive substances (e.g., absorption of fat-soluble micronutrients), providing essential substrate for the synthesis of metabolically active compounds (e.g., eicosanoid, vitamin D and bile acids), providing critical structural components (e.g., cell membranes and lipoprotein particles), preventing carbohydrate-induced hypertriglyceridemia, insulating the body against extreme temperature changes, cushioning vital organs, and serving an energy-dense form of reserve metabolic fuel (triacylglycerol [triglyceride]). The aspect of dietary fat that are classified as bad include serving as a reservoir for fat-soluble toxic compounds (adipose tissue in our bodies and fats we eat [e.g., fish]). The aspects of dietary fat that are classified as ugly include providing a concentrated form of metabolic fuel in times of excess and contributing saturated and *trans* fatty acids that promote atherosclerotic plaque formation, the underlying cause of heart disease, stroke, and phlebitis.

## Lipids—in food and in the body

### Fatty acids

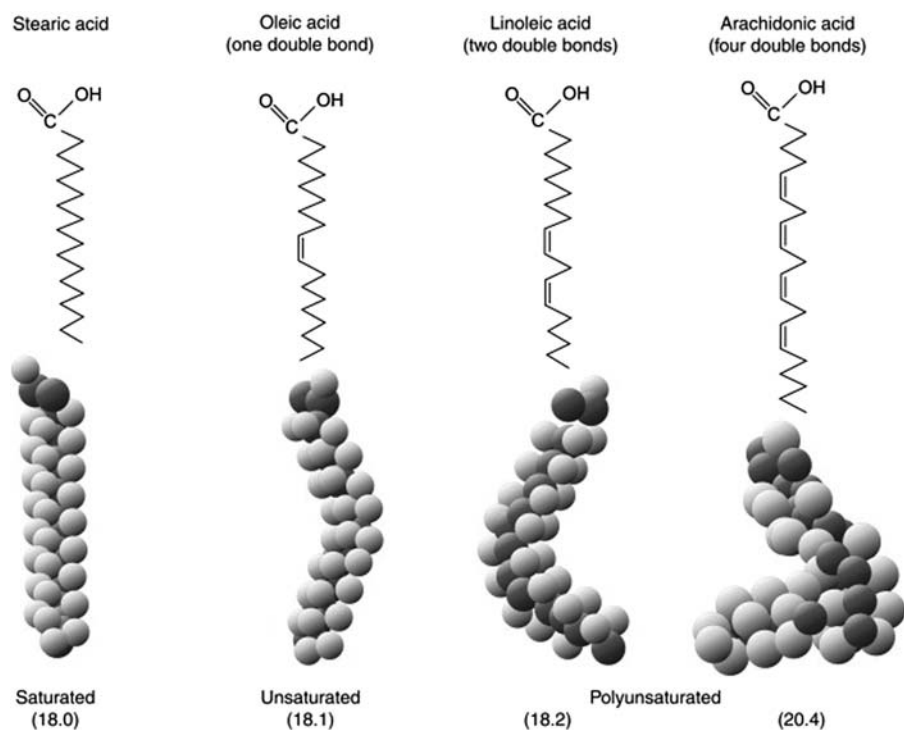

Fatty acids are the basic components of larger lipid compounds or serve as substrates for bioactive molecules. They are composed of an acyl (hydrocarbon) chain with a methyl and a carboxyl group at either end. The majority of fatty acids have an even number of carbons. The range of chain lengths for common fatty acids is broad, 12–22 carbons, although shorter- and longer-chain fatty acids occur naturally. The predominant fatty acids in the human body and food are depicted in [Table 1](#). In addition to chain length, fatty acids differ from each other in number, type, and location of double bonds. Fatty acids with no double bonds are referred to as saturated, with one double bond as monounsaturated, and with two or more double bonds as polyunsaturated fatty acids ([Fig. 1](#)).

The double bonds within unsaturated fatty acids, either monounsaturated or polyunsaturated, can be in either the *cis* (hydrogen atoms on same side of the acyl chain) or *trans* (hydrogen atoms on opposite sides of the acyl chain) conformation ([Fig. 2](#)). The presence of a *cis* relative to a *trans* double bond results in a greater bend or kink in the hydrocarbon chain. This kink impedes the fatty acids from aligning (packing together). In a cell membrane, this results in a higher level of fluidity; in food, it results in oils that are liquid or fats that are soft at room temperature. The vast majority of fatty acid double bonds occur in the *cis* conformation. Fatty acids with an identical number of carbons atoms and double bonds, but differ structurally are referred to as isomers. If the difference is in the conformation of the double bond, they are referred to as geometric isomers (e.g., oleic acid (18:1*cis*) and elaidic acid (18:1*trans*)) ([Fig. 2](#)).

If the difference is in the location of a double bond in the acyl chain, they are referred to as positional isomers (e.g.,  $\alpha$ -linolenic acid [18:3*n*-3] and  $\gamma$ -linolenic acid [18:3*n*-6]) ([Fig. 2](#)). Fatty acids in which the first double bond from the methyl end of the acyl chain occurs at the sixth carbon are termed an  $\omega$ -6 (*n*-6) fatty acids (e.g., linoleic acid [18:2*n*-6] and  $\gamma$ -linolenic acid [18:3*n*-6]). Fatty acids in which the first double bond from the methyl end of the acyl chain occurs at the third carbon are termed an  $\omega$ -3 (*n*-3) fatty

**Table 1** Common fatty acids.

<i>Code</i>	<i>Common name</i>
<b>Saturated</b>	
12:0	Lauric acid
14:0	Myristic acid
16:0	Palmitic acid
18:0	Stearic acid
<b>Monounsaturated</b>	
16:1 <i>n</i> -7 <i>cis</i>	Palmitoleic acid
18:1 <i>n</i> -9 <i>cis</i>	Oleic acid
18:1 <i>n</i> -9 <i>trans</i>	Elaidic acid
<b>Polyunsaturated</b>	
18:2 <i>n</i> -6,9 all <i>cis</i>	Linoleic acid
18:3 <i>n</i> -3,6,9 all <i>cis</i>	$\alpha$ -linolenic acid
18:3 <i>n</i> -6,9,12 all <i>cis</i>	$\gamma$ -linolenic acid
18:4 <i>n</i> -3,6,9,12,15 all <i>cis</i>	Stearidonic acids
20:4 <i>n</i> -6,9,12,15 all <i>cis</i>	Arachidonic acid
20:5 <i>n</i> -3,6,9,12,15 all <i>cis</i>	Eicosapentaenoic acid
22:5 <i>n</i> -3,6,9,12,15 all <i>cis</i>	Docosapentaenoic acid
22:6 <i>n</i> -3,6,9,12,15,18 all <i>cis</i>	Docosahexaenoic acid

**Fig. 1** Structures of saturated, monounsaturated, and polyunsaturated fatty acids.

acids (e.g., eicosapentaenoic acid [20:5*n*-3] and  $\alpha$ -linolenic acid [18:3*n*-3]). Most double bonds occur in a nonconjugated sequence, that is, a carbon atom with only single carbon-carbon bonds separates carbon atoms that are part of double bonds. Some double bonds occur in the conjugated form, without an intervening carbon separating carbons as part of double bonds. Conjugated double bonds tend to be more reactive chemically (e.g., more likely to become oxidized). The vast majority of enzymes that metabolize fatty acids distinguish not only on the basis of chain length and number of double bonds, but among isomers. The metabolic products of different fatty acid isomers, especially positional isomers, have distinct and at times opposing biological effects.

Some fatty acids are classified as an essential nutrient. An essential nutrient is a nutrient that the body cannot synthesize or cannot synthesize in amounts adequate to meet requirements. Linoleic acid (18:2*n*-6) and linolenic acid (18:3*n*-3) and their derived fatty acids are essential because unlike plants, humans cannot introduce a double bond after the ninth carbon in a fatty acyl chain (from the carboxyl end).

**Fig. 2** Examples of fatty acids geometric isomers (*trans*-oleic acid and *cis*-oleic acid) and positional isomers ( $\alpha$ -linolenic acid and  $\gamma$ -linolenic acid).

### Triacylglycerol (triglyceride)

Triacylglycerol is the predominant form of dietary lipid in fats and oils, whether derived from plants or animals, and the major form of lipid in the body. Triacylglycerol is composed of three fatty acids esterified to a glycerol molecule (Fig. 3). The physical properties of a triacylglycerol molecule are determined by the specific fatty acids esterified to the glycerol moiety and the actual position the fatty acids occupy. Each of the three carbons comprising the glycerol molecule allows for a stereochemically distinct fatty acid bond position: *sn*-1, *sn*-2, and *sn*-3. A triacylglycerol with three identical fatty acids is termed a simple triacylglycerol. These are exceedingly rare in nature. A triacylglycerol with two or three different fatty acids is termed a mixed triacylglycerol and make up the bulk of the triacylglycerol that occur naturally. The melting point of a triacylglycerol is determined by the physical characteristics and position of the fatty acids esterified to glycerol,—their chain length; number, position, and conformation of the double bonds; and the stereochemical position.

Approximately 90% of the molecular weight of triacylglycerol is accounted for by the three fatty acids. The fatty acid profile of the diet is reflected, in part, in the fatty acid profile of the adipose tissue triacylglycerol. Such data have been used to approximate long-term food intake patterns of humans.

**Fig. 3** Triacylglycerol molecule.

Mono- and diglycerides have one and two fatty acids, respectively, esterified to glycerol. In nature, they occur only in trace amounts. They are primarily intermediate products of triacylglycerol digestion, clearance from the bloodstream, or intracellular metabolism. They are used as emulsifiers in processed food.

Once consumed, triacylglycerol is hydrolyzed into non-esterified (free) fatty acids and monoglycerides by lipase that are synthesized in the pancreas and stored in the gallbladder until lipid in the small intestine signals for release. During absorption, these breakdown compounds enter the intestinal cells (enterocyte) and are used to resynthesize triacylglycerol. This triacylglycerol, along with intestinally derived cholesterol and fat soluble compounds such as fat soluble vitamins, are incorporated into nascent triglyceride-rich lipoprotein particles, termed chylomicrons. Chylomicrons are first secreted into the thoracic duct (lymph) which drains into the subclavian vein (peripheral circulation). Once in circulation, fatty acids are hydrolyzed from the triacylglycerol which enables them to cross the plasma membrane of peripheral cells. The primary enzyme that hydrolyzes triacylglycerol in plasma is lipoprotein lipase. The products of lipoprotein lipase are non-esterified fatty acids and 2-monoacylglycerol. The enzyme is attached to the luminal surface of capillary endothelial cells via a highly charged membrane-bound chain of heparin sulfate-proteoglycans. The ability of lipoprotein lipase to bind both the chylomicron particle and the cell surface ensures the cellular uptake of the liberated non-esterified fatty acids. Once inside the cell, the non-esterified fatty acids can be oxidized to provide energy, metabolized to biologically active compounds, or resynthesized into triacylglycerol for storage and subsequent use.

### Phospholipid

There are only trace amounts of phospholipid in dietary fats and oils. However, because the fatty acids in fats and oils provide substrate for the endogenous synthesis of phospholipid for the subsequent synthesis of cell membranes and lipoprotein particles, this subtype of fat is important to discuss. Phospholipid is composed of two fatty acids esterified to the *sn*-1 and *sn*-2 positions and a moiety frequently referred to as a polar head group is esterified to the *sn*-3 position of glycerol, the latter group via a phosphate bond (Fig. 4). Phospholipid molecules are amphipathic, that is, there are both hydrophobic and hydrophilic domains in the molecule. The two fatty acids confer hydrophobic properties and the polar head group confers hydrophilic properties. The specific fatty acids esterified to the glycerol backbone of phospholipid tend to be unsaturated. The most common polar head groups include phosphorylcholine, phosphorylserine, phosphorylinositol, and phosphorylethanolamine. In cells, because of their amphipathic nature, phospholipid form bilayers. These bilayers are the structural components of both plasma and intracellular membranes, and serve as a platform for proteins and cholesterol that sit either within or on the surface of the bilayers. The more unsaturated the fatty acids in phospholipid, the more fluid the membrane. The degree of fluidity can affect the activity of proteins located in the membrane (e.g., enzyme activity, receptor ligands). Cell membrane phospholipid also serves as a reservoir for metabolically active fatty acids. In the small intestine, phospholipids, because of their amphipathic properties, plays a critical role facilitating the emulsification of intestinal fat, subsequent formation of micelles and absorption of lipid compounds. As a monolayer on the surface of lipoprotein particles, phospholipids provide a critical component in the packaging and transport of lipid in circulation.

### Cholesterol

Dietary sources of cholesterol are limited to foods of animal origin. Cholesterol is an amphipathic molecule that is composed of a steroid nucleus and a branched hydrocarbon tail (Fig. 5). Cholesterol occurs naturally in two forms: non-esterified (free cholesterol) and esterified (cholesteryl ester). If esterified, the fatty acid is linked to cholesterol at the number 3 carbon of the sterol ring.

Non-esterified cholesterol is a component of cell membranes and along with degree of phospholipid fatty acid saturation, determines membrane fluidity. The more unsaturated, the more fluid. Cholesterol intercalates into the phospholipid bilayer restricting motility of the fatty acyl chains and decreases fluidity. In synaptic membranes, non-esterified cholesterol is critical for normal nerve

**Fig. 4** Phospholipid molecule (phosphatidylcholine).

**Fig. 5** Cholesterol molecule.

transmission. It makes up approximately 10% (dry weight) of total brain lipids. Cholesterol is a precursor of steroid hormones (e.g., estrogen, testosterone), vitamin D, adrenal steroids (e.g., hydrocortisone, aldosterone), and bile acids. This latter property is exploited in certain approaches to decrease elevated plasma LDL cholesterol concentrations by preventing the resorption of bile acids (recycling), hence, forcing the liver to use additional cholesterol for bile acid synthesis. In so doing, a potential route for net cholesterol excretion is expanded.

The receptor-mediated cellular uptake of cholesterol laden plasma lipoprotein particles is critical in maintaining intracellular and whole-body cholesterol homeostasis. Once internalized, the cholesterol component of lipoprotein particles is hydrolyzed to non-esterified cholesterol. This internalized cholesterol has three major metabolic effects. One, it inhibits the activity of 3-hydroxy 3-methylglutaryl CoA (HMGCoA) reductase, the rate-limiting enzyme in endogenous cholesterol biosynthesis. This property serves to decrease the rate of intracellular cholesterol biosynthesis commensurate with the uptake of cholesterol from extracellular sources (plasma lipoproteins), thereby minimizing intracellular accumulation. Two, intracellular non-esterified cholesterol inhibits the synthesis of receptors that take up lipoprotein particles containing apoproteins B100 or E from the plasma, thereby limiting cholesterol accumulation in the cell and avoiding excess accumulation. Lastly, intracellular non-esterified cholesterol increases the activity of acyl CoA cholesterol acyltransferase (ACAT), the intracellular enzyme that converts non-esterified cholesterol to cholesteryl ester. A high level of intracellular non-esterified cholesterol is cytotoxic, whereas cholesteryl ester is a highly nonpolar molecule that coalesces to form intracellular lipid droplets, averting high concentrations of non-esterified cholesterol interacting with intracellular components and having subsequent detrimental effects. ACAT uses primarily oleoyl CoA as substrate, resulting in the synthesis of cholesteryl oleate.

Non-esterified cholesterol can be not only esterified intracellularly but also in plasma. The reaction is catalyzed by the enzyme lecithin cholesterol acyltransferase (LCAT). The source of fatty acid is phosphatidylcholine. The products of LCAT are cholesteryl linoleate and lysolecithin. The resulting apolar cholesteryl ester migrates to the core of the lipoprotein particle.

Cholesterol in circulation is carried on all lipoprotein particle species: both intestinally derived chylomicrons and hepatically derived very LDL, intermediate-density lipoprotein, and high-density lipoprotein (HDL) particles. Non-esterified cholesterol is incorporated into the phospholipid monolayer surface of lipoprotein particles, whereas cholesteryl ester is incorporated into the core of lipoprotein particles. The majority of the cholesterol in circulation is carried on LDL. Cholesteryl ester is the major component of atherosclerotic plaque. In the arterial wall, cholesteryl ester is either derived from the infiltration of lipoprotein-associated cholesteryl ester resulting from LCAT activity or synthesized *in situ* as a result of ACAT activity. The fatty acid profile of the cholesteryl ester in arterial plaque can provide an indication of its origin.

Historically, dietary cholesterol has been associated with elevated LDL cholesterol concentrations and cardiovascular disease risk. However, within the range currently consumed in Western countries and on the basis of data indicating that dietary fat type has a greater effect on cardiovascular disease risk factors than dietary cholesterol, the emphasis has shifted (Carson et al., 2020). Hence, for the general public, target intakes have not been included in updated dietary guidance, however, recommendations not to increase intake have been included.

### Other sterols

Oils derived from plants contain a wide range of phytosterols, compounds structurally similar to cholesterol. The difference between phytosterols and cholesterol is related to their side-chain configuration and steroid ring double bonds. The most common dietary phytosterols found in edible oils are  $\beta$ -sitosterol, campesterol, and stigmasterol (Fig. 6). In contrast to cholesterol, phytosterols are absorbed in trace amounts. Because they compete with cholesterol for incorporation into intestinal micelles, they decrease the bioavailability of intestinal cholesterol, hence, its absorption efficiency. For this reason, plant sterols have been used therapeutically to reduce elevated plasma LDL cholesterol concentrations (Katan et al., 2003). They have been shown to have an additive effect to that of other LDL cholesterol lowering therapies, such as statins (Han, 2016). The concentration of plant sterols in plant oils is relative low. For use to treat hypercholesterolemia, doses only achievable with supplements, either from capsules or function foods, are efficacious.

**Fig. 6** Plant sterols and stanols.

## Dietary fats and oils

### Fatty acid profile of common dietary fats

Dietary fats and oils come from both animal and plant sources, primarily in the form of triacylglycerol. The fatty acid profile of commonly consumed dietary fats varies considerably (Fig. 7). In general, fats of animal origin tend to be relatively high in saturated fatty acids, contain cholesterol, and are solid at room temperature. Oils of plant origin tend to be relatively high in unsaturated fatty acids (monounsaturated and polyunsaturated) and are liquid at room temperature. Notable exceptions include tropical oils (e.g., palm, palm kernel, coconut oils) and partially-hydrogenated fat. Tropical oils are high in saturated fatty acids but remain liquid at room temperature because they contain a high proportion of very short-chain fatty acids. Partially-hydrogenated fat has a high proportion of fatty acids containing *trans* double bonds. The larger bond angle of *trans* double bonds compared to *cis* double bonds confers a straighter acyl chain conformation, more similar to saturated than unsaturated fatty acids. This results in a consistency comparable to solid animal fats than liquid plant oils.

### Major contributors of dietary saturated, monounsaturated and polyunsaturated fatty acids, and cholesterol

The major types of dietary fats and oils are generally broken down on the basis of animal and plant sources. The relative balance of animal to plant foods is an important determinant of the fatty acid profile of the diet. However, with the increasing prominence of processed, ultraprocessed, reformulated, and genetically modified foods, it is becoming difficult to predict the fatty acid profile of the diet on the basis of the animal versus plant distinction.

According to the National Health and Nutrition Examination Survey (NHANES) recall data, the 10 major dietary sources of saturated fatty acids in the US diet are regular cheese, whole milk, regular ice cream, 2% low-fat milk, pizza with meat, French fries, Mexican dishes with meat, regular processed meat, chocolate candy, and mixed dishes with beef (Table 2). Hence, regular dairy products contribute the majority (~16%) of saturated fatty acids in the diet, and the top 10 sources contribute ~30% of the saturated fatty acids consumed. The increased prevalence of fat-free and low-fat dairy products provides a viable option with which to encourage a population-wide decrease in saturated fat intake. To put the value of decreasing population-wide intakes of saturated fat into perspective, it has been estimated that the isocaloric replacement of 5% of energy from saturated fatty acids with complex carbohydrate, on average, would reduce total cholesterol concentrations by 10 mg dL<sup>-1</sup> (0.26 mmol L<sup>-1</sup>) and LDL cholesterol by 7 mg dL<sup>-1</sup> (0.18 mmol L<sup>-1</sup>). For a person at moderately high risk of developing cardiovascular disease with total cholesterol concentration of 220 mg dL<sup>-1</sup> (5.69 mmol L<sup>-1</sup>) and LDL cholesterol concentration of 140 mg dL<sup>-1</sup> (3.62 mmol L<sup>-1</sup>), such a dietary modification would decrease total and LDL cholesterol concentrations by 4.5% and 5%, respectively. Each 1% decrease in total cholesterol concentrations has been associated with a 2% reduction in the incidence of coronary heart disease. Using this example, such a difference would theoretically translate into a 9% decrease in cardiovascular disease risk. However, it is important to note that decreasing the saturated fatty acid content of the diet should not necessarily be done by replacing the fat with carbohydrate (Jakobsen et al., 2009). As will be discussed in the next section, the quantity of dietary fat, relative to carbohydrate and protein, also

**Fig. 7** Relative composition of common dietary fats.

**Table 2** Ten major sources of saturated, monounsaturated, and polyunsaturated fatty acids, and cholesterol in the US diet.<sup>a</sup>

<i>Saturated fatty acids</i>	<i>Monounsaturated fatty acids</i>	<i>Polyunsaturated fatty acids</i>	<i>Cholesterol</i>
Cheese, regular	Fried potatoes	Salad dressing, regular	Eggs, fried
Whole milk	Processed meat, regular	White bread, regular	Eggs, regular, including scrambled
Ice cream, regular	Cookies, regular	Mayonnaise, regular	Eggs, mixed dishes
2% milk	Snacks, regular	Fried potatoes	Beef, mixed dishes
Pizza with meat	Pizza with meat	Cakes, regular	Whole milk
Fried potatoes	Salad dressing, regular	Cookies, regular	Cheese, regular
Burritos/tacos with meat	Cheese, regular	Chicken/Turkey, mixed dishes	Fish, fried
Processed meat, regular	Burritos/tacos with meat	Snacks, regular	Chicken/Turkey, mixed dishes
Chocolate candy	Sausage	Potato chips, regular	Beef, lean/trimmed
Beef, mixed dishes	Beef, mixed dishes	Fish, fried	Processed meat, regular

<sup>a</sup>Ranks of food for adults older than 19 years from the NHANES recall data 1999–2000.

impacts on blood lipid concentrations and lipoprotein profiles. Current data suggest that replacing saturated fatty acids with polyunsaturated fatty acids would result in the greatest decrease in cardiovascular disease risk ([Sacks et al., 2017](#)).

The 10 major dietary sources of monounsaturated fatty acids in the US diet are French fries, regular processed meat, regular cookies, regular miscellaneous snacks, pizza with meat, regular salad dressing, regular cheese, Mexican dishes with meat, sausage, and mixed dishes with beef ([Table 2](#)).

The 10 major dietary sources of *n*-6 polyunsaturated fatty acids in the US diet are regular salad dressing, regular white bread, regular mayonnaise, French fries, regular cake, regular cookies, mixed dishes with chicken and turkey, regular miscellaneous snacks, regular potato chips, and fried fish ([Table 2](#)). The distribution of polyunsaturated fatty acids among commonly consumed foods is wide.

The 10 major dietary sources of cholesterol in the US diet are fried eggs, regular eggs including scrambled eggs, mixed dishes with eggs, mixed dishes with beef, whole milk, regular cheese, fried fish, mixed dishes with chicken and turkey, lean cut meat, and regular processed meat ([Table 2](#)). Eggs or foods high in eggs contribute ~30% of dietary cholesterol.

## Dietary fat and cardiovascular disease prevention

### Quantity of dietary fat

When considering the percentage of energy contributed by dietary fats and oils (amount of fat) and cardiovascular disease prevention and management, there are two major factors to consider, impact on body weight and plasma lipoprotein profiles. The potential relation with body weight is important because overweight and obesity are strongly associated with elevated dyslipidemia, hypertension, and type 2 diabetes. These factors are all associated with elevated cardiovascular disease risk. Plasma lipoprotein concentrations that are responsive to dietary modification include LDL and HDL cholesterol, the lipid triglyceride, and the ratio of total cholesterol to HDL cholesterol. When body weight is maintained at a constant level, decreasing the total fat content of the diet, expressed as a percentage of total energy, and replacing it with carbohydrate frequently results in an increase in triglyceride concentrations, decrease in HDL cholesterol concentrations, and higher (less favorable) total cholesterol/HDL cholesterol ratio. Low HDL cholesterol concentrations are an independent risk factor for cardiovascular disease. Very low fat diets are of particular concern to individuals with glucose intolerance and excess body weight who have a predisposition to low HDL cholesterol and high triglyceride concentrations or those individuals with metabolic syndrome (having three or more of the following: abdominal obesity, elevated triacylglycerol concentrations, low HDL concentrations, elevated blood pressure, elevated fasting glucose concentrations). Because of these findings, dietary guidance for cardiovascular disease risk reduction has shifted from low to moderate fat diets, with emphasis shifted to replacing saturated fat with unsaturated fat, particularly polyunsaturated fat. These modifications have been echoed in more recent updates of these guidelines.

With respect to the quantity of dietary fats and oils and body weight, comprehensive reviews of the long-term data have concluded that energy balance, not level or ratio of macronutrients, is the strongest determinant of body weight. Two relatively recent intervention study has concluded that there is no advantage, with respect to weight loss or cardiovascular disease risk indicators, of diets with different proportions of fat, carbohydrate, and protein ([Gardner et al., 2018](#); [Del Gobbo et al., 2018](#)). The major determinant of successful weight loss was adherence to the protocol.

### Quality of dietary fat

Early evidence demonstrated that diets relatively high in saturated fatty acids increase plasma total cholesterol concentrations. Subsequent work demonstrated that this elevation in total cholesterol concentrations is contributed to by increases in both LDL and HDL cholesterol concentrations, the former more so than the latter. Replacing saturated fatty acids with unsaturated fatty acids, monounsaturated or polyunsaturated fatty acids, is associated with lower LDL cholesterol concentrations and cardiovascular risk,

with polyunsaturated having a somewhat greater effect than monounsaturated (Hu and Willett, 2002; Sacks et al., 2017). Replacing saturated fatty acids with carbohydrate, particularly refined carbohydrate, elevates triglyceride and lowers HDL cholesterol concentrations. Observational data indicate that dietary patterns low in saturated fatty acids and high in polyunsaturated fatty acids are associated with the lowest cardiovascular disease risk (Blondin et al., 2019).

Quantitatively,  $\alpha$ -linolenic acid (ALA, 18:3 $n$ -3) is the most abundant  $n$ -3 fatty acid in the diet. Two other  $n$ -3 polyunsaturated fatty acids, sometimes referred to as the very long chain  $n$ -3 fatty acids, eicosapentaenoic acid (EPA, 20:5 $n$ -3) and docosahexaenoic acid (DHA, 22:6 $n$ -3), are present in smaller amounts. The major source of dietary ALA is canola and soybean oils. The major sources of dietary EPA and DHA is fish and seafood, specifically dark flesh fish such as salmon and mackerel. Dietary patterns higher in fish are associated with lower cardiovascular disease risk. Likewise, dietary patterns rich in oils high in ALA, such as soybean and canola oils (Fig. 7), are associated with lower cardiovascular disease risk. Although humans have the ability to elongate and desaturate ALA to form EPA and subsequently DHA, the capacity is low. Data on the benefits of supplementation with EPA and DHA have been inconsistent and more data is likely to emerge in the near future. Whether the benefit of diets rich in  $n$ -3 fatty acids on cardiovascular disease risk is due solely to direct effects of ALA, EPA and DHA or also to the additional benefits of dietary patterns rich in these fatty acids has yet to be determined. Current recommendations are to consume at least two fish meals per week, particularly those rich in EPA and DHA (salmon, mackerel) and replace fats rich in saturated fat with unsaturated fat, including those rich in ALA.

*Trans* fatty acids occur naturally in meat and dairy products as a result of anaerobic bacterial fermentation in ruminant animals (Mensink and Katan, 1990). *Trans* fatty acids are also formed as a result of the partial hydrogenation of plant oils. Oils are partially hydrogenated to increase viscosity (change a liquid oil into a semiliquid or solid) and extend shelf life (decrease susceptibility to oxidation). *Trans* fatty acid intake, regardless of the source, is associated with elevated LDL cholesterol concentrations and cardiovascular disease risk (Lichtenstein et al., 1999). Major contributors of dietary *trans* fatty acids had been commercially baked products, animal fats, traditional margarines and shortenings, and commercially fried foods. Mandatory inclusion of *trans* fatty acid content on Nutrient Facts Panels and removal of partially-hydrogenated fat from the FDA Generally Recognized As Safe list (GRAS) has resulted in secular decreased intake (Dahmubed et al., 2013). Replacing animal fat with plant oils resulted in a decrease in *trans* fatty acid intake from ruminant fat.

## Composition of dietary fats

Types of fat relatively high in saturated fatty acids include butterfat (62%), beef fat (50%), tropical oils (coconut 87%, palm kernel 81%, palm oil 49%), and lard (pork) fat (39%) (Fig. 7). The content of cholesterol in these fats is 33, 14, 0, and 12 mg tablespoon<sup>-1</sup>, respectively. Types of fat relatively high in monounsaturated fatty acids include canola oil (56%), olive oil (73%), and peanut oil (46%). Types of fat relatively high in polyunsaturated fatty acids include soybean oil (51%), corn oil (58%), and unmodified safflower oil (74%), and sunflower oil (66%). Plant oils do not contain cholesterol.

## Dietary guidance

The US government in the form of Dietary Guidelines for Americans and health advocacy organizations such as the American Heart Association and American Diabetes Association issue and update dietary guidance, including that for fats and oils (Lichtenstein et al., 2006; Evert et al., 2019). In general, current recommendations are to consume a diet moderate in total fat and rich in fruits and vegetables, whole-grain products, fish, low-fat and nonfat dairy products, legumes and nuts, and lean meat and poultry. Liquid plant oils are recommended in place of other types of fats (animal fat, partially-hydrogenated fat). Much dietary guidance now emphasizes the benefits, from a nutrition and environmental perspective, of plant-based foods. Important for any type of dietary guidance, especially when it is intended promote shifts in dietary patterns, is to take availability, affordability and personal preference, including regional, cultural and ethnic, into consideration. Also important is regardless of specific foods choices, that total energy intakes achieve and maintain a healthy body weight.

## Summary

Dietary fats and oils have both positive and negative attributes with respect to health outcomes. Fats and oils are made up primarily of triacylglycerol. The fatty acid profile of the triacylglycerol dictates the physical properties of the fat. During fatty acid biosynthesis, humans are unable to insert a double bond above the ninth carbon of the acyl chain. For this reason, linoleic acid and fatty acids derived from linoleic acid are classified as essential; hence, these must be consumed preformed. Animal fats are the major contributors of dietary saturated fatty acids. Plant oils, such as canola and olive, are the major contributors of dietary monounsaturated fatty acids. Plant oils, such as soybean and corn oils, are the major contributors of dietary polyunsaturated fatty acids. The plant oils canola and olive, and foods of marine origin (fish and seafood) are major contributors of  $n$ -3 fatty acids ALA, and EPA and DHA, respectively. Partially-hydrogenated fat has been major contributors of *trans* fatty acids; changes to labeling and regulatory policy has resulted in a dramatic decline in the food supply. Dietary patterns high in polyunsaturated and low in saturated fatty acids have been associated with optimal health outcomes. Very long chain  $n$ -3 fatty acids have been independently associated with

reduced cardiovascular disease risk. *Trans* fatty acids have been associated with elevated cardiovascular disease risk (Ascherio et al., 1999). Dietary fatty acid intakes are determined by the sum of individual foods. Current dietary guidance from the US government and major health advocacy organization recommend moderate-fat diets rich in fruits and vegetables, whole-grain products, fish, low-fat and nonfat dairy products, legumes and nuts, and unprocessed lean meat and poultry. There are multiple dietary patterns consistent with these recommendations that can accommodate personal preferences.

## Classification of Lipoproteins

### Classification of Serum Lipoproteins According to Their Electrophoretic Mobilities

With the development of techniques to separate proteins according to their electrophoretic behavior, it could be demonstrated that most of the lipid present in serum was associated with proteins migrating with  $\alpha_1$ - and  $\beta$ -globulin mobilities. This resulted in the first classification of lipoproteins as  $\alpha_1$ - and  $\beta$ -lipoproteins. The ratio of lipid to protein on the  $\alpha_1$ -lipoproteins was approximately 1:1, whereas the  $\beta$ -lipoproteins had a greater relative content of lipids. Application of more advanced electrophoretic techniques resulted in further discrimination among the lipoprotein classes and for many years lipoproteins were classified as  $\beta$ -, pre- $\beta$ -, and  $\alpha$ -lipoproteins. Careful observation of the electrophoretic lipoprotein profiles in normals and subjects with familial lipoprotein

**Table 1** Classification of plasma lipoproteins

Lipoprotein	Diameter (nm)	Density ( $\text{g mL}^{-1}$ )	Electrophoretic mobility	Major lipids	Major apolipoproteins
Chylomicrons	80–500	<0.95	Origin	Dietary triacylglycerols, cholesteryl esters	A-I, A-II, A-IV, B-48, C-I, C-II, C-III, E
Remnants	>30	<1.006	Origin	Dietary cholesteryl esters	B-48, E
VLDL	30–80	<1.006	pre- $\beta$	Endogenous triacylglycerols	B-100, C-I, C-II, C-III, E
IDL	25–35	1.006–1.019	pre- $\beta$ and $\beta$	Cholesteryl esters, triacylglycerols	B-100, E
LDL	18–28	1.019–1.063	$\beta$	Cholesteryl esters	B-100
HDL <sub>2</sub>	9–12	1.063–1.125	$\alpha$	Cholesteryl esters, phospholipids	A-I, A-II
HDL <sub>3</sub>	5–9	1.125–1.210	$\alpha$	Cholesteryl esters, phospholipids	A-I, A-II

disorders gave rise to the first classification of lipoprotein disorders by Fredrickson and colleagues. The equivalence between electrophoretic and ultracentrifugal separation is presented in **Table 1**.

Several electrophoretic supports have been used to separate plasma lipoproteins. These include paper, cellulose acetate, agarose, and polyacrylamide. Agarose gel electrophoresis remains the most commonly used for easy and rapid assessment of lipoprotein patterns in the clinical laboratory. This technique is especially useful for identifying the presence of a broad  $\beta$  band in the diagnosis of type III hyperlipidemia. Gradient agarose–polyacrylamide gel electrophoresis under nondenaturing conditions has been an essential tool to analyze low-density lipoprotein (LDL) and high-density lipoprotein (HDL) subclasses, providing a greater resolution than ultracentrifugation. LDL subfractions have been resolved by nondenaturing polyacrylamide gradient gel electrophoresis (2–16%) in up to seven LDL subclasses with densities ranging from 1.020 to 1.063 g ml<sup>-1</sup> and diameters ranging from 22.0 to 28.5 nm. Usually a major subpopulation and several (one–four) minor LDL subpopulations are found in most subjects examined. A predominance of smaller, more dense LDL, versus larger, more buoyant LDL particles in plasma has been associated with increased coronary heart disease (CHD) risk. There is evidence supporting the genetic origin of the distribution of LDL subfractions; however, age, gender, and environmental factors strongly influence the penetrance. HDL subfractions have been resolved using a similar technique, with a polyacrylamide gradient ranging from 4% to 30%, into five subclasses (HDL<sub>3c</sub>, HDL<sub>3b</sub>, HDL<sub>3a</sub>, HDL<sub>2a</sub>, and HDL<sub>2b</sub>). More recently 11–14 subclasses have been described, including  $\beta$ -migrating particles, using an improved electrophoresis technique. The clinical importance of these subfractions is still under investigation.

### Classification of Serum Lipoproteins According to Their Ultracentrifugal Characteristics

The presence of lipids within the lipoprotein particles confers these macromolecular complexes with a lower density compared with other serum proteins. With the arrival of the analytical ultracentrifugation in the 1940s, this characteristic allowed its initial separation as a discrete peak using this technique. During the following years, it was demonstrated that this fraction was made up of a wide spectrum of particle sizes and densities ( $d$ ) ranging from 0.92 to 1.21 g ml<sup>-1</sup>.

Lipoproteins were classically separated into four major classes designated as chylomicrons (exogenous triacylglycerol-rich particles of  $d < 0.94$  g ml<sup>-1</sup>), very low-density lipoproteins (VLDL, endogenous triacylglycerol-rich particles of  $d = 0.94$ – $1.006$  g ml<sup>-1</sup>), LDL (cholesteryl ester-rich particles of  $d = 1.006$ – $1.063$  g ml<sup>-1</sup>), and HDL (particles containing approximately 50% protein of  $d = 1.063$ – $1.21$  g ml<sup>-1</sup>). With subsequent improvements to the ultracentrifugation techniques, further heterogeneity was detected within each of those major lipoprotein classes; this resulted in the need for further subdivision into several density subclasses such as HDL<sub>2a</sub> ( $d = 1.10$ – $1.125$  g ml<sup>-1</sup>), HDL<sub>2b</sub> ( $d = 1.063$ – $1.10$  g ml<sup>-1</sup>), and HDL<sub>3</sub> ( $d = 1.125$ – $1.21$  g ml<sup>-1</sup>).

There is no doubt that the separation of lipoproteins by ultracentrifugation has been essential for the advances in this field; however, this technique is very labor intensive and the isolated lipoproteins are usually modified due to the high  $g$  force and salt concentrations used in this process. The development of new vertical and near vertical rotors has shortened considerably the runs and thus diminished some of these negative effects.

### Classification of Serum Lipoproteins According to Their Apolipoprotein Composition

Recent interest in the study of lipoprotein subfractions has resulted in an increased use of methods of separation based on affinity chromatography, especially those using immunoaffinity. Using columns containing antibodies against specific apolipoproteins (**Table 2**), a large number of HDL subpopulations have been resolved. Similarly, this technique allows the separation of several triacylglycerol-rich lipoproteins subfractions.

Lipoproteins containing apo A-I can be separated into two major species: those containing both apo A-I and apo A-II, known as LpA-I:AI, and those containing apo A-I but not apo A-II (LpAI). Small numbers of particles containing apo A-II, but not apo A-I, have been detected in normal subjects; however, these particles could become predominant in the presence of rare genetic disorders associated with HDL deficiency. Another HDL species containing apo A-I and apo E is important in reverse cholesterol transport by transporting cholesterol from the cell membranes to the liver for elimination from the body.

Lipoproteins containing apo B consist of four lipoprotein families. Lipoproteins containing apo B only (Lp(B)) are cholesteryl ester-rich and are found primarily within the LDL density range, but they have also been detected within the VLDL range. Particles containing both apo B and apo C (LpB:C), apo B and apo E (LpB:E), and all three apolipoprotein groups (LpB:E:C) are triacylglycerol-rich and are found within the VLDL and intermediate-density lipoprotein (IDL) density range. The apo C and apo E contents decrease as density increases.

More recently, the affinity for lectins of Lp(a), a lipoprotein containing apo B-100 as well as an antigenically unique apolipoprotein (apo(a)), has been used to develop a new technique to measure the levels of this lipoprotein in plasma.

## Synthesis and Catabolism of Lipoproteins

### Metabolism of Lipoproteins Carrying Exogenous Lipids

Dietary fats absorbed in the intestine are packaged into large, triacylglycerol-rich chylomicrons for delivery through the bloodstream to sites of lipid metabolism or storage. These lipoproteins interact with lipoprotein lipase (LPL) and undergo lipolysis, forming chylomicron remnants. The major sites of LPL activity are adipose tissue, skeletal muscle, the mammary gland, and the

**Table 2** Classification and properties of apolipoproteins

<i>Apolipoprotein</i>	<i>Amino acids</i>	<i>Tissue expression</i>	<i>Chromosomal localization</i>	<i>Functions</i>
apo A-I	243	Liver Intestine	11	Major structural component of HDL Ligand for HDL binding Activator of LCAT

apo(a)	Variable	Liver	6	Reverse cholesterol transport ?

myocardium. In these sites, the fatty acids from the triacylglycerols are used for storage, oxidation, or secretion back to the circulation. The triacylglycerol-depleted particles resulting from the lipolysis, known as chylomicron remnants, pick up apo E and cholesteryl ester from HDL and are rapidly taken up by the liver via a process mediated by the apo E receptor. This is a fast process and chylomicron particles are not usually present in the blood after a prolonged fasting period. The occurrence of chylomicronemia can be easily detected by the presence of a creamy supernatant floating on top of the plasma or serum kept for several hours at 4 °C.

### Transport of Endogenous Lipids

The liver cell secretes triacylglycerol-rich VLDL, which can be converted first to IDL and then to LDL through lipolysis by a mechanism similar to that described for chylomicrons. The excess surface components are usually transferred to HDL, and the triacylglycerol-depleted VLDL becomes an IDL. Some of these particles may be taken up by the liver via an apo E receptor, whereas others are further depleted of triacylglycerols, becoming cholesteryl ester-enriched particles known as LDL, which contain apo B as their only apolipoprotein. Consumption of fat-rich meals or glucose enhances VLDL production.

Some primary causes of elevated VLDL or IDL levels are familial endogenous hypertriglyceridemia (type IV according to Fredrickson's classification) and familial dysbetalipoproteinemia (type III hyperlipidemia). Genetic mutations at the apo E gene locus are responsible for the type III phenotype. Some secondary causes for elevated VLDL levels are obesity, diabetes mellitus, and alcohol consumption, as well as the use of high doses of certain drugs (e.g., thiazide diuretics and estrogens). The presence of elevated levels of IDL has been associated with an increased atherosclerotic risk.

LDL particles are major carriers of cholesteryl ester in the blood. An LDL receptor that recognizes apo B-100 and apo E, but not apo B-48, allows the liver and other tissues to catabolize LDL. High-fat and high-cholesterol diets can decrease the activity of the LDL receptor, leading to increased levels of circulating LDL. These particles supply cholesterol to cells in the periphery for synthesis of cell membranes and steroid hormones. Modified or oxidized LDL can also be taken up by the scavenger receptor on macrophages in various tissues, including the arterial wall. This process is a potential initiator of foam cell formation and atherosclerosis.

Several LDL subclasses have been identified using gradient gel electrophoresis. Large, less dense LDL particles are commonly found in premenopausal women and men at low risk for CHD, whereas the small, more dense particles have been associated with a significant increased risk for myocardial infarction. The distribution of these particles appears to have a significant genetic component modulated by age and environmental factors.

### Reverse Cholesterol Transport

HDL is synthesized by both the liver and the intestine. Its precursor form is discoidal in shape and matures in circulation as it picks up unesterified cholesterol from cell membranes and other lipids (phospholipid and triacylglycerol) and proteins (A-I, E, and C apolipoproteins) from triacylglycerol-rich lipoproteins (chylomicron and VLDL) as these particles undergo lipolysis. The cholesterol is esterified by the action of the lecithin-cholesterol acyltransferase (LCAT) and the small HDL<sub>3</sub> particle becomes a larger HDL<sub>2</sub> particle. The esterified cholesterol is either delivered to the liver or transferred by the action of cholesteryl ester transfer protein (CETP) to other lipoproteins (such as chylomicron, VLDL remnants, or LDL) in exchange for triacylglycerols. This cholesterol may then be taken up by the liver via receptors specific for these lipoproteins, or it can be delivered again to the peripheral tissues. The triacylglycerol received by HDL<sub>2</sub> is hydrolyzed by hepatic lipase and the particle is converted back to HDL<sub>3</sub>, completing the HDL cycle in plasma. In the liver, cholesterol can be excreted directly into bile, converted to bile acids, or reutilized in lipoprotein production.

Several genetic disorders have been identified associated with low levels or total deficiency of HDL.

### Effects of Dietary Fats and Cholesterol on Lipoprotein Metabolism

The cholesterolemic effects of dietary fatty acids have been extensively studied. The saturated fatty acids C<sub>12:0</sub>, C<sub>14:0</sub>, and C<sub>16:0</sub> have a hypercholesterolemic effect, whereas C<sub>18:0</sub> has been shown to have a neutral effect. Monounsaturated and polyunsaturated fatty acids in their most common *cis* configuration are hypocholesterolemic in comparison with saturated fatty acids. The effects of *trans* fatty acids on lipid levels are under active investigation. Our current knowledge shows that their effect is intermediate between those of saturated and unsaturated fats. The effect of dietary cholesterol on lipoprotein levels is highly controversial. This may be due in part to the dramatic interindividual variation in response to this dietary component. Specific effects of dietary fats and cholesterol on each lipoprotein fraction are the focus of other articles and they are only briefly summarized below and in [Table 3](#).

#### Effects of Diet on Chylomicron Metabolism

Diets very high in saturated fat have been associated with increased postprandial chylomicrons and chylomicron remnants compared with diets rich in n-6 polyunsaturated fats; however, human experiments carried out using moderate to high fat intake have not shown significant effects of different types of dietary fat or dietary cholesterol on postprandial lipoproteins.

The effects of dietary carbohydrates on postprandial lipoproteins have also been studied. Most protocols have used diets very high in simple carbohydrates. In general, high carbohydrate intake has been associated with increased levels of fasting triacylglycerols and increased postprandial levels of chylomicrons and chylomicron remnants.

#### Effects of Diet on VLDL Metabolism

It is well-known that diets high in simple carbohydrate increase hepatic secretion of VLDL. This carbohydrate induction of hypertriglyceridemia is the source of the current controversy regarding the optimal diet for subjects at high risk for cardiovascular disease. Some authors have demonstrated that the increased hepatic triacylglycerol secretion induced by high-carbohydrate diets was not accompanied by parallel increases in apo B-100 secretion. In other words, the consumption of low-fat, high-carbohydrate diets did not affect the number of particles but resulted in larger, more triacylglycerol-enriched VLDL particles.

Intake of saturated fat results in an increased secretion of the number of VLDL particles by the liver, whereas the opposite effect is observed with polyunsaturated fat. Of special note are the dramatic effects on VLDL production found following high intakes of n-3 fatty acids. These diets are associated with marked decreases in triacylglycerol secretion by mechanisms not fully understood. It has been speculated that n-3 fatty acids may stimulate intracellular degradation of apo B in hepatocytes. Dietary cholesterol, within the physiological range, appears to play a minor role in hepatic VLDL production.

**Table 3** Effects induced on the major lipoprotein fractions by different dietary components following isoenergetic replacement of saturated fatty acids

	MUFA	PUFA n-6	PUFA n-3	trans FA	Simple carbohydrate	Carbohydrate plus fiber
VLDL-C	≈	≈/↓	↓	↑	↑	≈
LDL-C	↓	↓	≈/↓	↑	↓	↓
HDL-C	≈/↑	≈/↓	↓	↓	↓	≈/↓

≈ Equivalent effect; ↓ concentration reduced; ↑ concentration increased.

### Effects of Diet on LDL Metabolism

The effects of dietary fat and cholesterol on LDL metabolism have been extensively studied. However, the effects of dietary cholesterol are still highly controversial. Whereas some studies have demonstrated increased LDL production and decreased catabolism associated with high cholesterol intakes, others have failed to find such associations.

Replacement of saturated by polyunsaturated fats has been associated with decreased LDL apo B production in some studies, whereas in other studies, increased ratios of polyunsaturated to saturated fats resulted in increased LDL apo B catabolism. Unlike the effects described for VLDL metabolism, intake of n-3 fatty acids appears to play a minor role on LDL metabolism.

### Effects of Diet on HDL Metabolism

Diets high in simple carbohydrates reduce HDL cholesterol levels. This effect appears to be mediated by increases in the catabolism of apo A-I; however, one study has also demonstrated an additional decrease in apo A-I production.

## Disorders of Lipoprotein Metabolism

For historical reasons the classification of disorders of lipoprotein metabolism will be presented according to the classical Fredrickson's classification (Table 4).

### Type I or Familial Chylomicronemia

This disorder is characterized by greatly elevated levels of exogenous triacylglycerols and it is the result of impaired lipolysis of chylomicrons due to a deficiency of LPL or its activator, the apo C-II. Several genetic mutations at the structural genes for both LPL and apo C-II have been reported. These are autosomal recessive traits. In the heterozygous state, subjects have normal to slightly elevated plasma triglycerides, whereas homozygotes have triacylglycerol levels that may exceed 1000 mg dL<sup>-1</sup> in the fasting state. The diagnosis of the homozygous state takes place during the first years of life from the presence of recurrent abdominal pain and pancreatitis. Eruptive xanthomas and lipemia retinalis may also occur.

The recommended treatment includes a diet low in simple carbohydrates and with a fat content below 20% of total energy. The use of medium-chain triglycerides (MCT) has also been reported to be efficacious. Body weight should be maintained within the normal limits and alcohol consumption should be avoided.

Other secondary causes leading to the presence of chylomicrons in the fasting state include uncontrolled diabetes mellitus, alcoholism, estrogen use, and hypothyroidism.

Fasting chylomicronemia has not been clearly associated with increased risk for atherosclerosis; however, there is considerable evidence supporting the atherogenic properties of chylomicron remnants.

### Type II or Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder characterized by elevation of plasma LDL cholesterol levels. Mutations at the LDL receptor gene locus on chromosome 19 are responsible for this disorder. Multiple different mutations have been described at this locus resulting in the FH phenotype. In the heterozygous state, subjects develop tendinous xanthomas, corneal arcus, and CHD. Elevations of LDL can result from well-characterized genetic disorders such as FH or familial defective apo B-100.

**Table 4** Classification of hyperlipidemias according to Fredrickson

Type	Plasma cholesterol	Plasma triacylglycerol	Lipoprotein fraction(s) affected	Atherosclerosis risk	Genetic disorder
I	Normal to elevated	Very elevated	Chylomicrons	No	Familial LPL deficiency Apo C-II deficiency
IIa	Elevated	Normal	LDL	High	Familial hypercholesterolemia Familial combined hyperlipidemia Polygenic hypercholesterolemia
IIb	Elevated	Elevated	LDL and VLDL	High	Familial hypercholesterolemia Familial combined hyperlipidemia
III	Elevated	Very elevated	IDL	High	Familial dysbetalipoproteinemia
IV	Normal or elevated	Elevated	VLDL	Moderate	Familial hypertriglyceridemia Familial combined hyperlipidemia
V	Normal or elevated	Very elevated	VLDL and chylomicrons	Moderate	Familial hypertriglyceridemia

The ranges of LDL cholesterol levels in plasma of FH subjects are 200–400 mg dl<sup>-1</sup> in heterozygotes and above 450 mg dl<sup>-1</sup> in homozygotes. The frequency of defects at the LDL receptor locus is approximately 1 in 500 for the heterozygous state and 1 in a million in the homozygous state.

Inhibitors of 3-hydroxy-3-methylglutaryl (HMG) coenzyme A are useful in the treatment of hypercholesterolemia. Most pharmacological therapies are ineffective in the homozygous state. FH homozygotes may be treated with LDL apheresis, liver transplantation, and portacaval shunt. More recently, encouraging results have been obtained using *ex vivo* gene therapy.

The genetic defect(s) associated with a common form of hypercholesterolemia present in most subjects with cholesterol levels between 250 and 300 mg dl<sup>-1</sup> has (have) not been elucidated. This disorder may be due to a combination of minor gene defects (i.e., presence of apo E-4 allele) that in combination with the environment (i.e., diet, lack of exercise) predispose individuals to moderately elevated LDL cholesterol levels. This disorder has been also named polygenic hypercholesterolemia.

### Familial Defective apo B-100

Familial defective apo B-100 is an autosomal dominant genetic disorder that presents with a phenotype similar to FH. The frequency of this disorder may be similar to that of FH; however, it varies considerably depending on the ethnicity of the population studied. The specific mutation responsible for this disorder is a point mutation at amino acid 3500 of the mature apo B. The diagnosis of this disorder requires molecular biology techniques.

### Type III or Familial Dysbetalipoproteinemia

In this disorder both plasma triacylglycerol and cholesterol are increased. Several mutations within the apo E gene locus have been found to be responsible for this disease; however, in most patients the complete expression of the clinical genotype needs additional interactions such as age, obesity, and diabetes. In addition to the accumulation in plasma of VLDL remnants and chylomicrons, other characteristics of this disorder are tuberous xanthomas and in some cases also planar xanthomas. Therapies include diet and hypolipidemic agents such as fibrates, statin, or nicotinic acid. In most cases, diagnosis can be carried out first by agarose gel electrophoresis, followed by molecular biology techniques to detect the presence of the apo E-2 allele.

### Familial Type IV and Type V Hypertriglyceridemias

These two disorders may have overlapping phenotypes. In type IV or familial endogenous hypertriglyceridemia, triacylglycerol levels are increased and HDL is usually decreased. This disorder appears to be autosomal dominant and relatively frequent in populations consuming high-fat diets. The precise molecular defect has not been defined; however, the increase in triacylglycerol is associated with overproduction of triacylglycerol by the liver and often with consequent reduced clearance. Diet should be the first step in therapy, followed if necessary by pharmacotherapy using fibrates or nicotinic acid. Premature CHD has been seen in some but not all cases presenting with this phenotype.

Type V hyperlipidemia is a much more rare disorder. Usually the first signs of this abnormality are abdominal pain or pancreatitis. VLDL levels are high and chylomicrons are present in the fasting state. This abnormality has not been linked to any specific molecular defect. Besides the primary genetic defect, other secondary causes of type V hyperlipidemia are poorly controlled diabetes mellitus, nephrotic syndrome, hypothyroidism, glycogen storage disease, and pregnancy. Recent data indicate increased susceptibility to atherosclerosis.

### Familial Dyslipidemia

Familial dyslipidemia may be a variant of the familial hypertriglyceridemias described previously. It is characterized by hypertriglyceridemia in combination with low HDL cholesterol. Patients are generally overweight, with male pattern obesity, insulin resistance, diabetes, and hypertension. These subjects have both increased hepatic triacylglycerol secretion and increased HDL apo A-I catabolism.

### Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCH) was initially described as the combination of hypercholesterolemia and hypertriglyceridemia within the same kindred, and with kindred members having one of these abnormalities or both. Moreover, most subjects with FCH have HDL cholesterol levels below the 10th percentile. Affected subjects have elevation in VLDL, LDL, or both. This disorder has a frequency of approximately 10% in survivors of premature myocardial infarction (less than 60 years of age) and approximately 14% in kindred with CHD.

It has been reported that affected subjects have overproduction of apo B-100. The precise molecular defect has not been elucidated, although there are already several candidate gene loci, including the LPL. The expression of this disorder may be triggered by other factors, such as overweight, hypertension, diabetes, and gout. The treatment should include diet and exercise and, if necessary, niacin, HMC CoA reductase inhibitors, or fibrates, depending on the major lipid present in excess.

### Familial Hyperapobetalipoproteinemia

Familial hyperapobetalipoproteinemia is characterized by apo B values above the 90th percentile in the absence of other lipid abnormalities; it has been suggested to be a variant of FCH. This disorder is relatively common (5%) in kindreds with premature CHD. The molecular defect is not known, but metabolic studies suggest overproduction of apo B-100.

### Familial Hypoalphalipoproteinemia

Severe HDL deficiency, characterized by HDL cholesterol levels  $<10 \text{ mg dl}^{-1}$  is rare and may be due to Tangier disease, apo A-I deficiencies, LCAT deficiency, or fish-eye disease. The apo A-I deficiency states are due to rare deletions, rearrangements, or point mutations within the apo A-I/C-III/A-IV gene complex. Familial hypoalphalipoproteinemia is relatively common and is characterized by HDL cholesterol levels below the 10th percentile of normal. These subjects have been reported to have either decreased HDL production or increased HDL apo A-I catabolism. This phenotype is present in approximately 4% of kindred with premature CHD.

The genetic defect or defects are not known; however, it has been suggested that FCH, familial hyperapobetalipoproteinemia, familial dysbetalipoproteinemia, and familial hypoalphalipoproteinemia may be variants of a single disorder. This disorder is characterized by a genetic predisposition in subjects consuming high-fat, high-cholesterol diets to an increased secretion of apo B-containing lipoproteins and an increased catabolism of apo A-I-containing lipoproteins. The expression of the phenotype is usually enhanced by the presence of male pattern obesity.

### Familial Lipoprotein (a) Excess

Lipoprotein (a) (Lp(a)) is an LDL particle with one molecule of apolipoprotein (a) attached to it. Elevated levels of Lp(a) ( $>35\text{--}40 \text{ mg dl}^{-1}$  or 90th percentile) have been associated with premature CHD. This increased risk appears to result from two different mechanisms: cholesterol deposition in the arterial wall and inhibition of fibrinolysis.

Lp(a) concentrations are highly variable among individuals; however, they tend to remain constant during a person's lifetime. Between 80% and 90% of the variability appears to be of genetic origin, owing, for the most part, to variations at the structural apo(a) gene locus. Lp(a) concentrations are inversely associated with a size polymorphism of apo(a). This polymorphism is due to differences in the number of a multiple repeat of a protein domain highly homologous to the kringle 4 domain of plasminogen. Diets and medications used to lower LDL cholesterol levels do not appear to have a significant effect on Lp(a) concentrations; however, niacin has been reported to decrease Lp(a) levels. There have been reports suggesting that diets high in *trans* fatty acids have some raising effects on Lp(a) levels, whereas estrogen replacement lowers Lp(a) in postmenopausal women.

### General Guidelines for the Treatment of Lipoprotein Abnormalities for CHD Prevention

There is a clear benefit from lowering LDL cholesterol with diet or drug therapy in patients with hyperlipidemia or CHD or both. Dietary therapy includes using diets that are restricted in total fat ( $<30\%$  of calories), saturated fat ( $<7\%$  of calories), and cholesterol ( $<200 \text{ mg day}^{-1}$ ). Pharmacological therapies include anion exchange resins, niacin, and HMG CoA reductase inhibitors. The latter agents have been demonstrated to also lower CHD mortality. It should be noted that dramatic interindividual variations have been demonstrated in response to diet and drug therapies. Consequently the efficacy of hypolipidemic therapies will vary from individual to individual. More information is needed about the benefits of HDL cholesterol raising in patients with low HDL cholesterol levels as well as the benefits of lowering triacylglycerol plasma concentrations, and more specifically the triacylglycerol carried in lipoprotein remnants. This is also true regarding the benefits of Lp(a) lowering using niacin in patients with elevated Lp(a) levels.

## Glossary

**Hypermagnesemia** High levels of magnesium in blood or serum.

**Hypermagnesuria** High levels of magnesium in urine.

**Magnesium** An alkaline earth element with symbol Mg, atomic number 12, the seventh most abundant element in the earth's crust and the 11th most abundant in the human body.

**Reabsorption** Movement of filtered substances (such as magnesium) and water from the kidney tubules back into the plasma.

Magnesium (Mg), the second intracellular cation after sodium, is an essential mineral. It is a critical cofactor in more than 300 enzymatic reactions. It may be required for substrate formation (Mg-ATP) and enzyme activation. It is critical for a great number of cellular functions, including oxidative phosphorylation, glycolysis, DNA transcription, and protein synthesis. It is involved in ion currents and membrane stabilization. Mg deficiency may be implicated in various metabolic disorders, including cardiovascular diseases, immune dysfunction, and free radical damage.

## Magnesium Metabolism

### Distribution of Mg within the Body

The normal adult body contains approximately 25 g of Mg, with more than 60% in bone tissue (Table 1). Only a fraction of bone Mg (at the surface of the bone crystal) is exchangeable with extracellular Mg. The muscle contains 25% of total body Mg, and extracellular Mg accounts for only 1%. Plasma Mg is approximately  $0.8 \text{ mmol l}^{-1}$ , half of which is ionized and active in physiological reactions half bound to proteins or complexed to anions. In cells, Mg is associated with various structures, such as the nucleus and intracellular organelles, and free Mg accounts for 1–5% of total cellular Mg. Intracellular free Mg is maintained at a relatively constant level, even if extracellular Mg level varies. This phenomenon is due to the limited permeability of the plasma membrane to Mg and the existence of specific Mg transport systems that regulate the rates at which Mg is taken up by cells or extruded from cells. Mechanisms by which Mg is taken up by cells have not been completely elucidated, and Mg efflux particularly requires the antiport  $\text{Na}^+/\text{Mg}^{2+}$ . Various hormonal and pharmacological factors influence Mg transport, and it can be assumed that recent developments in molecular genetics will lead to the identification of proteins implicated in Mg transport.

**Table 1** Magnesium in human tissues

	% distribution	Concentration
Bone	60–65	0.5% of bone ash
Muscle	27	6–10 mmol per kg wet weight
Other cells	6–7	6–10 mmol per kg wet weight
Extracellular	<1	
Erythrocytes		2.5 mmol l <sup>-1</sup>
Serum		0.7–1.1 mol l <sup>-1</sup>
Free	55	
Complexed	13	
Bound	32	
Mononuclear blood cells		2.3–3.5 fmol per cell
Cerebrospinal fluid		1.25 mmol l <sup>-1</sup>
Free	55	
Complexed	45	
Sweat		0.3 mmol l <sup>-1</sup> (in hot environment)
Secretions		0.3–0.7 mmol l <sup>-1</sup>

### Intestinal Absorption

Net Mg absorption results from dietary Mg absorption and Mg secretion into the intestinal tract via bile and gastric and pancreatic juice. In healthy adults, 30–50% of dietary Mg is absorbed. The secreted Mg is efficiently reabsorbed and endogenous fecal losses are only 20–50 mg day<sup>-1</sup>. Mg absorption occurs along the entire intestinal tract, but the distal small intestine (jejunum and ileum) is the primary site. It is essentially a passive intercellular process by electrochemical gradient and solvent drag. The active transport occurs only for extremely low dietary Mg intake and its regulation is unknown. Mg uptake in the brush border may be mediated by an Mg/anion complex, and Mg efflux across the basolateral membrane may involve Na<sup>+</sup>/Mg<sup>2+</sup> antiport systems. A gene implicated in Mg deficit in humans has been identified. It is expressed in intestine and kidney and appears to encode for a protein that combines Ca- and Mg-permeable channel properties with protein kinase activity. This gene may be implicated in Mg absorption. Because of the importance of the passive process, the quantity of Mg in the digestive tract is the major factor controlling the amount of Mg absorbed.

The possibility of an adaptive increase in the fraction of Mg absorbed as Mg intake is lowered is controversial. In fact, experimental studies indicate that fractional intestinal absorption of Mg is directly proportional to dietary Mg intake. Because only soluble Mg is absorbed, all the factors increasing Mg solubility increase its absorption while formation of insoluble complexes in the intestine may decrease Mg absorption. Most well-controlled studies indicate that high calcium intake does not affect intestinal Mg absorption in humans. In contrast, dietary phytate in excess impairs Mg absorption by formation of insoluble complexes in the intestinal tract. Negative effects of a high intake of dietary fiber have often been reported, but these actions have certainly been overestimated. In fact, only the impact of purified fiber was considered, but fiber-rich diets are a major source of Mg and roles of the intestinal fermentation and the large bowel in mineral absorption were neglected. It was demonstrated in animal models that fermentable carbohydrates (oligosaccharides and resistant starch) enhance Mg absorption in the large bowel and that a similar effect exists in humans. Other nutrients may influence Mg absorption but these effects are important only at low dietary Mg intake.

### Urinary Excretion

Magnesium homeostasis is essentially regulated by a process of filtration–reabsorption in the kidney. Urinary Mg excretion increases when Mg intake is in excess, whereas the kidney conserves Mg in the case of Mg deprivation. Usually, 1000 mmol per 24 h of Mg is filtered and only 3 mmol per 24 h is excreted in urine.

A total of 10–15% of the filtered Mg is reabsorbed in the proximal tubule by a passive process. The majority of filtered Mg (65%) is reabsorbed in the thick ascending loop of Henle. The reabsorption in this segment is mediated by a paracellular mechanism involving paracellin-1. It is also related to sodium transport by a dependence on the transepithelial potential generated by NaCl absorption. Thus, factors that impair NaCl reabsorption in the thick ascending loop of Henle, such as osmotic diuretics, loop diuretics, and extracellular fluid volume expansion, increase Mg excretion. At least 10–15% of the filtered Mg is reabsorbed in the distal tubule. The reabsorption occurs via an active transcellular mechanism and is under the control of special divalent cation-sensing receptors. Thus, elevated plasma Mg concentrations inhibit reabsorption of Mg from the distal tubule, leading to an increased magnesuria. Other active transport may also exist because some hormones (parathyroid hormone (PTH), glucagon, calcitonin, and insulin) may increase Mg reabsorption. Other factors may also influence Mg reabsorption, such as hypercalciuria

or hypophosphatemia, which inhibit the tubular reabsorption of Mg. Metabolic alkalosis leads to renal Mg conservation, whereas metabolic acidosis is associated with urinary Mg wasting. Thus, the chronic low-grade metabolic acidosis in humans eating Western diets may contribute to decreased Mg status.

## Dietary Sources of Magnesium

Mg is present in all foods, but the Mg content varies substantially (Table 2). Cereals and nuts have high Mg content. Vegetables are moderately rich in Mg, and meat, eggs, and milk are poor in Mg. A substantial amount of Mg may be lost during food processing, and refined foods generally have a low Mg content. In addition to Mg content, it is important to consider the Mg density of food (i.e., the quantity of Mg per unit of energy). Vegetables, legumes, and cereals thus contribute efficiently to daily Mg intake, whereas fat- and sugar-rich products have a minor contribution. Some water can also be a substantial source of Mg, but it depends on the area from which the water derives.

## Requirements

### Assessment of Mg Status

Several potential markers for estimating daily Mg requirement have been suggested. Plasma Mg concentration is the most commonly used marker to assess Mg status. In healthy populations, the plasma Mg value is  $0.86 \text{ mmol l}^{-1}$  and the reference value is  $0.75\text{--}0.96 \text{ mmol l}^{-1}$ . A low plasma Mg value reflects Mg depletion, but a normal plasma Mg level may coexist with low intracellular Mg. Thus, despite its interest, plasma Mg is not a good marker of Mg status.

Ion-specific electrodes have become available for determining ionized Mg in plasma, and this measurement may be a better marker of Mg status than total plasma Mg. However, further investigation is necessary to achieve a standardized procedure and to validate its use as an appropriate marker of Mg status.

Erythrocyte Mg level is also commonly used to assess Mg status, and the normal value is  $2.06\text{--}2.54 \text{ mmol l}^{-1}$ . However, erythrocyte Mg level is under genetic control, and numerous studies have shown no correlation between erythrocyte Mg and other tissue Mg.

The total Mg content of white blood cells has been proposed as an indicator of Mg status. However, lymphocytes, polymorphonuclear blood cells, and platelets may have protective mechanisms against intracellular Mg deficiency, and the determination of total Mg content in leukocytes and platelets to assess Mg status is of questionable usefulness.

Mg excretion determination is helpful for the diagnosis of Mg deficit when there is a hypomagnesemia. In healthy populations, the urinary Mg value is  $4.32 \text{ mmol day}^{-1}$  and the reference value is  $1.3\text{--}8.2 \text{ mmol day}^{-1}$ . In the presence of hypomagnesemia, normal or high urinary Mg excretion is suggestive of renal wasting. On the contrary, Mg urinary excretion lower than normal values is a convincing evidence of Mg deficiency.

The parenteral loading test is probably the best available marker for the diagnosis of Mg deficiency. The Mg retention after parenteral administration of Mg seems to reflect the general intracellular Mg content, and an Mg retention more than 20% of the administered Mg suggests Mg deficiency. However, this test is not valid in the case of abnormal urinary Mg excretion and is contraindicated in renal failure.

**Table 2** Mg density of foods

<i>Food</i>	<i>Magnesium density (mg MJ<sup>-1</sup>)</i>
Vegetables (lettuce, broccoli)	211
Legumes (bean)	113
Whole cereal (wheat)	104
Nuts (almond)	105
Fruits (apple)	30
Fish (cod)	75
Meat (roast beef)	40
Whole milk	38
Cheese (camembert)	15
Eggs	18
Dessert	
Biscuit	10
Chocolate	52

Determination of exchangeable Mg pools using Mg stable isotopes is an interesting approach to evaluate Mg status. In fact, Mg exchangeable pool sizes vary with dietary Mg in animals. However, more studies are necessary to better appreciate the relationship between Mg status and exchangeable Mg pool size in humans.

## **Magnesium Deficit**

Two types of Mg deficit must be differentiated. Dietary Mg deficiency results from an insufficient intake of Mg. Secondary Mg deficiency is related to dysregulation of the control mechanisms of Mg metabolism.

### **Dietary Mg Deficiency**

Severe Mg deficiency is very rare, whereas marginal Mg deficiency is common in industrialized countries. Low dietary Mg intake may result from a low energy intake (reduction of energy output necessary for physical activity and thermoregulation, and thus of energy input) or from low Mg density of the diet (i.e., refined or processed foods). Moreover, in industrialized countries, diets are rich in animal source foods and low in vegetable foods. This leads to a dietary net acid load and thus a negative effect on Mg balance. In fact, animal source foods provide predominantly acid precursors (sulfur-containing amino acids), whereas fruits and vegetables have substantial amounts of base precursor (organic acids plus potassium salts). Acidosis increases Mg urinary excretion by decreasing Mg reabsorption in the loop of Henle and the distal tubule, and potassium depletion impairs Mg reabsorption. Mg deficiency treatment simply requires oral nutritional physiological Mg supplementation.

### **Secondary Mg Deficiency**

Failure of the mechanisms that ensure Mg homeostasis, or endogenous or iatrogenic perturbing factors of Mg status, leads to secondary Mg deficit. Secondary Mg deficiency requires a more or less specific correction of its causal dysregulation.

Intestinal Mg absorption decreases in the case of malabsorption syndromes, such as chronic diarrhea, inflammatory enteropathy, intestinal resection, and biliary and intestinal fistulas.

Hypermagnesuria is encountered in the case of metabolic and iatrogenic disorders, such as primary and secondary hyperaldosteronism (extracellular volume expansion), hypercalcemia (competition Ca/Mg at the thick ascending loop of Henle), hyperparathyroidism, and phosphate or potassium depletion. Hypermagnesuria may also result from tubulopathy, as the selective defect of the Mg tubular reabsorption (chromosome 11q23), Bartter's syndrome (thick ascending loop of Henle), or Gitelman's syndrome (distal convoluted tubule).

Administration of medications can be a causal factor in the development of secondary Mg deficiency. Administration of diuretics is the main cause of iatrogenic deficit because it decreases NaCl reabsorption in the thick ascending loop of Henle and thus increases the fractional excretion of Mg.

### **Causes of Mg Deficit**

Complex relations exist between Mg and carbohydrate metabolism. Diabetes is frequently associated with Mg deficit and insulin may play an important role in the regulation of intracellular Mg content by stimulating cellular Mg uptake. Hypomagnesemia is the most common ionic abnormality in alcoholism because of poor nutritional status and Mg malabsorption, alcoholic ketoacidosis, hypophosphatemia, and hyperaldosteronism secondary to liver disease.

Stress can contribute to Mg deficit by stimulating the production of hormones and thus increasing urinary Mg excretion and by impairing neurohormonal mechanisms that spare Mg.

### **Consequences of Mg Deficit and Implications in Various Metabolic Diseases**

Mg deficit causes neuromuscular manifestations, including positive Chvostek and Trousseau signs, muscular fasciculations, tremor, tetany, nausea, and vomiting. The pathogenesis of the neuromuscular irritability is complex, and it implicates the central and peripheral nervous system, the neuromuscular junction, and muscle cells.

Mg deficit perturbs Ca homeostasis and hypocalcemia is a common manifestation of severe Mg deficit. Impaired release of PTH and skeletal end organ resistance to PTH appear to be the major factors implicated, probably by a decrease in adenylcyclase activity.

Perturbations in the action and metabolism of vitamin D may also occur in Mg deficit. Because Mg plays a key role in skeletal metabolism, Mg deficit may be a possible risk factor for osteoporosis. However, epidemiologic studies relating Mg intake to bone mass or rate of bone loss have been conflicting, and further investigation is necessary to clarify the role of Mg in bone metabolism and osteoporosis.

Hypokalemia is frequently encountered in Mg deficit. This is due to an inhibition of Na,K-ATPase activity that impairs K and Na transport in and out of the cell and to stimulation of renin and aldosterone secretion that increases K urinary excretion.

There is increasing evidence that Mg deficiency may be involved in the development of various pathologies. Mg deficit is frequent in diabetes and can be a factor in insulin resistance. It can modify insulin sensitivity, probably by influencing intracellular signaling

and processing. Mg deficit has also been implicated in the development or progression of micro- and macroangiopathy and neuropathy.

Mg deficit appears to act as a cardiovascular risk factor. Experimental, clinical, and epidemiological evidence points to an important role of Mg in blood pressure regulation. Mg deficit can lead to cardiac arrhythmias and to increased sensitivity to cardiac glucosides. Mg deficit may also play a role in the development of atherosclerosis. In experimental animal models, dietary Mg deficiency results in dyslipidemia, increased sensitivity to oxidative stress, and a marked proinflammatory effect, thus accelerating atherogenesis. Macrophages and polynuclear neutrophils are activated and synthesize a variety of biological substances, some of which are powerful inducers of inflammatory events (cytokines, free radicals, and eicosanoids). The effect of Mg depletion or Mg supplementation may result in the ability of Mg to modulate intracellular calcium. Pharmacological doses of Mg may reduce morbidity and mortality in the period following infarction. The beneficial effect of Mg may result from calcium-antagonist action, decreased platelet aggregation, and decreased free radical damage.

## Magnesium Excess

Magnesium overload can occur in individuals with impaired renal function or during massive intravenous administration of Mg. It is most often iatrogenic. Clinical symptoms such as drowsiness and hyporeflexia develop when plasma Mg is two- or three-fold higher than the normal value.

## Recommended Dietary Allowances

The estimated average requirement (EAR) is the nutrient intake value that is estimated to meet the requirement of 50% of individuals in a life stage and a gender group. Balance studies and data on stable isotopes suggest an EAR of  $5 \text{ mg kg}^{-1} \text{ day}^{-1}$  for males and females. This value is greater during growth in adolescents and is estimated to be  $5.3 \text{ mg kg}^{-1} \text{ day}^{-1}$ . The Mg requirement is also higher during pregnancy because of Mg transfer to the fetus in the last 3 months; therefore, an additional  $35 \text{ mg day}^{-1}$  is recommended.

In infants, the determination of the adequate intake (AI) is based on the Mg content of mother's milk and the progressive consumption of solid food. Thus, the AI is  $30 \text{ mg day}^{-1}$  during the first 6 months of life and  $75 \text{ mg day}^{-1}$  during the second 6 months of life.

The Recommended Dietary Allowance (RDA) is the average daily dietary intake that is sufficient to meet the nutrient requirement of 97.5% of individuals and is set at 20% above the EAR+2 CVs where the CV is 10%. During recent years, dietary reference intakes for the US and Canada have been revised by the Institute of Medicine. The recommended intakes of Mg are given in Table 3. It is not known whether decreased urinary Mg and increased maternal bone resorption provide sufficient amounts of Mg to meet increased needs during lactation. Thus, the French Society for Nutrition suggests adding  $30 \text{ mg day}^{-1}$  to intake for lactation, whereas no increase is recommended during lactation for the US and Canada.

The intake of Mg has been determined in various populations. Evidence suggests that the occidental diet is relatively low in Mg compared to recommended intakes, whereas the vegetarian diet is rich in Mg. For instance, the mean Mg intake of the subjects in the French Supplementation with Antioxidant Vitamins and Minerals Study was estimated to be  $369 \text{ mg day}^{-1}$  in men and

**Table 3** Recommended dietary allowances of Mg

Age	RDA ( $\text{mg day}^{-1}$ )		AI ( $\text{mg day}^{-1}$ )	
	Male	Female	Male	Female
0–6 months			30	30
6–12 months			75	75
1–3 years	80	80		
4–8 years	130	130		
9–13 years	240	240		
14–18 years	410	360		
19–30 years	400	310		
31–50 years	420	320		
51–70 years	420	320		
<70 years	420	320		
Pregnancy		+40		
Lactation		+0

280 mg day<sup>-1</sup> in women. However, it is possible that the recommended intakes are set somewhat high, as clinical problems are uncommon when such intakes are not caused or accompanied by metabolic diseases such as diabetes and alcoholism.

## Conclusion

Based on evidence of low Mg intake in industrialized countries, intervention studies are needed to test whether improving Mg status would improve health outcomes.

## Chemical and Physical Properties

Manganese is the twelfth most abundant element in the Earth's crust and constitutes approximately 0.1% of it. Chemical forms of manganese in their natural deposits include oxides, sulfides, carbonates, and silicates. Anthropogenic sources of manganese are predominantly from the manufacturing of steel, alloys, and iron products. Manganese is widely used as an oxidizing agent, as a component of fertilizers and fungicides, and in dry cell batteries. Methylcyclopentadienyl manganese tricarbonyl (MMT) improves combustion in boilers and motors and can substitute for lead in gasoline as an antiknock agent. Concentrations of manganese in groundwater normally range between 1 and 100  $\mu\text{g l}^{-1}$ , with most values being below 10  $\mu\text{g l}^{-1}$ . Typical airborne levels of manganese (in the absence of excessive pollution) range from 10 to 70  $\text{ng m}^{-3}$ .

Manganese is a transition element located in group VIIA of the periodic table. It occurs in 11 oxidation states ranging from  $-3$  to  $+7$ , with the physiologically most important valences being  $+2$  and  $+3$ . The  $+2$  valence is the predominant form in biological systems and is the form that is thought to be maximally absorbed. The  $+3$  valence is the form in which manganese is primarily transported in biological systems.

The solution chemistry of manganese is relatively simple. The aquo-ion is resistant to oxidation in acidic or neutral solutions. It does not begin to hydrolyze until pH 10, and therefore free  $\text{Mn}^{2+}$  can be present in neutral solutions at relatively high concentrations. Divalent manganese is a  $3d^5$  ion and typically forms high-spin complexes lacking crystal field stabilization energies. The previous properties, as well as a large ionic radius and small charge-to-radius ratio, result in manganese tending to form weak complexes compared with other first-row divalent ions, such as  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$ . Free  $\text{Mn}^{2+}$  has a strong isotropic electron paramagnetic resonance (EPR) signal that can be used to determine its concentration in the low micromolar range.  $\text{Mn}^{3+}$  is also critical in biological systems. For example,  $\text{Mn}^{3+}$  is the oxidative state of manganese in superoxide dismutase, is the form in which transferrin binds manganese, and is probably the form of manganese that interacts with  $\text{Fe}^{3+}$ . Given its smaller ionic radius, the chelation of  $\text{Mn}^{3+}$  in biological systems would be predicted to be more avid than that of  $\text{Mn}^{2+}$ . Cycling between  $\text{Mn}^{3+}$  and  $\text{Mn}^{2+}$  has been suggested to be deleterious to biological systems because it can generate free radicals. However, at low concentrations,  $\text{Mn}^{2+}$  can provide protection against free radicals, and it appears to be associated with their clearance rather than their production.

## Dietary Sources

Manganese concentrations in typical food products range from 0.4  $\mu\text{g g}^{-1}$  (meat, poultry, and fish) to 20  $\mu\text{g g}^{-1}$  (nuts, cereals, and dried fruit). Breast milk is exceptionally low in manganese, containing only 0.004  $\mu\text{g g}^{-1}$ , whereas infant formula can contain up to 0.4  $\mu\text{g g}^{-1}$ . Teas can be particularly rich in manganese, containing up to 900  $\mu\text{g g}^{-1}$  of the element. An important consideration with respect to food sources of manganese is the extent to which the manganese is available for absorption. For example, although tea contains high amounts of the element, the tannin in tea can bind a significant amount of manganese, reducing its absorption from the gastrointestinal tract. Similarly, the high content of phytates and fiber constituents in cereal grains may limit the absorption of manganese. Conversely, although meat products contain low concentrations of manganese, absorption and retention of manganese from them is relatively high. Based on studies utilizing whole body retention curves after dosing with  $^{54}\text{Mn}$ , the estimated percentage absorption of 1 mg of manganese from a test meal was 1.35%, whereas that from green leafy vegetables (lettuce and spinach) was closer to 5%. Absorption from wheat and sunflower seed kernels was somewhat lower than that from the leafy greens

at 1 or 2%, presumably due to a higher fiber content or to higher amounts of phytates and similar compounds in the wheat and sunflower seeds. The dephytinization of soy formula increased manganese absorption 2.3-fold from 0.7 to 1.6%.

## Analysis

Although manganese is widely distributed in the biosphere, it occurs in only trace amounts in animal tissues. Serum concentrations can be as low as 20 nM and typical tissue concentrations are less than  $4 \mu\text{mol g}^{-1}$  wet weight; tissue concentrations of  $4\text{--}8 \mu\text{mol g}^{-1}$  wet weight are considered high. Because of the high environmental levels of manganese relative to its concentration in animal tissues, considerable effort must be made to minimize contamination of samples during their collection and handling.

The most common analytical methods that can sensitively measure manganese include neutron activation analysis, X-ray fluorescence, proton-induced X-ray emission, inductively coupled plasma emission, EPR, and flameless atomic absorption spectrophotometry (AAS). Currently, the most common method employed is flameless AAS. All of these methods, with the exception of EPR, measure the total concentration of manganese in the samples. EPR allows selective measurement of bound versus free manganese.

## Physiological Role

### Tissue Concentrations

The average human body contains between 200 and 400  $\mu\text{mol}$  of manganese, which is fairly uniform in distribution throughout the body. There is relatively little variation among species with regard to tissue manganese concentrations. Manganese tends to be highest in tissues rich in mitochondria; its concentration in mitochondria is higher than in cytoplasm or other cell organelles. Hair can accumulate high concentrations of manganese, and it has been suggested that hair manganese concentrations may reflect manganese status. High concentrations of manganese are normally found in pigmented structures, such as retina, dark skin, and melanin granules. Bone, liver, pancreas, and kidney tend to have higher concentrations of manganese ( $20\text{--}50 \text{ nmol g}^{-1}$ ) than do other tissues. Concentrations of manganese in brain, heart, lung, and muscle are typically  $<20 \text{ nmol g}^{-1}$ ; blood and serum concentrations are approximately 200 and  $20 \text{ nmol l}^{-1}$ , respectively. Typical concentrations in cow milk are on the order of  $800 \text{ nmol l}^{-1}$ , whereas human milk contains  $80 \text{ nmol l}^{-1}$ . Bone can account for up to 25% of total body manganese because of its mass. Bone manganese concentrations can be raised or lowered by substantially varying dietary manganese intake over long periods of time, but bone manganese is not thought to be a readily mobilizable pool. The fetus does not accumulate liver manganese before birth, and fetal concentrations are significantly lesser than adult concentrations. This lack of fetal storage can be attributed to the apparent lack of storage proteins and the low prenatal expression of most manganese enzymes.

### Absorption, Transport, and Storage

Absorption of manganese is thought to occur throughout the small intestine. Manganese absorption is not thought to be under homeostatic control. For adult humans, manganese absorption has been reported to range from 2 to 15% when  $^{54}\text{Mn}$ -labeled test meals are used and to be 25% when balance studies are conducted; given the technical problems associated with balance studies, the  $^{54}\text{Mn}$  data are probably more reflective of true absorption values. Data from balance studies indicate that manganese retention is very high during infancy, suggesting that neonates may be particularly susceptible to manganese toxicosis.

The higher retention of manganese in young animals relative to adults in part reflects an immaturity of manganese excretory pathways, particularly that of bile secretion, which is very limited in early life. The avid retention of the small amount of manganese from milk and the postnatal changes in its excretory pattern underscore the considerable changes in manganese metabolism that occur during the neonatal period.

In experimental animals, high amounts of dietary calcium, phosphorus, fiber, and phytate increase the requirements for manganese; such interactions presumably occur via the formation of insoluble manganese complexes in the intestinal tract with a concomitant decrease in the soluble fraction available for absorption. The significance of these dietary factors with regard to human manganese requirements remains to be clarified. Studies in avian species have demonstrated that high dietary phosphorus intakes decrease manganese deposition in bone by approximately 50%. Given that the diet of many individuals may be marginal in manganese ( $\leq 2 \text{ mg day}^{-1}$  intake) whereas high in phosphorus ( $\geq 2000 \text{ mg day}^{-1}$  intake), this antagonism may have important implications for human health. For example, the low fractional absorption of manganese from soy formula has been related to its relatively high phytate content. The mechanism underlying this effect of soy protein on manganese absorption/retention has not been fully delineated. However, dephytinization of soy formula with microbial phytase can markedly enhance manganese absorption.

An interaction between iron and manganese has been demonstrated in experimental animals and humans. Manganese absorption increases under conditions of iron deficiency, whereas high amounts of dietary iron can accelerate the development of manganese deficiency. The chronic consumption of high levels of iron supplements ( $>60 \text{ mg Fe day}^{-1}$ ) can have a negative effect on manganese balance in adult women. The mechanisms underlying the interactions between iron and manganese have not been fully elucidated; however, they likely involve competition for either a transport site or a ligand. Both iron and manganese can utilize divalent metal transporter 1 (DMT1); however, the expression of DMT1 is regulated by iron status via the IRE/IRP system. Thus,

during iron deficiency, DMT1 is upregulated causing an increase in manganese absorption. Rats fed iron-deficient diets accumulate manganese in several brain regions compared with rats fed control diets; the involvement of DMT1 in this accumulation of manganese is an area of active study. It should be noted that the interaction between manganese and iron can also affect the functions of some enzymes. For example, manganese can replace iron in the iron–sulfur center of cytosolic aconitase (IRP-1), resulting in an inhibition of the enzyme and an increase in iron regulatory protein (IRP) binding activity. Given the central role of IRPs in cellular iron metabolism, elevated cellular manganese concentration could in theory disrupt numerous translational events dependent on IRPs. That this in fact occurs is illustrated by the observation that following the addition of manganese to cells in culture, there can be sharp reductions in ferritin protein abundance, whereas there are increases in transferrin receptor abundance. This results in changes in intracellular iron metabolism, as reflected by decreases in mitochondrial aconitase (m-aconitase) abundance.

Manganese entering the portal blood from the gastrointestinal tract may remain free or become associated with  $\alpha_2$ -macroglobulin, which is subsequently taken up by the liver. A small fraction enters the systemic circulation, where it may become oxidized to  $Mn^{3+}$  and bind to transferrin. Studies *in vivo* suggest that the  $Mn^{3+}$  complex forms very quickly in blood, in contrast to the slow oxidation of the  $Mn^{2+}$ –transferrin complex *in vitro*. Manganese uptake by the liver has been reported to occur by a unidirectional, saturable process with the properties of passive mediated transport. After entering the liver, manganese enters one of at least five metabolic pools. One pool represents manganese taken up by the lysosomes, from which it is transferred subsequently to the bile canaliculus. The regulation of manganese is maintained in part through biliary excretion of the element; up to 50% of manganese injected intravenously can be recovered in the feces within 24 h. A second pool of manganese is associated with the mitochondria. Mitochondria have a large capacity for manganese uptake, and the mitochondrial uptake and release of manganese and calcium are thought to be related. A third pool of manganese is found in the nuclear fraction of the cell; the roles of nuclear manganese have not been fully delineated, but one function may be to contribute to the stability of nucleosome structure. A fourth manganese pool is incorporated into newly synthesized manganese proteins; biological half-lives for these proteins have not been agreed upon. The fifth identified intracellular pool of manganese is free  $Mn^{2+}$ . Fluctuations in the free manganese pool may be an important regulator of cellular metabolic control in a manner analogous to those for free  $Ca^{2+}$  and  $Mg^{2+}$ . Consistent with this concept, in pancreatic islets manganese blocks glucose-induced insulin release by altering cellular calcium fluxes, and manganese directly augments contractions in smooth muscle by a mechanism comparable to that of calcium.

The mechanisms by which manganese is transported to, and taken up by, extrahepatic tissues have not been identified. Transferrin is the major manganese binding protein in plasma; however, it is not known to what extent transferrin facilitates the uptake of manganese by extrahepatic tissue. The concentration of manganese citrate in blood can be fairly high, and this complex may be important for manganese movement across the blood–brain barrier. DMT1 may be involved in manganese transport because it is expressed in discrete areas of the brain. Manganese uptake by extrahepatic tissue does not seem to be increased under conditions of manganese deficiency, suggesting that manganese, in marked contrast to iron, does not play a role in the induction (or suppression) of manganese transport proteins.

There is limited information concerning the hormonal regulation of manganese metabolism. Fluxes in the concentrations of adrenal, pancreatic, and pituitary–gonadal axis hormones affect tissue manganese concentrations; however, it is not clear to what extent hormone-induced changes in tissue manganese concentrations are due to alterations in cellular uptake of manganese-activated enzymes or metalloenzymes.

## Metabolic Function and Essentiality

Manganese functions as a constituent of metalloenzymes and as an enzyme activator. Manganese-containing enzymes include arginase (EC 3.5.3.1), pyruvate carboxylase (EC 6.4.1.1), and manganese–superoxide dismutase (MnSOD) (EC 1.15.1.1). Arginase, the cytosolic enzyme responsible for urea formation, contains 4 mol  $Mn^{2+}$  per mole of enzyme. Reductions in arginase activity resulting from manganese deficiency result in elevated plasma concentrations of ammonia and lowered plasma concentrations of urea. Reductions in arginase activity due to manganese deficiency may affect flux of arginine through the nitric oxide synthase (NOS) pathway, resulting in alterations in NO production. It has been suggested that arginase plays a regulatory role in NO production by competing with NOS for the same substrate, arginine. Rats fed manganese-deficient diets have shown effects indicative of increased NO production, such as increases in plasma and urinary nitrates plus nitrites and decreased blood pressure; however, neither NOS activity nor NO production have been measured directly. In addition, manganese binding by arginase is critical for the pH-sensing function of this enzyme in the ornithine cycle, suggesting that manganese plays a role in the regulation of body pH. With experimental diabetes, liver and kidney manganese concentrations and arginase activity can be markedly elevated. This manganese effect on arginase has been suggested to be due to an effect of  $Mn^{2+}$  on the conformational properties of the enzyme with a resultant modification of arginase activity. Whether this finding implies an increased manganese requirement for people with diabetes has not been determined.

Pyruvate carboxylase, the enzyme that catalyzes the first step of carbohydrate synthesis from pyruvate, also contains 4 mol  $Mn^{2+}$  per mole enzyme. Although the activity of this enzyme can be lower in manganese-deficient animals than in controls, gluconeogenesis has not been shown to be markedly inhibited in manganese-deficient animals.

MnSOD catalyzes the disproportionation of  $\cdot O_2^-$  to  $H_2O_2$  and  $\cdot O_2$ . The essential role of MnSOD in the normal biological function of tissues has been clearly demonstrated by the homozygous inactivation of the *SOD2* gene for MnSOD in mice. Mice with this phenotype die within the first 10 days of life with a dilated cardiomyopathy, accumulation of lipid in liver and skeletal muscle, and

metabolic acidosis. The activity of MnSOD in tissues of manganese-deficient rats can be significantly lower than in controls due to downregulation of MnSOD at the (pre)transcriptional level. That this reduction is functionally significant is suggested by the observation of higher than normal levels of hepatic mitochondrial lipid peroxidation in manganese-deficient rats. Tissue MnSOD activity can be increased by several diverse stressors, including alcohol, ozone, irradiation, interleukin-1, and tumor necrosis factor- $\alpha$ , presumably as a consequence of stressor-associated increases in cellular free radical (or oxidized target(s)) concentrations. Stressor-induced increases in MnSOD activity can be attenuated in manganese-deficient animals, potentially increasing their sensitivity to these insults. Transgenic mice have also been produced that overexpress MnSOD; a decreased severity of reperfusion injury has been noted in these animals, further supporting its physiological significance.

Considerable research is focused on the introduction of the human MnSOD gene into research animals utilizing viral vectors or plasmid/liposome delivery. This gene therapy has been shown to decrease radiation-induced injury, extend pancreatic islet transplant function, and slow the growth of malignant tumors in animal models via overexpression of the MnSOD protein. Another field of research that is rapidly advancing utilizes MnSOD mimetics for treatment of a variety of diseases in which the native SOD enzyme has been found to be effective. These mimetics are small manganese-containing synthetic molecules that have catalytic activity equivalent or superior to the native enzyme. They possess the additional beneficial properties of being nonimmunogenic because they are nonpeptides, able to penetrate cells, selective for superoxide (they do not interact with biologically important molecules), stable *in vivo*, and not deactivated by the destructive free radical peroxynitrite, which is capable of deactivating native MnSOD via nitration of tyrosine. These mimetic compounds have been found to be protective in animal models of acute and chronic inflammation, reperfusion injury, shock, and radiation-induced injury. Both of these therapies, MnSOD gene delivery and MnSOD mimetics, hold promise for future treatments in human chronic and acute conditions.

Finally, further evidence for the biological and research relevance of MnSOD is that experiments have been undertaken on the International Space Station to improve three-dimensional growth of MnSOD crystals in order to develop a better understanding of the role of structure in the reaction mechanism of this enzyme.

In contrast to the relatively few manganese metalloenzymes, there are a large number of manganese-activated enzymes, including hydrolases, kinases, decarboxylases, and transferases. Manganese activation of these enzymes can occur as a direct consequence of the metal binding to the protein, causing a subsequent conformation change, or by binding to the substrate, such as adenosine triphosphate (ATP). Many of these metal activations are nonspecific in that other metal ions, particularly  $Mg^{2+}$ , can replace  $Mn^{2+}$ . An exception is the manganese-specific activation of glycosyltransferases. Several manganese deficiency-induced pathologies have been attributed to a low activity of this enzyme class. A second example of an enzyme that may be specifically activated by manganese is phosphoenolpyruvate carboxykinase (PEPCK; EC 4.1.1.49), the enzyme that catalyzes the conversion of oxaloacetate to phosphoenolpyruvate, GDP, and  $CO_2$ . Although low activities of PEPCK can occur in manganese-deficient animals, the functional significance of this reduction is not clear.

A third example of a manganese-activated enzyme is glutamine synthetase (EC 6.3.1.2). This enzyme, found in high concentrations in the brain, catalyzes the reaction  $NH_3 + \text{glutamate} + \text{ATP} \rightarrow \text{glutamine} + \text{ADP} + P_i$ . Brain glutamine synthetase activity can be normal even in severely manganese-deficient animals, suggesting that the enzyme either has a high priority for this element or magnesium can act as a substitute when manganese is lacking. It should be noted that this enzyme can be inactivated by oxygen radicals; therefore, a manganese deficiency-induced reduction in MnSOD activity theoretically could act to depress further the activity of glutamine synthetase.

## Manganese Deficiency

Manganese deficiency has been demonstrated in several species, including rats, mice, pigs, and cattle. Signs of manganese deficiency include impaired growth, skeletal abnormalities, impaired reproductive performance, ataxia, and defects in lipid and carbohydrate metabolism.

The effects of manganese deficiency on bone development have been studied extensively. In most species, manganese deficiency can result in shortened and thickened limbs, curvature of the spine, and swollen and enlarged joints. The basic biochemical defect underlying the development of these bone defects is a reduction in the activities of glycosyltransferases; these enzymes are necessary for the synthesis of the chondroitin sulfate side chains of proteoglycan molecules. In addition, manganese deficiency in adult rats can result in an inhibition of both osteoblast and osteoclast activity. This observation is particularly noteworthy, given the reports that women with osteoporosis tend to have low blood manganese concentrations and that the provision of manganese supplements might be associated with an improvement in bone health in postmenopausal women.

One of the most striking effects of manganese deficiency occurs during pregnancy. When pregnant animals (rats, mice, guinea pigs, and mink) are deficient in manganese, their offspring exhibit a congenital, irreversible ataxia characterized by incoordination, lack of equilibrium, and retraction of the head. This condition is the result of impaired development of the otoliths, the calcified structures in the inner ear responsible for normal body-righting reflexes. The block in otolith development is secondary to depressed proteoglycan synthesis due to low activity of manganese-requiring glycosyltransferases.

Defects in carbohydrate metabolism, in addition to those described previously, have been shown in manganese-deficient rats and guinea pigs. In the guinea pig, perinatal manganese deficiency results in pancreatic pathology, with animals exhibiting aplasia or marked hypoplasia of all cellular components. Manganese-deficient guinea pigs and rats given a glucose challenge often respond with a diabetic-type glucose tolerance curve. In addition to its effect on pancreatic tissue integrity, manganese deficiency can directly

impair pancreatic insulin synthesis and secretion as well as enhance intracellular insulin degradation. The mechanism(s) underlying the effects of manganese deficiency on pancreatic insulin metabolism have not been fully delineated, but they are thought to be multifactorial. For example, the flux of islet cell manganese from the cell surface to an intracellular pool may be a critical signal for insulin release. It is also known that insulin messenger ribonucleic acid levels are reduced in manganese-deficient animals, which is consistent with their depressed insulin synthesis. In addition, insulin sensitivity of adipose tissue is reduced in manganese-deficient rats, a phenomenon that may be related to fewer insulin receptors per adipose cell. Manganese deficiency may also affect glucose metabolism by means of a reduction in the number of glucose transporters in adipose tissue by an unidentified mechanism. Finally, the effect of manganese deficiency on insulin production may also be due to the destruction of pancreatic  $\beta$  cells. It is worth noting that constitutive pancreatic MnSOD activity is lower than in most tissues; this, coupled with the observation that most diabetogenic agents function via the production of free radicals with subsequent tissue damage, suggests that an additional mechanism underlying pancreatic dysfunction in manganese-deficient animals may be free radical mediated.

In addition to its effect on endocrine function, manganese deficiency can affect pancreatic exocrine function. For example, manganese-deficient rats can be characterized by an increase in pancreatic amylase content. The mechanism underlying this effect of manganese deficiency has not been delineated; however, it is thought to involve a shift in amylase synthesis or degradation because secretagogue-stimulated acinar secretion is comparable in control and manganese-deficient rats.

Although a majority of studies concerning the influence of manganese deficiency on carbohydrate metabolism have been conducted with experimental animals, there is one report in the literature of an insulin-resistant diabetic patient who responded to oral doses of manganese (doses ranged from 5 to 10 mg) with decreasing blood glucose concentrations. Although this is an intriguing case report, others have reported a lack of an effect of oral manganese supplements (up to 30 mg) in diabetic subjects, and low blood manganese concentrations have not been found to be a characteristic of diabetics.

Abnormal lipid metabolism is also characteristic of manganese deficiency: Specifically, a lipotropic effect of manganese has been suggested in the literature. Severely manganese-deficient animals can be characterized by high liver fat, hypocholesterolemia, and low high-density lipoprotein (HDL) concentrations. Deficient animals can also be characterized by a shift to smaller plasma HDL particles, lower HDL apolipoprotein (apoE) concentrations, and higher apoC concentrations. As stated previously, tissue lipid peroxidation rates can be increased in manganese-deficient animals, possibly as a result of low tissue MnSOD activity.

There is considerable debate as to the extent to which manganese deficiency affects humans under free-living conditions. Manganese deficiency can be induced in humans under highly controlled experimental conditions. In one study, manganese deficiency was induced in adult male subjects by feeding a manganese-deficient diet ( $0.1 \text{ mg Mn day}^{-1}$ ) for 39 days. The subjects developed temporary dermatitis, as well as increased serum calcium and phosphorus concentrations and increased alkaline phosphatase activity, suggestive of bone resorption. Since the late 1980s, several diseases have been reported to be characterized, in part, by low blood manganese concentrations. These diseases include epilepsy, Msele disease, maple sirup urine disease and phenylketonuria, Down's syndrome, osteoporosis, and Perthes' disease. The finding of low blood manganese levels in subsets of individuals with the previously mentioned diseases is significant because blood manganese levels can reflect soft tissue manganese concentrations. The reports of low blood manganese concentrations in individuals with epilepsy are particularly intriguing, given the observations that manganese-deficient animals can show an increased susceptibility to drug and electroshock-induced seizures, and a genetic model for epilepsy in rats (the GEPR rat) is characterized by low blood manganese concentrations. It is evident that a deficiency of manganese may contribute to the pathology of epilepsy at multiple points, given that  $\text{Mn}^{2+}$  is implicated in activation of glutamine synthetase, a  $\text{Mn}^{2+}$ -specific brain ATPase; production of cyclic adenosine monophosphate (AMP); altered synaptosomal uptake of noradrenalin and serotonin; glutamate, GABA, and choline metabolism; and biosynthesis of acetylcholine receptors.

Evidence of widespread manganese deficiency in human populations is lacking. Typically, manganese intakes approximate the 2001 US Institute of Medicine's suggested adequate intakes as follows:  $3 \text{ } \mu\text{g day}^{-1}$  for infants 0–6 months old,  $0.6 \text{ mg day}^{-1}$  for infants 7–12 months old,  $1.2\text{--}1.9 \text{ mg day}^{-1}$  for children 1–13 years old,  $1.6\text{--}2.2 \text{ mg day}^{-1}$  for older children, and  $1.8\text{--}2.6 \text{ mg day}^{-1}$  for adults. The Tolerable Upper Intake Level (UL) is the highest level of a daily nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals. The Institute of Medicine's recommended intakes for manganese set ULs at 2, 3, and 6 mg day Upper Intake Level (UL) for children 1–3, 4–8, and 9–13 years old, respectively. Values were set at  $9 \text{ mg day}^{-1}$  for adolescents 14–18 years old and at  $11 \text{ mg day}^{-1}$  for adults.

## Manganese Toxicity

In domestic animals, the major reported lesion associated with chronic manganese toxicity is iron deficiency, resulting from an inhibitory effect of manganese on iron absorption. Additional signs of manganese toxicity in domestic animals include depressed growth, depressed appetite, and altered brain function.

In humans, manganese toxicity represents a serious health hazard, resulting in severe pathologies of the central nervous system. In its most severe form, the toxicosis is manifested by a permanent crippling neurological disorder of the extrapyramidal system, which is similar to Parkinson's disease. In its milder form, the toxicity is expressed by hyperirritability, violent acts, hallucinations, disturbances of libido, and incoordination. The previous symptoms, once established, can persist even after the manganese body burden returns to normal. Although a majority of reported cases of manganese toxicity occur in individuals exposed to high concentrations of airborne manganese ( $>5 \text{ mg m}^{-3}$ ), subtle signs of manganese toxicity, including delayed reaction time, impaired motor coordination, and impaired memory, have been observed in workers exposed to airborne manganese concentrations less than  $1 \text{ mg m}^{-3}$ . Therefore, an

inhalation reference concentration range for manganese has been established by the US Environmental Protection Agency to be between 0.09 and 0.2  $\mu\text{g m}^{-3}$ . Manganese toxicity has been reported in individuals who have consumed water containing high levels ( $\geq 10 \text{ mg Mn}$ ) of manganese for long periods of time. Recently, there has been concern that the risk for manganese toxicity may be increasing in some areas because of the use of MMT in gasoline as an antiknock agent, although there is little evidence that air, water, or food manganese concentrations have increased where this fuel is used.

In addition to neural damage, reproductive and immune system dysfunction, nephritis, testicular damage, pancreatitis, lung disease, and hepatic damage can occur with manganese toxicity, but the frequency of these disorders is unknown. Although there is a limited body of epidemiological data that suggests that high levels of manganese can result in an increased risk for colorectal and digestive tract cancers, most investigators do not consider manganese to be a carcinogen. In contrast, both divalent ( $\text{MnCl}_2$ ) and heptavalent forms ( $\text{KMnO}_4$ ) of manganese are recognized to be strong clastogens both *in vitro* and *in vivo*; exposure to high concentrations of either form results in chromosomal breaks, fragments, and exchanges. High concentrations of manganese can also induce forward and point mutations in mammalian cells. High levels of dietary manganese have not been reported to be teratogenic in the absence of overt signs of maternal toxicity. However, there are reports that exposure to high levels of manganese during prenatal development can result in behavioral abnormalities. High levels of brain manganese have been reported in subjects with amyotrophic lateral sclerosis, and it has been suggested that this increase may contribute to the progression of the disease. Similar to the cases in humans, chronic manganese toxicity in rhesus monkeys is characterized by muscular weakness, rigidity of the lower limbs, and neuron damage in the substantia nigra. Findings from a recent study suggest that iron and aluminum, which accumulate in the globus pallidus and the substantia nigra of these animals, induce tissue oxidation that may contribute to the damage associated with manganese toxicity. Neural toxicity is a consistent finding in rats exposed to chronic manganese toxicity. Significant manganese accumulation was accompanied by an increase in cholesterol content in the hippocampal region of manganese-treated rats, which was associated with impaired learning; this impairment was corrected by an inhibitor of cholesterol synthesis. The development of manganese toxicity in individuals with compromised liver function, or compromised biliary pathways, is well documented. Significantly, these individuals can have abnormal magnetic resonance imaging (MRI) patterns, which improve following the alleviation of the manganese toxicity. For example, in some cases improvements in brain function have been achieved after liver transplant. The mechanisms underlying the toxicity of manganese have not been agreed on but may involve multiple etiologies, including endocrinological dysfunction, excessive tissue oxidative damage, manganese-mediated disruptions in intracellular calcium and iron metabolism, and mitochondrial dysfunction caused by manganese inhibition of some pathways of the mitochondrial respiratory chain.

Severe cases of manganese toxicity in humans have been reported for adults, as well as isolated cases in other groups of individuals who are vulnerable, including children on long-term parenteral nutrition and parenteral nutrition patients who have cholestasis or other hepatic disease. In many cases, the previously mentioned groups of individuals have been reported to be characterized by high brain manganese concentrations based on MRI. Although no known cases have been reported, infants may be at a high risk for manganese toxicity due to a high absorptive capacity for the element or an immature excretory pathway for it. If manganese is taken up by extrahepatic tissues via the manganese–transferrin complex, the developing brain may be particularly sensitive to manganese toxicity due to the high number of transferrin receptors elaborated by neuronal cells during development, coupled with the putative need by neural cells for transferrin for their differentiation and proliferation. Newborn rats given daily doses of dietary manganese at a level equivalent to that of soy formula exhibited significant neurodevelopmental delays as assessed by several behavioral tests. It should be noted that the concentration of manganese in soy formula is relatively modest but approximately 60–100 times higher than that of breast milk. Brain manganese concentration was increased and striatal dopamine concentrations were significantly decreased even 45 days after the supplementation ended, suggesting that the impact of manganese on the brain and behavior was irreversible. Thus, dietary exposure to high levels of manganese during infancy can be neurotoxic to rat pups and result in developmental deficits. Further studies on human infants fed diets with different levels of manganese are needed to assess whether there are any long-term consequences of early manganese exposure of newborns.

Another group of neuropathological conditions that has been associated with elevated levels of brain manganese is transmissible spongiform encephalopathies. These diseases found in animals and humans are also referred to as prion diseases. There is strong evidence that in their native state, prions are normal brain glycoproteins that bind copper and have an antioxidant function. However, it has been suggested that in the disease process an abnormal isoform of the protein is generated in which manganese is substituted for copper. This isoform is proteinase resistant, no longer has antioxidant activity, and may play a role in the etiology of these diseases. Indeed, elevated levels of brain manganese, along with lower than normal levels of brain copper, have been measured in patients with the prion disease, Creutzfeldt–Jakob disease. Whether the elevated levels of brain manganese observed in these patients as well as in animal models of these diseases play an important role in their pathogenesis or are secondary to other factors remains to be determined.

## Assessment of Manganese Status

Reliable biomarkers for the assessment of manganese status have not been identified. Whole blood manganese concentrations are reflective of soft tissue manganese levels in rats; however, it is not known whether a similar relationship holds for humans. Plasma manganese concentrations decrease in individuals fed manganese-deficient diets and are slightly higher than normal in individuals consuming manganese supplements. Lymphocyte MnSOD activity and blood arginase activity are increased in individuals who

consume manganese supplements; however, their value as biomarkers for manganese status may be complicated due to the number of cytokines and disease states that may also increase their expression. Urinary manganese excretion has not been found to be sensitive to dietary manganese intake. With respect to the diagnosis of manganese toxicosis, the use of MRI appears to be promising because the images associated with manganese toxicity are relatively specific. Whole blood manganese concentrations can be correlated with MRI intensity and T<sub>1</sub> values in the globus pallidus even in the absence of symptoms of neurological damage. Thus, although it is relatively expensive, MRI may be particularly useful as a means of identifying susceptible individuals in, or around, manganese-emitting factories. In addition, the method may be useful in the evaluation of patients with liver failure.

## Glossary

**B-vitamins** There are seven B-group vitamins that are all essential components of human diets. All are either enzyme cofactors *per se* or are converted in the body to enzyme cofactors (which are small molecules that form part of the active site of specific enzymes and participate in their catalytic reactions). B-vitamins are efficiently absorbed in the gastrointestinal tract and are resistant to urinary excretion, unless intakes and blood concentrations exceed tissue requirements.

**Clinical deficiency** Often results from severe prolonged tissue (nutrient) deficiency, which may in turn result from inadequate (nutrient) intake, but may also arise from impaired absorption, increased turnover, and excretion, increased tissue demand, etc. Deficiency signs are directly observable; symptoms can be elicited by testing, and the response of these to interventions (e.g., nutrient supplementation) can help to confirm a diagnosis of deficiency.

**Estimated Average Requirement (EAR)** Similar to RDA and RNI, except that this is the mean (i.e., average) nutrient requirement of the individuals in a defined population group (USA and UK).

**Nutrient (e.g., vitamin) status** Is commonly assessed by measuring the concentration of the nutrient or a derivative in an accessible body fluid such as serum or urine or else the functionality of an enzyme or a biochemical pathway (functional status). Published 'normal ranges' enable the result to be classified as, for example, deficient, low, normal, or high.

**Recommended Dietary Allowance (RDA)** The amount of a nutrient (per day) that covers the needs of the majority (usually approximately 97.5%) of the individuals in a defined population group (e.g., adult males) in the USA. The term 'Reference Nutrient Intake' (RNI) is used for a similar concept in the UK.

## History, Signs and Symptoms of Deficiency, and Antimetabolites

Pellagra (meaning 'rough' or 'raw' skin) was common in western Europe (e.g., France, Italy) and especially in the southern half of the USA, up to the early twentieth century: it caused approximately 10 000 deaths in the USA in 1929 alone. The typical signs and symptoms of human pellagra are listed in [Table 1](#) and the history of its recognition and causation in [Table 2](#).

By 1810, a European source concluded that the disease was neither contagious nor hereditary but probably caused by poor diets, especially those in which grains such as corn (i.e., maize) were the principal staple; a good hospital diet was curative. By 1860, it was known that poor Mexican peasants, whose diet was mainly corn-based but roasted the corn with lime did not exhibit pellagra. However, for approximately the next 50 years, the 'toxin' theory of pellagra-causation held sway. In Europe, the prevalence of pellagra declined markedly, just as it was beginning to emerge as a major scourge in the southern USA. Poor sanitation, infection, insect-borne disease, and toxins from bacteria or molds were variously blamed – until Joseph Goldberger, from 1914 until his death in 1929, carried out controlled feeding studies in human convicts and an animal model ('blacktongue', a corn diet-induced condition in dogs ([Table 1](#))). The important outcome was that pellagra was now seen not as an infectious disease, but as primarily diet related.

Funk's newly formulated hypothesis of essential dietary vitamins and Gowland Hopkins' concept of 'accessory food factors' then initiated a search for curative organic substance(s). Goldberger classified foods according to their 'pellagra-preventative' (PP) properties, and found that both dried yeast and a water-soluble extract from yeast were curative in small quantities. During the 1930s, and following recognition of the role of pyridine nucleotide coenzymes in food energy release, the central roles of nicotinic acid and nicotinamide were elucidated and equated with the 'PP' factor. The term 'niacin' was then coined, because nicotinic acid was associated with tobacco and hence considered unsuitable for an essential dietary factor.

**Table 1** Signs and symptoms of niacin deficiency in humans and animals

---

1. <i>Human deficiency</i>
Loss of appetite and weight
Dermatosis (hyperpigmentation, hyperkeratosis, desquamation of the epidermis, especially where frequently exposed to strong sunlight)
Anorexia
Achlorhydria
Angular stomatitis, cheilosis, magenta tongue
Diarrhea
Anemia
Neuropathy (headache, dizziness, tremor, neurosis, apathy)
Death in severe and prolonged cases
2. <i>Blacktongue in dogs and cats</i>
Pustules in mouth and excessive salivation, darkening, and necrosis of the tongue
Diarrhea
3. <i>Pigs</i>
Neurological lesions affecting ganglion cells; histopathology of nerves
Anemia
Degeneration of intestinal mucosa and diarrhea
4. <i>Rats</i>
Reduced growth rate
Alopecia (roughened skin)
Damage to peripheral nerves (cells and axons)
5. <i>Birds (e.g., chickens, ducks)</i>
Inflammation of the upper gastrointestinal tract
Dermatitis
Diarrhea
Poor growth of feathers; bowed and weakened legs

---

Although pellagra in dogs and humans responds well to supplements of pure niacin, there were further strands to the story. For instance, the niacin content of foods, as measured by chemical analysis, was not always a good guide to their pellagra-producing or -preventing properties (as in [Table 3](#)). During the 1940s, it was shown that in rats (which respond to pellagragenic diets by a reduced growth rate but not by skin lesions), high dietary tryptophan levels reduced the requirement for niacin. Tryptophan was then shown to be effective in humans in reducing the pellagragenic properties of diets, and the metabolic pathway linking tryptophan to niacin and to the pyridine nucleotide coenzymes was elucidated ([Figure 1](#)). Between 34 and 86 mg tryptophan in human diets is now considered to be equivalent to 1 mg niacin, with a mean conversion ratio of 60 mg tryptophan per milligram of niacin, now the basis of niacin equivalents (NEs) value of a diet. This is a much better index of antipellagra potency than niacin content alone ([Table 3](#)).

The causes of pellagra in human populations, and indeed in Goldberger's experimental studies, are a complex mixture of B-vitamin deficiencies, of which niacin and tryptophan are the dominant effectors, but riboflavin is also important, followed by thiamin, vitamin B<sub>6</sub>, and other nutrients. Several bacterial, fungal, and other toxins can deplete the cellular levels of nicotinamide adenine dinucleotide phosphate (NAD(P)), and niacin in corn and other grains is often chemically bound into a macromolecular complex, niacytin, from which niacin cannot be released by digestive enzymes in the gastrointestinal tract, but that requires heat and alkali treatment (as in the preparation of Mexican tortillas) to make it bioavailable.

In India, the millet staple 'jowar' is frequently associated with pellagra signs and symptoms, even though it is apparently a reasonably good source of available niacin and tryptophan. Local studies suggested an association with jowar's high leucine content, which may impair the conversion of tryptophan to niacin coenzymes, but this remains controversial: balance studies in humans have failed to show a consistent effect of leucine on excretion of tryptophan metabolites, a sensitive test for impairment of tryptophan-conversion pathways. In parts of South Africa, iron overload has been reported to complicate the metabolic effects of low niacin intakes.

Estrogenic hormones affect the conversion of tryptophan to niacin coenzymes, hence women (except during pregnancy) are more susceptible to pellagra than men. Several drugs have antiniacin (iatrogenic) effects. Thus isoniazid, commonly used in the treatment of tuberculosis, inhibits kynureninase (an enzyme in the tryptophan conversion pathway) activity by inactivating the enzyme cofactor, pyridoxal phosphate. Any interference with vitamin B<sub>6</sub> metabolism is also likely to affect niacin economy as well. Because *ca.* 60% of Indians are genetically slow acetylators (i.e., deactivators) of isoniazid, this drug is especially likely to cause pellagra. Anti-Parkinsonism drugs Carbidopa and Benseride can cause pellagra symptoms and reduce the excretion of *N*-methylnicotinamide. Some antineoplastic drugs, for example 6-dimethylaminonicotinamide and 6-aminonicotinamide, inhibit key

**Table 2** History of pellagra, and recognition of its causes, in human populations

1. A poorly understood disease (dermatitis, gastrointestinal, and mental signs/symptoms) appeared in Europe in the eighteenth and nineteenth centuries, and then in southern USA in the first decade of the twentieth century and was named 'pellagra' (meaning raw/rough skin).
2. Favored causal hypotheses included infection, moldy grain, and insects.
3. 1914–1916, Joseph Goldberger disproved the infection hypothesis: by self-experimentation and then producing pellagra in prisoners fed mainly corn diets.
4. 1920s, Joseph Goldberger developed the 'blacktongue' model of pellagra in dogs, with corn diets.
5. 1930s, nicotinic acid was isolated as a pure water-soluble compound (vitamin) of known structure, from yeast and liver extracts, able to cure pellagra and blacktongue.
6. Mid-twentieth century, unavailable niacin is bound in the complex niacytin in corn. Heating in an alkaline environment (as in Mexican tortillas) can release it.
7. Niacin can be produced from tryptophan in the body. Pellagragenic diets are low in tryptophan as well as in niacin. The concept of 'niacin equivalents' (milligram niacin plus one-sixtieth of milligram tryptophan) in food developed. Human requirements estimated.
8. The Indian cereal 'jowar' is shown to be pellagragenic. Some, but not all, studies have implicated its high leucine content.
9. Niacin and riboflavin deficiencies often coexist; the signs and symptoms of pellagra-like disease are often attributable to multiple nutrient deficiencies.
10. Certain inborn errors of metabolism (genetic defects), or iatrogenic effects of drugs, can mimic the signs, symptoms, and metabolic defects of pellagra.

enzymes whose substrates are nicotinamide adenine dinucleotide (NAD) or NADP by being converted *in vivo* to analogs of the coenzymes. 3-Acetyl-pyridine, which also forms an analog of NAD, has either antagonistic or niacin-replacing properties, depending on the dose used. Metronidazole is a niacin antagonist, as is 2-amino-1,3,4-triazole.

Some inborn errors of metabolism can result in pellagra-like symptoms in humans. Thus in Hartnup disease, an autosomal recessive condition in which the cellular transport of tryptophan (and other neutral amino acids) is impaired, tryptophan is lost in the urine through a failure of renal tubular reabsorption. Supplementation with niacin or with tryptophan peptides (but not free tryptophan) can be palliative. Another genetic disease that may respond to niacin supplements is Fredrikson type I familial hypercholesterolemia; nicotinic acid lowers the raised blood cholesterol levels that are associated with it.

Other inborn errors of tryptophan economy include xanthurenic aciduria, hydroxykynurenuria, tryptophanuria (i.e., tryptophan dioxygenase deficiency), and excessive picolinate carboxylase activity. Tumors of the enterochromaffin cells, which synthesize excessive amounts of 5-hydroxytryptophan and 5-hydroxytryptamine, can also result in pellagra, because hyperactivity of this pathway results in the diversion of tryptophan.

Chronic alcoholics represent a high-risk for the development of pellagra in western society, having poor diets and liver damage due to alcohol abuse. Certain psychoses, including depression and schizophrenia, are associated with abnormalities of tryptophan

**Table 3** Niacin equivalents in selected foods

	Niacin equivalents from preformed niacin (mg per 100 g)	Niacin equivalents from tryptophan (mg per 100 g)	Total Niacin equivalents (mg per 100 g)/(mg per MJ)
Milk	0.2	0.6	0.8/2.9
Raw beef	5.0	4.7	9.7/18
Raw white fish	2.4	3.4	5.8/17
Raw eggs	0.1	3.7	3.8/6.1
Raw potatoes	0.6	0.5	1.1/3.4
Raw peas	2.5	1.1	3.6/10.5
Raw peanuts	13.8	2.9	19.3/8.2
White bread	1.6	2.0	3.6/2.5
Rice, uncooked	4.2	1.6	5.8/3.6
Maize (sweetcorn)	2.0	0.5	2.5/5.3
Cornflakes (fortified)	15.0	0.9	15.9/10.0
Coffee	24.8	2.9	27.7/87

*Note:* Coffee is a good source of niacin, because it is released from the bound form, trigonelline, by roasting. Much of the niacin in maize and part of that in other cereals, including unfortified bread, is unavailable for use by the body, being bound in large molecular complexes.

On average, 60 mg tryptophan yields 1 mg NE.

**Figure 1** *In vivo* conversion of tryptophan to nicotinic acid and NAD.

metabolism pathways, including those involved in the formation of 5-hydroxytryptamine (serotonin) and 5-hydroxytryptophan in the central nervous system. Some patients may benefit from the modulation of these pathways by drugs and supplements. People with AIDS exhibit impairment of NAD production, which can respond to niacin supplements, and high-dose nicotinic acid is being used as part of the treatment of cardiovascular diseases (see the Section on Dietary Sources and High Intakes below). Diet-associated pellagra is still prevalent in some African countries, e.g., refugees in Malawi, and in parts of India and China.

**Table 4** Recommended and reference intakes of niacin equivalents<sup>a</sup>

Age group	UK <sup>b</sup>		USA <sup>c</sup>
	LRNI (mg Niacin equivalents per day)	RNI	RDA (mg Niacin equivalents per day <sup>-1</sup> )
0–6 months	2	3	2
6–12 months	3–4	4–5	4
12 months–13 years	5–10	8–15	6–12
Adult	8–12	13–18	14–16
Lactation	10	15	17

This table provides a simplified summary of the published values.

<sup>a</sup>One niacin equivalent (mg NE) is equivalent to 1 mg niacin or one-sixtieth of the milligram tryptophan consumed.

<sup>b</sup>UK values are calculated on the basis of Lower Reference Nutrient Intake (LRNI) of 4.4 mg NE per 1000 kcal food energy, and Reference Nutrient Intake (RNI) of 6.6 mg NE per 1000 kcal, both of which are constant for all the population groups. The LRNI is intended to cover the needs of the lower 2.5% of a healthy population, whereas the RNI is intended to cover 97.5% of a healthy population.

<sup>c</sup>The US Recommended Dietary Allowances (RDAs) are intended to cover the needs of 97.5% of a healthy population.

## Absorption, Transport, and Storage

Preformed niacin (formerly vitamin B<sub>3</sub>) occurs in foods either as nicotinamide (niacinamide) or as the pyridine (i.e., nicotinamide) nucleotide coenzymes derived from it, or as nicotinic acid, which lacks the amide nitrogen, and is the form known as niacin in North America. Both nicotinamide and nicotinic acid are equally effective in vitamin potency, but in large doses, they exert markedly different pharmacological effects; thus, it is important, at least in that context, to make the distinction.

The most important sources of preformed niacin in most foods, particularly animal foods, are the pyridine (i.e., nicotinamide) nucleotides, NAD(H) and NADP(H). Hydrolases and pyrophosphatases in biological tissues convert these coenzymes to tissue sources of the vitamin. NAD glycohydrolase and pyrophosphatase enzymes are present in the gut mucosa, and absorption of nicotinamide or nicotinic acid by the mammalian intestine consists of a saturable transport system, dominant at low intakes and dependent on sodium, energy, and pH, plus a nonsaturable component that is dominant at high doses or intakes. Absorption is efficient even at high doses of 3 g or more: as much as 85% then being excreted in the urine. Absorption of test niacin doses introduced directly into the human upper ileum is rapid, peak levels appearing in blood plasma within 5–10 min. Absorption also occurs in the large intestine, making niacin from gut bacteria available to the intestinal cells.

Transport of niacin between the liver and the intestine can occur *in vivo*, as indicated by radioactive probes in animals, and the liver is a major site of conversion of niacin to its functional products: the nicotinamide–nucleotide coenzymes. Nicotinamide can pass readily between the cerebrospinal fluid and the plasma, thus ensuring a sufficient supply to the brain and the spinal cord. The liver contains greater niacin coenzyme concentrations than most other tissues, but all metabolically active tissues contain these essential coenzymes. As in the gut, both facilitated diffusion (which is sodium- and energy-dependent and saturable) and passive diffusion (which is nonsaturable) contribute to tissue uptake from the bloodstream. Except for muscle, brain, and testis, nicotinic acid is a better precursor of coenzymes than nicotinamide. The liver is the most important site of conversion of tryptophan to the nicotinamide coenzymes.

NAD is present mainly in an oxidized form in the tissues, whereas NADP is principally present in the reduced form, NADPH. There are important homeostatic regulation mechanisms that maintain appropriate ratios of the oxidized and reduced forms in healthy tissues. Once converted to coenzymes within the cells, the niacin is effectively trapped and can only diffuse out again after degradation into smaller molecules. This implies, of course, that the synthesis of coenzyme nucleotides must occur within each tissue and cell type, each of which must possess the enzymatic apparatus for their synthesis from niacin. Loss of nicotinamide and nicotinic acid into the urine is minimized (except when the intake exceeds requirements) by efficient reabsorption from glomerular filtrate.

## Metabolism and Excretion

The conversion pathway of tryptophan to nicotinic acid *in vivo* is shown in [Figure 1](#). The rate of conversion of tryptophan to niacin and the pyridine nucleotides is controlled by the activities of tryptophan dioxygenase (alternatively known as tryptophan pyrrolase), kynurenine hydroxylase, and kynureninase enzymes. These depend on other B-vitamins, glucagon, glucocorticoid hormones, and estrogen metabolites; moreover, competing pathways can affect the rate of conversion. The conversion may be increased threefold in pregnant women and in women taking oral contraceptives. Thus, a variety of nutrient deficiencies, toxins, genetic and metabolic abnormalities, etc. all influence the niacin status and requirements.

The two pyridine (i.e., nicotinamide) nucleotide coenzymes, formerly known as 'coenzymes I and II', then for a period as 'DPN and TPN,' but now as 'NAD' and 'NADP' are involved in hundreds of enzyme-catalyzed redox reactions *in vivo*. Although a few enzymes can use either cofactor, most are highly specific for one or the other.

Catabolism of the pyridine nucleotide coenzymes *in vivo* is achieved by four enzymes: NAD glycohydrolase, ADP ribosyl transferase, and poly (ADP ribose) synthetase (acting in sequence to liberate nicotinamide), and NAD pyrophosphatase (which releases nicotinamide mononucleotide for hydrolysis to nicotinamide). Turnover of nicotinamide then results in the formation of 1-methylnicotinamide ( $N^1$ -methyl nicotinamide or NMN), which is excreted into urine by the kidney, together with 1-methyl-2-pyridone-5-carboxamide and 1-methyl-4-pyridone-3-carboxamide (referred to as 2-pyridone and 4-pyridone, respectively). The concentrations of these excretory products can be used as indicators of whole-body niacin status (see the Section on Assessment of Niacin Status and Requirements below). At high intakes of niacin, as much as 85% may be excreted unchanged; however, the excretion of nicotinamide always predominates over that of nicotinic acid.

Other urinary excretion products of niacin include nicotinuric acid (nicotinoyl glycine), nicotinamide *N*-oxide, and trigonelline ( $N^1$ -methyl nicotinic acid); the latter may arise from bacterial action in the gut or from its absorption from foods. The pattern of metabolites varies between species and between diets (depending partly on the ratio of nicotinamide to nicotinic acid) and with niacin status, indicating complex regulatory mechanisms.

Hydrolysis of hepatic NAD to nicotinamide allows the release of niacin for other tissues. Protection of the coenzyme content of key enzymes such as glyceraldehyde 3-phosphate dehydrogenase confers protection on key metabolic pathways. In contrast, enzymes that catalyze pyridine nucleotide turnover may be hyperactivated in cells damaged by carcinogens, such as mycotoxins, thus starving them of essential cofactors and causing their death. This may help explain why moldy grain in the diet can increase the risk of pellagra when niacin and tryptophan intakes are marginal. In normal healthy cells, the compartmentalization of hydrolytic enzymes limits coenzyme turnover, but this is impaired in damaged cells.

## Metabolic Function and Essentiality

The key functions of niacin involve its coenzymes, NAD and NADP, in the hydrogen/electron-transfer redox reactions in living cells. Like most B-vitamins, niacin is not extensively stored. Inadequate dietary intake leads to tissue depletion within 1–2 months and then successively to biochemical abnormalities, clinical signs of deficiency, and eventually death. As with other B-vitamins, rates of turnover and hence rates of excretion of breakdown products decline progressively as dietary deficiency becomes more severe. Thus the tissue coenzymes are relatively spared.

NAD is responsible for the release of energy during the oxidation of energy-producing fuels. NADP, however, functions mainly in the reductive reactions of lipid biosynthesis, and the reduced form of this coenzyme is generated via the pentose phosphate cycle. NAD is essential for the synthesis and repair of DNA and for supplying adenosine diphosphate (ADP) ribose ligands to lysine, arginine, and asparagine residues in proteins such as histones, DNA lyase II, and DNA-dependent RNA polymerase, and to polypeptides such as bacterial (e.g., diphtheria and cholera) toxins. In the nucleus, poly (ADP ribose) synthetase is activated by binding to DNA breakage points and is involved in DNA repair. It is also concerned with condensation and expansion of chromatin during the cell cycle and in DNA replication. It regulates the fidelity of DNA transcription, and some inflammatory and immune responses. Three different enzyme classes catalyze ADP-ribose transfer: (1) poly-ADP-ribose polymerases (PARP), (2) mono-ADP-ribosyl transferases (which modify G-proteins that regulate cell signalling and glucose-regulated proteins such as GRP78, which is a molecular chaperone, regulating protein-folding in the endoplasmic reticulum), and (3) enzymes that form cyclic ADP-ribose, which mobilizes calcium from intracellular stores. Nicotinic acid-ADP (NAADP), formed by desamidation of NADP, is also a calcium transport regulator. NAD is also required for the activity of silent information regulators (SIR or sirtuin enzymes), which are protein deacetylases for transcription regulation, genome stability, neuronal protection, and longevity. One of their substrates is p53, a protein of genome stability, DNA repair, and apoptosis. Niacin status affects the level of ADP ribosylation of these and other proteins, and may affect (1) chronic degenerative diseases like cancer, diabetes, and dementia, and (2) acute inflammatory conditions such as septic shock or stroke or myocardial infarction, with complex outcomes that are difficult to predict precisely. Nicotinic acid is part of the chromium-containing glucose-tolerance factor, whose functions are still being studied. A high level of poly (ADP ribose) synthetase activity, which is found in some tumors, can result in lower levels of NAD.

Because the electron-transport functions of NAD frequently involve flavin coenzymes, and because both flavin coenzymes and vitamin B<sub>6</sub> coenzymes are involved in the conversion of tryptophan to niacin *in vivo*, there are important metabolic interactions between these B-vitamins. Their clinical deficiency signs also converge, sometimes making it difficult to distinguish between deficiencies of different B-vitamins.

The body's need for niacin can be met completely by dietary tryptophan; thus, it is not, strictly speaking, an essential vitamin. In this respect, it resembles carnitine, which can be synthesized entirely from lysine, but for which, under some circumstances, a dietary requirement arises. Traditionally, however, niacin is classified as an essential vitamin, because some human diets lack both niacin and its precursor, tryptophan. Some animals such as sheep and cattle can synthesize sufficient niacin from tryptophan and thus do not need preformed niacin.

## Assessment of Niacin Status and Requirements

Although the measurement of B-vitamin status is usually performed in blood samples, blood-based tests for niacin status are poorly developed. Some studies have suggested that erythrocyte concentrations of NAD or a reduction in the ratio of NAD to NADP may provide evidence of deficiency. The 95% range for healthy US adults for the NAD/NADP ratio was found to be 127–223, with a wide variation between different populations. The niacin coenzymes can be quantified either by enzyme-linked reactions or by their natural fluorescence in an alkaline solution.

At present, however, niacin status is most commonly assessed by assaying its breakdown products in urine. Of these,  $N^1$ -methyl nicotinamide (NMN) is the easiest to measure, by conversion *in vitro* to a fluorescent product. However, more reliable information can be obtained by measurement of urinary NMN plus the urinary pyridones ( $N^1$ -methyl-2-pyridone-5-carboxamide and  $N^1$ -methyl-4-pyridone-3-carboxamide), all of which can be detected and quantified by UV absorption following high-pressure liquid chromatography. The Interdepartmental Committee on Nutrition for National Defense (USA) has recommended an NMN excretion rate criterion of less than 5.8  $\mu\text{mol}$  (0.8 mg) NMN per day in 24-h urine samples as evidence of biochemical deficiency.

The requirement for niacin to prevent or reverse the human deficiency signs is not known very precisely and depends on ancillary dietary deficiencies or other insults and pathologies. To estimate niacin requirements for dietary reference values, restoration of urinary excretion of NMN during controlled human depletion–repletion studies has been used, and on this basis, the average adult requirement has been estimated as 5.5 mg (45  $\mu\text{mol}$ ) of NEs per 1000 kcal (4200 kJ). After adding a 20% allowance for individual variation, this becomes 6.6 mg (54  $\mu\text{mol}$ ) per 1000 kcal (4200 kJ), which is the current reference nutrient intake in the UK (Table 4). Niacin requirements used to be expressed as a ratio to energy expenditure.

The average content of niacin in human breast milk is 8 mg (65.6  $\mu\text{mol}$ ) per 1000 kcal (4200 kJ), and this content forms the basis for intake recommendations (and dietary reference values) for infants up to 6 months of age. In the UK, the Reference Nutrient Intake niacin increment during pregnancy is nil, but during lactation, it is 2 mg day<sup>-1</sup>.

## Dietary Sources and High Intakes

From Table 3, different foods differ considerably, not only in their total contribution to niacin equivalents but also in the ratio of the contribution from preformed niacin and from tryptophan. In a typical Western diet, preformed niacin provides approximately 50% of the niacin supply in the diet. As for other B-vitamins, meat, poultry, and fish are excellent sources of niacin equivalents, followed by dairy and grain products, but certain grains such as maize and highly polished rice are very poor sources. Both nicotinamide and nicotinic acid have potentially useful pharmacological properties at high intakes.

Nicotinic acid, which has marked antihyperlipidemic properties at daily doses of 2–6 g, is of greatest interest in pharmacological terms. Large doses of nicotinic acid reduce the mobilization of fatty acids from adipose tissue by inhibiting the breakdown of triacylglycerols through lipolysis and by inhibiting hepatic triacylglycerol synthesis (by inhibiting hepatic diacylglycerol acyltransferase 2), thus limiting the assembly and secretion of very low-density lipoproteins from the liver and reducing serum cholesterol. It inhibits high-density lipoprotein (HDL) catabolism by decreasing the surface expression of the hepatic ATP synthase beta chain, thereby increasing HDL levels, and it may increase the ratio of HDL<sub>2</sub> to HDL<sub>3</sub>, together with a reduced rate of synthesis of apolipoprotein A-II and a transfer of some apolipoprotein A-I from HDL<sub>3</sub> to HDL<sub>2</sub>. Such blood lipid effects appear to be due to binding of nicotinic acid to a receptor called a 'niacin receptor' or HM74A, linked to an inhibitory G-protein, and leading to reduced cyclic-AMP levels and inhibition of a hormone-sensitive lipase. Nicotinic acid and niacin can also increase the redox potential in arterial cells. The unwanted side-effect of skin flushing is linked to prostaglandin D<sub>2</sub> and E<sub>2</sub> formation by macrophages; this can now be reduced by a prostaglandin (DP<sub>1</sub>) receptor antagonist such as laropiprant. These effects of high-dose nicotinic acid may be beneficial in managing dyslipidemias and in reducing the risk of cardiovascular disease, and it has recently been successfully combined with statin therapy plus laropiprant. If given intravenously, large doses of nicotinic acid can, however, produce undesirable side-effects such as vasodilatation, hypotension, nausea, vomiting, diarrhea, and gastrointestinal disturbance, headache, fatigue, difficulty in focusing, skin discoloration, dry hair, sore throat, jaundice, changes in liver function tests, changes in carbohydrate tolerance, and changes in uric acid metabolism including hyperuricemia. Hyperuricemia may result from effects on intestinal bacteria and enzymes, or on renal tubular function, and is especially severe if sustained-release preparations of nicotinic acid are used. Except under medical supervision, the upper tolerable limit for niacin intake has been set at 35 mg NE per day for adults and 10–30 mg day<sup>-1</sup> for children and adolescents (1–18 years), and is linked to the skin flushing reaction to nicotinic acid supplements.

A large trial for the secondary prevention of myocardial infarction by high-dose nicotinic acid, with a 15-year follow-up, has produced convincing evidence for moderate but significant protection against mortality, which was attributed to the cholesterol-lowering effect or reduction of reinfarction.

Nicotinamide does not share these effects of nicotinic acid on lipid metabolism or its associated toxicity. However, it has been shown to act as an inhibitor of poly (ADP ribose) synthetase in pancreatic  $\beta$ -cells in animal studies, thereby protecting them from chemically-induced diabetes, albeit sometimes complicated by beta-cell tumor formation. Studies on human diabetes have so far yielded inconsistent results.

Because niacin deficiency or dependency can exacerbate some types of mental illness such as depression or dementia, and because the correction of depressed brain levels of serotonin would be advantageous, there have been attempts to treat depression

with tryptophan or niacin; however, these have so far had only limited success. Schizophrenic patients have been treated with nicotinic acid, because the synthesis of NAD is impaired in some parts of their brains. Recent research has indicated that nicotinamide riboside uniquely supports neuronal NAD synthesis, thereby deserving future therapeutic studies.

In conclusion, niacin and some of its related compounds have many wide-ranging metabolic effects, and their medical significance has attracted renewed interest in recent years.

## Introduction

Nucleic acids, vital components of all living cells, were isolated in 1869 from the nuclei of pus cells and the spermatozoa of Rhine salmon. Later, it was shown that the major constituents of nucleic acids are sugars, phosphate groups, and the characteristic purine and pyrimidine bases. The chemical structures of the purine bases, including uric acid – the end (waste) product of purine metabolism in humans – were established at the end of the 19th century. The role of the nucleic acids in storing and translating the genetic information in the cells was elucidated in the 20th century. Although their calorific contribution to the diet is trivial, nucleotides, nucleosides, and bases have essential roles in metabolism and signaling within the cell and organism.

This article outlines the structure of nucleic acids and gives a brief overview of the physiological functions of nucleosides, nucleotides, and nucleic acids. It describes the toxicity that may arise from degradation of both endogenous and dietary (exogenous) nucleic acids in humans and contains a summary of the nucleic acid content of foods.

## Physiology

### Structure

The hereditary material in the nucleus of human cells is packed into 46 chromosomes and additional DNA is found in the mitochondria. The capacity of DNA to be copied into two complementary strands arises from the well-known double-helical structure and underlies the transfer of genetic information in all living organisms. Interactions between the DNA and transcription factors determine the time and place in the body where genes are transcribed, controlling development and metabolism.

<sup>†</sup>Deceased.

**Figure 1** (a) Schematic representation of part of a DNA strand showing the structural formulae of the four constituent bases, adenine, guanine, cytosine, and thymine, linked via the 3'-OH group of the deoxyribose moiety to the 5'-phosphate group of the next nucleotide. Also shown is the numbering of the atoms in the deoxyribose, as well as the pyrimidine and purine rings. The bases are adenine (A), guanine (G), cytosine (C), and thymine (T). Two strands are wound in opposing chemical directions to allow the well-known double-helix structure, with hydrogen-bonding between complementary nucleotides (i.e., A-T and G-C), to form. The deoxyribose and phosphate groups form the outer sides of the 'ladder'. The RNA molecule is single-stranded, but double-helical regions arise when stretches of complementary sequences allow hairpin loops to form. In addition, the base uracil (U) is found instead of thymine, and the pentose is ribose. (b) Structural formula of ATP indicating that the ribose, as distinct from deoxyribose, has an OH group at the 2' position on the pentose ring. When a nucleoside triphosphate (NTP) is linked through the 5' phosphate groups to the 3' position of the previous residue on the growing chain, the chemical energy for the polymerization is provided by the removal of the second and third phosphate groups.

RNA molecules are synthesized initially on a DNA template by a DNA-dependent RNA polymerase in a process called transcription, where ribonucleotides complementary to the bases of one strand of DNA are joined by 3'-5' phosphodiester bonds (Figure 1(a)).

### Nucleic Acid Biosynthesis in Humans

The first step in nucleic acid synthesis involves the formation of the purine and pyrimidine ribonucleotides. There are two endogenous routes: either the energetically expensive *de novo* route from small molecules such as carbon dioxide, amino acids, and ribose sugars, or the energetically less expensive 'salvage' pathway. Purine bases and pyrimidine nucleosides from the breakdown of nucleic acids and nucleotide cofactors are salvaged within the cells, generating nucleotides that can be incorporated into nucleic acids. In most cells, salvage processes are more important, and the ribonucleotides recycled in this way exert feedback control on the *de novo* routes.

### Metabolic Roles of Nucleotides

The most abundant ribonucleotide in the body is adenosine 5'-triphosphate (ATP), which is the universal energy carrier in living organisms (Figure 1(b)). In addition, nucleotides are precursors of several coenzymes, used in many reactions including the conversion of food into energy. Within cells adenosine and guanosine nucleotides also have roles in the transduction of external signals into cellular responses, and in the translation and synthesis of proteins. Pyrimidine nucleotides are present at much lower concentrations in cells but also fulfill diverse functions. Uridine diphosphate (UDP)-glucose and Cytidine diphosphate (CDP)-lipids are active intermediates in the synthesis of glycogen and membranes, respectively, and sugars linked to UDP or GDP are used in the glycosylation of proteins. UDP-glucuronic acid is an essential component of the pathways that convert exogenous molecules and endogenous steroids into soluble forms for disposal from the body.

The free deoxyribonucleotides are very scarce in the normal cell because they are used exclusively for the synthesis of DNA.

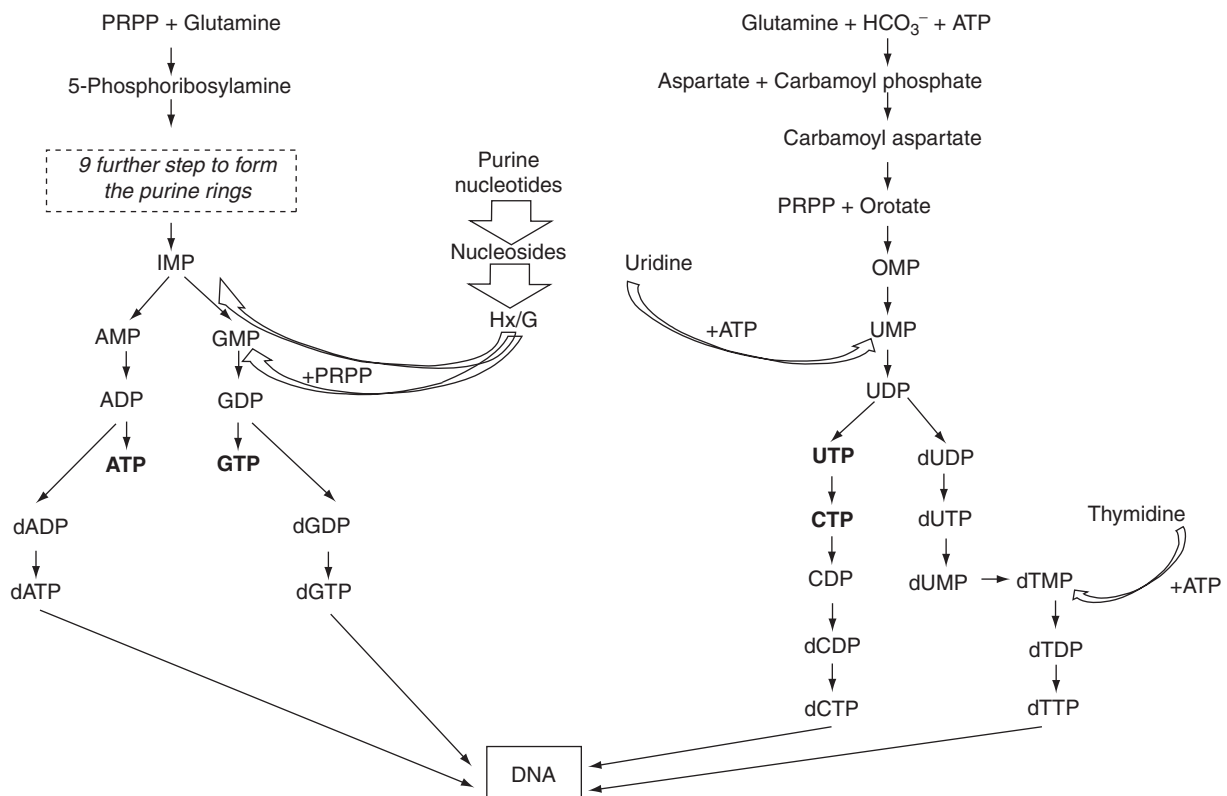

### Synthesis of Nucleic Acids

Synthesis of both DNA and RNA is prominent in cells and tissues with high turnover or metabolism (e.g., liver, gut epithelium, skin, dividing lymphocytes, bone marrow, and hair follicles). Different complements of enzymes are expressed in each cell type, and therefore tissues have characteristic profiles of internal metabolites, including nucleotides and nucleosides. For example, in cells that do not continuously divide, such as heart and muscle, nucleotide profiles are relatively simple, relating to the major requirement to sustain high levels of ATP and cofactors. Contrastingly, rapidly dividing cells in liver and intestine show a complex nucleotide pattern, identifying these organs as major sites of nucleic acid metabolism. The gut is particularly important in this respect. The rate of cell turnover in the luminal villi is high, and it has been calculated that in rats approximately 30 mg of endogenous nucleic acid derived from dead cells enters the gut lumen daily. This means that nucleic acid synthesis in liver and intestine is much higher than in tissues such as muscle.

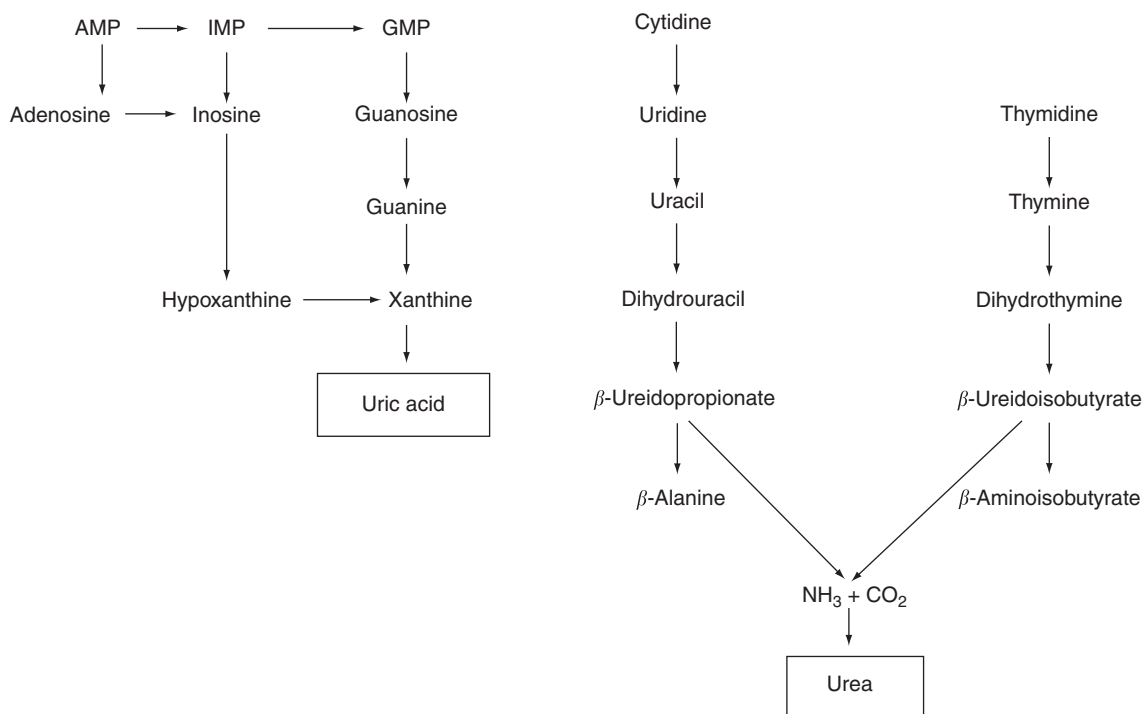

### Metabolism of Endogenous Nucleic Acids and Excretion of Metabolic End Products

There is a considerable daily turnover of endogenous nucleic acids and ribonucleotides during muscle work, wound healing, erythrocyte senescence, mounting an immune response, etc. However, only a small fraction of these vital endogenous compounds is degraded and lost from the body. Because *de novo* purine and pyrimidine synthesis is energetically expensive the contents of dead cells are normally used by other cells, and degraded RNA or cofactors are recycled within living cells using active 'salvage' routes.

Breakdown products of DNA and RNA enter the salvage pathways in the form of the purine bases hypoxanthine (Hx) and guanine or the pyrimidine bases uracil and thymine (Figure 2).

**Figure 2** *De novo* synthesis of ribonucleotides uses small molecules and amino acids. The purine base of IMP is built up in several steps on a ribose phosphate molecule, and separate pathways generate ATP and GTP. In pyrimidine biosynthesis, the six-membered ring is formed before addition of the ribose phosphate to orotate, and decarboxylation to form UMP. Ribonucleotides (ATP, GTP, UTP, and CTP, shown in bold) are used in the synthesis of RNA, whereas DNA is synthesized after conversion of the ribose to deoxyribose, and of dUMP to dTMP. Salvage pathways (shown with open arrows) all follow two patterns: purine nucleotides and nucleosides, entering the cells or derived from hydrolysis of cofactors or nucleic acids, are converted to the free bases hypoxanthine or guanine and then converted by a specific phosphoribosyltransferase enzyme to the nucleoside; in contrast pyrimidines are salvaged from the nucleosides uridine or thymidine using specific kinase enzymes. It should be noted that PRPP (phosphoribosyl pyrophosphate) is essential for both *de novo* pathways and the purine salvage pathways.

**Figure 3** Breakdown of DNA and RNA begins when the molecules are degraded by nuclease enzymes to liberate nucleotides. The next step, degradation by specific 5′-nucleotidases (removing the phosphate groups) to nucleosides or deoxynucleosides, is essentially irreversible. Nucleoside phosphorylases generate (a) the purine bases hypoxanthine and xanthine, which are converted to uric acid or (b) the pyrimidine bases uracil and thymine, which are converted to  $\beta$ -amino acids, ammonia, and  $\text{CO}_2$ , and thus to urea, a solute in urine.

Any pyrimidine bases that are not salvaged are then further catabolized in a series of steps to  $\beta$ -amino acids, which are soluble and readily excreted. There is thus normally no measurable toxic pyrimidine end product from endogenous or dietary nucleic acids, except in the case of a small number of very rare metabolic disorders (Figure 3).

The purine base Hx is converted in the liver to the insoluble metabolites xanthine and then uric acid by the enzyme xanthine oxidase/xanthine dehydrogenase (XDH) in man. Urate can normally be disposed of in the urine, but high concentrations can crystallize and form kidney stones or deposits in the joints and under the skin. Some rare genetic disorders can remove feedback regulation of purine biosynthesis, or excessive breakdown of cells may overload the salvage system, each resulting in very high endogenous levels of uric acid. However most other animal species (with the notable exception of some dog varieties) possess an additional catabolic enzyme, uricase, which cleaves the purine ring of uric acid forming the readily soluble allantoin. This compound in turn may be degraded to ammonia in water-dwelling species such as fish.

### Metabolism of Dietary Nucleic Acids in Humans

The human diet is naturally rich in nucleic acids because food is derived from once-living organisms. Because, as already described, nucleotides and nucleosides can be synthesized *de novo* and nucleobases liberated during catabolism can be salvaged, they are often considered to be dispensable nutrients in food. The metabolism of these exogenous nucleic acids follows a similar pattern to the intracellular process described above, but the bacterial flora of the intestine are the first point of degradation. This digestion is rapid. Studies in both pigs and humans demonstrated that up to 50% of dietary purine was degraded to carbon dioxide within 30 min, 43% was recovered in the urine and 5% excreted in the feces. Less than 2% of dietary purines is incorporated into nucleic acids.

Humans thus have no apparent essential requirement for purines from the diet and the intestinal mucosa provides an effective barrier to their uptake through a battery of enzymes that can rapidly degrade purine nucleotides, nucleosides, and bases especially unusual purines found in plant materials. Because of this enzyme activity, and the rapid turnover of intestinal mucosa, approximately 200 mg of urate is excreted daily in the feces. This phenomenon ensures that levels of ATP do not fluctuate in concert with the dietary intake of purines, or may represent an important evolutionary development to protect the integrity of cellular DNA.

On the other hand, pyrimidine ribonucleoside monophosphates (NMPs) and ribonucleosides are absorbed readily from the intestine and utilized for nucleic acid synthesis. This has been demonstrated by studies of humans with hereditary oroticaciduria, a rare defect in conversion of orotic acid to uridine monophosphate (UMP) in *de novo* pyrimidine synthesis. Such patients have severe megaloblastic anemia. They have been sustained on oral uridine, indicating that the dietary pyrimidine nucleoside can

**Table 1** A quick reference guide to the purine (nucleic acid) content of foods*Foods and Beverages Rich in Nucleic Acids/Purines*

Offal: sweetbreads, liver, kidney, heart, and paté  
 Wild or farmed game meats (venison, pheasant, rabbit, hare)  
 Seafoods: sardines, sprats, herring, bloaters, anchovies, fish roe, caviar, taramasalata, trout or salmon; lobster, crab, prawns  
 Vegetables: asparagus, avocado pears, peas, spinach, mushrooms, broad beans, cauliflower  
 Pulses and grains: legumes, pulses and soya products such as bean curd, tofu, Quorn  
 Cereals: all bran, oat, rye or wheat cereals and products; wholemeal, rye and brown breads  
 Other: beer and yeast extracts/tablets (Barmene<sup>TM</sup>, Tastex<sup>TM</sup>). Meat or vegetable extracts (Marmite<sup>TM</sup>, Vegemite<sup>TM</sup>, Bovril<sup>TM</sup>, Oxo<sup>TM</sup>) Blue-green alga extracts (Spirulina)

*Foods that are Moderate or Low Sources of Purines*

Beef, lamb, pork (steak or chops), bacon, ham, sausages, some poultry, tongue (all should be eaten in moderation)  
 Carrots, parsnip, other root vegetables, potatoes, lettuce, leeks, cabbage, sprouts, marrow, squash, courgettes  
 Peanuts, cashew nuts  
 Breakfast cereals  
 Some fish (see Table 2)

*Foods and Beverages that are Essentially Purine-Free*

Milk, cheese, eggs, butter, margarine, cream, ice cream  
 White bread or flour, cakes, scones, biscuits  
 Sugar, jam, marmalade, honey, and sweets  
 Cucumber, tomato, onions, pumpkin  
 Fresh, cooked or tinned fruits, nuts  
 Puddings, custards, yogurt  
 Fruit juices, soft drinks

compensate totally for lack of *de novo* synthesis in humans. Studies using radiolabelled purines and pyrimidines in mice provided further evidence for the incorporation of dietary pyrimidine nucleosides, but not purine nucleosides, into hepatic RNA.

**Nucleic Acid Content of Foods**

The nucleic acid content of foodstuffs is expressed generally in terms of purine equivalents or 'total potentially available nucleosides (TPAN)' released from food by hydrolysis with sodium hydroxide or hydrochloric acid and enzymes. The data for purines are thus derived by analysis of the resultant constituent bases. Analysis by Robert McCance, Elsie Widdowson, and colleagues from the 1930s onward forms the basis of tables listing the composition of foodstuffs although, with a few exceptions, this demanding work has not been repeated using more modern analytical methods such as liquid chromatography–mass spectrometry (LC–MS).

Foods can be classified into three groups; high, low, or essentially free of purines (and hence of pyrimidines too) (Tables 1 and 2). As a general rule growing organisms such as yeast, or rapidly metabolizing tissues such as liver, will be rich in both nucleic acids. Seeds and grain are good sources of the genetic material, DNA, as well as free nucleotides, which are stored for use in germination. Muscle tissue is an excellent source of the nucleotide ATP and the nucleic acids in mitochondria. Offal is also metabolically very active so is usually high in free nucleotides as well as nucleic acids. Fish and shellfish that are eaten 'whole' and fish eggs and roe are also high in nucleic acids. Extracts of meat and yeast e.g., Bovril, Marmite, Vegemite, have very high purine contents, as do supplements such as Spirulina for sale in 'Health Food' shops, but are usually eaten in small quantities.

Fats, white flour, sugar, and fruit juices have been separated from the 'living' part of the food and so they are poor sources of nucleic acids.

**Effect of Cooking on Nucleotide Content of the Diet**

Nucleic acids are relatively resistant to hydrolysis at the moderate temperatures and short periods of time associated with cooking in water or frying in oil. On the other hand nucleoside triphosphates (NTPs) and nucleoside diphosphates (NDPs) break down readily during boiling in water forming first their related NMP and then their base. The rate of hydrolysis is significantly increased in acidic solutions. The rate of degradation is enhanced if any enzyme activity is still present.

The levels of nucleic acids and NTPs are well maintained during prolonged storage at  $-20^{\circ}\text{C}$  or below.

**Nucleic Acid and Related Compounds in Beverages**

Tea, coffee, and cola drinks contain a number of unusual nucleobases based on xanthine (Figure 4). Caffeine (1,3,7-trimethylxanthine) and theobromine are the best known. Caffeine is found in various quantities in the beans, leaves, and fruit of many plants. It is mainly consumed by humans in infusions extracted from the coffee bean and leaves of the tea bush. A cup of coffee can contain up to 175 mg of caffeine whereas a cup of tea contains approximately 40 mg. Many popular soft drinks,

e.g., cola, may contain up to 300 mg per can. Theobromine (dimethylxanthine) occurs naturally in cocoa beans ( $20 \text{ mg g}^{-1}$  of cocoa powder) and is therefore present in chocolate. Theophylline (1,3-dimethylxanthine) occurs at trace levels in tea leaves and is now chemically synthesized for use as a drug treatment for asthma.

Caffeine is rapidly absorbed by the stomach and small intestine and is distributed throughout total body water. It is rapidly metabolized in the liver to paraxanthine (84%), theobromine (12%), and theophylline (4%).

In man, caffeine acts as a central nervous system stimulant, temporarily warding off fatigue and restoring alertness: it readily enters the brain and acts as a nonselective antagonist of purinergic adenosine receptors. Caffeine is the most widely consumed psychoactive substance; in North America, 90% of adults consume caffeine beverages daily. 'Energy drinks' contain very high levels of caffeine and some also contain alcohol, so over-use can lead to a 'wide-awake but drunken' state. The US Food and Drug Administration (FDA) lists caffeine as a 'multiple purpose drug generally recognized as safe food substance'.

Because beers and related drinks are produced by fermentation of grains with yeasts, the process is associated with vast increases in cell numbers and this leads to drinks with a considerable nucleic acid and nucleotide content, even if the yeasts are removed by filtration. The economic importance of brewing, as well as the clinical relevance of beer and wine in gout, means that there is considerable literature on the composition of beers and wines including their purine levels. A traditional British beer (ale or bitter) can contain up to 25 mg purine per litre ( $250 \mu\text{mol l}^{-1}$ ) but lager beers have up to  $20 \text{ mg l}^{-1}$ . Ciders contain  $<1 \text{ mg l}^{-1}$  of purine. Wine also contains significant amounts of purines. Some low alcohol beers may contain three times these levels of purines. Spirits contain very little in the way of purines because these compounds are removed in the distillation step.

**Figure 4** Chemical structures of unusual nucleobases derived from xanthine, and found in plant tissues such as cocoa beans, coffee beans, and tea leaves.

### Nucleotides in Human Breast Milk and Infant Formula Milks

Human breast milk contains nucleic acids, nucleotides, and nucleosides, particularly cytidine and uridine, with a profile that reflects the diet of the mother. Average TPAN concentrations in human milk are  $172\text{--}222\ \mu\text{mol l}^{-1}$  ( $59\text{--}76\ \text{mg l}^{-1}$ ) at all stages of lactation. The content derived from cells is approximately 18% of TPAN during the first few days of lactation but drops to less than 10% later. Proportions of nucleosides derived from RNA (43–48%); free nucleotides (36–40%); free nucleosides (6.6–8%); and nucleotide adducts (9–10%) are similar in milk from women of several races. It is not known if all of these compounds in human milk are used by the breast-fed infant. However there is also a movement to supplement formula milks (based on cow's milk) with ribonucleotides derived from hydrolyzed RNA. Cow's milk contains lower levels of nucleotides, with a different profile from the human, but significant levels of the *de novo* pyrimidine intermediate orotic acid, which is low in humans (raised in milk from mothers who smoke).

In the late 1990s the FDA agreed to the nucleotide supplementation of infant formula based on cow's milk, but at lower concentrations than in human milk. The EU Food Committee recommended in 2003 (updated advice in 2007) that the content of nucleotides, if added to infant formulae and in follow-on formulae, should not exceed 5 mg per 100 kcal. If added the maximum nucleotide contents should be: cytidine monophosphate (CMP) 2.5 mg per 100 kcal, uridine monophosphate (UMP) 1.75 mg per 100 kcal, adenosine monophosphate (AMP) 1.5 mg per 100 kcal, guanosine monophosphate (GMP) 0.5 mg per 100 kcal, inosine monophosphate (IMP) 1 mg per 100 kcal.

Several trials have evaluated the effects of nucleotide addition to formula milk in infants but only two of the trials have studied formulae with 'human' nucleotide levels of  $72\ \text{mg l}^{-1}$ . Thus, there is no adequate scientific basis at present to conclude that the addition of nucleotides in higher concentrations than presently permitted for infant formula would provide additional benefits. Formula milks based on soy protein have a high natural content of nucleotides and are therefore not supplemented.

### Beneficial Effects of Dietary Nucleosides and Nucleotides

In healthy adults, a normal varied diet is a good source of nucleic acids, nucleotides, and nucleosides, and supplementation is thought to be unnecessary.

There is substantial evidence (principally from research in animal models) that the presence of nucleotides or nucleosides in the diet helps cellular proliferation in the gut, in postoperative trauma, and in the development of the immune response in infants. A medical food supplement containing arginine, glutamine, nucleotides, and omega-3 fatty acids, demonstrates a better clinical outcome for (adult) surgical patients, and a 30% reduction in risk of infection. It should be noted that glutamine is a precursor for *de novo* synthesis of nucleosides as well as a source of energy for proliferating cells.

Dietary nucleotides have been shown to promote the incorporation of essential fatty acids into membrane lipids in healthy newborn babies, and to enhance the integrity and maturation of the intestine and of the immune system, and thus may contribute to the improved immunity seen in breast-fed infants. Studies in lower socioeconomic groups have found that supplementation of formula with 14.2 mg free nucleotides per 100 g milk powder resulted in a significant reduction of first episodes of diarrhea. This may be linked to an alteration in the bowel flora, leading to a predominance of lactobacilli as seen in breast-fed babies.

An extract from sugar cane (trade name NucleomaxX), containing 17% nucleosides, is used in the HIV-positive community to counteract the unpleasant side-effects of HIV drugs that inhibit the formation of mitochondrial DNA and hence energy-producing processes. The use of oral uridine in metabolic disorders is described later.

Nucleotides based on both adenosine and uridine can activate the purinergic receptors on a wide range of cell types. Nucleotides influence the transcription of several genes in intestinal cells, and have been shown to improve growth and maturation of the gut in weanling rats.

In lymphocytes and other cells, synthesis of nucleotides *de novo* is expanded dramatically when a signal for proliferation is received; the rate of pyrimidine biosynthesis increases more than purine biosynthesis. Thus nucleotides are now considered to be 'conditionally essential' because their provision in the diet may provide help through the salvage system where cells are dividing rapidly or where other nutrients, used as precursors, are scarce.

### Purine Ribonucleotides as Flavor-Enhancing Additives

The purine 5'-nucleoside monophosphates IMP and GMP, derived from degradation of RNA, have received much attention as the taste-active components in a variety of seafoods and meat. These purine 5'-nucleotides, but not the pyrimidine nucleotides CMP and UMP, enhance the savory flavor generated by monosodium glutamate (MSG), by interaction with receptors on the specific *umami* taste buds in the mouth. Because ATP is the major free nucleotide in muscle cells, its breakdown into the flavor-enhancing IMP provides a scientific rationale for the improved palatability of meat or game birds that have been hung for several days after slaughter. Similarly, the distinctive flavors of several cheeses are related to the metabolism, by bacteria, of the characteristic range of nucleotides present in the original milk.

### Purine Ribonucleosides and Bases as Markers of Food Quality

Related to the above topic is the role of hypoxanthine (Hx) in the determination of food quality. As described earlier, when an animal is killed the tissues become ischemic and the intracellular ATP starts to degrade, forming first AMP and then Hx. At room temperature the majority of ATP will have degraded within 24 h. The Hx level will be maximal at approximately 2 weeks in meat stored at 4 °C. The change in Hx content of the food alters the sensory perception of the food, with higher Hx levels causing a bitterness in the taste of meat. This aspect of purine catabolism has been particularly well documented in seafood, which is perhaps the most perishable of foods. Hx in fish and fish products such as fish fingers increases linearly with storage time, and measurement of the Hx levels has been recommended as a marker of fish spoilage.

## Toxicology

### Pharmacological Uses for Nucleosides and Nucleotides

Rare genetic disorders highlight the sensitivity of lymphocytes to the efficient removal of waste from DNA catabolism, and in fact have provided the basis for development of novel immunosuppressant drugs which inhibit enzyme activities crucial to removal of purine nucleotides, and lead to mis-incorporation of nucleotides in DNA synthesis. On the other hand, the use of certain nucleotide analogs as drugs depends on their incorporation into DNA – for example, analogs used in HIV therapy are incorporated by the reverse transcriptase of the virus, and bring the reaction to a halt. Toxicity associated with several analogs is now known to arise from erroneous incorporation into the patient's mitochondrial DNA, because of less stringent proof-reading by the mitochondrial DNA polymerase enzyme. Azidothymidine (AZT) remains one of the most effective and least toxic drugs for AIDS, albeit now usually taken in triple therapy.

Nucleotide analogs have been used to inhibit the *de novo* pathways for the synthesis of the precursor nucleosides and nucleotides, leading to depletion of metabolites and imbalance of dNTPs, and hence to mis-incorporation of nucleotides in RNA or DNA, respectively. Malaria and other parasites rely exclusively on *de novo* pyrimidine biosynthesis, thus they may be susceptible at drug doses that do not affect the host, because the human body can obtain nucleotides from the salvage pathway. Similarly, because of the increased requirement for nucleotides in rapidly proliferating cells, almost all the enzyme reactions (Figure 2) have been investigated as potential targets for treatment of cancer, inflammation, or to prevent rejection of transplanted organs. Once again, combinations of drugs with different modes of action have often proved most effective.

Oral uridine, as described earlier, can be used where *de novo* biosynthesis of pyrimidines is defective, and it may be useful in reversing some effects of mitochondrial dysfunction, and to minimize the toxic effect of the antitumor drug 5-fluorouracil. Oral administration of compounds such as benzylacyclouridine, or 2'3'5' tri-O-acetyl uridine (PN401), inhibits the degradative processes in the liver and delivers more uridine into the circulation than oral uridine alone. Uridine is also a precursor for UDP-glucose, essential for the deposition of glycogen in the liver, and UDP-glucose has been proposed as a dietary supplement.

Oral CDP-choline is rapidly converted to its components, CDP (which can be recycled to uridine) and choline, an essential component of lipid membranes. Each molecule can then cross the blood–brain barrier where CDP-choline is used in regeneration of membranes within and around nerve cells, and its pharmacological effects may extend to protection against dementia, memory loss, visual degeneration, and to recovery from ischemic strokes.

### Toxicity of Exogenous Nucleic Acids to Humans

The potential toxicity of dietary nucleic acids to humans usually arises from their metabolic end products (principally uric acid). Many investigators have shown that when normal subjects are fed RNA, the increase in the urate excretion is dramatic, but there is only a modest rise in plasma urate concentrations.

The body pool of urate, and hence the plasma urate concentration, is the result of a balance between production, ingestion, and excretion. If kidney function is normal, the chief causes of high plasma uric acid concentrations are either a high intake of exogenous nucleic acid in the diet or overproduction of endogenous purine. A low-purine (low-nucleic acid) diet containing less meat, seafood, and other purine-rich foods and beverages (Tables 1 and 2) leads to a lower risk of gout symptoms. In contrast, subjects with genetic defects that remove the usual controls on purine biosynthesis may have overwhelmingly high endogenous levels of the waste product, uric acid.

The contribution of the two sources can be assessed by placing the subject on a purine-free diet for a week, and measuring the total urinary uric acid. In this way fewer than 5% of patients with gout are found to excrete abnormally large amounts of urate (>3 millimoles per day) derived from endogenous purines. In these cases, overproduction of purine nucleotides leading to excess uric acid can be traced to a genetic defect. Two such sex-linked disorders are hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency and phosphoribosyltransferase superactivity (PRPS). Boys presenting in infancy usually have severe and eventually fatal neurological deficits. In those presenting as adolescents, neurological problems are milder or absent, and only gout may be evident.

### Urolithiasis and Other Kidney Stones

Although modest overindulgence in purine-rich food does not precipitate gout in normal subjects, it can predispose to uric acid lithiasis. Uric acid stones are relatively common in countries where the consumption of nucleic acid-rich beverages and food is high, and in hot climates if insufficient fluids are consumed.

A number of compounds, such as vitamin C, increase uric acid clearance and thus can precipitate urolithiasis. Perhaps not so well recognized is the uricosuric effect of a high-protein diet and the fact that purine-rich foods also predispose to renal calcium stones. This may be because many purine-rich foods such as spinach are equally rich in calcium oxalate. Some vegetables may provoke gout attacks by virtue of their oxalic acid content rather than of purines, but legumes, fast-growing parts of brassicas and asparagus tips may also have significant nucleic acid content. Pulses and grains have a particularly high nucleic acid content. Approximately 25% of vitamin C intake is also excreted as oxalate, which can compound the problem.

The solubility of uric acid is very sensitive to the pH of the urine, which in turn may be made more acidic by a high-protein diet. The solubility of uric acid in urine at pH 5.0 is low (approximately  $1 \text{ mmol l}^{-1}$ ), but it can be increased 12-fold by alkalinizing regimens such as sodium bicarbonate or potassium citrate, which raise the pH to 8.0.

Excess uric acid from dietary purines can also precipitate symptoms that may draw attention to endogenous uric acid accumulating in adults with milder forms of HPRT deficiency or PRPS superactivity, or to a defect leading to raised levels of a uric acid analog related to adenine. The ideal diet for subjects at risk of gout or of uric acid lithiasis is no more than one meat meal per day, using only the low-purine meat and vegetables indicated, and treatment with allopurinol.

The most common and effective treatment for gout is the drug allopurinol, which prevents conversion of xanthine to uric acid by inhibiting the enzyme xanthine oxidase. Although the uricase gene appears to be present in human cells, the promoter is not activated, so no enzyme activity is detected in the liver. Biochemical drugs using recombinant uricase are effective in refractory gout.

### Key points

- To obtain an overview of the role of pantothenic acid in intermediary metabolism.
- To understand the relationship between the chemical structure of this vitamin and its biological function.
- To know the processes of absorption, transport, storage and metabolism of this vitamin.
- To have information about the dietary intakes of this vitamin.
- To know the metabolic disorders related to pantothenic acid.
- To know the most important dietary sources and the requirements of this vitamin.

### Introduction

Vitamins constitute a group of chemically heterogeneous substances whose functions are also very diverse. Many of them share, however, a common mechanism of action: their participation as coenzymes in the metabolism of macronutrients (Combs and McClung, 2016). Within this group of vitamins, two subgroups can be considered. The first of these consists of thiamine, riboflavin, niacin, pantothenic acid, pyridoxine and biotin. These vitamins exert their physiological functions as coenzymes, which act in a very general way in the metabolism. Vitamin B<sub>12</sub> and folic acid belong to the other subgroup. These vitamins are also characterized by their metabolic action as coenzymes, but in this case their coenzyme functions are especially and directly involved in cell proliferation (Stipanuk and Caudill, 2018).

The vitamins of the subgroup with general coenzyme functions belong to the so-called “B complex”, are all water-soluble, are widely distributed in food, are not particularly stored in the organism and do not usually produce toxicity due to overdosage (Rodwell et al., 2018). Deficiencies in some of these vitamins have had historical relevance and are still important in some underdeveloped countries. In industrialized countries, however, these vitamin deficiencies have less clinical repercussions (Ross et al., 2014).

This article will consider the metabolic functions, the main food sources, the requirements, the processes of absorption, transport, storage and metabolism, and the assessment of the nutritional status of pantothenic acid.

### Absorption, transport, storage and status measurement

Much of the pantothenic acid (formerly vitamin B<sub>5</sub>; discovered by Williams, Elvehjem, and Jukes in the 1930s, see Fig. 1) that is present in food eaten by animals or humans exists as derivatives such as coenzyme A (CoA) and acyl carrier protein (ACP) (Kelly, 2011; Sanvictores and Chauhan, 2021). It is released as free pantothenic acid or pantetheine by pancreatic enzymes, and absorbed along the entire length of the small intestine by a combination of active transport and passive diffusion, of which the active

\*Corresponding author

†Deceased

Fig. 1 Structure of pantothenic acid.

transport process predominates at physiological intakes. This active transport process is dependent on sodium, energy, and pH, and is saturable: the  $K_m$  is approximately  $17 \mu\text{M}$  and  $V_{\max}$  is approximately  $1000 \text{ pmol cm}^{-2} \text{ h}^{-1}$ , with minor variations among species. The transport pathway is shared by biotin in colonic epithelial cells and is regulated by an intracellular protein kinase C-mediated pathway. Calmodulin is also implicated in cellular pantothenic acid transport pathways.

In mice, there is no evidence for adaptation of absorption to low or high intakes. However, studies on rats suggest that a limited secretion of enzymes that degrade CoA in the gut lumen may limit the availability of pantothenic acid from dietary CoA.

In humans, studies of urinary excretion of pantothenic acid after oral doses of either free pantothenic acid or the pantothenic acid in food have indicated an availability of approximately 50% from the food-derived vitamin. Urinary excretion of pantothenate was approximately  $0.8 \text{ mg day}^{-1}$  when a pantothenate-deficient diet was eaten, rising to  $40\text{--}60 \text{ mg day}^{-1}$  at an intake of  $100 \text{ mg day}^{-1}$ . At intermediate intakes, in the range  $2.8\text{--}12.8 \text{ mg day}^{-1}$ , the urinary excretion rate varied between 4 and  $6 \text{ mg day}^{-1}$ . Excretion levels of less than  $1 \text{ mg day}^{-1}$  are considered low. Urinary excretion rates reflect recent intakes more closely than most other biochemical indices.

The contribution of the gut microbiota to absorbed pantothenate in humans is unknown, but there is evidence that bacterial synthesis of the vitamin may be important in animals, especially ruminants, because severe deficiency can only be achieved here by using antibiotics or antagonists, and recent evidence suggests that absorption of pantothenate synthesized by the flora of the human large intestine may make an important contribution to the pantothenate supply of this tissue. Clinical conditions such as ulcers or colitis can adversely affect pantothenate status and excretion rates, and dietary fiber may affect its absorption.

After a dose of  $^{14}\text{C}$ -labeled pantothenate, approximately 40% of the dose appears in muscle tissue and approximately 10% in the liver, with smaller amounts elsewhere. The differential affinities of tissues determine their individual contents of the coenzyme derivatives, CoA and ACP, because there is no major surplus store of the vitamin anywhere in the body. Most organs, including placenta, exhibit evidence of a unidirectional active transport process for the intracellular accumulation of pantothenate, which again is dependent on sodium, energy, and pH. In placenta (and probably elsewhere), this transport process is also shared, and competed for, by biotin and some of its analogs.

The only tissues that have been shown to differ with respect to the transport mechanisms are red cells and the central nervous system. The uptake and efflux of pantothenate in red blood cells are unaffected by sodium, energy, or pH. They contain pantothenate, 4-phosphopantothenate, and pantetheine, but do not contain mitochondria, or carry out CoA-dependent processes. The functions of the pantothenate derivatives in red cells are unknown, but their formation results in higher concentrations of total pantothenate in red cells than in plasma, and red cell (or whole blood) total pantothenate is considered a better status index, and more predictably related to intake, than serum or plasma pantothenate. A concentration less than  $1 \mu\text{mol L}^{-1}$  of pantothenate in whole blood is considered low; the normal range being  $1.6\text{--}2.7 \mu\text{mol L}^{-1}$ . Pantothenate in serum appears to be a very short-term marker and it is not well correlated with changes in intake or status.

Concentrations in body fluids are traditionally measured by microbiological assay using *Lactobacillus plantarum*. If CoA is present, enzymatic hydrolysis is needed to liberate free pantothenic acid for the microbiological assay. Other assay methods include gas chromatography (after conversion to a volatile derivative), radioimmunoassay (RIA), or enzyme-linked immunoabsorbent assay (ELISA).

Unlike several other B-vitamin precursors of enzyme cofactors, pantothenate is not entirely converted to coenzyme forms inside the cell, and metabolic "trapping" is therefore less dominant than it is for some other B vitamins. Free pantothenate in tissues seems more closely related to dietary pantothenate than the coenzyme forms are; the latter are protected during periods of dietary deficiency. Uptake of pantothenate from plasma into most tissues is proportional to the plasma concentration because the active transport process is not saturated at typical plasma concentrations of approximately  $1 \mu\text{M}$  (or  $1.6\text{--}2.7 \mu\text{M}$  in whole blood).

Pantothenate in acetyl CoA is required for the hepatic acetylation of drugs, and pantothenate deficiency can impair it; moreover, 20–60% of human populations are slow acetylators, varying with ethnicity.

## Metabolism and turnover

The primary role of pantothenic acid is in acyl group activation for lipid metabolism, involving thiol acylation of CoA or of ACP, both of which contain 4-phosphopantetheine, the active group of which is  $\beta$ -mercaptoethylamine. CoA is essential for oxidation of fatty acids, pyruvate and  $\alpha$ -ketoglutaric, for metabolism of sterols, and for acetylation of other molecules, so as to modulate their

transport. Acyl carrier protein (ACP), which is synthesized from apo-ACP and coenzyme A, is involved specifically in fatty acid synthesis. Its role is to activate acetyl, malonyl, and intermediate-chain fatty acyl groups during their anabolism by the biotin-dependent fatty acid synthase complex (i.e., acyl-CoA: malonyl-CoA-acyl transferase (decarboxylating, oxoacyl- and enoyl-reducing, and thioester-hydrolyzing), EC 2.3.1.85) (Chan and Vogel, 2010).

The liver has the highest concentration of pantothenate, followed by adrenal cortex, because of the requirement for steroid hormone metabolism in these tissues. Ninety-five percent of the CoA within each tissue is found in the mitochondria. However, the initial stages of activation of pantothenate and conversion to CoA occur in the cytosol, and CoA is then transported across the mitochondrial membrane.  $\beta$ -Oxidation within the peroxisomes is also CoA dependent and is reduced by pantothenate deficiency.

The pathways of conversion of pantothenic acid to CoA and to ACP are summarized in Fig. 2. There are three ATP-requiring reactions and one CTP-requiring reaction in the synthesis of CoA. The rate of CoA synthesis is under close metabolic control by energy-yielding substrates, such as glucose and free fatty acids (via CoA and acyl CoA), acting at the initial activation step, which is catalyzed by pantothenate kinase (ATP: pantothenate 4-phosphotransferase, EC 2.7.1.33). There are also hormonal effects of insulin, corticosteroids, and glucagon, which result in important changes in tissue distribution, uptake, etc. (e.g., in diabetics). The mechanisms are complex and not yet fully understood; however, insulin represses and glucagon induces this enzyme. Although

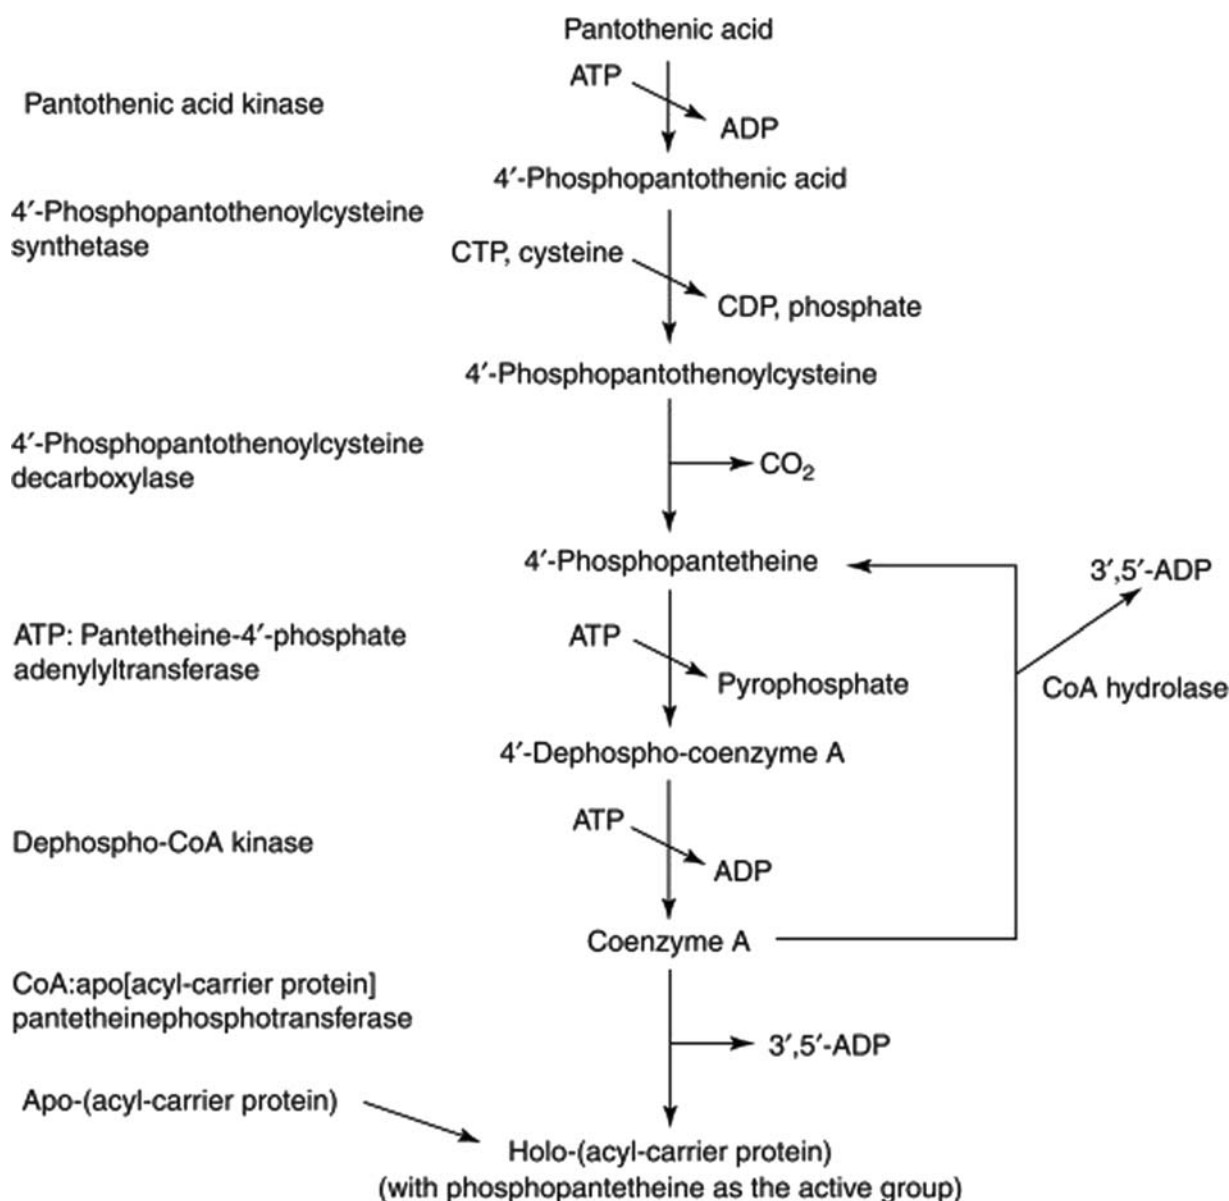

Fig. 2 Synthetic pathway between pantothenic acid, coenzyme A, and acyl carrier protein.

prokaryotes and eukaryotes carry out the same biochemical reactions in the synthesis of CoA, genome studies have revealed important protein-sequence differences, and there is new interest in this pathway for the design of antibacterial drugs.

The discovery of a human neurodegenerative disorder also stimulated research in this area. This rare genetic disease, formerly called Hallervorden–Spatz syndrome, results from mutations and hence a functional deficiency of pantothenate kinase, and is now known as pantothenate kinase-associated neurodegeneration (PKAN). Dystonia, involuntary movements, spasticity, optic atrophy, and iron deposits in the basal ganglia and globus pallidus occur, and although there is no cure, some palliative replacement is possible (Di Meo et al., 2019).

In humans, fasting results in a reduction of fatty acid synthase activity with loss of the coenzyme of ACP, which thus results in a shift away from fatty acid synthesis and toward breakdown. This interconversion of apo-ACP and holo-ACP is thus a very important process for the short-term regulation of fatty acid synthesis.

A deficiency of sulfur amino acids or copper overload (by interfering with sulfur amino acid function) can result in reduced CoA synthesis.

Free pantothenate in urine is the primary excretion route in humans; however, in other mammals its glucuronide or glucoside may be excreted, and pantothenate is very efficiently conserved in animals. Some bacteria can cleave it to pantoic acid and  $\beta$ -alanine. One breakdown product of CoA is taurine, via cysteamine, and is an essential nutrient for some carnivorous animals such as cats.

When dietary intakes are low, much of the circulating pantothenate, after filtration in the kidney tubules, is absorbed by the same sodium-dependent active transport process that occurs at most other sites in the body. Secretion into breast milk is proportional to intake and to blood levels of the vitamin; therefore, dietary supplements taken by the lactating mother generally increase the breast milk content of the vitamin.

## Metabolic function and essentiality

The biochemical functions, and hence the basis for the dietary requirement of pantothenic acid, arise entirely from its occurrence as an essential component of CoA and of ACP, because the vitamin cannot be synthesized *de novo* in mammals. Pantothenic acid was isolated as a chick, bacterial, and yeast growth factor, and as an antidermatitis dietary factor, in the 1930s. Use of omega-methyl-pantothenate as a vitamin antagonist in humans resulted in a syndrome of numbness and burning sensation in the extremities, increased sensitivity to insulin, impaired antibody production, and other symptoms.

In addition to the well-established roles of CoA in the degradation and synthesis of fatty acids, sterols, and other compounds synthesized from isoprenoid precursors, there are also a number of acetylation and long-chain fatty acylation processes which require CoA (Pietrocchi et al., 2015). The acetylation of amino sugars and many other functions of acetyl-CoA and succinyl-CoA have been known since the 1980s. However, the addition of acetyl or fatty acyl groups to certain proteins in order to modify and control their properties is a more recent discovery. Acetylation of N-terminal amino acid residues occurs in at least half of all the known proteins in higher organisms. The recipients of these acetyl groups are most commonly methionine, alanine, glycine, threonine, or serine. The purposes of this are not entirely clear and may include modifications of hormone function, of ligand-binding and site recognition, of tertiary peptide structure, and of susceptibility to degradation. Acetylation can also involve the amino groups of the side chain of internal lysine residues, notably the histones in the cell nucleus, and the  $\alpha$ -tubulin proteins of the cytoplasmic microtubules, which help to determine cell shape and motility. Its role in the synthesis of  $\alpha$ -tubulin appears particularly important.

Proteins can also be modified by acylation with certain long-chain fatty acids, notably the 16-carbon saturated fatty acid, palmitic acid, and the 14-carbon saturated fatty acid, myristic acid. Although structurally very similar to each other, these two fatty acids seek entirely different protein locations for acylation and have different functions. They have mainly been explored in viral and yeast proteins, but proteins in higher animals, in organs such as lungs and brain, can also become acylated with palmitoyl moieties, and enable transport of protein through the Golgi apparatus. Protein acylations may control protein interactions, especially in cell membranes, and palmitoylated proteins are associated with plasma membranes. Signal transduction (e.g., of the human  $\beta_2$ -adrenergic receptor) is one process that appears to be controlled by palmitoylation, and other palmitoylated proteins are structurally important, for example, in the protein–lipid complex of brain myelin. Acylation may be involved in the activation of some hormones and transcription factors. Clearly, these subtle protein modifications, all of which depend on CoA and hence on pantothenic acid, have wide-ranging significance.

Pantothenic acid is an essential component of the diet of all mammalian species studied, namely humans, bovines, pigs, dogs, cats, and rodents, as well as poultry and fish. Pantothenate deficiency signs in animals are nonspecific and vary between species and with age. Deficiency in young animals results in anorexia and impaired growth, and the requirement estimates based on maximum growth rates are between 8 and 15 mg kg<sup>−1</sup> diet. Rats fed a diet low in pantothenate also exhibit scaly dermatitis, alopecia, hair discoloration and loss, porphyrin-caked whiskers, spastic gait, anemia, leukopenia, impaired antibodies, sex organ disruption, congenital malformations, and adrenal necrosis. Deficient chicks have dermatitis, abnormal feather development, thymus involution, myelin degradation, locomotor abnormalities, neurological symptoms including convulsions, fatty liver, and hypoglycemia. Pigs exhibit dermatitis, intestinal problems, spastic gait, and abnormalities of dorsal root ganglion cells, and several species suffer nerve demyelination. Fish show fused gill lamellae, reproductive failure, clumping of mitochondria, and kidney lesions.

Signs specific for pantothenate depletion are not well characterized for humans. A syndrome that included “burning feet” has been described in tropical prisoner-of-war camps during World War II, and it was said to respond to pantothenic acid supplements; however, this was likely to have been a more complex deficiency. A competitive analog of pantothenate,  $\omega$ -methyl pantothenate, interferes with the activation of pantothenic acid and produces burning feet symptoms, Reye-like syndrome, cardiac instability, gastrointestinal disturbance, dizziness, paresthesia, depression, fatigue, insomnia, muscular weakness, loss of immune (antibody) function, insensitivity to adrenocorticotrophic hormone, and an increased sensitivity to insulin. Calcium hopantenate, another potential antagonist of the vitamin, has produced some similar effects. Large doses of pantothenate can reverse these changes. One of the earliest functional changes in mildly deficient rats was an increase in serum triacylglycerols and free fatty acids, resulting from impairment of  $\beta$ -oxidation. Paradoxically, CoA levels are relatively resistant to dietary pantothenate deficiency.

CoA is required for Golgi function, and hence protein transport; pantothenate deficiency therefore causes a reduction in the secretion of some proteins. Other metabolic responses to deficiency include a reduction in urinary 17-ketosteroids, a reduction in serum cholesterol, a reduction in drug acetylation, a general reduction in immune response, and an increase in upper respiratory tract infection.

Studies of wound healing and fibroblast growth have indicated that both pantothenic acid and ascorbic acid are involved in trace element distribution in the skin and scars of experimental animals and that pantothenic acid can improve skin and colon wound healing in rabbits. It is not yet known whether these observations are relevant to wound healing in humans. Reports that high-dose pantothenic acid supplements can alleviate some of the symptoms of rheumatoid arthritis or lupus erythematosus have yet to be confirmed.

## Requirements

The US/Canada adequate intake (AI) for pantothenic acid was set at 5 mg day<sup>-1</sup> for adults, rising to 6 mg in pregnancy and 7 mg in lactation; at 4 mg for children aged 9–13 years; at 3 mg for 4–8 years, at 2 mg for 1–3 years and at 1.7–1.8 mg for 0–1 year. There was insufficient evidence to set an estimated average requirement (EAR), a recommended daily allowance (RDA), or a tolerable upper intake level (UL). As for most water-soluble vitamins, maternal blood levels decrease during pregnancy, and the mean daily output of the vitamin in breast milk is of the order of 1.7 mg. Infant formulas should contain at least 2 mg pantothenate per liter (Institute of Medicine, 2006).

In a technical report issued in 2017, the European Food Safety Authority (EFSA) updated the AIs of all nutrients (EFSA 2017). The pantothenic acid AI for adults is set at 5 mg day<sup>-1</sup>. The AI for adults also applies to pregnant women. For lactating women, an AI of 7 mg day<sup>-1</sup> is proposed, to compensate for pantothenic acid losses through breast milk. For infants over six months, an AI of 3 mg day<sup>-1</sup> is proposed by extrapolating from the pantothenic acid intake of exclusively breast-fed infants aged zero to six months, using allometric scaling (body weight to the power of 0.75) and reference body weight for each age group, in order to account for the role of pantothenic acid in energy metabolism, and rounding to the nearest unit. The AIs for children and adolescents are set at 4 and 5 mg day<sup>-1</sup>, respectively, based on observed intakes in the EU.

There are few studies in communities where intakes are likely to be low; indeed, pantothenic acid is so widely distributed in human foods that it is unlikely that any natural diets with a very low content will be encountered. Some variations in status among communities have been described, but these do not define requirements. In a group of adolescents in the USA, daily pantothenate intakes were approximately 4 mg; total blood pantothenate was in the “normal” range of approximately 350–400 ng mL<sup>-1</sup>, and intakes were correlated with red cell pantothenate ( $r = 0.38$ ) and with urinary pantothenate ( $r = 0.60$ ), both  $P < 0.001$ . In adults, these correlations were less strong.

## Dietary sources and high intakes

Pantothenate is widely distributed in food; rich sources include animal tissues, especially liver, and yeast, with moderate amounts occurring in whole grain cereals and legumes (see Table 1). It is stable during cooking and storage, although some destruction occurs at high temperatures and at pH values below 5 or above 7. Highly processed foods have lower contents than fresh foods, and one-fifth to two-thirds may be lost during freezing, canning, etc. Commercial vitamin supplements containing pantothenate usually use the calcium salt, which is crystalline and more stable than the free acid.

Synthesis by gut microbiota in humans is suspected, and the rarity of diet-induced deficiency has been attributed partly to the likely contributions from gut microbiota.

Pantothenic acid supplements may be beneficial for treatment of rheumatoid arthritis and for enhancement of athletic performance, specifically while running. Pantethine, the disulfide dimer of pantetheine, may have cholesterol-lowering properties and pantothenol may enhance wound healing in animal models. The mechanisms of these reported effects are unclear and they require verification. A homolog of pantothenate, pantoyl  $\gamma$ -aminobutyrate (hopantenate, see section on metabolic function and essentiality), which can act as a pantothenate antagonist, has been used to enhance cognitive function, especially in Alzheimer disease. It acts on  $\gamma$ -amino-butyric acid (GABA) receptors to enhance acetylcholine release and cholinergic function in the brain. Some of the side effects of valproic acid (used in the treatment of epilepsy and bipolar disorder) may be susceptible to alleviation by pantothenate and carnitine supplements.

There is little evidence for pantothenate toxicity at high intakes, even up to 100–500 times the normal intake; at daily intakes of approximately 10 g, there may be mild diarrhea and gastrointestinal disturbance.

**Table 1** Pantothenate content of selected foods.

<i>Food</i>	<i>mg per 100 g wet wt</i>
<b>Meat, offal, and fish</b>	
Stewed minced beef	0.36
Grilled pork chop	1.08
Calf liver, fried	4.1
Lamb's kidney, fried	4.6
Cod, grilled	0.33
<b>Dairy products</b>	
Cow's milk, full cream	0.58
Cheese, cheddar	0.50
Yogurt (whole milk, plain)	0.50
Boiled chicken's egg	1.25
Human milk	0.25
<b>Fruits</b>	
Apples, eating, flesh and skin	Trace
Oranges, flesh	0.27
Pears, flesh and skin	0.08
Strawberries, raw	0.37
Dried mixed fruit	0.09
<b>Vegetables</b>	
Potatoes, boiled, new	0.50
Carrots, boiled, young	0.18
Brussels sprouts, boiled	0.40
Cauliflower, boiled	0.47
Onions, fried	0.04
<b>Grains, grain products, nuts</b>	
Wholemeal bread	0.63
Rice, boiled, white	0.20
Baked beans in tomato sauce	0.11
Peanuts, plain	2.66

## Conclusions

Pantothenic acid has two coenzyme derivatives of great biological importance. The acyl carrier protein (ACP) is part of the enzyme complex used for fatty acid synthesis and is therefore essential for lipogenesis. Coenzyme A is needed for metabolic activation of all acyl residues, including both fatty acids and acid metabolites originating from the catabolism of carbohydrates and some amino acids. Pantothenic acid is therefore essential in the energetic utilization of all types of macronutrients. Given its abundance in foods, isolated pantothenic acid deficiencies are very rare.

## Key points

- Phosphorus main functions include bone formation, regulation of gene transcription, enzymes activation, energy production and storage (ATP), blood buffer in extracellular fluids, and cellular signal transduction.
- The main dietary sources of phosphorus are high protein foods, dietary supplements, fortified food/water, and phosphorus added during food processing.
- Absorption has two main pathways: a sodium-dependent transcellular pathway, and the predominant sodium-independent paracellular pathway.
- Phosphorus is tightly regulated and homeostasis is maintained by the intestine, the kidney and the bone, and the activity of three hormones: parathyroid hormone (PTH), calcitriol and fibroblast growth factor 23 (FGF-23).
- Hypophosphatemia may be caused by low dietary intake, increased renal excretion, decreased intestinal absorption and a shift from extracellular to intracellular phosphorus causing bone loss.
- Hyperphosphatemia may be caused by decreased phosphorus renal excretion, excessive phosphorus intake and a shift from intracellular to extracellular phosphorus.
- The most common cause of hyperphosphatemia is acute or chronic renal disease. The high concentration of serum phosphorus in chronic kidney disease alters the homeostasis of phosphorus, causing secondary hyperparathyroidism, vascular calcification, and bone resorption.
- Elevated concentrations of phosphorus have been associated with impaired cognitive function, dementia and Alzheimer.
- Phosphorus, its transporters and polyPi may play an important role in cardiovascular, bone and brain health that should be further explored.

## Introduction

Phosphorus is an essential nutrient that is available naturally and added in many foods. It is the second most abundant mineral in the human body and approximately 80% is stored in the bone (Calvo and Lamberg-Allardt, 2015; Takeda et al., 2012). It is also present in the human body in the form of phospholipids (cell membrane and ATP), is a component of DNA and RNA, and other proteins and sugars that are phosphorylated (Takeda et al., 2012; Heaney, 2012). Its main functions include bone formation, regulation of gene transcription, enzymes activation, energy production and storage (ATP), blood buffer in extracellular fluids, and cellular signal transduction (Heaney, 2012; Calvo and Lamberg-Allardt, 2015; Takeda et al., 2012). Inorganic phosphate is the main form of serum phosphorus, representing less than 1% of the total inorganic phosphate in the body. It is highly regulated through intestinal absorption, renal excretion and bone formation to maintain a serum concentration between 2.5 and 4.5 mg/dL (Calvo and Lamberg-Allardt, 2015; Takeda et al., 2012).

The consumption of adequate dietary phosphorus is critical for the support of human metabolic functions. Under normal conditions, dietary phosphorus is sufficient to maintain its multiple functions. However, too much phosphorus may contribute to bone loss (with low calcium intake) and an increased risk of cardiovascular disease (CVD), coronary calcification and renal disease

(Fulgoni and Fulgoni, 2021). On the other hand, too little phosphorus with low calcium intake may not adequately maintain bone mass, particularly in the elderly.

This chapter looks into the main food sources of phosphorus, its absorption, homeostasis and consequences of both hypo- and hyperphosphatemia.

## Phosphorus requirements and food sources

The Recommended Daily Allowance (RDA) of phosphorus for men and women 19 years and older is 700 mg, and the Estimated Average Requirement (EAR) is 580 mg. The Upper Tolerable Level (UL) is 4000 mg/d for those 19–70 years old and 3000 mg/d for those over 71 years (IOM, 1998). Recently, the European Food Safety Authority (EFSA) established an Acceptable Daily Intake (ADI) of 40 mg of phosphorus/kg body weight/d (Younes et al., 2019). **Table 1** gives representative values of phosphorus in selected foods.

The three main sources of dietary phosphorus are: (1) organic phosphorus contained in high protein foods, (2) inorganic phosphorus from medications, dietary supplements, and fortified food/water, and (3) inorganic phosphorus added during food processing. Approximately 40–60% of the dietary phosphorus is naturally occurring organic phosphorus that comes from animal food sources (milk, milk products, meat, poultry, fish) and legumes and grain products (Calvo and Urivarri, 2013). According to data from the NHANES 2015–2016, the average daily phosphorus intake in the United States among children and teens (2–19 years) is 1237 mg (USDA, 2019). The mean intake of organic phosphorus of adults (>19 years old) in 2015–2016 was  $1113 \pm 10$  mg/d, and the main sources were cheese, pizza, chicken, reduced-fat milk and eggs (Fulgoni and Fulgoni, 2021). The bioavailability of phosphorus from animal food sources is higher than that from grains and legumes. The main form of storing phosphorus in the plants is phytate, and is present in the outer layer of grains and in the seed coats of legumes (Calvo and Urivarri, 2013). The bioavailability of phosphorus from phytate is low, thus, the amount of phosphorus from foods that is absorbed will depend on the total content of phosphorus in the diet and its bioavailability.

Most of the inorganic phosphorus that is added during the processing of many different foods are phosphate salts that have specific functions. These phosphorus-containing food additives are widely used for emulsification, leavening, acidification, and also as acidulants, flavorants, color stabilizers and buffers (Fulgoni and Fulgoni, 2021; Calvo and Urivarri, 2013). They also are used to improve texture and taste, and to reduce cooking time. Thus, the content of phosphorus additives is higher in processed

**Table 1** Calcium and phosphorus composition of selected foods.

<i>Food</i>	<i>Phosphorus mg/serving</i>
<b>Milk, dairy products and eggs</b>	
Cheese, cheddar, 100 g	458
Cheese, cottage, low fat, 2% milkfat, 1 cup	326
Milk 2% milkfat, 1 cup	252

foods. It has been reported that these additives contribute approximately 70 g/100 g of extra phosphorus compared with foods that have no phosphorus additives (Fulgoni and Fulgoni, 2021). However, intake of this added inorganic phosphorus is not easy to quantify and it is well-recognized that phosphorus intake may be underestimated. Recently, a novel approach has been used to calculate added phosphorus content in foods using data from the NHANES 2015–2016 (Fulgoni and Fulgoni, 2021). The added phosphorus intake was  $155 \pm 4.1$  mg/d in adults (>19-year-old), representing approximately 12% of the total phosphorus intake. The main sources of added phosphorus were cheese, soft drinks, cakes/pies, rolls/buns, and cookies/brownies (Fulgoni and Fulgoni, 2021). With this approach, it may be easier to estimate total phosphorus intake and associate it with health outcomes.

## Absorption

Phosphorus absorption in adults and children is very efficient (65–75%) and an increase in serum phosphorus can be observed within an hour after ingestion of a meal begins.

Absorption of dietary phosphate occurs in the gastrointestinal tract through at least two pathways: the transcellular, sodium-dependent pathway, and the paracellular, sodium-independent pathway. The main apical intestinal transporter in the transcellular absorption of phosphorus is the sodium-dependent phosphate cotransporter 2b (NaPi-2b), which is believed to be responsible for absorption when dietary phosphorus is low (Saurette and Alexander, 2019; Fishban and Nigwekar, 2021). The transporter NaPi-2b is highly regulated by the expression of calcitriol ( $1,25(\text{OH})_2\text{D}_3$ ) and by dietary phosphorus levels. For instance, when phosphorus concentrations are low, calcitriol levels increase, and then, calcitriol increases the expression of NaPi-2b to promote the intestinal absorption of phosphorus (Saurette and Alexander, 2019). On the contrary, when phosphorus concentration is high, the hormone phosphatidyl fibroblast growth factor 23 (FGF-23) is secreted in the bone, inhibits the synthesis of calcitriol, and thus, phosphorus absorption decreases. This pathway saturates at very low luminal phosphorus concentrations, so it is not very relevant in populations with high phosphorus intake.

The paracellular, sodium-independent pathway, is a passive transport of phosphorus through tight junction complexes between the intestinal cells, using electrical and chemical concentration gradients. These complexes include transmembrane adhesion proteins such as occludins and claudins (Fishban and Nigwekar, 2021; Saurette and Alexander, 2019). The paracellular absorption does not saturate, thus, when luminal phosphorus concentrations are high, absorption increases.

For years, the transcellular system has been thought to be the main pathway for phosphorus absorption, but now it is recognized that the paracellular pathway predominates and is the primary system of phosphate absorption (Saurette and Alexander, 2019).

Gut microbiota contributes with phosphorus absorption by degrading phytate and liberating inorganic phosphorus. In addition, it has been suggested that the microbiota provides short and long chain polyphosphated (polyPi) that are also absorbed and provide another source of phosphorus (Bird and Eskin, 2021). It has been suggested that polyPi, short, medium and long chains, can also be synthesized endogenously, and exert diverse physiological functions, both positive and negative.

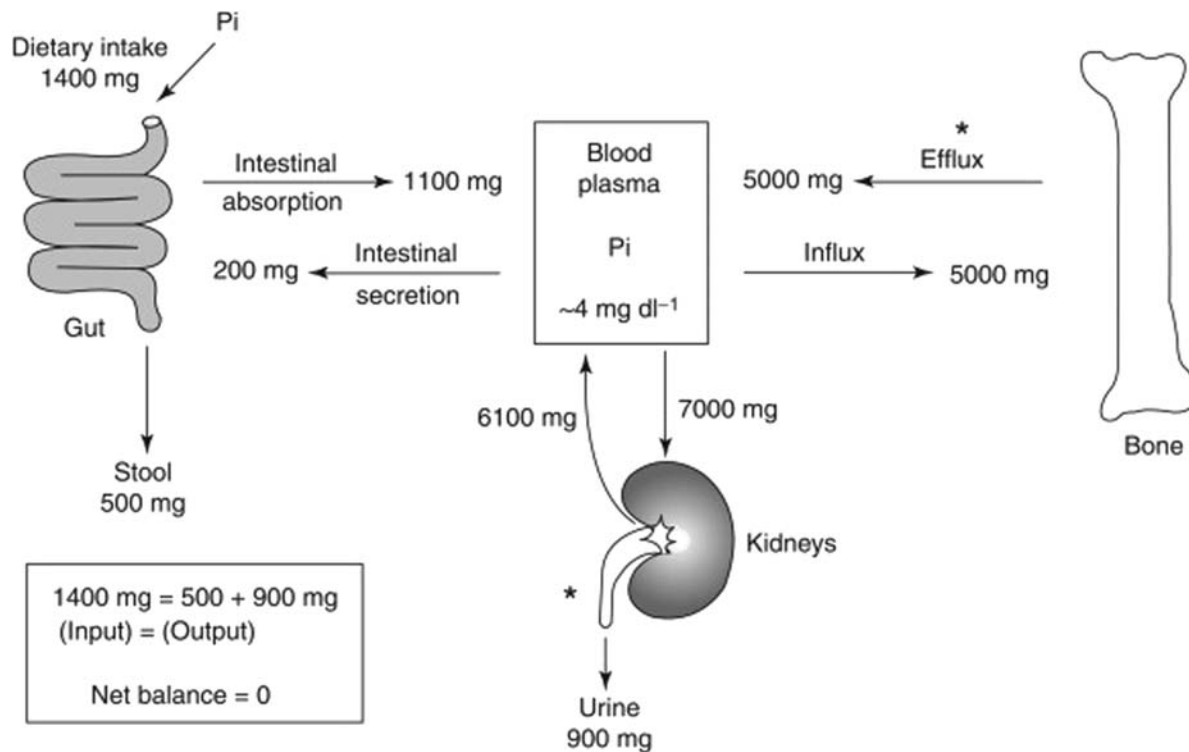

Once absorbed, phosphorus transporters are responsible for carrying phosphorus to different tissues and through different cells. These transporters belong to three families of solute carrier proteins (SLC): SLC17, SLC20 and SLC34. The intestinal transporter NaPi-2b, for instance, belongs to the SLC34 family, and is present also in the thyroid gland, lung, mammary glands, among others. Recent research has explored the importance of the SLC10 family, because they are expressed in the brain, liver and heart (Bird and Eskin, 2021). All these transporters contribute to phosphorus homeostasis.

## Phosphorus homeostasis

The blood concentration of phosphorus is tightly regulated, but less than other micronutrients, such as calcium. The kidney was believed to be the organ responsible for phosphorus homeostasis. However, phosphorus homeostasis in adults is maintained through urine losses and total phosphorus absorbed, and the amount of phosphorus that is resorbed and deposited in the bone. Therefore, it has been recognized recently that in order to maintain phosphorus homeostasis three organs are needed: the intestine, the kidney and the bone (Calvo and Lamberg-Allardt, 2015). This effective homeostatic action of the intestine, the bone and the kidney produces phosphorus balance (Fig. 1). These three organs work together with the activity of three hormones: parathyroid hormone (PTH), calcitriol and fibroblast growth factor 23 (FGF-23) (Bergwitz and Jüppner, 2010).

### PTH

High serum phosphorus concentration decreases calcium concentration, which in turn stimulates the parathyroid glands to secrete and synthesize PTH. Stimulation of PTH by high phosphorus concentration can occur independently of low calcium concentration. PTH acts on the kidneys to increase urinary phosphate excretion by inhibiting phosphate reabsorption, on the bone by increasing osteoblast activity, and finally, stimulates the synthesis of  $1,25(\text{OH})_2\text{D}_3$ , which together, lower serum phosphate concentration (Bergwitz and Jüppner, 2010). PTH can also increase phosphorus concentration by increasing its intestinal absorption through its effect on the kidney and on the production of  $1,25(\text{OH})_2\text{D}_3$ , and also by stimulating bone turnover and the release of phosphorus (Ureña and De Brauwere, 2011).

**Fig. 1** Phosphorus homeostasis and balance. The intestine, kidneys, and bone are organs involved in phosphate homeostasis. Fluxes of phosphate ions between blood and these organs are shown. Note the high fluxes in and out of bone each day. To convert phosphorus values from g to mmol, multiply by 32.29; from mg dl<sup>-1</sup> to mmol l<sup>-1</sup>, multiply by 0.3229. Steps enhanced by parathyroid hormone. Reproduced with permission from Anderson et al. (2001).

### Calcitriol 1,25(OH)<sub>2</sub>D<sub>3</sub>

Calcitriol can increase or decrease phosphorus serum concentration through its effect on the bone, the intestine and parathyroid gland. Calcitriol stimulates phosphorus intestinal absorption by increasing the expression of NPT2b, stimulates phosphate renal reabsorption and modulates bone resorption, thus, increasing phosphorus serum levels. On the contrary, 1,25(OH)<sub>2</sub>D<sub>3</sub> may decrease phosphorus concentration by stimulating the synthesis of FGF-23 (Bergwitz and Jüppner, 2010; Ureña and De Brauwere, 2011). High serum phosphate, calcium and FGF-23 levels downregulate the expression of 1,25(OH)<sub>2</sub>D<sub>3</sub>, and its expression is upregulated by PTH.

### FGF-23

FGF-23 is a hormone secreted in the bone that reduces phosphorus serum concentration by decreasing renal reabsorption and by decreasing 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis, which decreases intestinal phosphorus absorption (Ureña and De Brauwere, 2011). FGF-23 needs FGF receptors, and Klotho, a transmembrane protein, as a co-receptor in order to lower phosphorus concentrations (Bergwitz and Jüppner, 2010; Lanske and Razzaque, 2014; Ureña and De Brauwere, 2011). Both PTH and 1,25(OH)<sub>2</sub>D<sub>3</sub> can induce FGF-23 expression in the bone, and PTH can also regulate Klotho expression in the kidney (Lanske and Razzaque, 2014).

### Hyperphosphatemia and its consequences

Hyperphosphatemia (serum phosphate >4.5 mg/dL) may be caused by three main mechanisms: decreased phosphorus renal excretion, excessive phosphorus intake and a shift from intracellular to extracellular phosphorus. Signs and symptoms of hyperphosphatemia are similar regardless of the cause (Leung and Crook, 2019).

The most common cause of hyperphosphatemia is acute or chronic renal disease. In normal conditions, the kidney of healthy individuals has the capacity to excrete about 67% of their absorbed phosphate via the urine. However, when there is a decline in kidney function, the homeostasis of phosphorus is altered, and this occurs even at the early stages of kidney disease (Stremke and Gallant, 2018). Kidney disease is a progressive disease where glomerular filtration rate (GFR) is reduced, and phosphorus cannot be excreted, causing an increase in serum phosphorus concentration. In early renal disease, PTH secretions increase to maintain normal phosphorus concentrations, and though PTH concentrations are elevated, they remain within the upper limits of the normal range.

Both, serum phosphorus and PTH continue to climb as renal function declines, since more PTH is needed to maintain phosphorus homeostasis. As the disease progresses, the hyperphosphatemia persists as PTH is not able to lower phosphorus serum concentration. Thus, high concentration of serum phosphorus in chronic kidney disease alters the homeostasis of phosphorus, causing secondary hyperparathyroidism, vascular calcification, and bone resorption (Calvo and Urivarri, 2013). The condition where there is altered phosphorus (and calcium) metabolism, increased vascular calcification and bone loss is called chronic kidney disease-mineral bone disorder (CKD-MBD), which significantly increases the risk of bone fractures, cardiovascular disease, and ultimately, death (Leung and Crook, 2019; Stremke and Gallant, 2018).

It has been shown that hyperphosphatemia increases the risk of cardiovascular disease and mortality, even in healthy individuals (Calvo and Urivarri, 2013; Vervolet et al., 2017; Kendrick et al., 2011). Vascular calcification is caused when high concentrations of phosphate bind to calcium to create hydroxyapatite (calcium phosphate) and deposit in the arteries, the atheroma plaque and the cardiac valves, causing medial, intimal and heart valve calcification, respectively (Villa-Bellosta, 2021).

Recently, elevated concentrations of phosphorus have been found in patients with dementia and Alzheimer (Asharaf et al., 2019; Li et al., 2017). Dementia is now recognized as a comorbidity of CKD, where high serum concentrations of phosphorus are found. In addition, FGF-23 is also elevated, which has been indirectly associated with dementia and decline in cognitive functions because of its relationship with cerebral small vessel disease (Wright et al., 2014). Further research is needed to determine if measuring phosphorus concentration may be used as an indicator of cognitive impairment or dementia progression, and also to evaluate the effect a low phosphorus diet may have. In addition, the role polyPi has on the brain and other organs, needs to be further explored.

## Hypophosphatemia and its consequences

Hypophosphatemia (serum phosphate <2.5 mg/dL) may be caused by low dietary intake, increased renal excretion, decreased intestinal absorption and a shift from extracellular to intracellular phosphorus (Rudolph and Gonin, 2012; Leung and Crook, 2019). Hypophosphatemia is not common, but it may occur in patients that have undergone a renal transplant, patients with primary or secondary (to vitamin D deficiency) hyperparathyroidism, with protein-energy malnutrition, with intestinal malabsorption, or with alcoholism (Rudolph and Gonin, 2012; Leung and Crook, 2019). In addition, chronic use of anti-acids has been shown to develop hypophosphatemia.

There are usually no clinical signs of mild and moderate hypophosphatemia, though severe hypophosphatemia may cause irritability and respiratory difficulty (Rudolph and Gonin, 2012). Also, long term moderate hypophosphatemia has been known to cause rickets or osteomalacia (Leung and Crook, 2019). Hypophosphatemia can also occur in the elderly, mainly because of low phosphorus intake, that combined with low calcium intake, increases PTH, and hence, increases the risk of bone loss and more severe osteoporosis.

## Conclusion

It is well recognized that phosphorus is a mineral widely available from food sources, that is efficiently absorbed and tightly regulated by the intestine, the bone and the kidney. Both hyper and hypophosphatemia have adverse health consequences. Phosphorus, its transporters and polyPi may play an important role in cardiovascular, bone and brain health that should be further explored.

## Key Points

- Physical activity is associated with numerous health benefits;
- Contemporary evidence-based physical activity guidelines call for accumulating 150–300 min of moderate-intensity, or 75–150 min of vigorous-intensity physical activity weekly, while incorporating muscle-strengthening activity at least 2 days per week;
- More than a quarter of adults are not sufficiently active to achieve the associated health benefits;
- Up to 8% of premature mortality and noncommunicable diseases worldwide are directly attributable to physical inactivity.

## Introduction

An increasing volume of scientific evidence implicates physical inactivity as a major risk factor for several non-communicable diseases (NCDs) and premature mortality. Indeed, physical inactivity is considered the fourth leading cause of death globally, following closely behind high blood pressure, high blood glucose, and tobacco use (World Health Organization, 2009). Recent data from 1.9 million individuals from 168 countries indicate that 27.5% of adults are not sufficiently active to reap the associated health benefits, and the prevalence of physical inactivity is more than twice as high in high-income countries compared to low income countries (Guthold et al., 2018). The purpose of this article is to explore the health benefits associated with physical activity, and to describe the global health impacts of not meeting the current physical activity guidelines.

## Key terms and definitions

Physical activity refers to any bodily movement produced by skeletal muscles that results in energy expenditure (Caspersen et al., 1985). On the other hand, physical inactivity generally refers to a lack of physical activity, often in reference to not meeting physical activity guidelines or recommendations. In a similar vein, the term “insufficiently active” refers specifically to not meeting current physical activity guidelines (accumulating 150–300 min of moderate-intensity, or 75–150 min of vigorous-intensity physical activity weekly, while incorporating muscle-strengthening activity at least 2 days per week) (World Health Organization, 2020).

Sedentary behavior has been defined as any waking behavior characterized by an energy expenditure  $\leq 1.5$  METs (Metabolic Equivalents of Task) while in a sitting, reclining, or lying posture (Tremblay et al., 2017). Thus, sedentary behavior occurs at the opposite end of the energy expenditure spectrum compared to moderate-to-vigorous physical activity. Furthermore, the postural

component of the definition (i.e., sitting, reclining or lying) identifies it as a potential behavioral target for interventions that is separate from physical activity *per se* (Barone Gibbs et al., 2015).

Physical fitness is a concept that is adjacent to that of physical activity. While physical activity is a behavior, physical fitness is defined as an attained set of characteristics that relates to the ability to perform physical activity, and is determined by a variety of factors, including an individual's level of habitual physical activity, heredity and diet (Bouchard and Shephard, 1994). Although there are several components of physical fitness (i.e., cardiorespiratory, muscular, motor, morphological, metabolic, etc.) this article will focus on two of the most commonly studied components in relation to health outcomes: cardiorespiratory and muscular fitness.

## The genesis of modern physical activity epidemiology

The value of physical activity in promoting a sound mind and body was recognized by many ancient cultures, including those in China, India and Greece. Indeed, Hippocrates wrote extensively on the utility of exercise to address a number of afflictions in the fifth century BC, as did Galen in the first century AD (Pate, 2007). However, the systematic study of the health benefits of physical activity using modern research practices began in earnest during the 1950s.

The seminal studies on physical activity and coronary heart disease (CHD) in London Transport workers and British civil servants by Jeremy Morris and colleagues marked the beginning of the modern era of physical activity epidemiology (Morris et al., 1953; Paffenbarger et al., 2001). The initial studies observed that physically inactive bus drivers of London's double-decker buses had higher rates of CHD compared to the more active conductors who climbed the stairs. Morris continued to test his hypothesis, reproducing many of the findings when extending the study to London postmen and less active postal clerks (Morris et al., 1953). Subsequently, a series of investigations conducted by Ralph Paffenbarger, Jr. and colleagues on occupational (Paffenbarger and Hale, 1975) and leisure-time physical activity (Paffenbarger et al., 1986) identified physical inactivity as a powerful independent predictor of CHD and all-cause mortality.

## Summary of the evidence: physical activity

There has been an incredible amount of research conducted on the health benefits associated with physical activity over the last 60 years. This evidence has informed the development of evidence-based public health physical activity guidelines in individual countries in addition to global recommendations from the World Health Organization (World Health Organization, 2010, 2020). The research supporting these public health efforts has been summarized in extensive systematic reviews of the literature (2018 Physical Activity Guidelines Advisory Committee, 2018; Bull et al., 2020; Physical Activity Guidelines Advisory Committee, 2008; Powell et al., 2019). Table 1 provides a summary of the health benefits associated with physical activity in adults.

**Table 1** Health benefits associated with physical activity.

### Reduced risk of:

- All-cause mortality
- CVD mortality
- CVD (stroke and CHD)
- Hypertension
- Type 2 diabetes
- Depression
- Dementia
- Excessive weight gain
- Site-specific cancers (bladder, breast, colon, endometrium, esophagus, kidney, & stomach)
- Falls and fall-related injuries
- Excessive weight gain during pregnancy
- Gestational diabetes
- Post-partum depression

### Improved:

- Cognitive function
- Quality of life
- Sleep
- Physical function in older adults

Adapted from Powell et al. (2019).

A comprehensive review of all health benefits associated with physical activity is beyond the scope of this review; therefore, the focus will be on mortality and major non-communicable diseases (NCDs), including cardiovascular disease (CVD) and cancer.

### All-cause mortality

Regular physical activity is associated with a significantly reduced risk of premature all-cause mortality. This robust result has been replicated in numerous prospective cohort studies conducted over the past 60 years. The association between physical activity and all-cause mortality is best summarized in the results of a large pooled analysis of six prospective cohort studies comprising more than 600,000 adults (Moore et al., 2012; Arem et al., 2015). The results demonstrated a reverse J-shaped dose-response association between physical activity and all-cause mortality, where the risk of death was reduced by approximately 30–40% for individuals who were physically active for at least 150–300 min per week compared to inactive individuals. There are several characteristics of the dose-response curve there are common to studies of this type: there is no lower threshold for effect; there is a steep, early slope; about 70% of the benefit is reached by 150 min per week of moderate-intensity physical activity, there is no apparent upper threshold for effect; there is no evidence for increased risk at the greatest amounts of physical activity; and there is no obvious “best amount” (Kraus et al., 2019).

### Cardiovascular disease

Cardiovascular disease (CVD) is the leading cause of death worldwide, accounting for 32% of global deaths in 2017 (GBD 2017 Causes of Death Collaborators, 2018). Individuals with higher levels of habitual physical activity have a lower risk of developing and dying from CVD (Kraus et al., 2019). A recent meta-analysis characterized the dose-response association between physical activity and incident CVD based on data from 43 studies for CHD and 33 for stroke (Kyu et al., 2016). Fig. 1 presents the dose-response association between levels of total physical activity and risk of ischemic CHD and stroke. Those individuals in the highest category of physical activity have a 25% and 26% lower risk of CHD and stroke, respectively compared to individuals in the lowest physical activity category (Kyu et al., 2016).

### Cancer

In 2020, there are expected to be more than 19 million cancer cases worldwide and approximately 10 million deaths (International Agency for Research on Cancer (IARC), 2020). The 2008 Physical Activity Guidelines Advisory Committee found strong evidence for associations between physical activity and cancers of the breast and colon (Physical Activity Guidelines Advisory Committee, 2008). Based on a substantial increase in the evidence base in the subsequent decade, the 2018 Physical Activity Guidelines Advisory Committee confirmed these associations, and also found strong evidence for associations between physical activity and cancers of the bladder, endometrium, esophagus, kidney, and stomach (2018 Physical Activity Guidelines Advisory Committee, 2018;

**Fig. 1** Relationship between total physical activity and the risk of coronary heart disease (CHD) and ischemic stroke. The figure is drawn from data presented in Kyu et al. (2016) based on a meta-analysis of 43 studies for CHD and 33 studies for stroke.

**Fig. 2** Associations between leisure-time physical activity and the incidence of several cancers. The figure is drawn from data from a pooled analysis of 9 prospective cohort studies (Matthews et al., 2020).

McTiernan et al., 2019). Further, there is moderate evidence of an association between physical activity and lung cancer, but this association may be modified by smoking status (McTiernan et al., 2019).

The risks of developing site-specific cancers associated with physical activity were estimated using a pooled analysis of 1.44 million adults from 12 prospective cohort studies (Moore et al., 2016). Comparing the highest (90th percentile) versus lowest (10th percentile) levels of physical activity at baseline, the hazard ratios (HRs) were 0.84 (95% CI: 0.77 to 0.91) for colon cancer, 0.90 (95% CI: 0.87 to 0.93) for breast cancer, 0.87 (95% CI: 0.82 to 0.92) for bladder cancer, 0.79 (95% CI: 0.68 to 0.92) for endometrial cancer, 0.58 (95% CI: 0.37 to 0.89) for esophageal cancer, 0.77 (95% CI: 0.70 to 0.85) for kidney cancer, and 0.78 (95% CI: 0.64 to 0.95) for stomach cancer (Moore et al., 2016). Fig. 2 shows the dose-response associations between physical activity and the incidence of several cancers, based on a pooled analysis of 9 prospective cohort studies comprising more than 750,000 adults (Matthews et al., 2020). In general, there is a decreasing risk of incident cancer with increasing levels of physical activity.

### Leisure-time versus occupational physical activity

Physical activity occurs in a variety of settings, or domains. For example, physical activity can occur during an individual's leisure time, while they are completing household chores, or at work. The majority of the evidence of associations between physical activity and health outcomes has been based on studies of total or leisure-time physical activity, largely due to the nature of the physical activity questionnaires used in large prospective cohort studies. For example, greater leisure-time physical activity is associated with a lower risk of all-cause mortality (Lee et al., 2012), CVD mortality (Cheng et al., 2018), CHD (Sofi et al., 2008), type 2 diabetes (Huai et al., 2016), hypertension (Liu et al., 2017), and several cancers (Matthews et al., 2020).

As described above, the early studies of physical activity and the risk of CHD relied on comparisons of different occupations as proxies for physical activity. For example, studies of bus drivers versus conductors and postal carriers versus clerks provided some of the earliest evidence on the health benefits of physical activity (Morris et al., 1953). A recent umbrella review that summarized the evidence from 17 reviews covering 23 health outcomes found very low to moderate quality evidence that those who engaged in high versus low occupational physical activity had a lower risk of cancers of the colon and prostate, ischemic stroke, CHD, and mental health outcomes such as well-being and life satisfaction (Cillekens et al., 2020). On the other hand, there was also low to very low quality evidence that high levels of occupational physical activity were associated with a greater risk of all-cause mortality in men, depression, anxiety, osteoarthritis, and sleep quality and duration (Cillekens et al., 2020). However, it has been argued that these surprising results may be explained by inadequate classification of occupational demands and lack of proper adjustment for the effects of covariates, particularly from cigarette smoking and low socioeconomic status (Shephard, 2019).

There is a range of physical activity behavior in the population, and the prevalence of physical inactivity is approximately twice as high in high-income countries compared to low-income countries (Guthold et al., 2018). A recent study examined the effects of physical inactivity on mortality across 17 countries that ranged from low-income to high-income, given that the domains (recreational vs. occupational) where physical activity is occurring differ among countries at different levels of development (Lear et al., 2017). The results demonstrated that higher levels of both recreational and non-recreational physical activity were associated

with a lower risk of mortality in adults low-income, middle-income, and high-income countries (Lear et al., 2017). These results demonstrate the universality of physical inactivity as a risk factor for mortality across diverse contexts and settings.

### Muscle-strengthening activity

Most of the epidemiological evidence of the health effects associated with physical activity has been derived from studies of physical activity levels accumulated from participation in aerobic activities of different intensities, for example in moderate-to-vigorous physical activity (2018 Physical Activity Guidelines Advisory Committee, 2018). However, public health guidelines consistently call for participation in muscle-strengthening activities, usually for 2 days per week, as part of the physical activity recommendation (World Health Organization, 2020).

Although the effects of resistance exercise and health outcomes such as mortality and NCDs has been less studied, a recent umbrella review of 11 systematic reviews concluded that resistance training was associated with a reduction in all-cause mortality and cardiovascular disease incidence, and an improvement in physical functioning (El-Kotob et al., 2020). Of particular note, a recent meta-analysis showed that resistance training alone or in combination with aerobic exercise training was associated with a significantly lower risk of all-cause mortality; with HRs of 0.79 (95% CI: 0.69 to 0.91) and 0.60 (95% CI: 0.49 to 0.72), respectively (Saeidifard et al., 2019). However, the effects of resistance training on health-related quality of life or cognitive function were less certain (El-Kotob et al., 2020). More research is required to better define the dose and intensity of muscle-strengthening activities that promote optimal health outcomes.

### Light, moderate and vigorous physical activity

Early studies of physical activity and health outcomes were focused on measuring moderate-to-vigorous physical activity as the primary exposure. This is largely due to the reliance on self-reported physical activity, and the use of questionnaires that asked participants about their level of participation in a variety of physical activities of moderate or higher intensity ( $\geq 3$  METs). However, with the advent and application of devices such as accelerometers to assess physical activity, data are now more widely available on the associations between physical activity and health outcomes across a spectrum of activity intensity (light, moderate and vigorous). The associations of total, light and moderate-to-vigorous physical activity with all-cause mortality were explored in a meta-analysis of 8 studies including 36,383 participants (Ekelund et al., 2019). The shape of the dose-response curves is similar across the three exposure variables, and the results indicate that higher levels of physical activity of any intensity are associated with substantially reduced risk for mortality. Compared to the lowest quartile of activity, the HRs for premature mortality in the highest quartile were 0.27 (95% CI: 0.23 to 0.32), 0.38 (95% CI: 0.28 to 0.51), and 0.52 (95% CI: 0.43 to 0.61) for total activity (counts  $\text{min}^{-1}$ ), light intensity activity ( $\text{min day}^{-1}$ ) and MVPA ( $\text{min day}^{-1}$ ), respectively (Ekelund et al., 2019). The effect estimates based on these device-based measurements are greater than are observed in studies that rely on self-report.

A study using device-based measures of physical activity in the US National Health and Nutrition Examination Survey (NHANES) directly addressed the influence of physical activity intensity on the risk of all-cause mortality (Saint-Maurice et al., 2018). The results indicated that the total volume of activity seemed to be the key driver in reducing the risk for all-cause mortality, and the difference in mortality benefits associated with activities of different intensity (i.e., moderate-to-vigorous vs. light) were modest after accounting for the total volume of physical activity (Saint-Maurice et al., 2018). Fig. 3 presents the joint HRs for light physical activity and moderate-to-vigorous physical activity with all-cause mortality.

**Fig. 3** Joint associations of light and moderate-to-vigorous physical activity with risk of all-cause mortality. Activity counts expressed in thousands. The figure is drawn from analysis of the U.S. National Health and Nutrition Examination Survey in Saint-Maurice et al. (2018).

The results show that higher levels of light activity had a stronger influence on mortality among those doing the least amount moderate-to-vigorous activity, but there was only some evidence of an influence of light activity at higher levels of moderate-to-vigorous intensity activity, such as in the third quartile.

Taken together, the current evidence suggests that there are mortality benefits associated with physical activity of all intensities, including light activity. These results highlight that the benefits of activity can be derived from combining activities of different intensities, based on the preference of the individual.

### Summary of the evidence: sedentary behavior

Compared to the large body of evidence on the association between physical activity and health that has accumulated over the last 60 years, the study of sedentary behaviors, such as sitting, and health outcomes, is in its infancy. In the first comprehensive study of sitting and mortality, a clear dose-response relationship between greater daily sitting time and an increased risk of all-cause and CVD mortality was observed in the 12-year mortality follow-up of the Canada Fitness Survey (Katzmarzyk et al., 2009). At baseline, sitting time was classified into 5 groups: almost none of the time, one-fourth of the time, half of the time, three-fourths of the time, and almost all of the time. After adjustment for potential confounders, there was a higher risk of all-cause mortality (HRs: 1.00, 1.00, 1.11, 1.36, 1.54;  $P$  for trend  $<0.0001$ ) and CVD mortality (HR: 1.00, 1.01, 1.22, 1.47, 1.54;  $P$  for trend  $<0.0001$ ) across successively higher levels of sitting time (Katzmarzyk et al., 2009). The following year, similar results were obtained in a 6.6-year follow-up of the Australian Diabetes, Obesity and Lifestyle Study (AusDiab), where there was a significant positive association between television viewing time and mortality from all-causes and from CVD (Dunstan et al., 2010). After adjustment for covariates, the HRs for each 1 h increment in daily television viewing time were 1.11 (95% CI: 1.03 to 1.20) for all-cause mortality and 1.18 (95% CI: 1.03 to 1.35) for CVD mortality (Dunstan et al., 2010).

The results of these early investigations have been replicated in numerous prospective cohort studies in the intervening years (Katzmarzyk et al., 2019). Fig. 4 presents the results of a harmonized meta-analysis of 8 studies reporting the association between device-measured (accelerometry) sedentary time and risk of premature all-cause mortality (Ekelund et al., 2019). There is a clear dose-response association, with a statistically significant increased risk of mortality observed at more than 9.5 h of daily sedentary time (Ekelund et al., 2019).

The 2018 Physical Activity Guidelines Advisory Committee conducted a systematic review of the health effects associated with sedentary behavior (Katzmarzyk et al., 2019). In addition to all-cause and CVD mortality, they found moderate to strong evidence that higher levels of sedentary behavior are associated with an increased risk of incident CVD, type 2 diabetes, incident endometrial, colon and lung cancer, while there was only limited evidence that sedentary behavior is associated with cancer mortality and weight status (Katzmarzyk et al., 2019). A more recent systematic review expanded the slate of outcomes associated with sedentary behavior and reported that sedentary behavior is also unfavorably associated with cognitive function, depression, function and disability, physical activity levels, and physical health-related quality of life (Saunders et al., 2020).

**Fig. 4** Dose-response association between sedentary time and risk of all-cause mortality. Covariates in the model included age, sex, wear time, body mass index and socioeconomic position. Error bars are 95% confidence intervals. The figure is drawn from a meta-analysis of data from 8 studies (Ekelund et al., 2019).

## The intersection of physical activity and sedentary behavior

While sedentary behavior and MVPA are at opposite ends of the energy expenditure spectrum, they are also two distinct behaviors, and as such, could represent unique behavioral targets for interventions. One can easily imagine a situation where an individual is meeting the guidelines for physical activity (i.e., 150–300 min of moderate-to-vigorous physical activity per week and muscle-strengthening activity on 2 days) but also participates in high levels of excessive sedentary behavior (sitting). The question as to whether high levels of physical activity can attenuate the detrimental effects of sedentary behavior was investigated in a harmonized meta-analysis of over 1 million participants (Ekelund et al., 2016). Fig. 5 describes the joint association between physical activity and sedentary behavior with all-cause mortality (Ekelund et al., 2016). The figure shows that the risk of mortality associated with higher levels of physical activity decreases within categories of sitting, and that the risk of mortality increases across levels of sitting within physical activity categories. The highest risk category is low physical activity ( $\leq 2.5$  MET-h wk<sup>-1</sup>) and high levels of sitting ( $> 8$  h day<sup>-1</sup>) (HR = 1.59; 95% CI: 1.52 to 1.66). Furthermore, the risk associated with sedentary behavior is never significantly elevated in the high physical activity category (white bars;  $> 35.5$  MET-h wk<sup>-1</sup>). The results indicate that ~60–75 min per day of moderate intensity physical activity can eliminate the increased risk of death associated with high sitting time (Ekelund et al., 2016).

## Summary of the evidence: physical fitness

As described above, physical fitness can have many facets, including cardiorespiratory, muscular, motor, morphological, and metabolic components (Bouchard and Shephard, 1994). For the purpose of this article the focus will be on the health benefits associated with two main components that are relevant to both performance-related and health-related fitness: cardiorespiratory and muscular.

### Cardiorespiratory fitness

The Aerobics Center Longitudinal Study (ACLS) was a prospective observational study of physical activity, physical fitness, and health outcomes among men and women receiving a preventative medical examination, including a graded exercise treadmill test, at the Cooper Clinic in Dallas, TX. The results of an early analysis in the cohort indicated that men and women in the lowest cardiorespiratory fitness quintile were 3.44 (95% CI: 2.05 to 5.77) and 4.65 (95% CI: 2.22 to 9.75) times more likely to die over an average follow-up of 8 years compared with men and women in the upper quintile, respectively (Blair et al., 1989). Several studies have now replicated the results of this seminal study. Indeed, a meta-analysis of 21 studies reported a pooled relative risk (RR) of 1.70 (95% CI: 1.51 to 1.92) for all-cause mortality comparing participants with low versus high cardiorespiratory fitness (Kodama et al., 2009). More recently, the association between cardiorespiratory fitness and mortality was studied in a large cohort of 122,007 consecutive patients undergoing exercise treadmill testing in an academic medical center (Mandsager et al., 2018). The results showed that cardiorespiratory fitness was inversely associated with all-cause mortality without an observed upper limit of benefit; the HR comparing those with low fitness ( $< 25$ th percentile) to those with high fitness (75th to 97.6th percentile) was 3.90 (95% CI: 3.67 to 4.14) (Mandsager et al., 2018).

The beneficial effects of cardiorespiratory fitness are also observed for CVD. For example, a meta-analysis of 24 studies reported a pooled RR of 1.40 (95% CI: 1.32 to 1.48) for CHD/CVD events comparing participants with low versus high cardiorespiratory fitness (Kodama et al., 2009). Several studies have also demonstrated that cardiorespiratory fitness is associated with a lower risk of stroke (Wang et al., 2020). A meta-analysis of 14 cohort studies documented that high cardiorespiratory fitness was

**Fig. 5** Joint associations of sitting time and physical activity with all-cause mortality. The figure is drawn from data from a pooled meta-analysis of 1,005,791 individuals (Ekelund et al., 2016).

associated with a 42% lower risk of stroke (RR = 0.58; 95% CI: 0.51 to 0.66) compared to low cardiorespiratory fitness. Furthermore, ischemic stroke (RR = 0.71; 95% CI: 0.54 to 0.93) and hemorrhagic stroke (RR = 0.69; 95% CI: 0.47 to 1.00) demonstrated significant and similar associations with high cardiorespiratory fitness (Wang et al., 2020).

Studies have also documented a strong link between cardiorespiratory fitness and risk of cancer. A meta-analysis of six prospective studies demonstrated a strong, graded, inverse association between cardiorespiratory fitness and total cancer mortality (Schmid and Leitzmann, 2015). Compared to low cardiorespiratory fitness, the RRs for total cancer mortality for moderate and high levels of cardiorespiratory fitness were 0.80 (95% CI: 0.67 to 0.97) and 0.55 (95% CI: 0.47 to 0.65), respectively (Schmid and Leitzmann, 2015). Furthermore, a recent meta-analysis of seven studies showed that compared to low cardiorespiratory fitness, the HRs for moderate and high levels of cardiorespiratory fitness were 0.53 (95% CI: 0.39 to 0.68) and 0.52 (95% CI: 0.42 to 0.61) for lung cancer, 0.74 (95% CI: 0.55 to 0.93) and 0.77 (95% CI: 0.62 to 0.92) for colorectal cancer, and 0.86 (95% CI: 0.79 to 0.93) and 0.81 (95% CI: 0.75 to 0.87) for all cancer sites, respectively (Pozuelo-Carrascosa et al., 2019).

Moderate and high levels of cardiorespiratory fitness are also protective against developing type 2 diabetes. A recent meta-analysis of 22 studies demonstrated a negative linear association between cardiorespiratory fitness and the development of type 2 diabetes, such that the HR for each 1 MET higher cardiorespiratory fitness was 0.92 (95% CI: 0.92 to 0.92), after statistical adjustment for adiposity and other covariates (Tarp et al., 2019). These results were confirmed in a second meta-analysis of 15 studies which also showed a linear association between higher cardiorespiratory fitness and lower risk of type 2 diabetes, such that the HR associated with every 1 MET increase in cardiorespiratory fitness was 0.90 (95% CI: 0.86 to 0.94) for the general population (Qiu et al., 2019).

### Muscular fitness

Muscular fitness is generally assessed using tests of muscular strength and endurance. A commonly used test of muscular strength that can be conducted in the clinic, in a lab, or in the field, is grip strength, measured using a portable hand grip dynamometer. In recent years there has been increasing interest in understanding the health benefits associated with muscular fitness. The results from a large meta-analysis of data from 734,481 participants from 40 studies reported a HR of 0.71 (0.66–0.77) for all-cause mortality comparing highest versus lowest levels of grip strength (Wu et al., 2017). These results are supported by another recent meta-analysis of 1,907,580 participants from 38 studies which demonstrated that higher levels of handgrip strength were associated with a lower risk of all-cause mortality (HR: 0.69; 95% CI: 0.64 to 0.74) compared with lower handgrip strength (Garcia-Hermoso et al., 2018). This study also showed that higher levels of knee extension strength were associated with a lower risk of all-cause mortality (HR: 0.86; 95% CI: 0.80 to 0.93) compared with lower knee extension strength.

In addition to all-cause mortality, there is also evidence that muscular strength is associated with other health outcomes. For example, a large meta-analysis comparing highest versus lowest levels of grip strength reported a HR estimate of 0.61 (0.51–0.74) for incident CVD (1,789,942 participants from 12 studies) and 1.12 (0.83–1.52) for cancer (162,821 participants from 8 studies) (Wu et al., 2017). Another meta-analysis reported a RR for type 2 diabetes of 0.87 (0.81, 0.94) for each standard deviation increase in muscular strength (Tarp et al., 2019).

Fewer studies have examined the association between measures of muscular endurance and health outcomes. For example, data from the longitudinal follow-up of the 1981 Canada Fitness Survey found a significantly higher risk of all-cause mortality in the lowest quartile of sit-ups, compared to the highest quartile, in both men (RR: 2.72; 95% CI: 1.56 to 4.64) and women (RR = 2.26; 95% CI: 1.15 to 4.43) (Katzmarzyk and Craig, 2002). While the analysis from the Canada Fitness Survey did not find an association between push-ups and all-cause mortality (Katzmarzyk and Craig, 2002), a study of 1104 firefighters showed that men who completed more than 40 push-ups had a significantly lower risk of incident CVD compared with those who completed less than 10 push-ups (Incident rate ratio = 0.04; 95% CI: 0.01 to 0.36) (Yang et al., 2019).

### Global burden of physical inactivity

Given that physical inactivity is associated with an increased risk of several health outcomes at the level of the individual, it follows that this translates into substantial public health burden. Using data from 1.9 million participants from 168 countries, Guthold and colleagues reported that 27.5% of adults failed to meet the current physical activity recommendations (at least 150 min of moderate-intensity, or 75 min of vigorous-intensity physical activity per week) (Guthold et al., 2018). The prevalence of insufficient physical activity in high-income countries was more than double that of low-income countries, and there has been a significant increase in insufficient physical activity over time in high-income countries (Guthold et al., 2018).

An analysis conducted in 2012 estimated that physical inactivity was responsible for 6% of coronary heart disease, 7% of type 2 diabetes, 10% of breast and colon cancers, and 9% of all-cause deaths globally (Lee et al., 2012). Furthermore, physical inactivity cost health care systems \$53.8 billion globally in 2013, of which \$31.2 billion was paid by the public sector (Ding et al., 2016). Given the explosion of physical activity research that has been conducted in the last decade, an analysis recently updated the public health burden of physical inactivity to include 15 NCDs and mortality that exhibited strong evidence of association with physical inactivity, as determined by the 2018 U.S. Physical Activity Guidelines Advisory Committee (2018 Physical Activity Guidelines Advisory Committee, 2018). Fig. 6 presents the population attributable risks (PAR%) from this analysis, which represent the proportion of each of these diseases at the population level that is directly attributable to physical inactivity (Katzmarzyk et al.,

**Fig. 6** Global estimates of population attributable risk (PAR%) for mortality and noncommunicable diseases showing strong associations with physical inactivity. The figure is drawn from data presented in [Katzmarzyk et al. \(2021\)](#).

2021). The results demonstrated that up to 8% of these 15 NCDs and mortality is directly attributable to physical inactivity ([Katzmarzyk et al., 2021](#)). The PAR% estimates increase across low-, to middle-, to high-income countries in a graded manner, which reflects the greater prevalence of physical inactivity in middle- and high-income countries. However, the percentage of all CVD and all-cause deaths attributable to physical inactivity is highest in middle-income countries (74% and 69%, respectively) because of the larger overall number of deaths in these populations ([Katzmarzyk et al., 2021](#)).

## Conclusion

There is abundant evidence that physical activity and physical fitness levels are inversely associated with the risk of premature mortality and many NCDs including coronary heart disease, stroke, hypertension, type 2 diabetes, dementia, depression, and cancers of the bladder, breast, colon, endometrium, esophagus, stomach, and kidney. Given the high prevalence of physical inactivity in many countries and regions, the associated public health burden is substantial. The promotion of physical activity should be a priority for public health efforts in addition to clinical practice.

## Key points

- Dietary potassium is one of the major factors that determine blood pressure (BP) levels.
- Insufficient potassium together with excess sodium intake raise BP, an extraordinarily common and important risk factor for cardiovascular disease, particularly stroke, and kidney diseases.
- In addition to high BP, an insufficient intake of potassium leads to greater salt sensitivity, an increased risk of kidney stones and possibly increased bone loss.
- Individuals should strive to increase their consumption of potassium-rich foods, particularly fruits and vegetables.
- Replacement of regular salt with potassium-enriched salt is a promising approach to raise potassium intake and lower sodium intake and BP.

## Introduction

The major intracellular cation in the body is potassium, which is maintained at a concentration of approximately 145 mmol/L in intracellular fluid but at much lower concentrations in the plasma and interstitial fluid (3.8–5 mmol/L of extracellular fluid). The high intracellular concentration of potassium is maintained via the activity of the  $\text{Na}^+/\text{K}^+$ -ATPase pump. Because this enzyme is stimulated by insulin, alterations in the plasma concentration of insulin can affect cellular influx of potassium and thus plasma concentration of potassium. Relatively small changes in the concentration of extracellular potassium greatly affect the extracellular/intracellular potassium ratio and thereby affect nerve transmission, muscle contraction, and vascular tone.

In unprocessed foods, potassium occurs mainly in association with bicarbonate-generating precursors such as citrate and, to a lesser extent, with phosphate. In processed foods to which potassium is added and in supplements, the form of potassium is potassium chloride. In healthy people, a large fraction of dietary potassium is absorbed. Most potassium is excreted in urine, whereas the remainder is excreted mainly in feces, with much smaller amounts excreted in sweat (Agarwal et al., 1994). Interestingly, there are large racial differences in the percentage of dietary potassium that is excreted in the urine. Blacks excrete a lower percentage of dietary potassium than whites (e.g., 67% in blacks vs. 74% in whites); this racial difference also differs by concomitant diet (Turban et al., 2008). Because most potassium that is filtered by the glomerulus of the kidney is reabsorbed (70–80%) in the proximal tubule, only a small amount of filtered potassium reaches the distal tubule. The majority of potassium in urine results from secretion of potassium into the cortical collecting duct, a secretion regulated by a number of factors including the hormone aldosterone. An elevated plasma concentration of potassium stimulates the adrenal cortex to release aldosterone, which in turn increases secretion of potassium in the cortical collecting duct.

## Acid–base considerations

A diet rich in potassium from fruits and vegetables favorably affects acid–base metabolism because these foods are also rich in precursors of bicarbonate. Acting as a buffer, the bicarbonate-yielding organic anions found in fruits and vegetables neutralize non-carbonic acids generated from meats and other high-protein foods. In the setting of an inadequate intake of bicarbonate precursors,

which is commonplace in contemporary Western diets, excess acid in the blood titrates bone buffer (Frassetto et al., 2001). As a result, bone becomes demineralized, calcium is released, and urinary calcium excretion increases. This state has been termed a “low-grade metabolic acidosis.” Increased bone breakdown and calcium-containing kidney stones are adverse clinical consequences of excess diet-derived acids. Diets rich in potassium with its bicarbonate precursors might prevent kidney stones and bone loss. Studies also suggest that a diet rich in bicarbonate precursors might also retard the progression of chronic kidney disease (Scialla et al., 2012). In processed foods to which potassium is added and in potassium supplements, the conjugate anion is typically chloride, which cannot act as a buffer.

### Adverse effects of insufficient potassium

The adverse effects of potassium insufficiency depend on the extent of the potassium deficit (Institute of Medicine (US) Panel on Dietary Reference Intakes for Electrolytes and Water, 2005). Severe potassium deficiency, which most commonly results from diuretic-induced potassium losses, is characterized by a serum potassium concentration of less than 3.5 mmol/L, termed hypokalemia. The adverse consequences of hypokalemia are cardiac arrhythmias, muscle weakness, and glucose intolerance. Moderate potassium deficiency, which commonly results from an inadequate dietary intake of potassium, occurs without hypokalemia and is characterized by increased BP, increased salt sensitivity, an increased risk of kidney stones, and increased bone turnover. Through its effects on BP, an inadequate intake of dietary potassium increases the risk of cardiovascular (CV) and kidney diseases, more specifically, stroke, myocardial infarction, heart failure, kidney failure and likely cognitive decline. Independent of its effects on BP, an insufficient intake of potassium might also increase the risk of stroke and perhaps other diseases as well.

### Kidney stones and bone demineralization

Because of its effects on acid–base balance, an increased dietary potassium intake might have favorable effects on kidney stone formation. In one large observational study of women (Fig. 1), there was a progressive, inverse relationship between greater intake of potassium and incident kidney stones (Curhan et al., 1997). At a median potassium intake of 4.7 g day<sup>-1</sup> (119 mmol day<sup>-1</sup>), the risk of developing a kidney stone was 35% less compared to that for women with an intake of <2.0 g day<sup>-1</sup> (52 mmol day<sup>-1</sup>). Similar results were evident in men (Curhan et al., 1993). In the one available trial, an intake of approximately 3.6–4.7 g day<sup>-1</sup> (92–120 mmol day<sup>-1</sup>) of potassium in the form of potassium citrate reduced the risk of recurrent kidney stones (Barcelo et al., 1993).

Epidemiologic studies have consistently documented that increased potassium intake is associated with greater bone mineral density (Institute of Medicine (US) Panel on Dietary Reference Intakes for Electrolytes and Water, 2005). In trials, supplemental potassium bicarbonate and potassium citrate reduced bone-turnover as manifest by less urinary calcium excretion and by favorable changes in biomarkers of bone turnover (Moseley et al., 2013; Dawson-Hughes et al., 2015). Few trials have examined the effects of potassium on bone density, and none on clinical outcomes related to osteoporosis.

### Elevated blood pressure

High levels of potassium intake are associated with reduced BP. Observational data have been reasonably consistent in documenting this inverse relationship, whereas data from individual trials have been less consistent, particularly in trials of nonhypertensive individuals. Several meta-analyses of these trials have each documented a significant inverse relationship such that higher potassium

**Fig. 1** Relative risk of kidney stones during 12 years of follow-up by quintile of potassium intake in 91 731 women. Data from Curhan et al. (1997).

intake, most often from potassium chloride, lowers BP. In a recent meta-analysis of 18 trials, average net systolic/diastolic BP reductions were 6.4/3.5 mmHg (National Academies of Sciences, 2019). In these meta-analyses, BP reductions are statistically significant in trials that enrolled persons with hypertension, whereas BP reductions in individuals without hypertension are typically non-significant. In general, BP reductions from potassium are greater in African Americans than non-African Americans (Whelton et al., 1997). Most of the trials that tested the effects of potassium on BP used pill supplements, typically potassium chloride. In the few available trials, potassium chloride and potassium bicarbonate had similar effects on BP (He et al., 2005). Mechanisms by which potassium affects BP and its sequelae has recently been reviewed (Gritter et al., 2019).

Likewise, potassium-enriched salt substitutes lower BP. In a recent meta-analysis of trials, most conducted in China, potassium-enriched salt substitutes lowered mean systolic/diastolic BP by 5.6/2.9 mmHg, in comparison to regular salt. The effects are most evident in persons with hypertension; in those without hypertension, available evidence is sparse, without clear evidence of BP reduction. Still, in a large, population-based study in Peru, potassium-enriched salt substitutes significantly reduced mean systolic/diastolic BP by 1.3/0.8 mmHg (Bernabe-Ortiz et al., 2020). It is noteworthy that 82% of participants were non-hypertensive at baseline; in this subgroup, use of the salt substitute was associated with a 51% reduced risk of developing hypertension compared with regular salt. Such evidence is consistent with observational studies suggesting that dietary potassium might retard the age-related rise in systolic BP (Rose et al., 1988).

A high potassium intake has been shown to blunt the rise in BP in response to increased salt intake. The term “salt-sensitive BP” applies to those individuals or subgroups who experience the greatest reduction in BP when salt intake is reduced. One metabolic study of 38 healthy, nonhypertensive men (24 African Americans and 14 non-African Americans) investigated the effect of potassium supplementation on the pressor effect of salt loading (5.7 g day<sup>-1</sup> of sodium (250 mmol)). Before potassium was supplemented, 79% of the African American men and 26% of the non-African American men were termed “salt sensitive,” as defined by a salt-induced increase in mean arterial pressure of at least 3 mmHg. There was a progressive reduction in the frequency of salt sensitivity as the dose of potassium was increased. In the African Americans with severe salt sensitivity, increasing dietary potassium to 4.7 g day<sup>-1</sup> (120 mmol day<sup>-1</sup>) reduced the frequency of salt sensitivity to 20%, the same percentage as that observed in non-African American subjects when their potassium intake was increased to only 2.7 g day<sup>-1</sup> (70 mmol day<sup>-1</sup>) (Morris et al., 1999). A recent review of intervention studies confirms this association and suggests that when potassium intake is high in African-Americans, there is no evidence of racial disparities in salt sensitivity (Kurtz et al., 2021).

Other studies indicate that potassium has greater BP lowering in the context of a higher salt intake and lesser BP reduction in the setting of a lower salt intake (Whelton et al., 1997). Conversely, the BP reduction from a reduced-salt intake is greatest when potassium intake is low (Sacks et al., 2001). These data are consistent with sub-additive effects of reduced-salt intake and increased potassium intake on BP.

### Cardiovascular disease

Through its effects on BP, an increased intake of potassium should reduce the occurrence of BP-related cardiovascular disease. Potassium may also have protective effects that are independent of BP reduction. This possibility has been tested in experimental studies conducted in rodents. In a series of animal models, the addition of either potassium chloride or potassium citrate markedly reduced mortality from stroke (Tobian et al., 1985). Interestingly, these reductions occurred in the setting of stable BP. Such data indicate that potassium has both BP-dependent and BP-independent properties that are cardioprotective.

In humans, observational studies often document that at higher levels of potassium intake, there is a reduced risk of subsequent stroke (Aburto et al., 2013). Meta-analyses of such studies have likewise been reasonably consistent. For example, in the Health Professionals Follow-Up Study, there was a significant inverse relationship between baseline potassium intake and stroke after

**Fig. 2** Relative risk of ischemic stroke by quintile of potassium intake in 43,738 men. Data from Ascherio et al. (1998).

adjustment for established cardiovascular disease risk factors, including BP and caloric intake (Fig. 2) (Ascherio et al., 1998). In this study, a median potassium intake of  $4.3 \text{ g day}^{-1}$  ( $110 \text{ mmol day}^{-1}$ ) was associated with a 41% reduced risk of stroke in comparison to those with a median intake of  $2.4 \text{ g day}^{-1}$  ( $61 \text{ mmol day}^{-1}$ ). Consistent with these studies are other observational studies that have repeatedly documented a reduced risk of stroke from an increased intake of fruits and vegetables. In contrast to the inverse relationship of potassium intake and stroke, the relationship of potassium intake with myocardial infarction and mortality is inconsistent.

In observational studies, clinical events such as stroke are often more strongly associated with the dietary sodium/potassium ratio, than either sodium or potassium alone. As discussed previously, such a relationship is biologically plausible. However, there is also the potential for methodological artifact, specifically, the sodium/potassium ratio is less prone to errors from under- and overreporting in dietary assessment and urinary electrolyte excretion than estimated intakes of sodium and potassium alone.

Recent studies have strengthened the evidence base in support of a higher potassium and reduced sodium intake. First, a major trial documented that replacement of regular salt with a potassium-enriched salt substitute significantly reduced the risk of stroke (14%) and total mortality (12%) in rural China, where potassium intake is low (Neal et al., 2021). Second, a meta-analysis of observational studies in generally healthy adults documented that lower potassium and higher sodium intakes, as estimated from multiple 24 h urine samples, were associated in a dose-response manner with a higher cardiovascular risk (Ma et al., 2021).

### Adverse effects of excess potassium intake

In the generally healthy population with normal kidney function, a high-potassium intake from foods, potassium supplements, and potassium-enriched salt substitutes poses no risk because excess potassium is readily excreted in the urine. Under unusual circumstances, an extremely high intake of potassium from supplements can lead to acute toxicity in healthy individuals (Institute of Medicine (US) Panel on Dietary Reference Intakes for Electrolytes and Water, 2005).

However, in individuals whose urinary potassium excretion is impaired, there is concern about the occurrence of hyperkalemia, which can cause cardiac arrhythmias. Drugs that commonly impair potassium excretion are angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics. Common medical conditions associated with impaired potassium excretion are diabetes, chronic renal insufficiency, end stage renal disease, severe heart failure, and adrenal insufficiency. Elderly individuals are at increased risk of hyperkalemia because they often have one or more of these conditions or take one or more of the medications that impair potassium excretion.

A contemporary issue is the effect of dietary potassium and potassium-enriched salt substitutes on blood levels of potassium and the occurrence of hyperkalemia in persons with impaired potassium excretion (Greer et al., 2020). The relevance of this issue is highlighted by replacement of regular salt with potassium-enriched salt substitutes as a means to lower BP, an approach which led to significant reductions in stroke and total mortality in a major trial conducted in China (Neal et al., 2021). In the general population without potassium excretion, a meta-analysis of trials documented that  $45 \text{ mmol/d}$  ( $1755 \text{ mg/d}$ ) led to a small increase in mean serum potassium levels of  $0.14 \text{ mmol/L}$ . Unfortunately, there is sparse evidence on the effects on serum potassium of increased potassium intake from any source in persons with impaired potassium excretion. In the one available trial, which enrolled persons with chronic kidney disease, a higher potassium diet that provided  $2300 \text{ mg/d}$  ( $60 \text{ mmol/d}$ ) more than a lower potassium diet increased mean net serum potassium levels by  $0.21 \text{ mmol/L}$ , and two participants had confirmed hyperkalemia (serum  $K \geq 5.5 \text{ mmol/L}$ ) (Turban et al., 2021).

### Recommended potassium intake, current intake, and dietary sources

On the basis of available data, a National Academy of Medicine committee set an Adequate Intake for potassium of  $3400 \text{ mg}$  per day for healthy men and  $2600 \text{ mg}$  per day for healthy women (National Academies of Sciences, 2019). This level of dietary intake should lower BP levels and have the potential benefits of reducing the adverse effects of salt on BP, reducing the risk of kidney stones, and possibly decreasing bone loss (Institute of Medicine (US) Panel on Dietary Reference Intakes for Electrolytes and Water, 2005). Currently, dietary intake of potassium is lower than these levels. In recent surveys, the mean intake of potassium in the United States was  $\sim 3200 \text{ mg/day}$  in adult men and  $\sim 2400 \text{ mg/day}$  in adult women (Bailey et al., 2015). Because African Americans have a relatively low intake of potassium and a high prevalence of high BP and salt sensitivity, this subgroup of the population would especially benefit from an increased potassium intake. Worldwide, dietary potassium intakes by country vary considerably, with a very low, average intake in China and a much higher average intake in Finland (van Mierlo et al., 2010).

Dietary intake surveys typically do not include estimates from salt substitutes and supplements. However, less than 10% of those surveyed in NHANES reported using salt substitutes or a reduced-sodium salt. Because a high dietary intake of potassium can be achieved through diet rather than pills and because potassium derived from foods also comes with bicarbonate precursors, as well as a variety of other nutrients, the preferred strategy to achieve the recommended potassium intake is to consume foods. In addition, replacement of regular salt with potassium-enriched salt substitutes is a promising strategy to reduce sodium intake, not just raise potassium intake.

Dietary sources of potassium, as well as bicarbonate precursors, are fresh fruits, fruit juices, dried fruits, and vegetables. Although meat, milk, and cereal products contain potassium, their content of bicarbonate precursors does not sufficiently balance the amount

**Table 1** Foods rich in potassium.

<i>Food</i>	<i>Portion size</i>	<i>Potassium content, g (meq)</i>
<b>Beans</b>		
Cooked dried beans	1/2 cup	0.4 (10.7)
Lima beans	5/8 cup	0.4 (10.8)
<b>Fruit</b>		
Apple	1 medium	0.1 (2.8)

Whole milk	8 oz.	0.4 (9.0)

of acid-forming precursors, such as sulfur amino acids, found in higher protein foods. The typical content of potassium-rich foods is displayed in **Table 1**. Potassium-enriched, salt substitutes currently available in the marketplace range from 0.4 to 2.8 g/teaspoon (11–72 mmol/teaspoon) of potassium, all as potassium chloride; salt substitutes with no more than 30% potassium avoid the bitter, metallic taste of potassium chloride and are virtually indistinguishable from regular salt.

## Conclusion

Potassium is an essential nutrient that is required for normal cellular function. Although humans evolved on diets rich in potassium, contemporary diets are quite low in potassium. An increased intake of potassium from foods should prevent many of the adverse effects of inadequate potassium intake, which are higher BP levels, greater salt sensitivity, increased risk of kidney stones, and possibly increased bone loss. Based on the results of one major trial, replacement of regular salt with potassium-enriched salt reduces the risk of stroke in persons with a low potassium intake. In view of the high prevalence of elevated BP, stroke, and conditions related to bone demineralization (i.e., osteoporosis and kidney stones) in the general population, individuals should strive to increase their consumption of potassium-rich foods, particularly fruits and vegetables.

## Key points

- Understand importance of protein and amino acid intakes in humans
- Understand the dynamic nature of protein metabolism and the relationship between protein intakes and protein needs
- Understand the influence of life-stage on protein deficiency
- Understand the causes and, principles of treatment of protein deficiency

## Introduction

“Protein” is derived from the Greek word, “*proteios*”, which means of the first rank or position (Elango and Laviano, 2019). Originally coined in 1838, the word was chosen to represent the fundamental nature of protein’s role in human nutrition. Protein as a macronutrient is unique for its source of nitrogen, when compared to the other 2 macronutrients—carbohydrates and fats. The nutritional importance of protein is also because of their constituent amino acids. The 20  $\alpha$ -amino acids which are part of mammalian protein are classified based on their nutritional importance into indispensable (essential) amino acids, conditionally indispensable (essential) amino acids and the dispensable (nonessential) amino acids (Table 1). From a dietary point of view, protein quantity, and protein quality of the dietary protein sources, to provide all amino acids in the right balance, are important to ensure normal bodily functions (Pencharz et al., 2016). From a body cellular, tissue and organ point of view all 20 amino acids are needed in different proportions and amounts at any given time to ensure adequate protein synthesis. Protein and individual amino acids are also necessary for several key nitrogen containing compounds including creatine, nucleic acids, nucleotides, neurotransmitters, and hormones such as insulin, growth hormone, etc (Table 2).

**Table 1** Indispensable, conditionally indispensable and dispensable amino acids for humans.

<i>Indispensable</i>	<i>Conditionally indispensable</i>	<i>Dispensable</i>
Histidine	Arginine	Alanine
Isoleucine	Cysteine	Aspartic acid
Leucine	Glutamine	Asparagine
Lysine	Glycine	Glutamic acid
Methionine	Proline	Serine
Phenylalanine	Tyrosine	
Threonine		
Tryptophan		
Valine		

**Table 2** Examples of roles of amino acids other than protein synthesis.

Precursor amino acids	End product	Function
Tyrosine	Catecholamines	Stimulation of glycogenolysis, lipolysis
Tryptophan	Serotonin	Vasoconstrictor, stimulates smooth muscle contraction
Aspartate, glutamate	Nucleic acids	Cell division
Methionine, glycine, serine	Methyl group metabolism	DNA methylation
Cysteine, glutamate, glycine	Glutathione	Antioxidant
Arginine	Nitric oxide	Vasodilation, polyamines

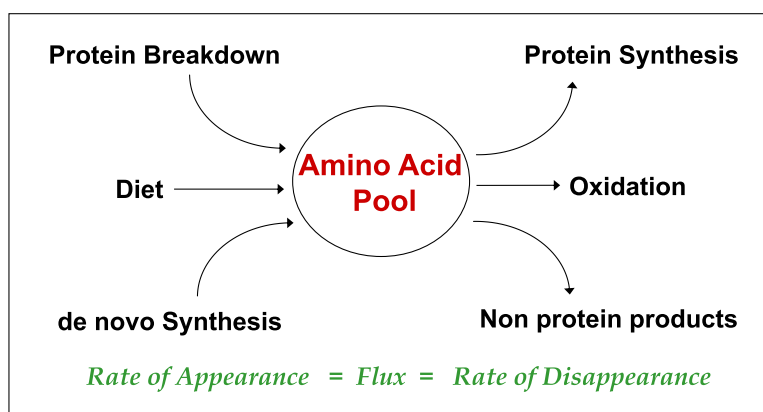

## Protein needs

Protein in the body is in a dynamic state referred to as protein turnover (**Fig. 1**), which involves continuous degradation to free amino acids, and re-synthesis of new proteins (**Waterlow, 2006**). The free amino acids are also constantly degraded and oxidized to carbon dioxide and nitrogenous end products, principally urea and ammonia (**Fig. 2**). Dietary protein is necessary to replenish these losses of amino acids to maintain protein homeostasis. Furthermore, in children, and other active stages of growth, including pregnancy and lactation there is an increased need from dietary protein to allow new tissue growth. The requirement for dietary protein is therefore composed of two components: maintenance and growth.

Within the context of the above description, the definition of protein needs, as currently accepted by a joint World Health Organization/Food and Agriculture Organization/United Nations University (**WHO/FAO/UNU, 2007**) consultation is: “the lowest level of dietary protein intake that will balance the losses of nitrogen from the body, and thus maintain the body protein mass, in persons at energy balance with modest levels of physical activity, plus, in children or in pregnant or lactating women, the needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health”.

Key points to be considered in the current definition of protein need includes “energy balance”, and “physical activity”. Energy needs and protein needs are interconnected, and thus if energy needs are not met, protein needs are proportionally increased, and increases the probability of protein deficiency. The influence of energy needs are more during active stages of growth and development (**Uauy, 2013**).

Current recommendations for protein needs through different life stages are primarily based on nitrogen balance studies in adult humans. All other life-stage needs for protein are based on the concept of maintenance (in adults) plus growth (tissue deposition x efficiency of utilization) (**Table 3**). Human milk is the optimal source of nutrients for normal, full-term infants throughout the first year of life and is recommended as the sole nutritional source for infants during the first 4–6 months of life. For infants weaned to solid foods, and up to 10 years of age the recommendations are combined for both sexes. For children 10 years and above—18 years, the recommendations are separated by sexes to take the different trajectories of growth. For pregnancy, the recommendations are provided based on trimesters, with maintenance needs plus additional needs for fetal growth which progressively increase with stages of gestation. For lactation, the recommendations are based on milk production rates, combined with the concentration of protein and non-protein nitrogen in human milk. The values are provided based on infants receiving exclusive human milk for the first 6 months post-partum, and partial milk feeding for 6–12 months post-partum (**Table 3**).

**Fig. 1** Protein metabolism is dynamic. Protein is in a constant state of flux, with the rate of appearance and disappearance from the freely available amino acid pool. Amino acid flux is regulated by diet, breakdown, and endogenous (de novo) synthesis on the one hand, and protein synthesis in tissues, oxidation and synthesis of nitrogen containing metabolites on the other.

**Fig. 2** Overview of protein metabolism. Protein metabolism is influenced by digestion and absorption from the gut to release amino acids in circulation. Protein metabolism, via the carbon skeletons of amino acids interacts with the other macronutrients—carbohydrates (CHO) and fats. Protein synthesis into new tissues and tissue degradation to release amino acids occur constantly. Amino acids are also involved in synthesis of key metabolites which play functional roles. Complete catabolism of amino acids releases the carbon skeleton as  $\text{CO}_2$ , and the nitrogen is excreted, primarily as urea in stool and urine

These recommendations have been argued to be underestimates based on other end-point criteria, other than nitrogen balance, such as stable-isotope based oxidation studies (Elango et al., 2010). Although from a severe protein deficiency point of view, intakes below these current recommendations would certainly not be sufficient.

### Relationship between protein intake and needs

The human body does not have a major store of amino acids, other than skeletal muscle protein, which is not freely available. Thus, in order to maintain the constant state of protein turnover (Fig. 1) a daily intake of protein is required to maintain homeostasis (Fig. 2). Both high or low protein intakes will influence all aspects of protein turnover including protein synthesis, protein degradation, amino acid synthesis, amino acid oxidation and urea production (Young and Marchini, 1990). The rate at which changes occur in each of these inter-related components is regulated by

- protein/nitrogen intake
- degree to which pattern of amino acid intake matches the amino acid need in the body
- balance between indispensable, conditionally indispensable and dispensable amino acid intake
- degree to which energy intake matches energy needs

### Protein quality

In the context of dietary protein sources, it is important to note that animal sources such as milk, eggs, meat are considered “complete proteins” due to the balance in amino acid composition (indispensable:dispensable amino acids). On the other hand, plant sources such as legumes/pulses, and cereal grains are considered “incomplete proteins” since they are limiting in one or more indispensable amino acids. Pulses/legumes which are considered the primary proteins in plant-based diets include lentils, beans, chickpeas etc. are limiting in methionine. Cereal grains such as rice, wheat, corn/maize are limiting in lysine. Protein complementation, where a pulse is combined with a cereal in a meal is one way that reduces the impact of the imbalanced amino acid content (Manary et al., 2016). Furthermore, plant-based proteins are also relatively lower in total protein/nitrogen content, are also less digestible compared to animal sources, and have a lower energy density. Recently the FAO has recommended that each individual amino acid be considered a “nutrient”. This has huge significance, since the amino acid digestibility, and the proportion that is subsequently bioavailable varies considerably among the amino acids, and can influence the overall protein quality of foods. In the overall context, likelihood of protein deficiency is higher when populations are predominantly consuming plant-based diets (Bandyopadhyay et al., 2020).

## Adaptation to low protein intakes

Within the context of protein homeostasis, the human body does respond in the short-term to a reduced protein intake by altering several mechanisms. Amino acid oxidation rates are reduced quite quickly, with reduced plasma concentrations of amino acids. Whole body protein synthesis and degradation are reduced, although there might be some tissue specific differences, where the liver and muscle response rates differ, due to an acute reduction in protein intakes. The urea cycle whose principal role is to facilitate the removal of excess protein/nitrogen in the diet and its accumulation as ammonia in the body, adapts to a low protein diet by reducing the cycle activity to promote nitrogen conservation (Young and Marchini, 1990). These adaptive responses are considered successful, as it allows the maintenance of a steady state in body homeostasis, although there is a change in function of one or more

mechanism to achieve this. On the other hand, when the restriction of protein continues in the long-term, there will be accommodative responses, where a loss of function as a consequence of low protein occurs. This influence (adaptive vs. accommodative) can result in significant health impacts, and they vary based on life-stage and the presence of disease.

## Protein deficiency and influence of life-stage

### Children

Traditionally protein deficiency has been associated with young growing children and the term Protein-Energy Malnutrition (PEM). Historically, PEM were defined as marasmus and kwashiorkor. Marasmus was characterized with low intakes of both energy and protein, while kwashiorkor was characterized with intakes of sufficient energy and low protein. It is now recognized that there are several different gradations of protein deficiency including Severe Acute Malnutrition (SAM), Moderate Acute Malnutrition (MAM), and chronic malnutrition—stunting (Jahoor et al., 2008).

Based on the involvement of edema, SAM is further classified as non-edematous (marasmus) and edematous (kwashiorkor and marasmic-kwashiorkor). In both marasmus and marasmic-kwashiorkor wasting is involved. Wasting is defined by WHO as mid-upper arm circumference (MUAC) less than 115 mm or weight-for-height z score (WHZ) less than  $-3$  for ages 6 months–59 months. The edematous forms of malnutrition are characterized by several metabolic perturbations beyond edema, including anorexia, hypopigmentation of skin, hair and liver steatosis. In general, the edematous forms are more difficult to treat and manage. From a protein metabolism point of view, in children with edematous SAM a slower protein breakdown rate is observed with a reduction in plasma amino acid concentrations of indispensable amino acids, particularly of methionine and phenylalanine. Since Methionine and phenylalanine are the pre-cursors of cysteine and tyrosine, respectively, their plasma concentrations are remarkably reduced as well. Cysteine is a key limiting factor for synthesis of glutathione (the body's primary antioxidant); tyrosine is the pre-cursor for synthesis of neurotransmitters and catecholamines (Table 2). Deficiency of these two conditionally indispensable amino acids needs to be corrected by dietary supplementation as part of the management of SAM. Methionine deficiency, which is often observed in SAM has also been the focus of new studies. Methionine via S-adenosyl Methionine, is the primary methyl donor for nearly all methylation reactions in the body. As part of the methionine cycle, several methyl (one-carbon metabolites) such as betaine, choline, homocysteine are altered in edematous SAM, and complicates the management of this disorder (May et al., 2022). Non-edematous SAM on the other hand protein breakdown rates are not different and thus children are able to maintain plasma amino acid concentrations.

Globally, MAM defined as a weight-for-age between  $-3$  and  $-2$  z-scores below the median of the WHO child growth standards is also more prevalent. Progression from MAM to SAM is likely if protein and/or energy deficiency continues to persist.

Compared to SAM and MAM, stunting in children is a marker of chronic undernutrition, and is more widespread with nearly a quarter of the world's children affected. Stunting is defined as height-for-age less than  $-2$  z-scores below the median of the WHO child growth standards. Using a large data set and country-level data, it was shown that a significant relationship exists between population risk of dietary protein inadequacy and prevalence of stunting. It was also shown that protein quality of the diet remained significantly related to stunting rates after adjustment for dietary energy, house-hold income, and prevalence of infection. In response to infection protein metabolism changes occurs at the hepatic level with the production of acute phase proteins (APP) (Jahoor et al., 2008). Some APP involved in host defense mechanisms increase in serum concentrations, and are referred to as positive APP ( $\alpha_1$ -antitrypsin, haptoglobin, fibrinogen) and some APP involved in transport mechanisms decrease and are referred to as negative APP (albumin, transthyretin, retinol binding protein). These negative APP are usually rich in specific amino acids including cysteine, glycine, serine and thus protein and amino acid deficiency contribute to the further reduction in plasma concentrations.

### Pregnancy & lactation

Protein deficiency during the critical stage of pregnancy has negative consequences for both the mother and infant. Low birthweight and preterm birth have both been associated with lower protein intakes during pregnancy (Bandyopadhyay et al., 2020). In turn, these neonates have increased mortality, morbidity and long-term developmental impacts which extend into adulthood. Mothers who themselves are undernourished have increased child birth related consequences, increased risk for preeclampsia, gestational diabetes in the current pregnancy. Furthermore, it also increases the risk for chronic diseases later including type 2 diabetes, hypertension and metabolic syndrome. There is also evidence that protein needs progressively increase with gestation stages, however amino acid needs do not proportionally increase (Elango and Ball, 2016). For example, phenylalanine needs increase early in pregnancy, and continue to increase during later stages. Lysine needs in early gestation is similar to non-pregnancy needs, but increase significantly by later stages. Recently it was also shown that glycine, a dispensable amino acid in adults, is conditionally-dispensable in later stages of pregnancy (Rasmussen et al., 2021).

Lactation stages, especially during the immediate post-partum period is an extremely energy demanding stage. While lactation protein needs are yet to be determined directly, earlier nitrogen balance studies have shown that to maintain positive nitrogen balance, a substantially higher protein intake than current recommendations (Table 3) is required. Human milk content is influenced by the maternal diet; however, protein deficiency has not been shown to directly reduce milk output in the short-term. It is likely that maternal endogenous turnover compensates to a certain extent, but this needs to be confirmed. Current evidence does

point to the long-term impact of perinatal and postnatal influence of maternal nutrition on child health through the concept of developmental origins of health and disease, and protein/amino acids have a large regulatory role in this paradigm.

## Elderly

Older adults (65 y+) increasingly form a large proportion of the human population and they are also at increased risk of protein-energy malnutrition. Aging is associated with progressive loss of muscle mass, which impacts mobility, loss of function, decreased immune function and increased risk of infection (Wolfe, 2012). Simultaneously there is a loss of appetite, inability to eat a variety of foods and dysphagia. Protein synthesis can be stimulated in older individuals with protein intake; however a higher quantity and quality of protein is required, compared to younger individuals to see a similar effect. This effect referred to as “anabolic resistance” is observed in older adults with a reduced appearance of amino acids in circulation following a meal, and the blunted response in muscle protein synthesis in response to protein ingestion. Combination of resistance exercise, high quality proteins and more protein energy dense meals have shown to increase protein synthesis (Phillips and Martinson, 2019). Leucine, an indispensable amino acid has been the widely studied amino acid in elderly, and there is evidence to suggest that leucine requirements might be considerably higher compared to younger individuals. There are also considerable sex-based differences in responses to protein and amino acid ingestion, and thus contributes to the response to protein supplements in older adults.

## Causes of protein deficiency

The primary cause for protein deficiency is usually lack of availability of food or starvation. The reason for this could be multi-fold, due to socio-economic conditions, geo-political issues, season of the year (rainy vs. dry), famine and an emergency (natural/man-made). Food insecurity can exist in both developed and developing countries, and can contribute to protein deficiency.

A deficiency in protein could also occur under conditions of higher physiological demands, due to chronic stress, moderate persistent inflammation. Clinical conditions such as burns, post-surgical individuals and trauma victims also will have elevated protein demands due to a significant increase in protein turnover (both protein synthesis and degradation). In the various forms of pediatric malnutrition protein deficiency could be multifactorial due to the presence of acute infections, environmental toxins and an overall lack of hygiene (Golden, 2010). Furthermore, underlying pathologies such as small intestinal damage due to mucosal atrophy, villous blunting, and intestinal inflammation could impact digestion and absorption of protein and several other nutrients. Parasitic infestation is also common in many populations living in poor sanitary conditions, and presence of parasites has been shown to increase specific amino acid (lysine, leucine) and protein needs.

## Principles of treatment of protein deficiency

The key to treating protein deficiency is to ensure a thorough understanding of the underlying cause(s) has been fully examined. This includes an assessment of the physiological stage (life-stage), presence of other clinical symptoms, diagnoses of disease, and any other associated infections. This should be combined with a thorough assessment of food intake, which will allow the characterization of energy, protein, other macro- and micro-nutrient intakes. It is important to note that many key micronutrients, vitamins and minerals accompany dietary protein. Thus, deficiency of protein is likely associated with micronutrient deficiency, which would exacerbate the problem. This aspect is perfectly highlighted with the example of methionine deficiency that was discussed earlier in SAM. As part of the methionine cycle, 4 key B vitamins interact—folate, B12 (cobalamin), pyridoxine and riboflavin. Some of the impacts of methionine deficiency can be reduced if optimal B vitamin status is maintained.

For the treatment of specific forms of child undernutrition, WHO has created guidelines and products available to use. These include F75 (which is considered a starter), F100 (for catch-up growth) which are used for acute management of SAM (Golden, 2010). The F75 has relatively less calories and protein, with the goal being to correct electrolyte imbalance, correct edema, and allow a slow recovery to body homeostasis. The F100 is more dense with energy, calories and other electrolytes/minerals to allow catch up growth to occur and a pathway to recovery in these malnourished children. In a community setting, for these children recovering from SAM, as well as to treat MAM, stunting, Ready to Use Therapeutic Foods (RUTF) are available. These are blends of peanut - milk base, corn-soy, etc which are produced and packaged to be food-safe. The protein quality of these RUTF is an intense area of research, with an emphasis on locally resourced and produced products, such that the treatment is both context relevant and allows the local communities to be self-reliant in managing protein malnutrition.

For older individuals in developed countries, similar energy-nutrient dense easy to drink products are available, although the products could be expensive. Similar to young children, the underlying cause of protein deficiency must be explored, to ensure other pathologic conditions, micro-nutrient deficiencies are corrected, and more often physical activity with some form of resistance exercise will be required to ensure a full recovery from protein deficiency is possible.

## Summary and conclusions

In summary, protein deficiency can occur to individuals, primarily during vulnerable stages of growth and development (childhood, pregnancy, lactation) and in the elderly. While the major cause is a reduction in dietary protein intake, overall reduction in food intake, lower protein quality of the foods being consumed, presence of underlying infections, or disease can exacerbate protein deficiency. Treatment and management of protein deficiency in children is primarily based on the type of protein malnutrition, with the SAM forms requiring correction of underlying biochemical, physiological and immunological factors first. During the catch-up phase in children recovering from protein deficiency, in children with chronic undernutrition and stunting, pregnant, lactating mothers and in elderly the focus is on both adequate quantity of protein and quality of the protein source. Therefore, consumption of “high quality” protein rich in all the indispensable amino acids, principally animal sources, or a balanced blend of complementary mixtures of plant proteins are recommended.

## Key points

- After food ingestion, dietary proteins are subjected to digestion in the gastrointestinal tract, and a part of protein entering the gastrointestinal tract daily is also derived from endogenous sources.
- The purpose of protein digestion is the cleavage of protein into smaller fragments constituted by amino acids, dipeptides, and tripeptides so that they can be absorbed as amino acids made available to the organism to support anabolic and catabolic processes.
- Protein digestion starts in the stomach with the actions of pepsins. In the duodenum and the small intestine protein released from the stomach are subjected to hydrolysis by pancreatic proteolytic enzymes (trypsin, chymotrypsin, carboxypeptidase A and B) and intestinal brush-border enzymes.
- Protein digestion produces amino acids and di- and tripeptides absorbed through transporters present in the brush-border membranes of the enterocytes. Small peptides are further hydrolyzed by peptidases within the cytoplasm, so that products that reach the bloodstream are single amino acids.
- The fraction of protein not digested and absorbed in the small intestine reaches the large intestine where amino acids are not quantitatively absorbed but metabolized by the microbiota. They can be directly incorporated into bacterial cells as building blocks of proteins or can enter catabolic pathways.
- Food protein digestion occurs in the stomach and small intestine and produces amino acids absorbed in the small intestine. In the colon unabsorbed amino acids are mostly metabolized by colonic bacteria and converted to ammonia that can be absorbed.
- The intricate and coordinated system of digestion ensures that under normal conditions, approximately 95% of ingested protein in the intestinal lumen is digested and the amino acid absorbed and made available to the organism to support anabolic and catabolic processes.
- As intestinal amino acid absorption is practically complete at the end of the small intestine, oro-ileal digestibility is preferred to oro-faecal digestibility. As digesta contain nitrogen and amino acids from both exogenous and endogenous, true oro-ileal digestibility is corrected by the endogenous losses.
- Protein digestibility is an important component of protein quality. The digestibility of a protein is dependent on the relative ease with which peptide bonds can be hydrolyzed, and on several other factors including the presence of additional dietary factors such as trypsin inhibitors.

## Introduction

Proteins represent a significant part of animal and plant tissues and microorganisms and are the main nitrogenous constituents with approximately 16% nitrogen by weight. The basic structural units of proteins are the amino acids which are characterized by the presence of an amine function, an acid carboxyl group and a specific lateral chain. Protein are constituted by 20 amino acids which are linked together by peptide bonds. Units of two or three amino acid residues are called di- or tripeptides, units of less than 100 amino acid residues are called peptides or polypeptides, and units above 100 amino acid residues are called protein. Dietary proteins are the sources of nitrogen and amino acids, including the 9 indispensable amino acids which cannot be synthesized by humans. They are crucial for the synthesis of body tissues proteins, regulatory proteins, and different amino acid-derived metabolites. The digestion of proteins in the gastrointestinal tract involves a coordinated series of events with sequential processes by which ingested protein are progressively hydrolyzed by proteolytic enzymes, leading to the release of amino acids which are absorbed and transferred into the bloodstream. The intricate and coordinated system of digestion ensures that under normal conditions, approximately 95% of ingested protein in the intestinal lumen is digested and the amino acid absorbed and made available to the organism to support anabolic and catabolic processes.

## Protein digestion in the intestinal lumen

The daily dietary protein intakes in different adult populations range from 40 to 100 g day<sup>-1</sup> that constitute on average approximately 10–20% of daily energy intake. After food ingestion, dietary proteins are subjected to digestion in the gastrointestinal tract, and a part of protein entering the gastrointestinal tract daily is also derived from endogenous sources (Fig. 1). The endogenous luminal proteins include salivary, gastric, biliary, pancreatic, and intestinal secretions for approximately 20–30 g day<sup>-1</sup>, desquamated villus epithelial cells and mucous proteins for an additional 30 g, and a relatively smaller amount (2 g) derived from plasma proteins leaking into the lumen. Exogenous dietary proteins derived from the food consumed and endogenous proteins are mixed

**Fig. 1** Protein digestion is a complex process with continuous movements and exchange of protein, amino acids and nitrogen between the gut lumen and the systemic pools.

**Fig. 2** Cascade of protein hydrolysis in the gastrointestinal tract.

in the intestinal lumen and the daily protein load requiring digestion within the gastrointestinal tract is approximately 100–150 g daily. The purpose of protein digestion is the progressive cleavage of protein into smaller fragments constituted by amino acids, dipeptides, and tripeptides so that they can be absorbed (**Fig. 2** and **Table 1**). Food digestion proceeds into three phases with different regulatory mechanisms, namely the cephalic, gastric, and intestinal phase initiated by the sensory experience of seeing and eating food, the presence of food within the stomach, and the emptying of stomach contents into the small Intestine, respectively.

### Protein digestion in the stomach

Protein digestion starts with chewing to mechanically increase the surface area and after swallowing, and contractions of the stomach facilitate gastric mixing and chemical breakdown by gastric acid and pepsins (**Bornhorst and Paul Singh, 2014**). Digestion

**Table 1** Proteolytic enzyme activity in the gastrointestinal tract.

Enzyme	Precursor	Products	Catalyst	Substrate	Action
<b>Stomach</b>					
Pepsins	Pepsinogens	Polypeptides of diverse sizes and some amino acids	Acid pH	Protein	Hydrolyze bonds between aromatic amino acids (e.g., phenylalanine or amino acid)
<b>Pancreatic proteases</b>					
Trypsin	Trypsinogen	Oligopeptides	Enterokinase	Proteins	Cleaves internal bonds at lysine or arginine amino acids; cleaves other pancreatic proenzymes
Chymotrypsin	Chymotrypsinogen	Oligopeptides	Trypsin	Polypeptides	Cleaves bonds of aromatic or neutral amino acids
Elastase	Proelastase	Oligopeptides	Trypsin	Elastin	
Carboxypeptidase A	Procarboxypeptidase A	Aromatic amino acids and peptides	Trypsin	Other proteins	Cleaves aromatic amino acids from C-terminal end of protein and peptides
Carboxypeptidase B	Procarboxypeptidase B	Arginine, lysine, and peptides	Trypsin	Polypeptides at the free C-terminal end of the chain	

**Fig. 3** Postnatal development of gastric acid secretion and titratable acidity. Modified from Koldovsky (1985), with permission from Little Brown and Company.

of proteins in the stomach involves the actions of pepsins, which are secreted as the precursor pepsinogen by the gastric mucosa main cells. The release of pepsinogens is induced by gastrin, histamine, and cholinergic stimulation and pepsinogens are converted to the active form pepsins by the loss of a small basic peptide. Pepsins are most active at a pH of approximately 2 and totally inactive at a pH above approximately 5. So, for pepsins to produce any digestive action on protein, the stomach juices must be acidic. Pepsins have a broad proteolytic specificity, splitting peptide bonds mostly involving phenylalanyl, tyrosyl, and leucyl residues. Immunohistochemistry indicates two distinct forms of pepsinogen, Pepsinogen I only found in acid-secreting regions of the stomach, and pepsinogen II also found in the mucous cells of the oxyntic and pyloric regions of the stomach as well as in the duodenal Brunner's glands. Although these two forms of pepsinogen have slightly different pH optima, their substrate specificity is very similar, and both are rapidly inactivated by the alkaline pH beyond the pylorus. A gelatinase liquefying gelatin is also found in the stomach. The completeness of gastric protein digestion is dependent on several factors, including the rate of gastric emptying, the pH of intragastric contents, and the type of protein ingested. Given the significant buffering capacity of food, it is unlikely that gastric proteolysis plays a major role in protein digestion. This agrees with the observation that neither patients with achlorhydria nor those recovering from major gastric surgery appear to have a major problem with protein digestion. The level of peptic activity and acid production is lower in premature infants and increases in relation to gestational age; pepsin activity increases approximately twofold between infancy and adulthood (Fig. 3). There is controversy regarding the presence of rennin (a peptidyl peptide hydrolase) in the stomach of young infants; however, the mild clotting activity in human infants is rapid.

### Protein digestion in the small intestinal lumen

The exocrine pancreas secretes an aqueous mixture into the duodenum composed of digestive enzymes, which aid in further degradation of ingested food, and bicarbonate which helps neutralize stomach acid. Neutralization of gastric acid is a critical function of the pancreas as the small intestine mucosa is specialized for nutrient absorption and thus cannot possess a thick protective mucous layer like that of the stomach. Furthermore, pancreatic digestive enzymes are optimally active at basic pH and thus pancreatic bicarbonate secretion is a key requirement for proper digestion.

Pancreatic secretions are primarily regulated by three factors acting synergistically. Acetylcholine released by vagal efferent primarily stimulates synthesis of digestive enzymes by pancreatic acinar cells. Cholecystokinin released by I Cells in the duodenum and jejunum upon entry of food primarily stimulates synthesis of digestive enzymes by pancreatic acinar cells. Secretin released by S Cells of duodenum in response to entry of low pH stomach acid primarily stimulates production of aqueous sodium bicarbonate solution by pancreatic ductal cells, the composition of pancreatic secretions is slightly different during the three phases of food digestion with different regulatory mechanisms.

The cephalic and gastric phases primarily involve vagus nerve stimulation of acinar cells to produce digestive enzymes. Because little aqueous sodium bicarbonate solution is produced by ductal cells these enzymes lie inactive within the pancreatic acini and ducts. By the end of the cephalic and gastric phases, the pancreatic ducts are filled with inactive digestive zymogens ready for washing out into the intestinal lumen by aqueous sodium bicarbonate solution. The intestinal phase involves release of both secretin and cholecystokinin which stimulate the generation of aqueous sodium bicarbonate solution by pancreatic ductal cells that washes out the inactive pancreatic enzymes within the pancreatic ducts into the duodenum where they are activated.

Gastric emptying determines the rate at which the ingested protein is delivered in the duodenum, where segmentation contractions further facilitate luminal hydrolysis by pancreatic proteolytic enzymes, such as trypsin, chymotrypsin, carboxypeptidase A and B, and intestinal brush-border enzymes (Guerra et al., 2012). The pancreatic proteases are secreted as proenzymes and are activated in the lumen. The enteropeptidase (also called enterokinase) released from the brush border membrane removes a hexapeptide from the N-terminal end of trypsinogen, converting it to the active form trypsin. Trypsin, in turn, activates the other protease proenzymes and autocatalytically promotes further activation of trypsinogen. The pancreatic endopeptidases trypsin, chymotrypsin, and elastase, primarily split peptide bonds located within the protein molecules resulting in the production of short-chain polypeptides. These are further hydrolyzed by the exopeptidases carboxypeptidase A and B, acting on aromatic/aliphatic C terminals or basic C terminals residues to remove single amino acids, respectively. These pancreatic peptidases cannot hydrolyze peptide bonds with

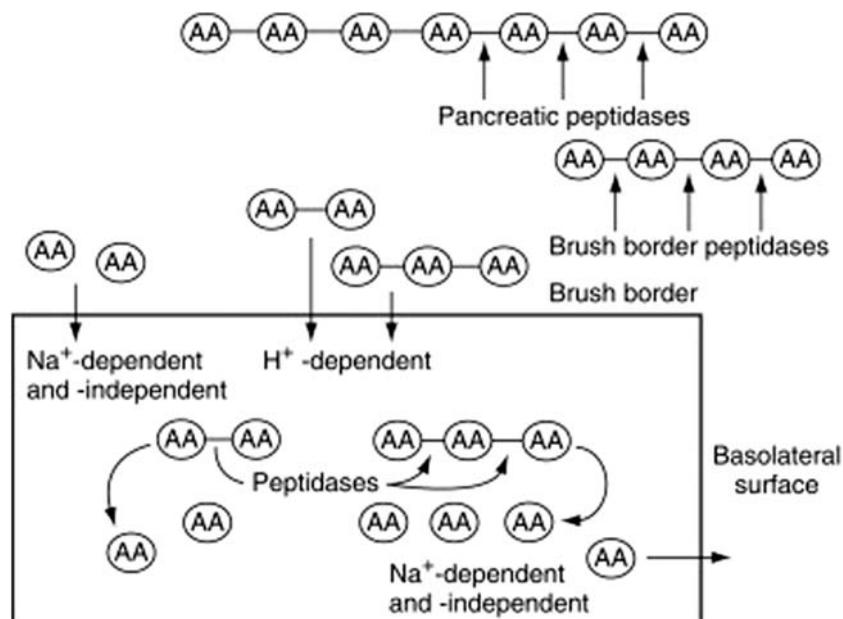

proline at the C-terminal. The product of this coordinated intraluminal digestion by the endopeptidases and exopeptidases is a mixture of neutral and basic amino acids (30%), and peptide with chains varying in length from two to six amino acids (70%). The presence of excess amino acids in the lumen can further limit peptide hydrolysis (product inhibition). The activity of enterokinase is noticeable after 26 weeks of gestation and its activity at term is approximately 10% of that of adults. Although pancreatic trypsin levels are substantial in both preterm and term infants, the secretory response to secretin and pancreozymin stimulation is somewhat blunted at birth compared with that at 2 years of age. However, such comparatively lower levels of protease activity in newborn infants do not appear to limit protein digestion significantly.

### Intestinal epithelial digestion and absorption of peptides and amino acids

An important step in the digestion of protein in the small intestine is the cleavage by peptidases at the level of the intestinal brush border ([Guerra et al., 2012](#)). Subsequently, amino acids, dipeptides, and tripeptides, are released and taken up across the intestinal mucosa, after which they are absorbed. An important physiological observation is that absorption at the brush-border membrane can occur both as amino acids and as di- and tripeptides. Amino acid absorption is the process of amino acid, dipeptide, and tripeptide uptake from the gastrointestinal lumen. Peptides and amino acids are transported from the lumen to the portal blood-stream through a variety of transporters present in the brush-border and baso-lateral membranes of the enterocytes. Although the end-product of protein digestion is amino acids, small peptides are the dominant form of entry of amino acids into enterocytes, where they are further hydrolyzed into amino acids by peptidases within the cytoplasm and absorbed into the bloodstream ([Fig. 4](#)). Thus, most products of protein digestion that reach the bloodstream are single amino acids.

#### Brush border membrane and cytoplasmic peptidases

A range of peptidases are present at the level of the brush border membrane or cytoplasm with the capability of hydrolyzing oligopeptides of up to eight amino acid residues ([Tobey et al., 1985](#)) ([Table 2](#)). These oligopeptidases are synthesized in the rough endoplasmic reticulum of enterocytes and, after transfer through the Golgi apparatus, are transported to the brush border membrane and extruded by exocytosis. There is little posttranslational processing of these peptidases, and they are attached to the brush border membrane by short anchoring pieces. Most oligopeptidases are aminopeptidases, acting at the *N*-terminal amino acid. The brush border proteolysis rate is most rapid for tripeptides and least rapid for dipeptides, whereas the rates of hydrolysis of tetrapeptides and pentapeptides are somewhat intermediate. The brush border peptidases can hydrolyze peptide bonds with proline at the *C*-terminal. Of the cytoplasmic peptidases, the most abundant is a dipeptidase that cleaves neutral dipeptides, whereas the aminotripeptidase has a high specificity toward tripeptides with *N*-terminal amino acids or those containing proline terminally. The brush border peptidases differ in several ways from the cytoplasmic peptidases; the bulk of the hydrolysis of tetrapeptides and longer peptides occurs at the brush border, whereas the converse is true for dipeptidase activity, which is primarily within the

**Fig. 4** Small intestinal protein digestion and absorption. Adapted from [Shulman \(1993\)](#).

**Table 2** Peptidases present at the brush border membrane and cytoplasm of villous epithelial cells.

Peptidase	Action	Products
<b>Brush border membrane peptidase</b>		
Amino-oligopeptidases (at least two types)	Cleave amino acids from C-terminal of 3–8 amino acid peptides	Amino acids dipeptides
Aminopeptidase A	Cleaves dipeptides with acidic amino acids at N-terminal	Amino acids
Aminopeptidase I	Cleaves methionine-containing dipeptides	Amino acids
Aminopeptidase III	Cleaves glycine-containing dipeptides	Amino acids
Dipeptidyl aminopeptidase IV	Cleaves proline-containing peptides with free C-terminal	Peptides and amino acids
Carboxypeptidase P	Cleaves proline-containing peptides with free C-terminal	Peptides and amino acids
Angiotensin I converting enzyme (ACE) $\gamma$ -glutamyl transpeptidase	Cleaves $\gamma$ -glutamyl bonds and transfers	$\gamma$ -glut amino and/or peptide
Endopeptidases (two, including PABA peptidase)		
Folate conjugase	Cleaves pteroyl polyglutamates	Monoglutamate
<b>Cytoplasmic peptidases</b>		
Endopeptidases (several, including Gly–Leu dipeptidase)	Cleaves most dipeptides	Amino acids
Aminotripeptidase	Cleaves tripeptides	Amino acids
Proline dipeptidase	Cleaves X-Pro bonds in proline-containing dipeptides	Proline and amino acids

PABA, *para*-aminobenzoic acid.

cytoplasm. In general, the cytoplasmic peptidases are more heat labile than brush border peptidases. Very little is known about the developmental aspects of brush border and cytoplasmic proteases. However, the activity of many of these proteases is discernible by 10–16 weeks of gestation and progressively increases during development. In contrast,  $\gamma$ -glutamyl transpeptidase activity decreases with increasing gestational age, but the significance of this transition is unknown.

### Absorption of di- and tripeptides

Di- and tripeptides can cross the brush border membrane by a peptide transport system with broad specificity. This transporter (Pept-1) can transport dibasic as well as diacid peptides and peptides consisting of up to three amino acid residues. However, there is some stereospecificity for this transporter because the longer the length of the amino acid side chain on the peptides, the easier the absorption. The transporter system also has greater affinity for dipeptides than tripeptides, and the acidic and basic amino acid residues in dipeptides lower the affinity for the transport system compared with neutral amino acids. In general, the absorption of L-isomers of amino acids in dipeptides is preferred over the D forms. The peptide transport system is coupled to the proton pump system rather than the sodium gradient. The absorption as di- and tripeptides is the major mechanism for absorption of protein-derived amino acids from the human intestinal lumen and is considered a more efficient way of amino acid absorption compared with that of single amino acids (Adibi et al., 1975) (Fig. 5). Even when a di- or tripeptide is subject to rapid hydrolysis by brush border peptidases, 30–50% of it is directly absorbed unconverted. The recognition that peptides are the main physiological routes of entry of amino acids into the enterocytes is a point of fundamental importance in the formulation of special protein hydrolyzates and enteral feeds. Several factors may determine the levels of Pept-1, such as insulin, which may stimulate membrane insertion of the transporter from a preformed cytoplasmic pool, and cholera toxin, which decreases the activity of Pept-1 through an increase in the intracellular concentration of cyclic AMP. Once in the absorbing cell, the di- and tripeptides are further hydrolyzed to the constituent amino acids by the cytoplasmic peptidases before absorption. Some small peptides are known to enter the portal blood directly but their relative proportion in comparison to free amino acids is inconsequential. It is also recognized that the intestinal permeability of the preterm and newborn infant may be high, allowing the entry of small amounts of undigested proteins. The maternal antibodies from colostrum can enter the newborn's bloodstream relatively unaltered by a process of endocytosis and subsequent exocytosis. Although the intestinal permeability decreases with age, adults can still absorb larger proteins in abnormal circumstances. However, the predominant form of absorption and presentation of large foreign proteins is through the specialized microfold or M cells overlying the lymphoid Peyer's patches. This mode of absorption of intact proteins or polypeptides, however, is nutritionally insignificant.

### Amino acid transport systems

Although some diffusion of amino acids does occur, they are mostly absorbed by active transport systems (Bröer and Fairweather, 2011). Unlike peptides, which are absorbed equally well in both proximal and distal small intestine, amino acids are absorbed more rapidly in the duodenum and jejunum. In contrast to the parsimonious peptide transport system, there are multiple transport mechanisms for various amino acids at both the luminal end and the basolateral membrane of the enterocyte (Table 3). At the luminal end, the transporters are mostly located at the villous enterocytes. The villous enterocytes utilize approximately 10% of

**Fig. 5** Rates of glycine absorption (mean  $\pm$  SEM) from perfusion solutions containing equivalent amounts of glycine in free or peptide form. Reproduced from Adibi et al. (1975), with permission from American Society for Clinical Investigation.

ASC	Neutral amino acids (e.g., alanine, serine), cysteine	+
N	Glutamine, histidine, asparagine	+

Modified from Shulman (1993).

the absorbed amino acids for their own protein production, whereas the crypt cells derive their amino acid supply from the portal circulation. There are at least five different sodium-dependent transport systems for amino acid uptake. Most energy-dependent transporters are coupled either to cotransport of Na<sup>+</sup> or Cl<sup>–</sup> or to the counter transport of K<sup>+</sup>. The sodium-dependent transport can be facilitated by energy derived from Na<sup>+</sup>/K<sup>+</sup>-exchanging ATPase at the basolateral membrane. An additional system of sodium-independent facilitated diffusion also exists and is predominantly geared toward basic and dipolar  $\alpha$  amino acids. These passive transporters are either facilitated transporters or channels. Amino acid transport systems develop *in utero* by the end of the first trimester, whereas peptide transport systems can be demonstrated by the beginning of the second trimester (Lonnerdal, 1994).

### First-pass splanchnic extraction

Most of the absorbed amino acids are released into the systemic circulation where they are transported and taken up by peripheral tissues. However, following absorption, a substantial part of the ingested amino acids undergoes first-pass splanchnic extraction, i.e., amino acid uptake and disposal in intestinal and hepatic tissues. A part of amino acids is metabolized during their transcellular transport through the absorptive intestinal cells. This metabolism corresponds to both local utilization of amino acids for protein synthesis and to the production of metabolites from several amino acids including for instance arginine, proline, and cysteine. Some

of these metabolites are used in the intestinal mucosa. It corresponds also to the production of metabolites that are used peripherally outside the intestinal mucosa. For instance, ornithine and citrulline which are not present in proteins can be synthesized in enterocytes from several amino acids present in proteins and play roles in the interorgan metabolism. In addition, the enterocytes use several amino acids (glutamine, glutamate and aspartate) as fuels in the context of a high energy requirement for the cell renewal in the epithelial layer and for nutrient absorption. Of the various amino acids, glutamine appears to have a major role in the nutrition and regeneration of enterocytes, and it is now recognized that in the human intestine the predominant mechanism for assimilation of glutamine dipeptides is absorption as intact dipeptide rather than hydrolysis.

### Digestion and fermentation in the distal intestine

The fraction of ingested protein that is not digested and absorbed in the small intestine reaches the large intestine where amino acids are not quantitatively absorbed but metabolized by the microbiota. The contributory role of colonic protein digestion may become particularly important for people with reduced small intestinal function such as short bowel syndrome. Colonic digestion and fermentation are important for energy production. Colonic fermentation may lead to the production of short-chain fatty acids from undigested starch, non-starch polysaccharides, or proteins reaching the colon, providing approximately 5–10% of daily energy requirements. In the first steps of protein catabolism by the intestinal bacteria, these compounds are hydrolyzed by extracellular proteases and peptidases into amino acids and peptides. Provided specific transporters are present, amino acids and peptides are taken up into bacterial cells and undergo different fates. Amino acids can be directly incorporated into bacterial cells as building blocks of proteins or can enter catabolic pathways.

#### Amino acid catabolism by the gut microflora

The first step in the catabolic fate of amino acids by the gut microflora is transamination or deamination, mostly leading to the corresponding keto acids or saturated fatty acids related to central intermediates that can be easily degraded. Several amino acids released from proteins in the large intestine are precursors for short chain fatty acids synthesis. Many anaerobic bacteria metabolize these amino acids through the fermentation pathways with pyruvate as a central intermediate leading to the production of short chain fatty acids (mainly acetate, propionate, and butyrate), organic acids (mainly formate, lactate and succinate), ethanol and gases (mainly H<sub>2</sub> and CO<sub>2</sub>). Usually, organic acids do not accumulate since they are rapidly metabolized by other bacterial species to short chain fatty acids. Acetate can be produced by the microbiota from glycine, alanine, threonine, glutamate, lysine, and aspartate, butyrate from glutamate and lysine and propionate from alanine and threonine (Macfarlane and Macfarlane, 2012). The branched-chain fatty acids (isobutyrate, 2-methylbutyrate and isovalerate) are derived from branched-chain amino acids valine, isoleucine, and leucine (Macfarlane, 1991). These branched-chain fatty acids originate exclusively from the breakdown of proteins and are not produced from carbohydrates and are present in lower quantities than short-chain fatty acids in the large intestine content.

Primary amines can be deaminated by the same processes as amino acids and urea is hydrolyzed in carbon dioxide and ammonia. The ammonia generated by the deamination can be utilized as a nitrogen source or excreted (Macfarlane and Macfarlane, 2012). The gases generated (H<sub>2</sub> and CO<sub>2</sub>) can also be consumed by hydrogenotrophic microorganisms (mainly methanogenic archaea, acetogenic bacteria and sulfate reducing bacteria) to generate methane, acetate (by reductive acetogenesis) and hydrogen sulfide. Acetate can be used as energy source by different types of epithelial cells and by other intestinal bacteria. Sulfides released by the microbiota can be further metabolized by colonocytes while methane is a stable end-product that is not further metabolized in the gut. Amino acids can also be metabolized via decarboxylation leading to the production of amines and polyamines. Deaminases and decarboxylases are amino acid-specific enzymes. In vitro, the production of amino acids deaminases and decarboxylases are favored by alkaline and acidic pH, respectively. Some specific amino acids do not solely undergo these reactions and are the precursors of various metabolic end-products. Tyrosine gives rise to 4-ethylphenol, phenol and p-cresol whereas tryptophan results in the production of indole, skatole, kynurenine. Sulfur-containing amino acids yield to the release of sulfide that can be utilized by colonocytes or directly incorporated in de novo-synthesized amino acids.

#### Amino acid synthesis by the gut microflora

Bacteria can synthesize de novo some if not all the twenty amino acids required for protein biosynthesis. The human distal gut microbiome is enriched for a variety of clusters of orthologous groups of genes involved in amino acid biosynthesis. The amino acids are formed from metabolic precursors derived from the central metabolism. Pyruvate, oxaloacetate and oxoglutarate are the precursors of 13 of the 20 amino acids and among amino acids, glutamate and glutamine are important intermediates in nitrogen metabolism. The microbiota can recycle amino acids to the host, raising the view that the amino acid exchange between the microbiota and the host can proceed in both directions. The observation that conventional but not germ-free rats can incorporate <sup>15</sup>N from <sup>15</sup>NH<sub>4</sub>Cl into body lysine (an amino acid that does not transaminate in mammalian tissues) indicates that <sup>15</sup>N-lysine in the host was from microbiota origin (Torrallardona et al., 1996). In the pig, lysine produced by the microbiota is mainly used for protein synthesis in the splanchnic area, intestine and liver. In human volunteers, <sup>15</sup>NH<sub>4</sub>Cl given orally is rapidly incorporated into microbial amino acids and <sup>15</sup>N threonine from intestinal microbiota origin appears in the blood plasma even if this

contribution to whole-body threonine metabolism could not be quantified. In human infants, amino acids in plasma can derive from urea after hydrolysis and utilization of nitrogen by the intestinal microbiota but the mechanisms by which amino acids synthesized by the microbiota enter the systemic amino acid pool remains unclear.

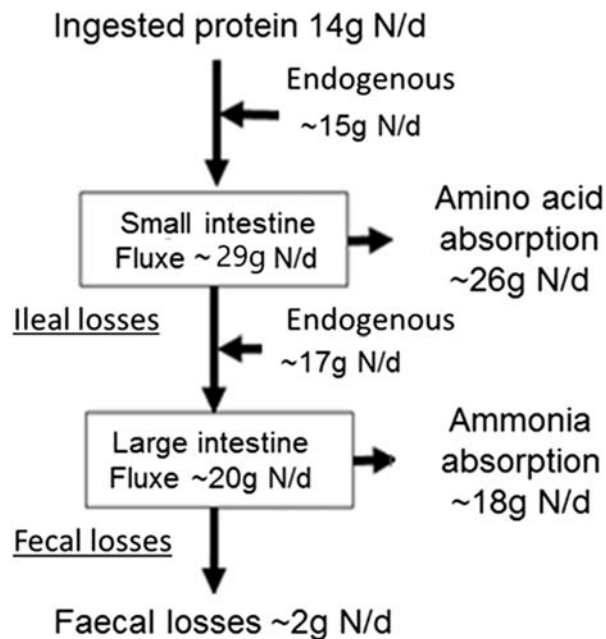

## Protein digestibility

Protein and amino acid digestibility is a measure of the amount or proportion of dietary protein derived nitrogen and amino acids that are made available to the organism after digestion and absorption. As the capacity of the small intestinal mucosa to absorb amino acids, dipeptides, and tripeptides is generally far greater than the amounts in which they are released in the lumen, protein digestion mainly represents the limiting step in amino acid absorption. Digestibility is determined by measuring the digestive losses at the level of the terminal ileum or in the feces (Fig. 6).

## Fecal and ileal digestibility

Dietary protein-derived nitrogen and/or amino acid absorption is assessed by measuring their disappearance in different part of the gastrointestinal. The oldest approach determines nitrogen or amino acid absorption by measuring the difference between oral intake of protein-derived nitrogen or amino acids and nitrogen or amino acids fecal excretion (oro-faecal nitrogen and/or amino acid disappearance).

A major limitation of this oro-faecal approach is that food protein digestion occurs in the stomach and small intestine and produces amino acids absorbed in the small intestine while in the colon amino acids are not absorbed and mostly metabolized by colonic bacteria with the release of ammonia that can be absorbed. While there is some suggestion that amino acids can be absorbed in the large intestine, there is no evidence that this occurs in relevant amounts. The amino acid composition of fecal material is impacted by microbial metabolism in the large intestine, and the oro-faecal disappearance of nitrogen and/or amino acids that include metabolism in the large intestine does not necessarily reflect amino acid absorption by the host organism. To avoid interference from microbial metabolism in the large intestine, the disappearance of ingested nitrogen and/or amino acids is determined at the terminal ileum, i.e., at the end of the small intestine (oro-ileal disappearance). As intestinal amino acid absorption is practically complete at the end of the small intestine, oro-ileal disappearance is considered to represent dietary protein-derived nitrogen amino acid absorption more accurately than oro-faecal disappearance.

**Fig. 6** Digestibility issue of proteins: ileal versus faecal digestibility. Adapted from (WHO, 2007). Digestibility is determined by measuring the digestive losses at the level of the terminal ileum or in the faeces. Food protein digestion occurs in the stomach and small intestine and produces amino acids absorbed in the small intestine. In the colon unabsorbed amino acids are mostly metabolized by colonic bacteria and converted to ammonia that can be absorbed.

### Apparent and true digestibility

Another limitation for both fecal and ileal disappearance approaches is that digesta in the feces or terminal ileum contain undigested and/or unabsorbed nitrogen and amino acids from both exogenous and endogenous origin. Moreover, gut endogenous nitrogen and amino acid losses can be distinguished into basal or obligatory and specific losses. The exact estimation of endogenous losses is only possible with isotopic methods. Basal or obligatory losses represent the minimal amount of loss and are not impacted by dietary composition, such as digestive enzyme secretion and epithelial cell turnover, and have been variably estimated to range from 20 mg kg<sup>-1</sup> day<sup>-1</sup> in young infant and preschool children to approximately 12 mg kg<sup>-1</sup> day<sup>-1</sup> in adults. Specific losses are additional nitrogen and amino acid losses above basal losses that result from stimulation by dietary composition. When oro-fecal or oro-ileal disappearance is not corrected for endogenous losses either in the feces or at the terminal ileum, the terms apparent fecal or ileal digestibility are used. When oro-fecal or oro-ileal disappearance are corrected for basal fecal or ileal endogenous amino acid losses, the terms standardized fecal or ileal digestibility are used. When fecal or ileal digestibility is corrected for total fecal or ileal endogenous losses (i.e., both basal and specific losses), the term true fecal or ileal digestibility is used. The True Ileal Digestibility assay is the best currently available approach to assess amino acid absorption.

$$\text{Apparent digestibility} = [(\text{Dietary} - \text{Total fecal or ileal}) / \text{Dietary}] \times 100$$

$$\text{True digestibility} = [(\text{Dietary} - (\text{Total fecal or ileal} - \text{Total endogenous fecal or ileal})) / \text{Dietary}] \times 100$$

The estimated value of true digestibility of food proteins is dependent on the excretion of gut endogenous nitrogen and amino acid losses. For example, dietary fiber and anti-nutritional factors have been shown to enhance digestive enzyme secretion and epithelial cell turnover and consequently increase specific losses and lowers the true digestibility of the diet protein.

### Differences in protein digestibility

Protein digestibility is an important component of protein quality. The amino acid scoring approach has been adopted by FAO/WHO as the preferred index for protein value in human diets (Lee et al., 2016; Shivakumar et al., 2020). The protein digestibility-corrected amino acid score (PDCAAS) and the more recently developed Digestible Indispensable Amino Acid Score (DIAAS) correct the chemical score of the limiting amino acid of a protein by the digestibility of the protein or of the limiting amino acid, respectively. There is strong evidence that true ileal, and not fecal, digestibility is the correct parameter for correction of these amino acid scores (Shivakumar et al., 2020). Uniformly 15N, 13C and/or 2H-labeled dietary proteins from microbes, plants or animal sources are used for assessing ileal digestibility and metabolic utilization of dietary protein-derived amino acids. The direct determination of true ileal nitrogen or amino acid digestibility requires the collection of ileal digesta that can be performed either in rat model, in pig model equipped with a T-cannula, or in human by using naso-ileal intubation methods or by collection of digesta from surgically exteriorized ileum (ileostomates) (Lee et al., 2016; Shivakumar et al., 2020). Minimally-invasive stable isotope signature-based methods for amino acid digestibility were proposed including the indicator amino acid oxidation technique, based on comparison with a mixture of free amino acids, and the dual stable isotope tracer approach. These methods contribute to accumulate values for true protein and amino acid digestibility from human food sources (Table 4).

The digestibility of a protein is dependent on the physical shape of the protein and the relative ease with which peptide bonds can be hydrolyzed. Fibrous proteins with long polypeptide chains, such as collagen, keratin, and elastin, are relatively insoluble. In contrast, globular proteins, which are coiled and tightly packed, are comparatively soluble and thereby more digestible. Such proteins are insulin, enzymes, hemoglobin, and albumin. In general, milk and eggs have the highest true digestibility values of approximately 97%, followed by meats, fish, and poultry. Digestibility of protein and amino acid from plant protein sources are usually lower than for animal protein sources and the difference is more important when plant proteins are consumed in the form of complex flour or whole grains. Plant and legumes have protein digestibility values ranging from 75% to 85%. However, some fibrous animal proteins, such as keratin and collagen, are relatively indigestible. A useful approximation is to assume a protein digestibility of 75–80% for diets based on whole grain cereals and vegetables, 95% for diets based on refined cereals and animal proteins, and 85–90% for mixed diets. In the context of infant nutrition, breast milk is extremely well digested, but some proteins, such as secretory IgA, lactoferrin, and  $\alpha_1$ -antitrypsin, escape digestion.

Several other factors affect protein digestibility of a diet, including the presence of additional dietary factors such as trypsin inhibitors. The latter may be present in certain foods, such as navy beans and soybeans, and can be largely inactivated by heating, thus improving protein digestibility. Although moderate heating can promote digestibility by promoting breakdown of peptide cross-linkages and inactivation of protease inhibitors in natural food, strong heating, especially in the presence of a carbohydrate or oxidized lipids, may make the protein resistant to enzymatic hydrolysis. The Maillard or browning reaction occurs after high, usually prolonged heating of a protein in the presence of a reducing sugar such as lactose or glucose, resulting in cross-linkages of the sugar with the free side chain of the lysine residues. This may make up to 30% of the lysine biologically unavailable. These changes are of particular importance in situations of marginally sufficient protein intake, in which cooking procedures may further aggravate protein malnutrition. The Maillard reaction is highly influenced by the pH of foodstuffs or other agents. The reduction of pH that may be performed by fermentation in the baking industry lessens the decomposition of lysine and tryptophan in proteins. Fermentation is widely used as a strategy to increase the digestibility of starch and improve the organoleptic properties of weaning foods and cereal-based preparations in developing countries. However, although the impact of fermentation on starch digestion is

**Table 4** Illustrative values of protein digestibility in humans.

<i>Protein sources</i>	<i>True fecal digestibility (%)</i>	<i>Protein source</i>	<i>True ileal digestibility %</i>
Eggs	97	Egg	80–97
Milk and cheese	95	Milk	94–99
Meat and fish	94	Meat	80–99
Corn	85	Corn	60–70
Soy flour	86	Soy	75–90
Soybean isolate	94

well established, the impact on protein digestibility is variable. Although some studies have suggested an impact on protein quality and digestibility of legumes and finger millet-based foods, other studies suggest that fermentation only modifies the gastric emptying rate and does not significantly affect the level of diet hydrolysis, the endogenous nitrogen stimulation, or the digestibility rate.

## Conclusion

Digestion of protein is a complex process with numerous exchanges of protein, amino acid, and nitrogen along the gastrointestinal tract. It is more usually an efficient process leading to the absorption of more than 90% of the ingested protein as amino acid made available to the organism to support anabolic and catabolic process. The efficiency is due for a part to the cascade of numerous and different proteolytic enzyme action and specificity that progressively hydrolyze protein to the end-products small peptides and amino acids. Moreover, the capacity of the small intestinal mucosa to absorb amino acids, dipeptides, and tripeptides is very high and the efficiency of absorption is amplified by the simultaneous transfer of free amino acid and di and tripeptides. In these processes, the limiting step is the digestion of food in the intestinal lumen and as consequence protein digestibility is identified as an important component of food protein quality.

## Key Points

- Whole-body proteostasis during growth and development is achieved through both within-tissue responses to daily anabolic and catabolic influences of the feeding and fasting cycle and through longer-term interactions within a protein-stat mechanism, involving dietary protein-mediated long-bone length-growth regulating muscle growth through a passive stretch mechanism, with the growth of most other tissues reflecting their metabolic work.
- Protein turnover occurs within a proteostasis network within which protein synthesis and proteolysis systems are the main nutritionally sensitive components.
- Protein synthesis reflects its capacity, provided by the ribosomal and tRNA apparatus necessary to translate mRNA molecules, and its efficiency in terms of the rate of translation per ribosome.
- Nutritionally sensitive proteolysis involves both lysosomal-autophagy and ubiquitin proteasome systems, each of which are capable of selective proteolysis.
- The mTORC1 complex mediates acute nutritional control of protein synthesis and proteolysis, with amino-acids and insulin initiating signal transduction, mediating nucleolar ribosomal RNA synthesis and assembly, cytoplasmic activation of mRNA translation, and inhibition of proteolysis.
- Whole-body and tissue protein-turnover can be studied with isotope tracer techniques measuring both the amino-acid flux through the plasma amino-acid pool or the  $\alpha$ -amino pool by  $^{15}\text{N}$ -end product methods, and the turnover of tissue proteins.
- Protein turnover in the human adult, about 300 g/day, accounts for a significant fraction of the RMR, a minimum of 14%.
- The balance between changes in proteolysis, protein synthesis and amino-acid oxidation with feeding determines the efficiency of postprandial protein-utilization, with the most efficient mechanism involving the inhibition of proteolysis with minimal increases in protein synthesis and amino-acid oxidation, and with amino-acid signaling initiated from the extracellular pool.

## Introduction

About 20.4 K putative protein-coding genes are predicted by the human genome of which about 9 K are expressed in all tissues suggesting these include housekeeping proteins needed to maintain basic cellular structure and function, i.e., ribosomal and associated proteins involved in protein synthesis, enzymes essential for cell metabolism and gene expression, and mitochondrial proteins needed for energy generation, as well as proteins responsible for the structural integrity of the cell. Proteins also vary greatly in abundance, from fewer than 50 copies per cell in the case of certain transcription factors to more than 10 million molecules for histones, cytoskeletal, ribosomal, and myofibrillar proteins. Protein abundance must be carefully controlled to support cell signaling and the proper flux of substrates through metabolic pathways and to allow the stoichiometric assembly of large macromolecular machines, such as ribosomes, the mitochondrial respiratory chain and the myofibrillar contractile apparatus. Proteostasis is the maintenance of an intact proteome within cells, acting through the proteostasis network, (PN) which exerts strict control of the initial production and folding of a protein, its conformational maintenance, control of abundance and subcellular localization, and disposal by degradation (Klaips et al., 2018; Hipp et al., 2019; Pey, 2020) see Fig. 1. Various molecular chaperones and co-chaperones are of central importance ensuring correct de novo folding and maintenance of a soluble, nonaggregated state as

**Fig. 1** Scheme showing the proteostasis network in relation to protein turnover. Production of functional proteins requires not only their synthesis by the ribosomal apparatus but also their correct folding and assembly. The proteostasis network achieves this and also minimizes non-productive misfolding or formation of harmful aggregates through remodeling and removal by proteolysis by the ubiquitin-proteasome and lysosomal autophagic systems. Proteolytic removal of native state proteins, identified here as protein turnover, also occurs at variable rates according to both the structural and physicochemical properties of the protein which influence their susceptibility to proteolysis and the type of tissue within which it occurs in terms of the relative abundance of proteolytic systems. Amino acids released by proteolysis are recycled for protein synthesis. It is estimated that the proteostasis network comprises ~2000 proteins in human cells, ~400 associated with protein synthesis and folding, ~300 with maintenance of conformational stability and >1000 with protein breakdown, of which ~300 are molecular chaperones which orchestrate the processes shown.

well as targeting misfolded proteins for degradation or spatial sequestration to protect the rest of the proteome from aberrant interactions. Some of the PN is concerned with environmental stress responses (thermal, pathogen and oxidative stress) which can be triggered and coordinated by proteostasis transcription factors and it is believed that the accumulation of protein aggregates such as occurs in the brain with aging represents a failure of proteostasis. Thus protein turnover, in its classical context of the degradation and resynthesis of cellular proteins can now be described as the consequence of the action of the ~2000 components of the PN specifically involved in protein synthesis, chaperone-mediated folding and proteolysis mainly by the lysosomal-autophagic system, (LAS) and ubiquitin-proteasomal systems (UPS). The term proteostasis will be extended here to also include the whole body, in terms of the regulation of and relationships between proteomes of different tissues and organs.

### Whole-body proteostasis during growth and development

The growth of an individual in height and overall shape is mainly a function of bone growth which is genetically determined but subject to a favorable diet and hazard-free environment. During the initial few months of life food intake occurs at very frequent intervals, but after this growth and development adapts to a diurnal cycle of day-time feeding and nocturnal fasting during sleep. This means from early-life the nutritional regulation of whole-body proteostasis during growth and development responds to not only the background diet but also to the diurnal-changes in overall protein balance mediated by the acute daily responses to feeding

and fasting. Such changes have been investigated in detail in relation to the skeletal–muscle mass and the viscera, especially liver. However less is known about the acute nutritional sensitivity of the proteome of organs and tissues like the brain and nervous system although both human and primate studies have shown postnatal brain growth in size and structure is nutritionally sensitive. Certainly neurons contain an active PN which is important in limiting the accumulation of protein aggregates in the aging brain and the UPS in brain has been associated with memory.

The whole body proteome, the fat-free lean-body mass, (FFM), comprises two major compartments, skeletal muscle, accounting for about 40% FFM in young children increasing to over 50% in young adults and exhibiting a sexual dimorphism from puberty, and the non-muscle FFM. In both children and adults, muscle is highly regulated at a fixed maximum genotypic-size relative to overall stature unlike the non-muscle FFM which can expand with increasing protein and food intakes and adiposity (Millward, 1995, 2021). Regulation of the whole body proteome has been described by a protein-stat mechanism, the central feature of which is an interaction between linear growth of bone, protein deposition in skeletal muscle and dietary protein intake (see Fig. 2). The first controller is nutritional, the minimum dietary protein intake required to exert a sufficient anabolic-drive, mediated by indispensable amino-acids and the endocrine system acting both on linear bone-growth to allow the genetic programming of its postnatal growth trajectory to be expressed, and on skeletal–muscle to maintain its mass at a specific size set by the linear dimensions of the organism. The second controller is internal, namely linear bone-growth which mediates muscle myofibre-growth capacity, with a passive stretch, mechanotransduction mechanism, acting on muscle stem, (satellite), and other cells which provide extra myonuclei enabling myofibre growth and which modify the architecture of the muscle extracellular matrix (ECM) enveloping each myofibre. The ECM can be visualized as connective tissue “bags” which define maximum myofibre volume and potential protein content, so that myofibre expansion during growth, i.e., “bag” enlargement and “bag” filling is dependent on ECM remodeling (see Millward and Smith, 2019; Millward, 2021). The bone-muscle interaction is two way, in that subsequent to bone length growth driving muscle growth, the force on bone of muscle contraction drives bone strength and mineralization via a mechanostat mechanism. The growth of most other organs is secondary to this main interaction, determined primarily by the level of food and protein intake and the consequent metabolic work of, and functional demand for, the organ and is not specifically limited in size.

The third controller is appetite, controlled by an amino-static appetite mechanism, sensing the effect of the flow of amino-acids into muscle to satisfy the metabolic demand for growth, on the circulating amino-acid pool (Millward, 1995). This allows food protein intake to match capacity for muscle growth and is most obvious in catch-up growth in children and may also accompany saltatory growth-spurts in children. Muscle growth ceases in the absence of passive stretch when bone length-growth ceases at the end of puberty, requiring stretch through resistance-exercise to induce any further growth in adulthood. Such a mechanism would mean that any reduction in bone-length will result in loss of muscle-mass and this may be one explanation of sarcopenia, the loss of

**Fig. 2** Scheme showing protein-stat mechanism for coordinated regulation of whole body proteostasis during growth and homeostasis. Whole-body protein content is controlled through an amino-static appetite mechanism, acting primarily to maintain skeletal-muscle mass at a level set by the linear dimensions of the organism. Bone lengthening occurs at rates determined by genetic programming (canalization) mediated by growth hormone, thyroid hormones and by the sex steroids during puberty, acting together with an appropriate anabolic drive deriving from dietary protein and mediated by amino acids, insulin, IGF-1 (and in the rat T3) and other important nutrients like zinc and vitamin D, and provides the regulatory stimulus for protein deposition in all tissues. Net protein deposition during skeletal muscle growth occurs within myofibres which are limited in volume by the extracellular matrix of connective tissue which surrounds individual and groups of myofibres like concentric “bags”. Thus, increased myofibre diameter and length during muscle growth requires remodeling of the muscle ECM to enable “bag” enlargement which is mediated by the passive stretching of skeletal muscle subsequent to bone length growth, activating satellite and other cells through mechanotransduction mechanisms. The linkage of bone length to muscle mass allows muscle size to be regulated at a genotypic muscle weight–bone length ratio. Increasing muscle size and force generation acts via the mechanostat to increase bone mineralization and strength commensurate with muscle mass. Any dietary protein-derived amino acid intake in excess of that required for maximal “bag filling” will either expand the non-muscle lean body mass or be oxidized with the carbon skeletons leaving the liver as ketones and glucose, the latter to be taken up in adipose tissue for lipogenesis together with excess branched chain amino acids. Modified from Millward (2021).

appendicular muscle in old age. Although long-bone shortening in old age has not been described in detail, some shortening could accompany loss of mineral mass with osteoporosis. Given the sensitivity of muscle-mass to changes in bone length, (muscle mass varies with length<sup>4</sup>), it may be that only very small reductions in length are sufficient to mediate measurable sarcopenia.

Evidence for the limitation of muscle growth in the absence of ECM remodeling comes from *in vivo* studies of muscle protein synthesis in adults during nutritional stimulation by amino-acids which show a tachyphylaxis while the nutritional stimulation is still present, i.e., the development of an inhibition following the initial stimulation. This is consistent with the inability of the muscle fiber proteome to expand beyond its regulated “bag-full” level though protein feeding alone (Millward and Smith, 2019; Millward, 2021).

## Protein turnover and its regulation

Within the PN, protein turnover is mediated by genomic transcription, ribosomal translation, folding and conformational maintenance of the protein's native state and disposal by proteolysis.

### Protein synthesis

This can be discussed in terms of its capacity, i.e., ribosomal and tRNA necessary to translate mRNA molecules, and its efficiency in terms of the rate of translation. This is operationally measurable as protein synthesis per unit RNA, and occurs at a rate of about 4 amino-acids/second when fully active and is regulated by nutritional and mechanical factors as discussed below. The PN includes many factors controlling the faithfulness of ribosomal mRNA translation and subsequent protein folding. Nevertheless protein synthesis and folding is imperfect despite the presence of abundant chaperone systems, and it has been estimated that 5–30% of all newly synthesized proteins do not properly fold and need to be targeted for immediate degradation (see Hipp et al., 2019).

Overall, the rates of protein synthesis and degradation within most cells are balanced precisely to avoid rapid growth or atrophy of cellular mass, (proteostasis), although for muscle there is the additional constraint imposed by the ECM on maximum myofibre volume. Fine control is achieved through highly complex multiple signaling systems with signal transduction involving receptor mediated hormone action, cytokines, metabolites which provide energy, and amino-acids, the latter acting both as substrates for and specific activators of protein synthesis. The mTOR complex is at the center of the regulatory network in most cells and comprises a highly conserved serine/threonine kinase which phosphorylates, (activating or inhibiting), other proteins involved in signal transduction pathways regulating cell growth and metabolism. Of the two structurally and functionally distinct multiprotein complexes, mTORC1 and mTORC2, mTORC1 is the important control-center for the nutritional regulation of protein turnover, integrating signals from insulin, amino-acids and the energy status of the cell all of which change after food intake, promoting protein synthesis and inhibiting proteolysis. Thus in the postabsorptive state mTORC1 is inhibited in part because of the low energy state within tissues. The energy state of the cell is sensed as AMP levels by AMP-activated protein kinase (AMPK) which inactivates mTORC1. Recent work has also shown that cyclic AMP levels are a major mechanism for mTORC1 inactivation. Thus adenylyl cyclase, which forms cyclic AMP can be activated through G-protein coupled receptors, which respond to glucagon for example, and cyclic AMP activates a kinase (protein kinase A) which inhibits mTORC1 (Jewell et al., 2019). Even in the presence of amino acids increased cAMP inhibits mTORC1.

Food intake reverses this inhibition of mTORC1. Thus in muscle for example, a meal providing protein and energy which increases plasma amino-acids and insulin, transforms the net catabolic postabsorptive state of decreased protein-synthesis and increased proteolysis, into postprandial anabolism through the combination of amino-acids stimulating protein synthesis, and insulin, inhibiting proteolysis (see Millward and Smith, 2019). The limitation on muscle myofibre expansion by the ECM within the protein-stat model shown in Fig. 2, is observable in terms of a “bag-full” signal when the elevation of protein synthesis in muscle by a meal or by amino-acids is terminated after a short period even though amino-acid levels in muscle remain elevated. For the whole body proteome as indicated by measurements of the plasma flux, (as discussed below), feeding responses appear to be less influenced by muscle and more by the splanchnic organs with feeding-induced changes in proteolysis more marked than protein synthesis.

Recent studies of amino-acid sensing mechanisms in a variety of cell types have revealed a complex (not entirely understood) system in which mTORC1 is activated at the lysosomal surface by leucine, arginine, S-adenosylmethionine and glutamine (Jewell et al., 2019; Takahara et al., 2020), see Fig. 3 which are sensed by both cytosolic and lysosomal amino-acid specific sensors. In fact it appears that a total of 10 amino-acids, (alanine, arginine, asparagine, glutamine, histidine, leucine, methionine, serine, threonine, and valine), can promote mTORC1 activity. However of these amino-acids, leucine is the most rapidly acting. The amino-acid transport system participates in this regulation not only delivering amino-acids as substrates for protein synthesis and activators of mTORC1, but also initiating signal transduction like hormone receptors: i.e., acting as multifunctional “amino-acid transceptors”. Thus the Na<sup>+</sup>/Gln cotransporter in muscle appears to be able to directly signal to mTOR during its transport of Gln into the muscle cell. This is one way in which changes in amino-acids in the EC pool can signal through mTORC1 to activate protein synthesis.

Downstream of mTORC1, p70-S6 kinase (S6K) and 4E-binding protein (4E-BP) are the main effectors of regulation of protein synthesis which is necessarily complex at both transcriptional and translational levels. Transcriptional control of ribosome concentrations in tissues determines the capacity for protein synthesis and in this way controls the overall tissue protein turnover rate and the changes associated with postnatal development. Animal studies have indicated that cellular ribosome concentrations can

**Fig. 3** Scheme showing amino acid activation of mTORC1. Glutamine activates mTORC1 through a Rag GTPase-independent pathway involving Arf 1 (left). Leucine, arginine and methionine activate mTORC1 through a Rag GTPase-dependent pathway (right). From Jewell et al. (2019) copied under the terms of the Creative Commons Attribution License.

change acutely, e.g., during the diurnal cycle of feeding and fasting, and chronically in response to the composition of the background diet, increased functional demand, and hormones such as insulin, thyroid, growth hormone, and the glucocorticoids. Furthermore these influences are tissue specific with glucocorticoids for example increasing hepatic ribosome concentrations, (as part of the hepatic acute phase response), and decreasing ribosome concentrations in muscle. In contrast thyroid hormones increase ribosomes and proteolytic enzymes in both muscle and liver in association with a generalized increase in protein turnover.

Transcriptional control of specific gene expression is rapid and extensive to the extent that changes in specific mRNA concentrations have become surrogate measures of acute changes in rates of synthesis of specific proteins, as for hepatic export-protein synthesis. Thus the down regulation of albumin synthesis in response to lack of dietary protein or during the pro-inflammatory cytokine-mediated acute-phase response is mediated largely through reductions in mRNA for albumin and other hepatic export proteins and increases in mRNA for acute phase proteins.

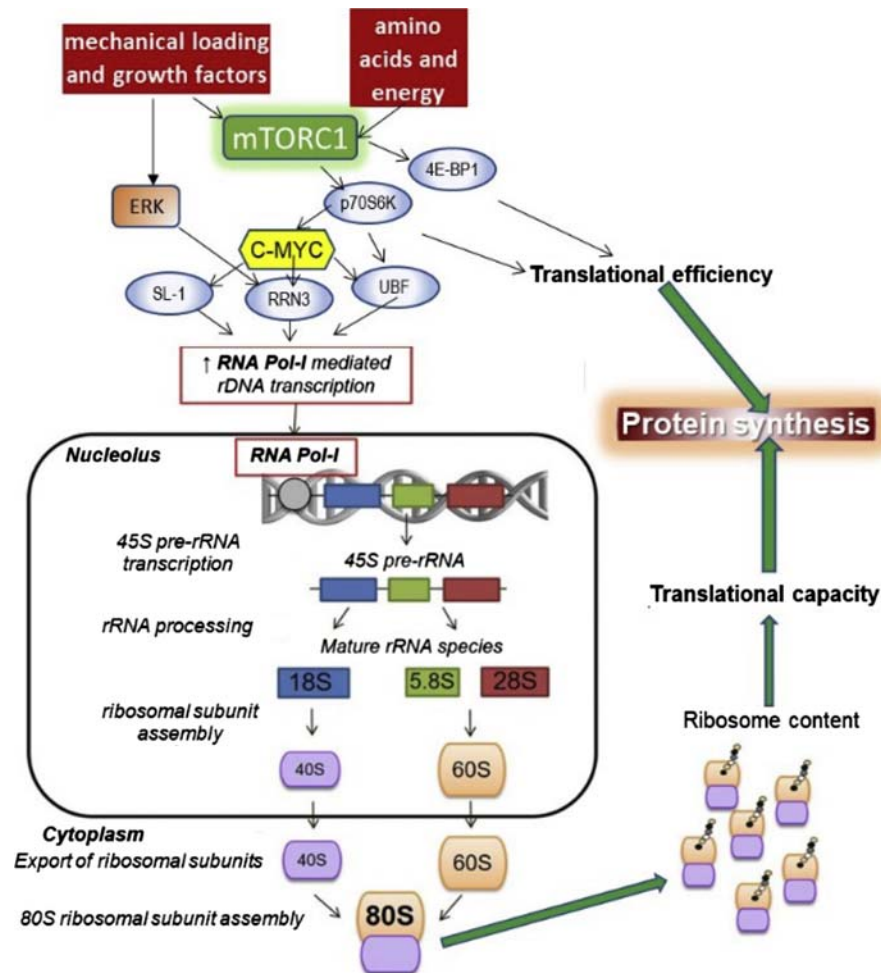

Initiation of translation is a key target process with reversible phosphorylation known to regulate at least four separate steps of the initiation cycle enabling very rapid changes in protein synthesis. Animal studies indicate that insulin, glucocorticoids, and amino-acids have all been implicated in such regulation. However there is uncertainty still about the detail with major differences between the mechanisms observed in the young rapidly-growing compared with the adult animal. Thus in skeletal muscle in the young rat, an insulin-mediated stimulation of translation occurs while in adult human muscle, insulin is relatively ineffective with amino-acid levels the main stimulatory influence (Millward and Smith, 2019).

A summary of key steps in the regulation of muscle protein synthesis in terms of ribosomal capacity and efficiency by nutritional and mechanical factors is shown in Fig. 4.

### Proteolysis

Of the six major proteolytic systems in tissues, lysosomal,  $\text{Ca}^{2+}$ -dependent, caspase-dependent, ubiquitin–proteasome system, (UPS), metalloproteinases and the mitochondrial Lon protease), the lysosomal-autophagic system, (LAS), and UPS are each under nutritional control and are likely to account for most of whole body protein turnover (WBPT) (see Dikic, 2017).

The LAS, is present in all cells and involves acid hydrolases including proteinases, (cathepsins), within a distinct vacuolar structure. Autophagy-related genes control the LAS which removes misfolded proteins, damaged organelles, and pathogens and native proteins and which includes 3 major categories of autophagy: microautophagy, macroautophagy, and chaperone-mediated autophagy as shown in Fig. 5. Microautophagy and macroautophagy are mainly non-selective although the processes can mediate the selective degradation of mitochondria and ubiquitylated aggregates under particular conditions. Chaperone-mediated autophagy is the selective pathway involving recognition of soluble proteins with a specific amino-acid sequence motif common to many proteins, by a cytoplasmic heat shock protein, HSC70 enabling the substrate unfolding and translocation to the lysosomal lumen via a transmembrane lysosomal associated protein structure (LAMP2A).

**Fig. 4** Flow diagram of regulation of muscle protein synthesis in terms of ribosomal capacity and efficiency by nutritional and mechanical factors. Multiple signaling pathways including extracellular signal-regulated kinase (ERK) and mTORC1 mediate activation of the nucleolar RNA Polymerase I (Pol-I) by a number of factors which form a transcriptional complex, the “Pol I regulon”, at the rDNA promoter. The elevated expression of the proto-oncogene transcription factor C-MYC, achieved through mTORC1/S6K1 plays a central role stimulating the Pol II-dependent transcription of a cohort of factors associated with Pol I regulon including RNA polymerase I-specific transcription initiation factor RRN3 and upstream binding factor (UBF). Ribosome biogenesis involves transcription of the 45S ribosomal RNA precursor (45S pre-rRNA), processing of the 45S pre-rRNA into the smaller rRNAs (18S, 5.8S and 28S rRNAs) followed by assembly of these rRNAs and other ribosomal proteins into ribosomal subunits (40S and 60S) which are exported into the cytoplasm. The 80S ribosome is the mRNA translating unit, requiring mTORC1-mediated activation of initiation through p70S6K (p70 kDa ribosomal protein subunit kinase 1) and 4E-BP1 (eukaryotic initiation factor 4E binding protein 1). mTORC1 also regulates RNA Pol-II (which transcribes the ribosomal proteins and other proteins required for transcription) and Pol-III, (which synthesizes small structural RNAs such as 5S rRNA and transfer RNA (tRNA) (not shown). Modified from Millward (2021) under a Creative Commons Attribution 4.0 International License.

The UPS (see Fig. 6) is also widely distributed among tissues. It consists of a cascade of enzymes that activate with ATP, conjugate, and ligate the 76-amino-acid protein ubiquitin onto a lysine residue of a target protein. Because ubiquitin contains several lysine residues itself, both linear or branched chains of polyubiquitin can be assembled. Chains coupled to different ubiquitin lysine residues act as signaling motifs for proteolysis by the 26S proteasome (as well as other processes including the LAS). The 26S particle is a giant multifunctional protease complex consisting of a 19S regulatory particle which includes the “lid” to the 20S core particle within which proteolysis occurs. This recognizes, unfolds, and degrades ubiquitinated proteins in an ATP-dependent process. The molecular determinants of selective proteolysis, i.e., which proteins are targeted for ubiquitination are defined by the E3 ubiquitin ligase enzymes, of which ~700 different species are encoded in the human genome. The 26S proteasome catalyzes proteolysis to peptides averaging about 8 amino-acids long and proteolysis of these peptides is achieved by soluble peptidases.

Thus both the LAS and the UPS can achieve selective turnover and can be assumed to account for most of WBPT although the relative importance of the two systems for WBPT in different tissues has yet to be quantified. As far as their nutritional regulation, early studies focused on hepatic macroautophagy through which hepatic protein mass appeared to be regulated by both insulin and a receptor-mediated, amino-acid dependent inhibitory process, each acting through mTORC1 (Ueno et al., 2012; Meijer et al., 2015). Less is known about which is the dominant system in muscle although some suggest that the LAS is a crucial pathway

**Fig. 5** Scheme showing the three key types of autophagy in eukaryotic cells: macroautophagy, microautophagy, and chaperone-mediated autophagy. Each type delivers cargoes of substrates to the lysosomes for degradation through the different pathway prior to releasing their components as amino acids, fatty acids, and nucleotides back into the cytosol for cellular reuse. for muscle mass maintenance with its regulation different from that in liver in that unlike rapid and transient activation of the LAS by starvation in liver, in muscle such induction is sustained (Combaret et al., 2016). The ubiquitin-proteasome system is activated in skeletal muscle during fasting and following glucocorticoid treatment, supporting a role in the physiological regulation of protein turnover. Activation can be achieved by increasing rates of ubiquitination and by phosphorylation of the 19S subunit Rpn6 by protein kinases (VerPlank et al., 2019). This can occur in physiological conditions which increase cAMP and activate protein kinase A including in human muscles following intense exercise, in mouse muscles and liver after a brief fast and in hepatocytes after epinephrine or glucagon. These are the same conditions, (increased cAMP), under which the LAS is stimulated through inhibition of mTORC1 (see Jewell et al., 2019). Thus it may be that in the fasted state, the increased proteolysis in muscle reflects activation of both the LAS and the UPS via similar, coordinately regulated mTORC1-related mechanisms (Zhao and Goldberg, 2016). Another important but poorly understood control mechanism involves changes in cell volume. Thus, swelling acts like a proliferative anabolic signal, inhibiting proteolysis while cell shrinkage is catabolic, stimulating proteolysis. These effects have been shown in liver and there is some evidence for such a mechanism in skeletal muscle (see Millward, 2021). What is clear is that the nutritional regulation of proteolysis in muscle is mainly mediated by insulin, which mediates the post-prandial inhibitory response independently of amino acid availability (see Millward and Smith, 2019).

### Models and tracer methods for the study of protein turnover

Study of protein turnover has utilized isotope tracer techniques, radioactive tracers ( $^3\text{H}$ ,  $^{14}\text{C}$  and  $^{35}\text{S}$ ) in animals and stable isotopes ( $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^2\text{H}$ ) in both animal and human studies. Whole-body protein-turnover, (WBPT), can be measured simply as a function of the amino-acid flux through the plasma amino-acid pool during a primed continuous intravenous infusion of trace-labeled amino-acid, e.g.,  $^{13}\text{C}$ -1 labeled leucine. The infused tracer isotopic enrichment is diluted by unlabeled amino-acid from proteolysis ( $D$ ) and the diet ( $I$ ). At isotopic equilibrium (i.e., a plateau or constant degree of labeling of the tracee), the tracer/tracee ratio in relation to the infusion rate, ( $i$ ), indicates the flux, ( $Q$ ), which is the appearance into or irreversible loss from the plasma leucine pool. Appearance,  $R_a$ , is partitioned into intake, ( $I$ ), from diet (and tracer infusion if it is significant), and entry from proteolysis of body protein, ( $D$ ), (i.e., no de novo synthesis of leucine occurs). Loss or disappearance,  $R_d$ , is partitioned into protein synthesis, ( $S$ ), and oxidative catabolism, ( $O$ ), as  $^{13}\text{CO}_2$ , calculated from measurement of the production of labeled  $^{13}\text{CO}_2$  in the breath and the labeling of the leucine or its keto acid in the plasma.

$$\text{i.e., } Q = i \times \text{tracer dilution} = I + D = S + O$$

This allows the components of protein turnover, ( $D$  and  $S$ ), to be calculated as  $S = Q - O$  and  $D = Q - I$ . With the free leucine pool relatively small and turning over rapidly, isotopic equilibrium can be reached in 2–4 h when an initial priming dose is given as a bolus injection. Using the leucine content of tissue proteins, rates of leucine appearance and loss can be converted into rates of

**Fig. 6** Scheme showing the ubiquitin-proteasomal system for proteolysis. The Ubiquitin Proteasome System. (1) Ubiquitin, 8.5 kDa, is thiolated to ubiquitin-activating enzyme (E1) and subsequently transthiosterified to a cognate ubiquitin-conjugating enzyme (E2, of which 40 different species are coded in the human genome). E3 ubiquitin ligases (~700 types in two major classes), recognize specific target proteins and facilitate linkage of ubiquitin to the  $\epsilon$ -amino group of target lysine residues. (2) Subsequent turnover of ubiquitinated proteins is mediated by the 26S proteasome. This comprises the 19S regulatory particle, composed of lid (orange), ubiquitin receptors (red) and ATPases (green) which sit on top of the heptameric rings (yellow), that constitute the entry portal to the 20S catalytic chamber (magenta). Ubiquitin is released and recycled and peptides released are further degraded to amino acids by soluble peptidase enzymes. Modified from Scholz et al. (2020) under a Creative Commons Attribution License.

whole-body protein synthesis and proteolysis.  $^{13}\text{C}$ -1 leucine is especially useful since its essentiality enables  $D$  to be calculated; it has a small pool enabling equilibrium to be achieved in a short period; decarboxylation is the first irreversible step in its catabolism releasing  $^{13}\text{CO}_2$  quantitatively; and its intracellular transamination product  $\alpha$ -ketoisocaproate, ( $\alpha$ -KIC), rapidly equilibrates with its plasma pool and can be sampled to serve as a measure of the labeling of the intracellular leucine precursor pool. This is particularly important since the problem of definition of isotopic enrichment of the actual precursor amino-acid pool for protein synthesis is the most serious problem in these studies. During leucine infusions the  $\alpha$ -KIC enrichment at equilibrium is lower than that of leucine so that the plasma flux calculated from  $\alpha$ -KIC enrichment is higher ( $\approx 25\%$ ).

When tissues can be sampled, as in animal experiments or with muscle biopsies for example, tracer incorporation into protein will indicate tissue rates of protein synthesis, and a variety of approaches have been exploited to study regulation of tissue protein mass. In animal studies, a "flooding large dose" measurement of protein synthesis was introduced in 1980 using L- $^{3}\text{H}_4$ phenylalanine which proved much more convenient than previous constant intravenous infusions. This enables all tissue phenylalanine precursor pools to become equally labeled very quickly allowing protein synthesis rates in individual tissues to be assessed from isotope uptake into protein during short periods after the dose. While the large dose of  $^{3}\text{H}$  phenylalanine was shown not to influence the rate of protein synthesis in the original rat studies, problems arose when the method was adopted for human use. Thus large doses of  $^{13}\text{C}$  leucine, and several other essential amino-acids were shown to stimulate the rate of protein synthesis whereas the non-essential amino-acids, (arginine, glycine, serine and proline), did not. Thus the flooding dose method with  $^{13}\text{C}$  or  $^{15}\text{N}$  proline was successfully applied to the study of collagen synthesis in muscles, bones, tendons, and ligaments (Millward and Smith, 2019).

Quantification of rates of proteolysis is especially problematical. In animal studies proteolysis can be estimated from measured rates of synthesis in non-growing tissues or, during growth, ( $G$ ) of tissue protein as  $D = S - G$ , and with careful design, proteolysis rates can be measured by this method over relatively short periods when protein mass is changing quickly such as during stretch-induced growth of skeletal muscle or endotoxin-induced catabolism. While urinary excretion rates of the post-translationally modified amino-acid 3-methyl histidine was proposed as a measure of myofibrillar protein degradation, since it is excreted quantitatively

in the urine, the main source was shown to be small, rapidly turning-over pools, most likely actin-microfilaments of the cytoskeleton present in most cell-types. This invalidates this approach as far as whole body studies of skeletal muscle turnover are concerned. Nevertheless its release from incubated or perfused muscle can be used to determine myofibrillar protein degradation.

Simultaneous determination of protein synthesis and degradation can be made, in principle at least, from organ tracer balance studies, (i.e., measurements of concentrations and isotopic enrichments of tracer amino-acids across tissues like leg or forearm that have been combined with measurements of 3-methyl-histidine release). Such studies in humans have identified an inhibitory effect of insulin on muscle proteolysis and stimulatory influences of amino-acids on muscle protein synthesis.

All of these methods allow study of turnover of individual amino-acids in protein and measurement of their nonprotein metabolic fate (e.g., oxidation). A different approach is to use  $^{15}\text{N}$  glycine, often given orally as a single dose, to study overall amino-nitrogen turnover. Because of nitrogen exchange between amino-acids by transamination, this label acts as a tracer for total free amino nitrogen. The whole body nitrogen flux is estimated from the relative proportion of administered tracer excreted in the end product, which is assumed equal to the relative proportion of the flux which is excreted as total N. This is then resolved into protein synthesis and proteolysis from measurements of N intake and excretion. While simple in concept this approach is metabolically complicated with two urinary end products of nitrogen metabolism, urea and ammonia, each deriving from different pathways and each giving different flux values, explaining why it is used infrequently.

Finally approaches involving heavy water ( $^2\text{H}_2\text{O}$ ) have recently re-emerged (see Millward and Smith, 2019), as a suitable tracer to study muscle protein metabolism. Following a bolus of  $^2\text{H}_2\text{O}$ ,  $^2\text{H}$  exchange occurs with H atoms in multiple biological substrates including amino-acids. Thus with alanine for example, of its four carbon-hydrogen bonds, an average of 3.7 are exchanged with  $^2\text{H}$ , enabling precursor product approaches to measurement of muscle protein synthesis with  $^2\text{H}_2\text{O}$  and protein bound alanine. Orally administered  $^2\text{H}_2\text{O}$ , which is relatively inexpensive, has obvious advantages enabling volunteers to be studied in free-living conditions, over extended time periods, providing a cumulative measure of for example myofibrillar protein synthesis measured over 12 days. The potential for measurement of turnover with  $^2\text{H}_2\text{O}$  in a wide range of macromolecules including ribosomal RNA is an exciting feature of  $^2\text{H}_2\text{O}$  studies. Also proteome dynamics can be explored employing the recent advances in LC-MS-MS instrumentation coupled with either  $^2\text{H}_2\text{O}$  studies, uniformly deuterated valine [ $^2\text{H}_8$ ]valine or [ $^{13}\text{C}_6$ ] lysine to study individual protein turnover rates within the entire proteome in vivo (Hammond et al., 2016; Claydon et al., 2012), or  $^{13}\text{C}_6$  arginine and  $^{13}\text{C}_6$ lysine to study the proteome in cultured dermal fibroblasts isolated from different mammalian species with life spans ranging from 3 to 200 years (Swovick et al., 2021).

The choice of method must depend on the questions asked and circumstances of the subjects under study.  $^{13}\text{C}$  carbon labeling is more suited to short-term (e.g., 3 or 4 h–24 h) clinical measurements for which frequent blood and breath sampling is possible. Thus, the efficiency and mechanisms of post-prandial protein utilization during meal feeding has been studied by means of  $^{13}\text{C}$ -1 leucine balance and turnover measurements.  $^{15}\text{N}$  methods are more suitable for free living subjects and patients, when urine sampling is possible but regular blood and breath sampling are inconvenient. The most famous examples are use of this method in an unassisted Antarctic crossing, and in the space station. Both methods involve many assumptions but in practice the two approaches have been shown to give similar results.

## Extent and physiological implications of protein turnover

Early studies of the variability of protein turnover rates between tissues and for different proteins in the same tissues (Waterlow et al., 1978; Bates et al., 1983) demonstrated quite clearly that for an individual protein, its turnover reflected the proteolytic environment within which it occurred, identified as coarse control, with fine control involving individual susceptibility to proteolysis. Thus in the rat, mean half-lives of whole tissue proteins ranged from <1 day for liver to >10 days for skeletal muscle with comparable differences for mixed mitochondrial proteins. Also for mixed myofibrillar-proteins extracted from different muscles half-lives varied between 5.5 days in heart, 9–23 days in different skeletal muscle types in the rat, and 4.5 and 12.8 days in slow and fast contracting muscle in fowl. Within myofibrils actin turnover is half that of myosin heavy chain (MHC). One aspect of the variation in “proteolytic environment” was shown to be cell or nuclear domain size, as indicated by the protein/DNA ratio, with turnover rates highest for small cells and falling as cell or nuclear-domain size increased. This is the case for liver, (small cell), and skeletal muscle, (larger cell), and for muscle during post natal development with the protein/DNA ratio increasing markedly but reaching an equilibrium adult value which is a function of the muscle fiber type. The protein/DNA ratios are higher and turnover is proportionately slower in fast-twitch, compared with slow-contracting tonic muscles. These relationships mean that overall rates of proteolysis per diploid nucleus (per unit DNA) do not vary much but the interaction of the proteolytic systems with their cellular protein substrates does vary. For the liver, its function appears to be best served, (for reasons which are by no means clear), by its dominant lysosomal-autophagic system degrading its cellular proteins rapidly and replacing them. In fact although hepatocyte sizes do vary this involves variation in polyploidy so that protein/DNA ratios do not change. For muscle, its function, speed and duration of its contractions, and its resulting ultrastructure; i.e., highly branching slow tonic muscles or non-branching fast twitch muscles, as seen in classical examples of the anterior and posterior latissimus dorsi muscles of the fowl, (see Millward, 2021), determines the susceptibility of its myofibrils to the UPS, the likely main system involved in muscle proteolysis, with individual proteins like actin less susceptible than MHC. It is to be hoped that the recent advances in stable isotope-proteomic approaches to tissue protein turnover rates (Hammond et al., 2016; Swovick et al., 2018, 2021) can throw more light on these questions.

In the human adult about 300 g of protein turnover occurs each day, ( $4 \text{ g kg}^{-1} \text{ d}^{-1}$ )- that is, three or four times the daily dietary intake. This is less per kg than in infancy with turnover rates of  $10\text{--}20 \text{ g kg}^{-1} \text{ d}^{-1}$  because of the different body composition in terms of the higher proportion of metabolically active more rapidly turning-over tissues in infancy.

Protein turnover constitutes an appreciable fraction of resting energy expenditure (REE) although the extent of this is not clear, with reports of regressions of fasting WBPT on REE indicating turnover accounting for between 20% (Welle and Nair, 1990), to >50% (Boirie et al., 2001) of REE with no clear reason for the difference. While the former, lower value is more consistent with the stoichiometric calculations based on about 5 mol ATP/GTP per mole of protein turnover, (4 mol per peptide bond with an extra mole for amino-acid transport, RNA turnover and proteolysis), the latter value is discrepant. Thus at an energy cost of ATP synthesis from glucose of  $\sim 75 \text{ kJ/mol}$ , and a molecular weight of 110 per mole of peptide bond, 5 mol ATP/GTP per mole of protein turnover is equivalent to about 3.41 kJ/g protein turnover or about 14.3% of the adult REE for 300 g/day WBPT. Thus the mismatch with the higher energy cost of  $\geq 50\%$  REE is a factor of  $\sim 3.5$ . Although the ATP consumption by the proteosome is now known to be higher than earlier estimates, (at about 0.5 mol per peptide bond), it is difficult to construct a stoichiometry whereby WBPT accounts for >50% of the REE without including a large number of extra ATP-consuming reactions per peptide bond formed or cleaved. Whatever the actual figure it is clear that WBPT is a very important driver of the REE and it is the case that the fall with age in both protein turnover and metabolic rate from birth to adulthood involve a factor of 3–4 in each case.

As far as any relationship between protein turnover and protein requirements, there is no *a priori* reason for this and little evidence of any. Thus turnover does not consume significant quantities of amino-acids and amino-acid catabolism and oxidation is not known to be linked to turnover. Maintenance protein requirements are assumed to decrease relatively little with age, (<20%) compared with the 3–4 fold fall in turnover.

### The diurnal cycle of feeding and fasting and postprandial protein utilization

Overall proteostasis of the whole body proteome is maintained within a diurnal cycle of postprandial protein gains and postabsorptive losses, with human studies, mainly in adults, focusing on the nutritional regulation of these diurnal changes within the whole body (Pacy et al., 1994; Fereday et al., 1998) or in muscle because of its accessibility, (see Millward and Smith, 2019). Thus the stimulation of protein synthesis and inhibition of proteolysis with protein feeding has been examined together with the relative importance of insulin or amino-acids as mediators of the feeding response. One key question is what influences the efficiency of postprandial protein utilization and consequent protein requirements for overall balance? This depends on the balance between post prandial protein deposition and amino acid oxidation.

Because many indispensable amino-acids are potentially toxic and are maintained at very low concentrations in tissues, their rapid and regulated postprandial disposal is important for metabolic homeostasis. After a protein meal two pathways for amino-acid disposal exist. One is disposal through the high-capacity, finely regulated oxidative pathways with rates mainly influenced by their tissue concentrations, (generally similar to the  $K_m$  of the rate limiting enzymes), together with substrate activation and covalent enzyme modification. Examples are phenylalanine hydroxylase, and branched-chain  $\alpha$ -keto acid dehydrogenase, which are both regulated by substrate binding and reversible phosphorylation and dephosphorylation. The second pathway is net protein deposition. This can be achieved by stimulation of protein-synthesis or inhibition of proteolysis by postprandial hyper-amino-acidemia as described above. However the increased intracellular amino-acid levels which stimulate protein synthesis may also increase amino-acid oxidation rates and while this allows effective removal of amino-acids, this would not be the most efficient protein utilization mechanism. If signal transduction could commence in the extracellular amino-acid pool, i.e., increases in plasma amino-acid concentrations can signal an increase in protein synthesis while intracellular amino-acids need not increase to the same extent, this would minimize any increase in oxidation. There is increasing evidence that this is the case (see Millward and Smith, 2019).

For proteolysis, amino-acids exert an inhibitory influence as described above, and this inhibition will reduce endogenous intracellular amino-acid supply, minimizing any increases in amino-acid levels and amino-acid oxidation and maximizing dietary protein utilization. Furthermore since inhibition of proteolysis and lowering of intracellular amino-acid levels can be achieved by receptor mediated mechanisms involving insulin as well as specific amino-acids, (e.g., leucine), this allows the postprandial increases in plasma amino-acids to mediate sufficient amino-acid transport into cells for protein deposition, without marked increases in intracellular amino-acid levels thus minimizing increases in amino-acid oxidation. Thus as a strategy for mediating postprandial protein utilization, inhibition of proteolysis would be predicted to be more efficient than increasing protein synthesis.

$^{13}\text{C}$ -1 leucine studies of WBPT have provided clear experimental support for such a mechanism. In adult subjects habituated to increasing protein intakes from below to twice habitual levels, isoenergetic meals of increasing, (i.e., habitual), protein intake induced a clear inhibition of proteolysis at all levels of protein intake, to an increasing extent with intake, but much less obvious changes in protein synthesis, with slight inhibition or no change at low intakes to stimulation at high intakes (Pacy et al., 1994). The relative importance of the energy/insulin as opposed to protein/amino acid component of the feeding response was established in other  $^{13}\text{C}$ -1 leucine feeding studies examining the response to habitual protein intakes fed as small-repeated milk meals (Fereday et al., 1998). These involved three phase, ( $3 \times 3 \text{ h}$ ), continuous infusions, i.e., fasting, followed by isoenergetic low, and then habitual protein-feeding. Insulin levels were similar throughout the two feeding phases: i.e., the phase 2 response reflected energy/insulin and the phase 3 complete meal response reflected insulin/energy plus protein/amino acids (Gibson et al., 1996; Fereday et al., 1998). The results are shown in Fig. 7. In all 25 subjects studied, the complete meal reduced proteolysis by 46% on

**Fig. 7** Scheme showing feeding-induced responses of proteolysis and protein synthesis in the whole body as indicated by leucine kinetics. Studies involved 3 by 3 h continuous, primed constant intravenous infusions of 25 healthy adults, (10 females, 15 males) with  $^{13}\text{C}$ -1 leucine, initiated in the fasted state with feeding of frequent small liquid meals providing subjects energy needs, with low (3–6 h) followed by high protein (6–9 h) equivalent to habitual daily protein intakes. A constant insulinemia was maintained during the two feeding phases. Protein kinetics calculated from the plasma flux based on enrichment of plasma  $^{13}\text{C}$ -1  $\alpha$ -keto isocaproate at plateau at the end of each 3 h period. Data from [Fereday et al. \(1998\)](#).

average and stimulated protein synthesis by 20% with the amino acids effecting similar changes in proteolysis and synthesis, but with energy/insulin mediating an additional inhibition of proteolysis. Further analysis of the interindividual variability of these responses in terms of the efficiency of post-prandial protein-utilization showed clearly that the most efficient utilization, (minimal increase in amino acid oxidation), involved maximal inhibition of proteolysis by protein feeding with minimal increases in protein synthesis. Thus the efficiency of protein utilization in individuals appears to be determined mainly by the sensitivity of the insulin-mediated inhibition of proteolysis to amino-acid supply.

These and other studies suggests a mechanism indicated in [Fig. 8](#), in which the major target of insulin is inhibition of proteolysis with extracellular amino-acids acting to both enhance the inhibition of proteolysis and stimulate protein synthesis and with intracellular amino-acids stimulating their own oxidation. With extracellular amino-acid levels controlled by diet, and tissue levels controlled by endogenous supply from proteolysis, inhibition of proteolysis will minimize any increase in amino-acid levels, minimize oxidation, and maximize protein utilization. Since protein synthesis and amino-acid oxidation appear to be stimulated in

**Fig. 8** Scheme for the action of insulin and amino-acid supply on postprandial protein utilization. During the post prandial response to food, insulin exerts an inhibitory influences on proteolysis through a receptor mediated mechanism, a, and extracellular amino-acids signal a stimulation of protein synthesis through b. Intracellular amino-acid levels are regulated by amino-acid transporters, c, and by proteolysis, and their increases stimulate amino-acid oxidation and protein synthesis to some extent in parallel. Maximal inhibition of proteolysis and minimal increases in intracellular amino-acid levels is the optimal response. Modified from [Millward et al. \(1996\)](#).

parallel, the optimum strategy for maximum efficiency of postprandial protein utilization would appear to involve maximal inhibition of proteolysis ensuring minimal postprandial increases in tissue amino-acid levels with a stimulation of protein synthesis mediated from extracellular amino-acid supply.

Clearly these whole body responses reflect weight average responses of different tissues but as indicated above the much higher turnover rate of the splanchnic proteome means that its response to feeding will dominate the whole body response. However although measurements in muscle show a robust feeding response of protein synthesis, extracellular amino acid signaling has been clearly demonstrated in muscle as in the liver. Obviously when amino-acid dietary supply exceeds the capacity for its net deposition, intracellular amino-acids will rise stimulating their disposal via oxidation.

## Conclusion

Ideas about proteostasis within the proteostasis network (PN) have emerged in the last decade. Thus the proteomic identification of the thousand or so proteins in the PN involved in the regulation of protein synthesis, folding, transport, and degradation is revealing how cellular health is maintained and shining new light on our understanding of protein turnover. At the level of the whole body proteome we now have a better understanding of the coordination of growth of muscle and stature through mechanotransduction mechanisms which prevent any dietary protein-induced muscle growth in excess of that allowed by growth in stature, a limitation extending throughout the life cycle, at least in the absence of resistance exercise. The importance of amino-acids and insulin in mediating nutritional regulation of protein turnover has been strengthened through new findings about their mTORC1-mediated control mechanisms of protein synthesis and proteolysis. Nevertheless much mystery remains especially in skeletal muscle including how complex protein structures such as the myofibrillar apparatus are assembled and dismantled, how much of this occurs during the daily cycle of gains and losses of tissue protein, and how the constraint to muscle myofibre expansion by its ECM, observed as the tachyphylaxis of the anabolic response to protein feeding, is exerted at the molecular level.

## Key points

- To obtain an overview of the role of riboflavin in intermediary metabolism.
- To understand the relationship between the chemical structure of this vitamin and its biological function.
- To know the processes of absorption, transport and storage of this vitamin, and the formation of the corresponding coenzymes.
- To have information about the dietary intakes of this vitamin.
- To know the metabolic disorders related to riboflavin deficiency.
- To know the most important food sources of this vitamin.

## Introduction

Riboflavin is a derivative of a flavin compound, isoalloxazine. It has a weak basic character, crystallizes in yellowish needles and is soluble in water, but much less than other vitamins of its group (Ross et al., 2014; Stipanuk and Caudill, 2018). It is resistant to heat and oxidation, stable in acid solution, but unstable in alkaline solution, and especially sensitive to ultraviolet light, which destroys it irreversibly, forming lumiflavin, if in an alkaline medium, or lumichrome, if in an acid or neutral medium (Peechakara and Gupta, 2020).

This article will consider the processes of absorption, transport, storage, metabolism and excretion, the functions, the assessment of the nutritional status, the requirements, the dietary sources, and the status measurement of riboflavin.

\*CJ Bates passed away on January 2018.

## Absorption, transport, and storage

Riboflavin (vitamin B<sub>2</sub>) is not synthesized by higher animals, in which it is an absolute dietary requirement for the synthesis of certain essential coenzymes needed for intermediary metabolism (Combs and McClung, 2016; Rodwell et al., 2018). It is transported from food sources in the gastrointestinal tract, across the gut wall into the circulatory system, and thence via the blood to the tissues. This occurs against a concentration gradient, thus retrieving even small amounts from food and from the low concentrations in plasma to the higher concentrations inside cells (Barile et al., 2016).

Three human riboflavin transporters have been cloned and characterized, belonging to the SLC52 family of solute carriers, whose more recent nomenclature is hRFVT1, hRFVT2 and hRFVT3. They are encoded by genes SLC52A1-3, respectively. hRFVT1 is mainly expressed in placenta, intestine and kidney. hRFVT2 is rather ubiquitously expressed but is particularly abundant in nervous tissues and salivary glands. hRFVT3 is most highly expressed in testis but also in prostate, intestine, stomach and pancreas. These different but overlapping expression profiles might explain the vulnerability of certain tissues to mutations in one or more of the SLC52A genes (O'Callaghan et al., 2019).

Gut riboflavin transport system at low (e.g., micromolar) concentrations is temperature and energy-dependent (it is inhibited by inhibitors of adenosine tri phosphates (ATP) production from energy substrates), it becomes saturated as the concentration of riboflavin increases, and it is sodium ion dependent. These characteristics are shared with many other types of small molecules that are actively transported across the gut wall. More specifically for riboflavin, the active transport mechanism involves phosphorylation (to riboflavin phosphate, also known as flavin mononucleotide (FMN)), followed by dephosphorylation back to riboflavin, both steps occurring within the intestinal cells (Fig. 1). This is one of a number of strategies that the gut uses to entrap essential nutrients and then transfer them in a controlled manner. A similar strategy is used at other sites in the body, to ensure entrapment of circulating riboflavin by cells whose nascent flavin-dependent enzymes need a regulated supply of the vitamin.

Although the active transport of riboflavin across the gut wall and across other cell membrane barriers within the animal is a saturable process, if pharmacological amounts are present, then the slower and less efficient, but nonsaturable, process of passive absorption predominates. The active transport process is increased in riboflavin deficiency and is decreased if the riboflavin content of the tissues is high, and it involves calcium and calmodulin, but not sodium. Specific riboflavin receptors and a role for the microtubules have been identified.

Although some of the riboflavin in foods is present as the free vitamin, a larger fraction is in the phosphorylated coenzymes FMN and flavin adenine dinucleotide (FAD), and there may also be small amounts of a glucoside. These forms are all efficiently converted into free vitamin by enzymes secreted into the gut lumen and thus become available for absorption. There are also small amounts of covalently bound and thus unavailable forms of riboflavin, present in enzymes such as succinate dehydrogenase (succinate: ubiquinone oxidoreductase EC 1.3.5.1), monoamine oxidase, and gulonolactone oxidase, which cannot be released by the hydrolytic enzymes in the gut. Also unavailable (or very poorly available) in humans is the riboflavin synthesized by the gut microbiota of the large bowel. Certain animal species such as rodents can utilize this riboflavin source by coprophagy.

Analogues of riboflavin have been prepared to explore riboflavin economy. Some of these have riboflavin-like activity; others are inactive, whereas some are antagonists and can cause functional deficiency. These structural variations can affect absorption and the

**Fig. 1** Characteristics of the absorption process for riboflavin and its coenzymes.

conversion of riboflavin into its coenzyme forms. Certain drugs such as phenothiazines (antipsychotics) have sufficient structural similarity to riboflavin to act as antagonists.

### Absorption in humans

Studies of riboflavin absorption by human subjects require a test dose taken by mouth, and a sampling procedure to estimate the amount absorbed and its subsequent fate. The sampling compartment is generally urine, because plasma is unsatisfactory (see the last paragraph of this section and the section on Assessment of riboflavin status below), and fecal sampling is useless because of the synthesis of riboflavin by bacteria in the large bowel. Riboflavin labeled with radioactive or stable isotopes has not yet been widely used in human studies. Instead, most studies have relied on relatively large bolus oral doses of several milligrams of riboflavin, with urinary monitoring over a few hours. Riboflavin can be quantified in urine by its characteristic fluorescence, by a microbiological assay, or high-performance liquid chromatography (HPLC). The duration of exposure in the upper ileum is critical, because this is the region of greatest absorptive efficiency. Slow-release forms of the vitamin do not enhance its absorption, but there does appear to be some absorptive advantage for synthetic lipophilic esters, such as the tetrabutryrate ester, which becomes hydrolyzed to free vitamin during or after absorption. These esters possess beneficial (e.g., antioxidant) properties in some model systems. Food can enhance absorption, possibly by increasing bulk transit time. The efficiency of absorption does not vary markedly with age or sex in humans.

The large intestine is known to possess efficient and specialized carrier-mediated systems that are capable of mediating the absorption of bacterially synthesized B-vitamins, including riboflavin, and this is likely to be especially important for local colonicocyte nutrition.

Plasma is of little use as a sampling fluid because redistribution to other tissue sites and urine occurs too rapidly. Although the urinary response to a test dose is preferred, it has the disadvantage that physiological intakes, and especially intakes from poor food sources, cannot be measured accurately. A more sensitive biochemical marker of riboflavin status at low intakes is the index known as the "erythrocyte glutathione reductase activation coefficient" (EGRAC).

### Riboflavin transport at other sites and storage

Free riboflavin is trapped as one of its phosphorylated coenzyme forms, which are then associated (and in a few cases covalently linked) to the protein chains of catalytic flavoenzymes. If not covalently linked, the flavin coenzyme can often be released, for example, by extremes of pH. At some locations, such as mature red cells, flavoenzymes such as glutathione reductase (NADPH: oxidized-glutathione oxidoreductase EC 1.6.4.2) may exist partly in their apoenzyme form, i.e., without the flavin coenzyme and therefore without enzyme activity. An increased supply of riboflavin will allow the depleted coenzyme (in this case FAD) to be synthesized so that holoenzyme and activity can be restored.

Different enzymes and different tissue sites differ in the tenacity with which they retain flavin coenzymes during riboflavin deficiency; thus, there is a characteristic pecking order for flavoenzyme protection, reflecting the metabolic importance of the pathways affected. However, there is no repository of unused or nonfunctional riboflavin that can act as a store in times of dietary deficiency. Although some organs (such as the liver) have relatively high concentrations of flavin enzymes, all of the flavin is present as coenzyme in flavin holoenzymes. Each tissue has a characteristic ceiling level of riboflavin at saturation and a floor level characteristic of severe depletion, and these are determined, respectively, by the total amount of apoflavoprotein and the irreducible amounts of the holoenzymes, which cannot be depleted of their cofactor complement.

Riboflavin is secreted into milk, whose concentration is species-specific and dependent on maternal status and intake. There is active transport from the maternal to the fetal circulation in pregnancy, the flavin concentration being greater on the fetal side. Studies from India have identified a riboflavin carrier protein (RCP) present in bird (e.g., chicken) eggs, which is specific for riboflavin, and essential for normal embryological development. If it is rendered ineffective (e.g., by immunoneutralization), embryonic development ceases and the embryo dies. A genetic mutant lacking RCP was infertile. A homologous protein, which was rendered ineffective by the antibody to pure chicken riboflavin carrier protein, was found to occur in several mammalian species, including two species of monkeys, and in humans. Circulating RCP levels and the immunohistochemical staining of RCP in biopsy specimens may provide new markers for breast cancer diagnosis and prognosis. Termination of pregnancy occurred after immunoneutralization of RCP in monkeys. The role(s) of RCP in humans, however, remain controversial, and other, less specific riboflavin binders in blood, including gamma-globulins, also seem to play an important role. Further evidence of the flavin needs of developing embryos has been provided by the demonstration that riboflavin analogs can cause teratogenic changes in the absence of any detectable damage to maternal tissues.

### Metabolism and excretion

The riboflavin coenzymes are depicted in Fig. 2. Both coenzymes are much more soluble in water than riboflavin. ATP is a cosubstrate and driving force (in energy terms) for both stages of the conversion of riboflavin into FAD. Some flavoenzymes specifically require FAD, whereas others specifically require FMN. Table 1 lists the broad categories (by two alternative classification options) of flavoenzymes found in living tissues: all revolve around redox processes. The central biochemical reaction of the flavin coenzymes

**Fig. 2** Structure of riboflavin and its coenzyme derivatives. (A) Riboflavin; (B) riboflavin phosphate (flavin mononucleotide, FMN); and (C) flavin adenine dinucleotide (FAD).

**Table 1** Two classification options for flavoenzyme categories.

Category	Example
<b>Classification by reaction-type</b>	
Electron transferases	Mitochondrial electron-transfer flavoprotein
Dehydrogenases	Mitochondrial NADH dehydrogenase and succinate dehydrogenase; (cytosolic) glutathione reductase
Dehydrogenase-oxygen reductases (with O <sub>2</sub> reduction to H <sub>2</sub> O <sub>2</sub> )	Monoamine oxidase
Flavoprotein monooxygenases	Bacterial lactate monooxygenase, microsomal FAD-containing monooxygenase
<b>Classification by flavin-type</b>	
Enzymes with FMN	NADH-FMN oxidoreductase
Enzymes with FAD	Glutathione reductase, methylene tetrahydrofolate reductase
Enzymes with both FMN and FAD	NADPH-cytochrome P-450 reductase
Enzymes with covalently bound flavin (formed by posttranslational flavinylation)	Succinate dehydrogenase

involves the interconversion of the reduced, dihydro form of the flavin ring and the oxidized form. One of the most important sites of action of flavoenzymes in higher animals is the electron transport chain in the mitochondria. Flavins in succinate dehydrogenase and NADH dehydrogenase form essential redox links between the oxidizable energy-rich substrates of aerobic metabolism and the cytochrome chain, leading to molecular oxygen, which can generate approximately 38 mol of ATP per mole of glucose oxidized.

Hormone status can affect riboflavin economy and riboflavin status can affect hormone production. One important control point for riboflavin economy is thyroid hormone status: hypothyroidism leads to lower tissue levels of flavin coenzymes, and hence to inactivation of certain flavoenzymes, thus resembling the effects of dietary riboflavin deficiency. Both flavokinase (ATP: riboflavin 5'-phosphotransferase EC 2.7.1.26) and FAD pyrophosphorylase (ATP: FMN adenylyltransferase EC 2.7.7.2) are regulated by thyroid hormone status. In the kidney, the synthesis of flavokinase and hence of flavin coenzymes is controlled by aldosterone.

The amount of absorbed riboflavin that remains in the circulation (in blood plasma) is regulated by glomerular and tubular filtration, and tubular reabsorption, in the kidneys. This is an active, saturable, transport process, with characteristics similar to those of active transport in the gastrointestinal tract. It is mainly responsible for the very sharp and characteristic transition between minimal urinary excretion of riboflavin at low intakes, and a much higher level of excretion, proportional to intake, at higher intake levels. This transition point has been used to define and to measure riboflavin status and requirements and to allow studies of intestinal absorption *in vivo*. Excretion of riboflavin is affected by some chemicals (such as boric acid, which forms a complex with it) and by certain diseases and hormone imbalances.

In addition to the excretion of unchanged riboflavin, there are small urinary amounts of hydroxylated breakdown products of the vitamin, which arise through normal turnover, either within the tissues of the body or in the gastrointestinal tract from bacterial action, before absorption. The rate of destruction of riboflavin by this turnover pathway is low in all species examined and riboflavin within the mammalian body is efficiently conserved.

## Metabolic functions

FMN and FAD are tightly bound to a large number of proteins (flavoproteins or flavoenzymes) that perform electronic transport functions through oxidation-reduction processes. In some cases, these reactions involve the transfer of two electrons, so that both FMN and FAD accept the two hydrogen atoms given up by the substrate. A typical example of these reactions is the succinate to fumarate step in the Krebs cycle, a reaction catalyzed by succinate dehydrogenase (EC 1.3.5.1). Another reaction of this type, of great metabolic interest, is the oxidation of acyl-CoA by acyl-CoA dehydrogenases, which constitutes a fundamental step in the mitochondrial catabolism of fatty acids.

In other cases, these coenzymes can accept a single electron, giving rise to a stable chemical species of the semiquinone type. This class of reactions is essential in mitochondrial electron transport chains (respiratory chains). Specifically, electrons from FADH<sub>2</sub> bound to acyl-CoA dehydrogenases are transferred to another flavoprotein, called electron transfer flavoprotein (ETF), by this mechanism. In turn, this protein transfers the electrons to proteins with iron and sulfur that have ETF:ubiquinone oxidoreductase activity (EC 1.5.5.1). Finally, the electron acceptor is ubiquinone.

These reactions also occur in the electron transport chains located in the endoplasmic reticulum (microsomal electron transport chains). There are two main types of these chains. One of them performs the desaturation of fatty acids. This process involves enzymatic proteins (desaturases), cytochromes (cytochrome b<sub>5</sub>) and flavoproteins. An electronic transport from NADH to oxygen takes place, as in the respiratory chains. The difference is that, in this case, the hydrogens of the substrate are also used to form water, thus leading to the formation of the double bond.

Other microsomal electron transport chains carry out the hydroxylation of molecules with a steroid structure, enabling, for example, the formation of cholesterol and 1,25-dihydroxycholecalciferol (or calcitriol). This system works analogously to the previous one, although it is a more complicated process. In this case, the source of electrons is NADPH, instead of NADH, and a special cytochrome called cytochrome P-450 is used, in addition to the corresponding enzymatic proteins and flavoproteins. As these are enzymes with very low substrate specificity, this system also performs oxidations on exogenous molecules (xenobiotics), such as alcohol and drugs.

An additional capacity of flavoenzymes is to react directly with oxygen, forming hydrogen peroxide. This is how, for example, xanthine oxidase (EC 1.17.3.2), the enzyme responsible for the formation of uric acid, functions.

Given the great versatility of riboflavin-derived coenzymes, it is not surprising that there are numerous flavin enzymes. Most of them are involved in the oxidative metabolism of nutrients in their different stages. But, in addition, some are part of the antioxidant defense, such as glutathione reductase, or are used in the biosynthesis of other coenzymes, such as pyridoxal phosphate or 5'-methyltetrahydrofolic acid. It is therefore easy to deduce that riboflavin deficiency can influence many biochemical areas.

## Essentiality

The following section addresses the biochemical and physiological actions of flavins that are responsible for the characteristic functional effects of riboflavin deficiency (Balasubramaniam *et al.*, 2019; Mahabadi *et al.*, 2020; Mosegaard *et al.*, 2020; Plantone *et al.*, 2021; Saedisomeolia and Ashoori, 2018; Thakur *et al.*, 2017).

### Fatty acid oxidation

An early effect of serious metabolic disturbance seen in moderate riboflavin deficiency is a disturbance of fatty acid oxidation. The normal first stage in the spiral process of beta-oxidation of fatty acids within the mitochondria is the removal of two hydrogen atoms from the two carbons located alpha and beta to the activated carboxyl end of the fatty acid chain. The fatty acyl coenzyme A substrate is acted on by one of several fatty acyl CoA dehydrogenase flavoprotein enzymes (e.g., long-chain acyl-CoA:(acceptor) 2,3-oxido-reductase EC 1.3.99.13), each of which is specific for a narrow range of acyl chains. The second stage involves transfer of the electrons via electron-transferring flavoprotein dehydrogenase (ETF: ubiquinone oxidoreductase EC 1.5.5.1, mentioned above) and thence to the mitochondrial cytochrome chain and to oxygen. These flavoenzymes, unlike the flavoenzymes that are linked to carbohydrate oxidation, are highly sensitive to dietary riboflavin depletion. Characteristic disturbances of lipid metabolism therefore arise in riboflavin-deficient tissues and organisms.

Disturbances in fatty acid oxidation by isolated mitochondria, for example, from the livers of deficient animals, have been demonstrated, and one of the most characteristic metabolic changes, observed even in a mild deficiency state in experimental animals, is the appearance of abnormal dicarboxylic acids and their derivatives in the urine. These products may arise because fatty acyl intermediates become diverted away from the usual pathway of mitochondrial beta-oxidation, toward abnormal partial oxidation in the peroxisomes.

Humans normally do not accumulate these urinary products but individuals with an abnormal gene resulting in dicarboxylic-aciduria (as in multiple acyl CoA dehydrogenase deficiency or glutaric aciduria type II) do respond to riboflavin supplements quite frequently, showing a reduction in their excretion and clinical improvement. High-dose riboflavin can thus overcome the genetic abnormality, by providing more coenzyme, thereby ensuring that the residual fatty acid oxidation pathway works at optimum capacity. The accumulation of dicarboxylic acids in urine is characteristic of riboflavin-deficient mammals but not of birds; thus, chick embryos deprived of riboflavin via a genetic lesion affecting riboflavin carrier protein seem to die of hypoglycemic shock, but do not exhibit dicarboxylic-aciduria.

### Iron economy

An important interaction of riboflavin with iron economy is indicated by the fact that iron-deficient animals fail to respond to iron supplements if they are also riboflavin deficient and that the redox system involving riboflavin and its coenzymes interacts readily with the redox system between ferric and ferrous iron.

Studies in experimental animals indicate impairment of iron absorption in riboflavin-deficient animals, changes in its distribution between body compartments; and an increase in rate of iron loss from the intestinal mucosa, resulting in impaired retention of the body iron stores. This enhanced rate of iron loss is accompanied by hyperproliferation of crypt cells, and increased cellular transit along the villi, leading to an excessive proportion of immature villi and a reduction in absorptive area. These studies help to explain how a combination of iron deficiency and riboflavin deficiency, which is frequently encountered in human populations in developing countries, may lead to a gradual deterioration of iron status, which is often accompanied by other intestinal lesions and impaired gut function.

Riboflavin enhances the hematological response to iron, and deficiency may account for at least some of the anemia seen in human populations. Unlike iron-deficiency anemia, the anemia of riboflavin deficiency is usually normocytic and normochromic.

### Malaria

Low-dietary riboflavin intakes are frequently encountered in malarious areas of the world, and in some studies, biochemical riboflavin deficiency is associated with a reduced level of blood cell parasitemia. Although neither animal nor human studies have indicated that riboflavin deficiency protects from the life-threatening sequelae of malaria, there may be an interaction between the parasite and flavins within cells. Some prophylactic drugs used to prevent malaria infection have riboflavin-like structures.

### Cataracts and photoreceptors

Several micronutrients, especially those with antioxidant-type functions in living tissues, might provide some protection against degenerative eye diseases, such as cataract. Animal models, epidemiological studies, and an intervention study in China support the suggestion that good riboflavin status, or riboflavin supplements, may be protective and this possibility deserves further study.

Another intriguing role of flavoproteins in the eye involves a photoreceptor function that synchronizes circadian rhythms with the solar light-dark cycle, acting via cryptochromes 1 and 2, which contain FAD and function as blue light-sensitive photoreceptors.

### Interaction with vitamin B<sub>6</sub>

Riboflavin and vitamin B<sub>6</sub> are metabolically interrelated. The conversion of pyridoxine or pyridoxamine phosphates into pyridoxal phosphate is catalyzed by a flavoenzyme (pyridoxaminephosphate oxidase EC 1.4.3.5) and a deficiency of riboflavin can, at certain sites, result in a secondary deficiency in vitamin B<sub>6</sub>-dependent pathways.

### Effect on folate metabolism

FAD is an essential coenzyme for 5,10-methylene tetrahydrofolate reductase (EC 1.5.1.20), a key enzyme of the folate activation pathway, catalyzing the interconversion of 5,10-methylene tetrahydrofolate and 5-methyltetrahydrofolate. Of several single nucleotide polymorphisms affecting this enzyme, the best known are the C699T and A1298C variants. The former confers thermolability and lowered reductase activity in the TT homozygote, apparently explained by enhanced loss of the FAD cofactor. Marginal riboflavin status is associated with increased plasma homocysteine levels (possibly predictive of increased vascular disease risk), arising from the reduced activity of this key enzyme in TT subjects. The same polymorphism appears to modulate the risk of some cancers, notably colorectal cancer.

Another polymorphism in the 5,10-methylene tetrahydrofolate reductase gene, C677T, seems to be related to blood pressure variation. Supplementation with riboflavin can lower blood pressure in hypertensive individuals with the TT genotype but not in those with the CC or CT genotype (Horigan et al., 2010).

### Assessment of riboflavin status

Assessment of riboflavin status is closely linked to the estimation of its dietary requirement and the monitoring of human populations for intake adequacy. It is often cheaper, easier, and more accurate to collect a sample of blood or urine from an individual and then perform biochemical analyses that determine status, than attempting to measure food intakes, because the latter requires more cooperation from the subject and has the limitations of imprecision and poor applicability of food table riboflavin values.

Riboflavin status estimates are generally based on urinary excretion or measurements of erythrocyte glutathione reductase (NADPH: oxidized-glutathione oxidoreductase EC 1.6.4.2) and its reactivation with FAD in red cell lysates. Other biochemical indices, such as plasma or red cell flavin concentrations, have been less widely used, but their potential may increase with new assay techniques such as capillary electrophoresis with laser-induced fluorescence detection. Functional indices linked to flavin-requiring pathways *in vivo* are rarely used, except for the investigation of errors of metabolism or of rare diseases. The two principal status tests are as follows:

#### Urinary excretion

The amount of riboflavin excreted in the urine is negligible at low intakes of the vitamin. As the dietary level increases, there is slow increase to a transition point, above which the slope of the excretion rate increases very sharply and then remains proportional to intake until absorption is saturated. For population studies, it has been found convenient to use the creatinine excretion rate as the denominator, and the suggested interpretation of urinary riboflavin excretion rates is  $<27 \mu\text{g riboflavin g}^{-1}$  as deficient;  $27\text{--}79 \mu\text{g g}^{-1}$  as low; and  $>80 \mu\text{g g}^{-1}$  as acceptable. This index is sufficiently sensitive to distinguish riboflavin requirements between individuals on low-fat, high-carbohydrate diets and the slightly higher requirement associated with high-fat, low-carbohydrate diets. However, one serious drawback of the urinary excretion index is that it is relatively insensitive to intake variations at low to moderate riboflavin intakes. Another is that 24 h urine samples are not easy to collect and excretion rates may fluctuate over short time periods. In addition, metabolic states associated with tissue catabolism may release riboflavin during cell turnover, resulting in increased urinary excretion even when the dietary intake is low.

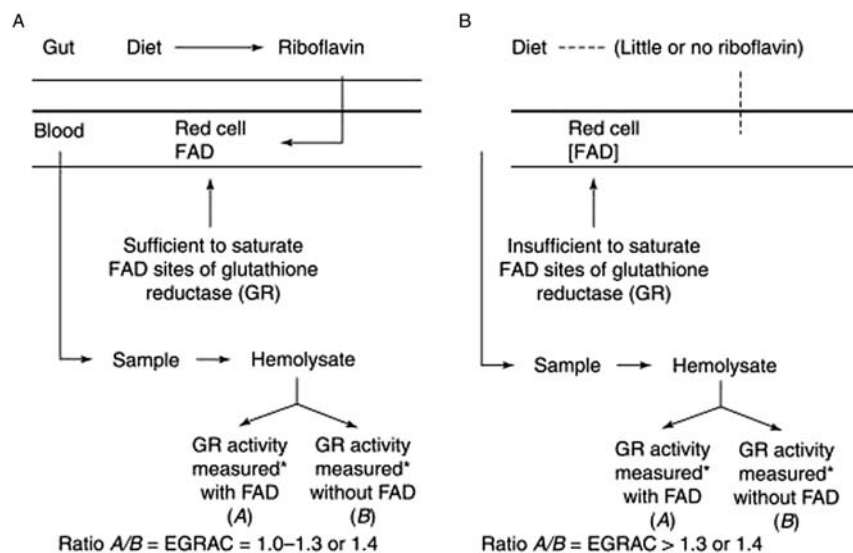

#### The glutathione reductase test

A more reliable status index is the degree of unsaturation of the red blood cell enzyme, glutathione reductase (NADPH: oxidized-glutathione oxidoreductase EC 1.6.4.2), with respect to its flavin cofactor, FAD (Fig. 3).

Inadequate dietary riboflavin results in low circulating levels and hence a gradual progressive loss of cofactor from this red cell flavoenzyme over a period of several weeks. Because the enzyme protein (apoenzyme) remains intact and is re-activatable by FAD, it is possible to assess riboflavin status by measuring glutathione reductase activity with, and without, its FAD cofactor, in washed red cells. If riboflavin replete, FAD has little effect and the activation coefficient or the ratio of FAD stimulated to unstimulated activity (EGRAC) is between 1.0 and 1.3–1.4. If deficient, FAD produces a larger stimulation and the activation coefficient is much higher. For individuals living in communities with very low intakes of riboflavin and a significant prevalence of clinically recognizable deficiency, activation coefficients as high as 2.0–3.0 are common. In Western countries, few values as high as 2.0 are encountered. However, recent population surveys in the UK have indicated that the proportion of values between 1.3 and 1.8 is considerable across all age ranges. Whether this reflects suboptimal intakes of riboflavin-rich foods, such as cow's milk, remains uncertain.

This blood test is highly sensitive to, and predictive of, the extent of tissue depletion in the range of severe to moderate deficiency. It is robust and requires only a small sample of blood and can be automated by commercial enzyme rate reaction analyzers. When deficient subjects are provided with riboflavin supplements, there is rapid restoration of saturation of the enzyme, and graded supplements can be used to estimate human requirements.

There are minor operational differences among different published versions of the analytical procedure for EGRAC, which result in small between-laboratory differences in the definition of the normal range, and there are external factors that may cause ambiguity of interpretation. One of these is the genetic variant, glucose-6-phosphate dehydrogenase (D-glucose-6-phosphate: NADP+ 1-

**Fig. 3** Basis of the glutathione reductase for riboflavin status: (A) riboflavin sufficient; (B) riboflavin deficient. \*Reaction of oxidized glutathione with reduced nicotinamide adenine dinucleotide phosphate.

oxidoreductase EC 1.1.1.49) deficiency. Both homo- and hetero-zygotes are affected, and their erythrocyte glutathione reductase is almost saturated with FAD, even when their tissues are riboflavin deficient. Alternative tests of status, such as HPLC measurement of riboflavin in blood fractions, are then required.

Some groups of individuals have increased requirements for riboflavin. There is, for instance, a progressive increase in requirement during pregnancy, followed by a gradual decrease during lactation. Babies exposed to phototherapy for neonatal jaundice have increased requirements. Oral contraceptives may increase requirements, but the evidence is conflicting. Individuals with inborn metabolic errors leading to dicarboxylic-aciduria and associated clinical abnormalities may have a functional deficiency. Some drugs affect riboflavin status indices, but their need for riboflavin supplements is uncertain.

## Requirements

As for all micronutrients, the evidence on which requirement estimates are based can be subdivided into the following broad classes of criteria:

1. Prevention of clinical (pathological) deficiency.
2. Attainment of specified blood levels or tissue stores of riboflavin.
3. Titration to the urinary excretion threshold.
4. Tests based on cofactor saturation of one or more accessible, diet-sensitive, flavin-dependent enzymes, such as erythrocyte glutathione reductase.
5. Optimization of riboflavin-dependent physiological functions.

Of these five classes of criteria, the first has been useful in defining “minimum” requirements, but as a practical test of status, it has several drawbacks. Clinical signs of deficiency in human communities tend to be nonspecific and multifactorial and signs such as angular stomatitis and cheilosis do not always correlate closely with, or respond rapidly to, changes in dietary riboflavin supply or biochemical evidence of deficiency. Factors such as local infection are also likely to be critical.

The use of physiological functional indices in relation to riboflavin deficiency (analogous to dark adaptation for vitamin A; clotting factors for vitamin K, etc.) has not proved possible, because the analogous riboflavin-sensitive physiological processes are insufficiently specific for use in population studies. Of the biochemical indices, urinary excretion and reactivation of erythrocyte glutathione reductase are the most favored for human studies.

In the US, the current recommended dietary allowances (RDAs) are 1.3 mg day<sup>-1</sup> for men and 1.1 mg day<sup>-1</sup> for women, increasing to 1.4 mg day<sup>-1</sup> in pregnancy and 1.6 mg day<sup>-1</sup> in lactation, with proportional amounts, based on metabolic body weights and growth requirements, for children and adolescents. RDAs are set 20% higher than the estimated average requirement (EAR) for each group (Institute of Medicine, 2006).

According to the European Food Safety Authority (EFSA), new scientific data have become available for adults since the publication of the Scientific Committee for Food (SCF) report in 1993, and therefore updated average requirements (ARs) and population reference intake (PRIs) can be set for adults, children, pregnant and lactating women (European Food Safety Authority, 2017). For adults, EFSA considers that an AR of 1.3 mg day<sup>-1</sup> (after rounding) can be determined from the weighted mean of riboflavin

intake associated with the inflection point in the mean urinary riboflavin excretion curve in relation to riboflavin intake as reported in four intervention studies in different nonEuropean Union (EU) countries. The EFSA considers that the potential effect of physical activity and of MTHFR 677TT genotype on riboflavin requirement is covered by the data presented from the studies considered, thus is accounted for in the assumed the coefficient of variation (CV) applied to set the PRI for riboflavin. A CV of 10% was used to calculate PRIs from the ARs for adults, i.e.,  $1.6 \text{ mg day}^{-1}$  after rounding, and the same CV was used for all other population groups. EFSA considers that there is no indication of different riboflavin requirement according to sex or between younger and older adults, and sets the same DRV for men and women (without correction per difference in body weight) of all ages. For all infants aged 7–11 months, in the absence of sufficient data to set an AR, the EFSA sets an AI of  $0.4 \text{ mg day}^{-1}$  based on the estimated intake of riboflavin of exclusively breastfed infants from birth to six months, and upward extrapolation by allometric scaling (on the assumption that riboflavin requirement is related to metabolically active body mass), taking into account the difference in reference body weight.

For children aged 1–17 years, EFSA sets ARs by downward extrapolation from the AR of adults, by allometric scaling (on the assumption that riboflavin requirement is related to metabolically active body mass), applying growth factors and taking into account the differences in reference body weight. EFSA considers unnecessary to set sex-specific ARs and PRIs for boys and girls of all ages. EFSA sets ARs ranging from 0.5 (children aged 1–3 years) to  $1.4 \text{ mg day}^{-1}$  (children aged 15–17 years) and PRIs ranging from 0.6 (children aged 1–3 years) to  $1.6 \text{ mg day}^{-1}$  (children aged 15–17 years). For pregnant women, EFSA considers that data are insufficient to estimate the additional needs for dietary riboflavin during pregnancy based on fetal uptake and riboflavin accretion in the placenta during pregnancy. EFSA sets an AR of  $1.5 \text{ mg day}^{-1}$ , calculated by allometric scaling from the AR for nonpregnant women, considering the mean gestational increase in body weight of 12 kg, and also sets a PRI of  $1.9 \text{ mg day}^{-1}$ . For lactating women, an additional riboflavin requirement of  $0.31 \text{ mg day}^{-1}$  is calculated considering the secretion of riboflavin into milk during lactation ( $0.291 \text{ mg day}^{-1}$ ), the mean milk transfer during the first six months of lactation in exclusively breastfeeding women ( $0.8 \text{ L day}^{-1}$ ), and an absorption efficiency of 95%. An AR of  $1.7 \text{ mg day}^{-1}$  is calculated by EFSA, considering the additional requirement above the AR of non-lactating women, and a PRI of  $2 \text{ mg day}^{-1}$  is set for lactating women. Based on data from 13 surveys in nine countries of the EU, riboflavin intake mean estimates ranged across countries from 0.6 to  $1.2 \text{ mg day}^{-1}$  in infants (<1 year), from 0.9 to  $1.4 \text{ mg day}^{-1}$  in children aged 1 to <3 years, from 1 to  $1.8 \text{ mg day}^{-1}$  in children aged 3 to <10 years, and from 1.2 to  $2.2 \text{ mg day}^{-1}$  in children aged 10 to <18 years. Riboflavin intake mean estimates ranged between 1.4 and  $2.2 \text{ mg day}^{-1}$  in adults.

## Dietary sources and high intakes

**Table 2** lists the riboflavin contents of some commonly consumed foods in Western countries. As is the case with most other B vitamins, the richest food sources comprise items such as offal and yeast extract, with meat and dairy products such as milk also providing generous amounts (In the UK, milk intake by children and young adults has tended to decline in recent decades, being affected by changes in government policy on provision of free milk to school children, and by the increasing popularity of manufactured soft drinks). Fruit and vegetables provide modest amounts of riboflavin, and ungerminated grains and seeds, such as nuts, are relatively poor sources. There is an enormous difference in intakes and in status observed between most Western countries, on the one hand, where the dietary intake tends to be relatively generous, and many developing countries, on the other, where the common staples tend to be riboflavin-poor foods such as polished rice. Although riboflavin deficiency is not as life threatening

**Table 2** Riboflavin content of selected foods.

<i>Food</i>	<i>mg per 100 g fresh wt</i>
<b>Meat, offal, and fish</b>	
Stewed minced beef	0.06
Grilled pork chop	0.18
Calf liver, fried	2.89
Lamb's kidney, fried	3.10
Cod, grilled	0.10
<b>Dairy products</b>	
Cows' milk, full cream	0.23
Cheese, cheddar	0.39
Yogurt (whole milk, plain)	0.27
Boiled chicken's egg	0.47
Human milk	0.03
<b>Fruits</b>	
Apples, eating flesh and skin	0.04
Oranges, flesh	0.03
Pears, flesh and skin	0.04

<b>Grains, grain products, nuts</b>	
White bread	0.07
Wholemeal bread	0.05
Rice, boiled, white	Trace
Cornflakes (kellogg)	1.3
Baked beans in tomato sauce	0.03
Peanuts, plain	0.10
<b>Other</b>	
Marmite (yeast hydrolysate)	11.9
Bovril (beef hydrolysate)	8.5

Compiled from data in the McCance and Widdowson's composition of foods integrated dataset, 2021. Public Health England. (<https://www.gov.uk/government/publications/composition-of-foods-integrated-dataset-covid>).

as some other types of malnutrition that are commonly encountered in the Third World, it can nevertheless cause debility, through skin lesions and metabolic dysfunctions. Therefore, optimization of riboflavin nutrition deserves a place in public health improvement programs.

As with most other B vitamins, riboflavin and its cofactors are remarkably nontoxic even at high intakes. The reasons for this are probably the upper limit on absorption and very rapid urinary excretion of any absorbed vitamin that exceeds cellular requirements. Some recent studies have suggested that high-dose riboflavin may benefit certain medical conditions, such as migraines, lactic acidoses, myopathies, and Leigh disease.

## Conclusions

Riboflavin plays a fundamental role in the metabolism of carbohydrates, lipids and amino acids through the formation of the coenzymes flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). These coenzymes are intimately linked to the corresponding enzymes (flavoenzymes) that catalyze oxidation-reduction reactions. Therefore, these enzymes are also part of the cellular antioxidant defense. Although the coenzyme derivatives of riboflavin are not directly involved in cell proliferation phenomena, their fundamental importance in metabolism may explain why deficiency in this vitamin is particularly evident in tissues with a more rapid cell turnover, such as skin and epithelia.

## Key points

- Selenoproteins are the main mediators of selenium effects
- Newly developed reference values for selenium are based on optimizing selenoprotein P plasma levels
- A plant-based diet provides less selenium which is most pronounced in geographic areas with low soil selenium concentrations
- Both selenium deficiency and excess are resulting in impaired health

## Glossary

**Antioxidants** Antioxidants are molecules which can safely interact with free radicals and terminate the chain reaction, thereby inhibiting the oxidation and damage to cells that may play a role in heart disease, cancer and other diseases

**Kaschin–Beck disease** A selenium-responsive endemic osteoarthropathy with necrosis of joints and epiphyseal plate cartilage

**Keshan disease** An endemic cardiomyopathy responsive to selenium with clinical features of cardiac insufficiency and enlargement, electrocardiographic changes, and fibrosis

**Selenium** Selenium is a trace element with an atomic mass of 78.96, which is an essential nutrient for good health but required only in very small amounts. Selenium is incorporated into selenoproteins, which have a variety of functions including antioxidant, redox and thyroid function regulation

**Selenoproteins** Proteins requiring selenium for functionality and containing the selenoamino acid, selenocysteine, at the active site

**Single nucleotide polymorphisms** A single-nucleotide polymorphism (SNP) is a DNA sequence variation occurring when a single nucleotide—A, T, C, or G—in the genome (or other shared sequence) differs between members of a biological species or paired chromosomes in an individual

## Introduction

Selenium is an essential trace element for humans indicating that it needs to be taken up via the food to maintain body's health. The identification of Keshan and Kaschin–Beck diseases as endemic selenium-responsive conditions, occurring in a central belt of China and areas of Russia and Africa, demonstrated conclusively that selenium is not only an essential element for man but also that deficiencies occur naturally. As it is a trace element, small amounts of selenium are sufficient for supporting growth, fertility, immune response and overall health. If provided at too high dosages, selenium becomes toxic because of its accumulation in the body resulting in selenosis. A large body of research over the past decades has provided information on the metabolism of selenium and its importance to human health, and has led to the establishment of recommended dietary intakes based on amounts required for maximal plasma selenoproteins. But the challenge still is to define the “optimal” selenium supply for humans considering additional factors such as health status, age, and stress and to maintain this supply through a healthy diet. The focus of research has now expanded further to possible benefits of selenium in preventing certain types of cancer and cardiovascular disease (CVD), and for the maintenance of an optimal immune system. In addition, rare diseases attributed to mutations in selenoproteins or the selenoprotein synthesis machinery provide further information on the relevance of selenoproteins in humans which are the main functional units of selenium in the body.

## Functions of selenium

Selenium functions mainly as a constituent of selenoproteins encoded by 25 genes in humans (Kryukov et al., 2003). In addition to selenoproteins, selenium can be bound to selenium-binding proteins which are less well characterized so far and it can be incorporated as selenomethionine instead of methionine to any regular protein. The latter one, however, mainly take place under conditions of a high selenium supply (see “Selenium Toxicity”) (Ferreira et al., 2021).

The selenoproteins have a number of functions but the common denominator is their participation in redox reactions and thus maintenance of redox homeostasis by their antioxidant function (e.g., glutathione peroxidases, thioredoxin reductases). Furthermore, selenoproteins are important for thyroid metabolism (iodothyronine deiodinases), immune and, reproductive function. Selenium is in the active site of all selenoproteins as selenocysteine, which is cotranslationally inserted into proteins through a process described in the Section on “Metabolism and distribution” (Schomburg, 2021).

GPX1 was the first selenoprotein to be characterized, and is now known to belong to a family of enzymes with eight members out of which five contain a selenocysteine in the active center while the others have cysteine instead. All of them catalyze the reduction of hydrogen peroxide and other hydroperoxides. The selenocysteine residue is oxidized by the peroxide forming selenenic acid, which is then reduced back to the selenolate by thiols, in most cases glutathione. The GPX isoenzymes differ mainly in their localization. While GPX1 and GPX4 are rather ubiquitously expressed, GPX2 is specifically located in epithelial cells, and GPX6 is only expressed in the olfactory epithelium. In contrast, GPX3 is an extracellular protein which contributes to the selenium concentration in plasma. GPX1 is one of the most highly responsive selenoproteins to changes in selenium status and deficiency. Its hepatic expression is discussed to serve as an indirect storage of selenium in the body. GPX4, also called phospholipid hydroperoxide GPX differs from the other GPXs in that it can metabolize phospholipid hydroperoxides in cell membranes, and thus may protect biomembranes against oxidation. GPX4 is also specifically involved in regulatory processes such as inhibition of lipoxygenases and ferroptosis. In sperm, GPX4 also can be transformed into a structural protein required for sperm maturation.

There are three distinct thioredoxin reductases in humans (TXNRD1, 2, 3). These are NADPH-dependent flavoprotein oxidoreductases that reduce the disulfide of thioredoxin. They support redox-regulated signaling cascades and cell proliferation and may be involved in spermatogenesis, embryonic development, and other redox-related aspects of health and disease including cancer (Roman et al., 2014).

The three iodothyronine 5′ deiodinases (DIO1, 2, 3) are involved in synthesis and metabolism of thyroid hormones, which regulate most metabolic functions and are essential for growth and development. The deiodinases catalyze the conversion of thyroxine (T<sub>4</sub>) to its active metabolite triiodothyronine (T<sub>3</sub>) and severe selenium deficiency results in an increase in plasma T<sub>4</sub> and a decrease in T<sub>3</sub>. If selenium and iodine are both deficient in a human population, the thyroid deficiency is more severe (and goiters are larger) than if only iodine is lacking, a situation which occurs in some areas of Central Africa (Schomburg and Kohrle, 2008).

SELENOP is the major selenium transport protein in plasma, providing approximately 50% of total plasma selenium. SELENOP is a glycoprotein which is the only selenoprotein that contains multiple selenocysteine residues. One of them is located in the N-terminal domain as part of a thioredoxin-like motif indicating an antioxidant activity. Up to nine additional selenocysteine residues can be found in the C-terminal domain of human SELENOP which interacts with the APOER2 receptor mediating selenium uptake into organs such as brain, testis, placenta, and bone.

The additional selenoproteins can be categorized based on their intracellular localization resulting in a major group of ER-resident selenoproteins (DIO2, SELENOM, T, F, K, S, N) which are involved in proper protein folding, degradation of misfolded proteins or calcium homeostasis. Another way of classifying selenoproteins is based on the localization of their selenocysteine within a thioredoxin-like fold. These selenoproteins (SELENOP, H, M, V, W) are called redoxins (Roman et al., 2014). Further functions of selenoproteins are described in Table 1.

**Table 1** Functions of selenoproteins.

<i>Selenoprotein</i>	<i>Function</i>
Glutathione Peroxidases (GPX)	Reduction of hydroperoxides
Thioredoxin Reductases (TXNRD)	Oxidoreductase activity having NADPH as a cofactor
Iodothyronine 5' deiodinases (DIO)	Production of active thyroid hormone T3, reverse T3 (rT3) and T2
Selenophosphate Synthetase (SEPHS2)	Synthesis of selenophosphate as part of selenoprotein synthesis
SELENOF	Protein folding, redox regulation
SELENOH	Redox-sensitive DNA binding protein
SELENOI	Ethanolamine phosphotransferase, phospholipid synthesis
SELENOK	Degradation of misfolded proteins, protein palmitoylation
SELENOM	Calcium release from the ER
SELENON	Calcium homeostasis, cofactor for ryanodine receptors
SELENOO	Redox regulation in mitochondria
SELENOP	Selenium transport, redox regulation
SELENOR/Methionine Sulfoxide Reductase B1 (MSRB1)/SELENOX	Reduction of methionine R sulfoxides
SELENOS	Degradation of misfolded proteins, immune response
SELENOT	Calcium homeostasis, neuroendocrine function
SELENOV	Male reproduction
SELENOW	Redox regulation in muscle and heart

## Selenium homeostasis

### Nutritional supply of selenium

The main forms of selenium in foods are the selenoamino acids, selenomethionine, and selenocysteine. The inorganic forms selenite and selenate are used as supplements or can be found in the drinking water even though the latter only marginally contributes to the overall selenium supply. Selenate is also localized in plant-derived food.

Selenium is not essential for plants, but it is normally taken up and substituted in place of sulfur depending on the selenium concentration of the soil. Thus, dietary intake of selenium via plant-derived food varies greatly with geographic source of foods e.g., the selenium content of cereals and grains grown in soils poor or rich in selenium may vary 100-fold. Brazil nuts are an exceptionally good plant-based sources of selenium (concentrations up to 300 µg selenium per g) because they only grow in the Amazon region in South America which has high selenium soil contents. Some vegetables, such as garlic, mushrooms, and cabbage, can tolerate high selenium soil concentrations better than other plants and thus can accumulate selenium from soil if there are high concentrations. Therefore, these selenium accumulating plants may contain high levels of selenium that are stored as many different selenocompounds, the most prominent ones are selenomethyl selenocysteine and  $\gamma$ -glutamyl selenomethyl selenocysteine. Synthesis of these non-proteinogenic selenocompounds is the plant's attempt to cope with high selenium concentrations and to avoid selenium toxicity which is driven by selenomethionine that is overtly incorporated into proteins instead of methionine.

Selenomethionine is not only present in plant but also in animal foods while selenocysteine is mainly located in animal foods as part of selenoproteins. As most livestock are substituted with selenium (at least in Europe) to fulfill their selenium requirement the selenium supply via animal-derived food items is rather stable and less variable depending on the geographic origin of food production. Rich animal sources of selenium include meat, liver, shellfish, and some other types of fish. Thus, vegetarians and especially vegans take up lower total selenium amounts but a broader variety of selenocompounds as compared to people consuming omnivorous diets. Average daily intakes of selenium range from 10 µg in low-selenium areas of China, to medium intakes in New Zealand or Europe of 40–50 µg to over 200 µg or more in seleniferous areas in Venezuela and parts of the USA (Ferreira et al., 2021).

### Intestinal absorption and bioavailability

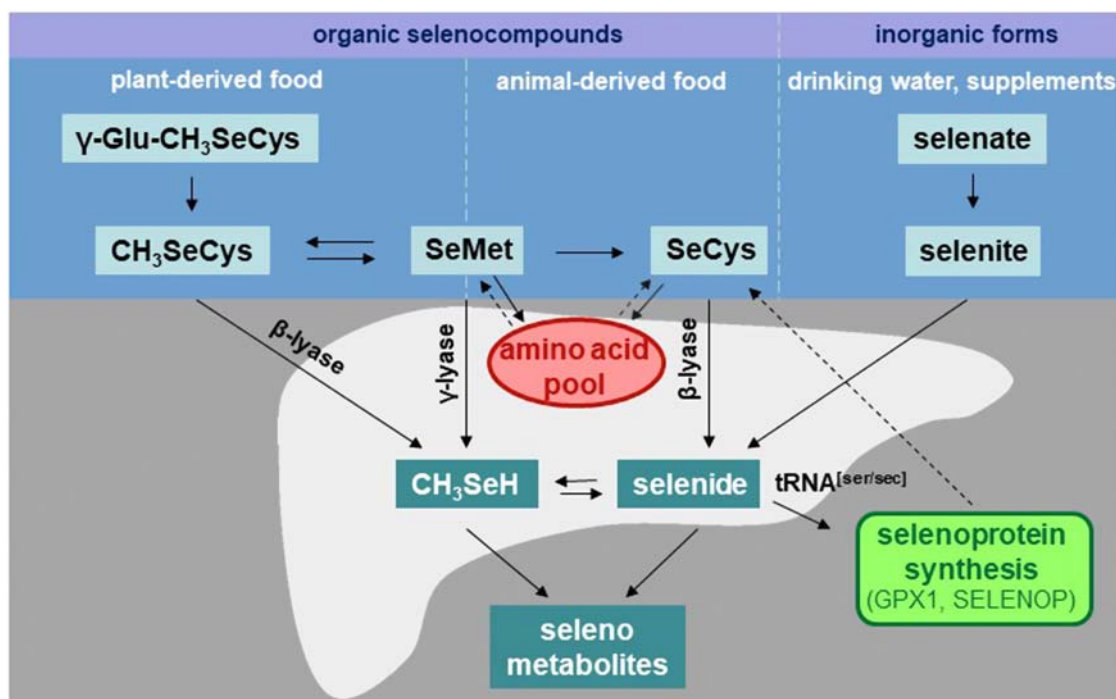

Selenium is readily absorbed, especially in the small intestine. Selenoamino acids are almost completely taken up by enterocytes (70–90%) in a sodium-dependent, active manner using the methionine transporter in case of selenomethionine and the cysteine transporter for selenocysteine. Selenate is supposed to be absorbed using the solute carrier 26 (SLC26) family of multifunctional anion exchangers or via a paracellular path. Absorption efficiency for selenite is lower and mechanisms are less clear but it might be enhanced by binding to glutathione in the intestinal lumen. Intestinal absorption does not depend on the selenium status, indicating that there is no homeostatic regulation at this stage. In addition, selenium bioavailability is influenced by the amount of protein, fat, and heavy metals in the diet. Many bacteria also have a requirement for selenium including those of the intestinal microbiota. If there is enough selenium taken up by the diet bacteria contribute to the metabolism of selenocompounds which reach the lower gastrointestinal tract. However, under limited selenium supply bacteria and host appear to compete with each other resulting in lower availability of selenium for the host (Ferreira et al., 2021).

## Metabolism and distribution

Fig. 1 summarizes the main pathways of interconversion of selenocompounds in mammalian tissues with a focus on liver which is the main organ for selenium homeostasis. Unlike other elements, selenium can be incorporated in two distinct ways into proteins, either as a functional active center (in specific selenoproteins) via a selective incorporation mechanism that ensures selenocysteine insertion, or alternatively by a nonspecific incorporation pathway. In this nonspecific pathway, selenomethionine (or selenocysteine) can enter the general amino acid pool and replace methionine (or cysteine) at random, without apparently conferring any special functional characteristics on recipient proteins. This is followed by a gradual release of selenium upon degradation of these proteins to again enrich the specific incorporation pathway. Inorganic selenium, in contrast, feeds directly into the specific incorporation pathway via selenide. As a result, the form administered also influences levels in tissues and retention of selenium. Thus, selenomethionine is on the one hand more effective in raising blood selenium levels than selenite or selenate but on the other hand is supposed to mediate selenium toxicity at high concentrations.

Both inorganic and organic forms of selenium are transformed to selenide, the precursor of selenophosphate which is used for selenocysteine synthesis to be inserted at the active site of selenoproteins. Selenite and selenate are reduced to selenide, organic selenocysteine is directly lyzed to selenide, and selenomethionine is transformed to selenocysteine and then lyzed to selenide. As an alternative route, selenomethionine can be degraded to methyl selenol ( $\text{CH}_3\text{SeH}$ ) by  $\gamma$ -lyase which is further metabolized to selenide. Selenide (-2 oxidation state) is converted to selenophosphate by the selenoprotein selenophosphate synthetase 2 (SPHS2) which is the main precursor for selenocysteine synthesis. In fact, the amino acid selenocysteine is the only amino acid that does not have its own tRNA synthetase. Instead, this amino acid is synthesized on its cognate tRNA in a three step process. First, the  $\text{tRNA}^{\text{Ser/Sec}}$  is loaded with serine which becomes phosphorylated. In the third step of the process, the synthesis of selenocysteinyl- $\text{tRNA}^{\text{Ser/Sec}}$  is catalyzed by selenocysteine synthase (SEPSECS).

The selenocysteinyl residue is then incorporated into selenoproteins by the UGA codon, which has the dual function of selenocysteine insertion and termination of protein synthesis. An RNA stem-loop structure, designated the selenocysteine insertion sequence (SECIS) element in the 3' untranslated region of eukaryotic mRNAs, directs incorporation of selenocysteine into proteins by stabilizing the ribosome and selenoprotein mRNAs. Additional factors including the SECIS binding protein 2 (SECISBP2) are needed to support these processes. The turnover of selenoproteins results in the release of selenocysteine which is again degraded to selenide by selenocysteine  $\beta$ -lyase. In the liver, the highest expression levels are observed for the selenoproteins SELENOP and GPX1. While SELENOP ensures the selenium transport from the liver to other organs, high GPX1 levels within the liver might serve as an indirect selenium storage which can be immediately released upon limited selenium supply.

**Fig. 1** Ingested selenocompounds and metabolic pathway in human liver. SeMet, selenomethionine; SeCys, selenocysteine;  $\text{H}_2\text{Se}$ , hydrogen selenide;  $\text{CH}_3\text{SeCys}$ , selenomethyl selenocysteine;  $\gamma\text{-Glu-CH}_3\text{SeCys}$ ,  $\gamma$ -glutamyl selenomethyl selenocysteine;  $\text{CH}_3\text{SeH}$ , methyl selenol.

Selenoprotein synthesis is regulated by the selenium supply and there is a hierarchy of expression of individual selenoproteins and of retention of selenium in different organs and tissues. The organ-specific hierarchy under selenium deficiency mostly depends on the APOER2-mediated uptake of SELENOP from the blood maintaining e.g., brain selenium levels at the expense of other organs. Selenium crosses the placenta readily, and breast milk selenium concentration is responsive to changes in maternal selenium intake. The liver is supposed to react most sensitive toward a limited selenium supply with a drop of selenoprotein expression, especially GPX1. Nonspecific incorporation of selenomethionine into proteins contributes to tissue selenium levels but is not immediately available for synthesis of selenoproteins until protein is catabolized. Selenium levels in tissues are influenced by dietary intake, as reflected in the wide variation in blood selenium concentrations of residents of countries with differing soil selenium levels (Hong and Diamond, 2020; Roman et al., 2014).

## Excretion

Urine is the main route of selenium excretion, and is thus very important for selenium homeostasis. The major urinary metabolites are selenosugars (e.g., 1  $\beta$ -methyl seleno-*N*-acetyl-D-galactosamine). Urinary selenium tends to reflect recent intake rather than tissue status. Fecal selenium is mainly unabsorbed selenium. Excess selenium is methylated mainly to trimethylselenonium ion and is excreted via the urine. In addition, volatile dimethylselenide is formed which is excreted in expired air. Urinary trimethylselenonium may be used as a biological marker for excessive selenium doses (Hong and Diamond, 2020).

## Selenium requirement

### Selenium deficiency diseases

Keshan disease, an endemic cardiomyopathy occurring in low-selenium areas of China and Russia, is associated with low selenium intake and low levels of selenium in blood and hair, and affects mainly children and women of childbearing age. The main clinical features of Keshan disease are cardiac insufficiency and enlargement, electrocardiographic changes, and fibrosis. In 1979 Keshan disease was reported to be responsive to supplementation with sodium selenite and was initially thought to be a simple selenium deficiency. However, some features of Keshan disease (e.g., seasonal variation) cannot be explained solely by very low selenium status. Involvement of a viral factor is likely, as a strain of a Coxsackie B virus has been isolated from infected individuals. This hypothesis is strengthened by the demonstration that Coxsackie B3 virus, in the presence of selenium deficiency in mice, mutates to a more virulent form that impairs heart function.

Another condition that has been associated with severe selenium deficiency is Kaschin–Beck disease, with clinical features of osteoarthropathy and necrosis of joints and epiphyseal plate cartilage. Kaschin–Beck disease occurs during preadolescent or adolescent years in rural areas of China, Tibet, and Siberia. However, other factors such as iodine deficiency or presence of mycotoxins may be more important than selenium deficiency.

Severe selenium deficiency in combination with inadequate iodine status contributes to the pathogenesis of myxedematous cretinism. Even mild to moderate selenium deficiency appears to be responsible for initiation and progression of autoimmune thyroid disorders.

Selenium deficiency has also been reported in patients on long-term intravenous nutrition, because of previously negligible amounts of selenium in the fluids. Cardiomyopathy, muscle pain, and weakness in these patients are responsive to selenium supplementation, but are not seen in all patients with low selenium status (Hong and Diamond, 2020).

### Mutations and inborn errors of selenoprotein biosynthesis and functions

In 2001, the first selenoprotein human genetic disorder had been described belonging to the group of rare diseases. A congenital rigid spine muscular dystrophy was shown to be caused by mutations in the SELENON gene. Since then, different diseases have been associated to mutations in selenoproteins such as GPX4 and TXNRD1 and 2. Loss of GPX4 results in Sedaghatian disease and those patients die prematurely by cardiorespiratory failure. TXNRD1 mutations cause oxidative stress and concomitant epilepsy. Mutations in TXNRD2 result in different phenotypes, including dilated cardiomyopathy and familial glucocorticoid deficiency.

In addition, mutations in selenoprotein synthesis factors have been identified including SEPSECS, SECISBP2 and TRU-TCA1-1 encoding for tRNA<sup>[Ser/Sec]</sup>. While loss of the two latter ones mainly affects thyroid hormone levels and down-stream target tissues such as bone, inner ear, and muscle, SEPSECS mutations, which result in an overall selenoprotein deficiency, target mainly brain and causes more severe phenotypes. Overall, the current knowledge reveals that comparable organs are affected by mutations of single selenoproteins or factors important for selenoprotein synthesis as described for nutritional selenium deficiency. Accordingly, this strengthens the concept that effects of selenium are mainly mediated by selenoproteins (Fradejas-Villar, 2018).

A growing body of research indicates that next to mutations also single nucleotide polymorphisms (SNPs) in selenoproteins most likely affect their efficiency of selenocysteine incorporation. Thus, SNPs can explain the individual variation of selenoprotein expression in response to selenium consumption, irrespective of the baseline selenium status. In addition, selenoprotein SNPs have been associated with a higher risk of a number of diseases, especially cancer but also autoimmune disease (Schomburg, 2021).

### Assessment of the selenium status

Selenium status can be measured by concentrations in plasma or serum (in the following only plasma will be mentioned meaning both), whole blood or erythrocytes, or in platelets, hair, or nails. Plasma selenium reflects short-term status, erythrocyte concentration is a medium-term index, whereas hair and nail concentrations reflect longer-term status. Urinary excretion of selenium can be used to assess daily dietary intake, estimated as twice the daily excretion.

Furthermore, selenoproteins can be analyzed as functional biomarkers for the selenium status. The GPX enzymatic assay in plasma or erythrocytes is another frequently used approach because of the close relationship between plasma GPX3 or erythrocyte GPX1 activity and selenium concentrations. In situations of severe to marginal deficiency, this is a sensitive and responsive index, however, once a selenium supply is achieved, which results in plasma selenium concentrations above  $80\text{--}90\text{ }\mu\text{g L}^{-1}$ , a plateau of activity is reached that does not respond to further increases in selenium intake. Therefore, if a population exhibits a strong correlation between plasma (or erythrocyte) selenium concentrations and GPX activity, or there is a significant increase in GPX activity after supplementation, this can be taken as evidence of suboptimal selenium status. If there is no correlation or response to supplementation, the population is likely to have adequate selenium intake.

SELENOP accounts for more than 50% of selenium in blood and has been shown to be a reliable marker of selenium status in populations with low-to-moderate selenium status. SELENOP reaches a plateau at higher plasma selenium concentrations of  $100\text{--}120\text{ }\mu\text{g L}^{-1}$ . Thus, it is supposed to cover a wider concentration range than GPX3 and should be preferentially measured as biomarker together with plasma selenium concentrations. However, hepatic SELENOP synthesis is modulated by additional factors besides selenium resulting in decreased expression under conditions of inflammation, hypoxia or a high intake of eicosapentaenoic acid (EPA). Thus, if there is no correlation between plasma selenium and SELENOP in the concentration range of up to  $120\text{ }\mu\text{g L}^{-1}$  the results need to be interpreted with caution. Plasma selenium concentrations above  $120\text{ }\mu\text{g L}^{-1}$  generally do not correlate with SELENOP anymore because of the decline of selenoprotein biosynthesis rates under conditions of an increasing supraphysiological selenium supply. This plateauing effect on circulating selenoproteins is supposed to efficiently protect from over activation of selenoproteins over a wide intake range and increases the excretion of the surplus of selenium (Burk and Hill, 2009; Xia et al., 2010).

Because of different responses of tissues and selenoproteins to deficient, adequate, or high levels of selenium, conclusions drawn from measurement of one selenoprotein may not apply to all biological functions of selenium. It may be necessary to measure several markers of functional selenium status, in particular those that apply to specific problems associated with suboptimal selenium status. To cover increasing selenium concentrations resulting from a supranutritional intake selenium concentrations are most conclusive (Bornhorst et al., 2018).

### Selenium requirements and recommended dietary intakes

The requirement to prevent selenium deficiency is based on comparison of intakes in endemic and nonendemic Keshan disease areas of China. However, dietary reference intakes in most countries are based on an estimate of the intake at which saturation of plasma GPX activity occurs, obtained from studies in China and New Zealand. This estimate indicated a physiological requirement of approximately  $45\text{ }\mu\text{g day}^{-1}$  (Estimated Average Requirement, EAR for USA/Canada), which translated into a recommended dietary allowance (RDA) of  $55\text{ }\mu\text{g day}^{-1}$ . An increment of  $5\text{ }\mu\text{g day}^{-1}$  was added for pregnancy and  $15\text{ }\mu\text{g day}^{-1}$  for lactation. In contrast, the World Health Organization (WHO) recommendations are lower ( $40\text{ }\mu\text{g day}^{-1}$ ) based on the premise that full saturation of GPX is unnecessary and two-thirds saturation is probably adequate (Thomson, 2004).

More recent reference values, however, consider the saturation of plasma SELENOP as adequate selenium status and were based on additional supplementation studies measuring this biomarker (Xia et al., 2010). For example, in Australian/New Zealand and Germany/Austria/Switzerland, this results in a recommended daily intake (RDI) of  $70$  and  $60\text{ }\mu\text{g day}^{-1}$  for males and females, respectively. Preventive aspects were not taken into account for calculating these reference values (Kipp et al., 2015). But the available data also indicate that a plasma selenium concentration of up to  $120\text{ }\mu\text{g L}^{-1}$  which should be achievable by following the RDI may reduce the risk of cancer and CVD while a further increase has no additional protective effect (see sections on “Cancer” and “CVD”).

### Selenium toxicity

Toxicity of selenium or selenosis may occur from consuming high-selenium foods grown in seleniferous areas in Venezuela, Colombia, northern USA and Enshi county in China or from uncontrolled usage of supplements. Loss of hair and nails is the most common sign of poisoning, and changes in hair and nails are currently the only diagnostic technique for selenium toxicity. Other overt signs of selenosis include skin damage, mottling of teeth, nerve lesions, nausea, weakness, and diarrhea. Garlic odor on the breath from breathing out dimethylselenide also indicates excessive selenium exposure. Effects of selenium toxicity are seen at chronic daily dietary intakes of above  $900\text{ }\mu\text{g}$ . The upper safe limit of dietary intake (UL) was set at  $400\text{ }\mu\text{g day}^{-1}$  by the US/Canadian, Australian/New Zealand and FAO/WHO committees, based on a no-adverse-effect-level of  $800\text{ }\mu\text{g day}^{-1}$  divided by an uncertainty (i.e., safety) factor of 2. The European Food Safety Authority (EFSA) defines a tolerable upper limit for the daily selenium intake of  $300\text{ }\mu\text{g}$ . Toxic effects are supposed to be mediated by selenomethionine getting randomly incorporated into proteins and disturbing their proper folding and function (Schomburg, 2021).

## Selenium and human health

### Immune function

Selenium is important for optimal function of both innate and acquired immune systems, and is involved in defense against bacterial and viral infections. The underlying mechanisms are likely to be related to specific selenoproteins such as SELENOS (Table 1) and antioxidant selenoproteins such as GPXs and TXNRDs modulating redox signaling pathways. Accordingly, they are mediating cytokine production with subsequent effects on activation, proliferation, and differentiation of immune cell types such as T cells or natural killer cells. A low selenium status is often observed during acute and chronic infections acting as a vicious cycle to further impair the immune response, a situation also recently described during the COVID-19 pandemic. Under conditions of sepsis, the decline of the selenium status is a mortality risk factor for patients. In HIV-infected individuals, progression to AIDS and decline in T helper (CD4) cell counts are accompanied by a parallel decrease in blood selenium levels. Selenium deficiency appears to increase the probability of mortality in HIV-infected subjects. Selenium supplements can improve several indices of immune function, even in individuals whose selenium status is not severely deficient. This includes stronger vaccine responses and a robust immunity to pathogens.

Studies in mice infected with strains of Coxsackie virus B3 showed that selenium deficiency results in changes in the viral genome which makes them more potent to induce heart lesions. This is relevant to the etiology of Keshan disease, which has been attributed in part to a viral factor. Selenium deficiency also causes mutational changes in another RNA virus, influenza A, and in the protozoan parasites *Trypanosoma cruzi* and *Heligmosomoides polyurus*, enhancing the intensity of infection (Avery and Hoffmann, 2018; Beck et al., 2003).

### Cancer

A considerable body of evidence suggests a possible link between increased selenium intakes or status and protection against certain cancers. *In vitro* and animal studies provide evidence for a role of antioxidant selenoproteins to protect from oxidative DNA damage and accordingly to have anticarcinogenic properties during tumor initiation. Evidence from prospective studies investigating the link between low selenium status and increased incidence of cancer at various sites is still weak due to the partially poor quality of the available studies. However, the analysis of samples from the EPIC cohort, conducted in Europe, clearly revealed that low plasma selenium as well as low SELENOP levels were strongly associated with an increased risk to develop colorectal and hepatobiliary cancer. This correlation is less pronounced in areas with higher selenium intake than in Europe. This indicates that selenium plays a role in the primary prevention of cancer development but obviously there is a threshold for this protective effect.

Indeed, intervention studies such as the NPC (Nutritional Prevention of Cancer Trial) und SELECT (Selenium and Vitamin E Cancer Prevention Trial) show that increasing the systemic selenium status up to  $120 \mu\text{g L}^{-1}$  plasma lowers the risk to develop cancer. Above this border, as indicated by the tertile of participants with the highest initial selenium status, no further protective effects of selenium supplementation could be detected. As the selenium concentration is in the same concentration range as the one needed to optimize SELENOP levels most probably selenoproteins are mainly mediating the anticarcinogenic effects of selenium. Besides this, a direct anticarcinogenic function of methylated selenocompounds such as selenomethyl selenocysteine is still discussed.

In contrast to primary prevention of cancer by selenium, the situation appears to be completely different in cancer patients. There is strong evidence that selenium is preferentially taken up by tumor cells and that these cells profit from being well supplied with selenium because higher selenoprotein levels (e.g., GPX2, TXNRD1, SELENOP) support tumor growth and protect from apoptosis. Indeed, high expression levels of individual selenoproteins within the tumor can predict a shorter survival probability of the patient. Further studies are needed to better understand the function of selenoproteins and their response to the selenium supply during different phases of tumor development. Based on this, recommendations for the selenium intake of cancer patients should be deduced.

Very high supraphysiological selenium concentrations way beyond those needed to modulate selenoprotein expression are studied to specifically kill tumor cells as part of a therapeutic approach. Under these conditions, selenite is supposed to accumulate within tumor cells resulting in a massive oxidative stress to induce tumor cell death. But this pharmacological selenite intervention is far away from any nutrition-related modulation (Kipp, 2020; Rayman, 2012).

### Cardiovascular disease

Selenium deficiency results in Keshan disease which is a cardiomyopathy but has also been correlated with an increased risk for heart failure and myocardial infarction. Also, a moderate inverse relationship between plasma selenium and coronary heart disease was demonstrated in several meta-analyses of observational studies. However, attempts to demonstrate a reduction of CVD by selenium intervention have proven disappointing. Clinical trials show no evidence of an effect of selenium supplementation on cardiovascular protection in populations with adequate selenium status. Confirmation of this came from the SELECT trial in which selenium had no beneficial effects on atherosclerosis progression. In contrast, individual selenoproteins appear to be of relevance. For example, low activity of GPX1 in erythrocytes was shown to be a predictor of cardiovascular events in patients with coronary artery disease. GPXs protect against processes relevant to atherosclerosis such as inhibition of LDL oxidation, inhibition of

proatherogenic 15-lipoxygenase, and alteration of expression of adhesion molecules induced by cytokines. Further controlled intervention trials considering modulation of selenoprotein expression are needed to clarify this situation (Shimada et al., 2021; Zhang et al., 2018).

## Conclusion

The essential role of selenium in human nutrition and its discrete biochemical functions are of no doubt. Although the number of selenoproteins in the human body is now finite, the extent and diversity of their functions needs to be discovered further. Accordingly, their relationship to known consequences of selenium deficiency or to chronic disease is being clarified. This is being accelerated by genomics research, which indicates that SNPs in selenoproteins may influence susceptibility to the etiology of many diseases. Optimal human intakes of selenium are still a matter of debate because some studies have reported benefits (e.g., anticarcinogenic and immunological effects) when supplements are given, even to populations that appear to be generously supplied with the nutrient, whereas others have identified adverse effects. The distinction between nutritional and pharmacological benefits is unclear, and further trials to determine risk–benefit balance at different intake levels are needed in a range of populations considering age and gender groups. As selenium is only one micronutrient of human nutrition taken up as part of a very complex mixture of a multitude of components interactions with other nutrients and food components need to be taken into account. There appear to be interactions with other essential trace elements such as copper and zinc which are currently under investigation.

## Introduction

Acting as the osmotic skeleton of extracellular fluid, sodium is the most important cation with key roles in solute transport, membrane excitability and stability of cell volume. Sodium is the major determinant of extracellular volume (ECV), arterial blood pressure and thus organ perfusion in the body.

The mean body content of sodium in the adult male is 90–100 g or approximately 4200 mmol (Edelman and Leibman, 1959). 40% of Na<sup>+</sup> is located in the extracellular fluid (10% in plasma and 30% in interstitial fluid). The main tissues that serve as Na<sup>+</sup> storage are bone and cartilage, muscle and connective tissue and skin (Bie, 2018). The extracellular Na<sup>+</sup>-concentration is 135–145 mmol/L under physiological conditions, while the intracellular Na concentration is ~10 mmol/L. The large difference in Na<sup>+</sup> concentration between inside and outside of the cell is established and maintained by the Na<sup>+</sup>/K<sup>+</sup> pump (Na<sup>+</sup>/K<sup>+</sup>-ATPase), which pumps Na<sup>+</sup> out and K<sup>+</sup> into the cell. The resulting gradient poses the base for the creation of a membrane potential, which

allows for essential activities like neural conduction and myocyte contraction. In addition, the sodium gradient is crucial for secondary active transport processes across membranes.

Having such central roles, it is crucial that the  $\text{Na}^+$  concentration in the extracellular and intracellular volume (ICV) remains stable. This is achieved by a sophisticated regulation, that allows to maintain  $\text{Na}^+$  balance, even at quite wide ranges of  $\text{Na}^+$  intake: from 0.03 to 6 mmol/kg/day (Oliver et al., 1975). The fine regulation is only in minimal part regulated by limiting the absorption of  $\text{Na}^+$  in the intestine and mainly mediated by  $\text{Na}^+$  reabsorption/excretion in the kidneys. Under physiologic conditions, the kidneys excrete >95% of the ingested sodium.  $\text{Na}^+$  has such an important role, that evolution has generally favored mutations that limited sodium deficiency. This is why we are prone to absorb large amounts of  $\text{Na}^+$ , which we eventually eliminate. In fact, omnivores, especially humans, dogs, and laboratory rats, routinely have dietary sodium intakes well above their nutritional requirement.

In the present chapter the following aspects will be reviewed: Sodium sources, absorption, storage, its physiological role in maintaining osmolarity and ECV as well as its elimination.

### $\text{Na}^+$ sources, intake and absorption

Due to the essential role of  $\text{Na}^+$  in the vital processes mentioned above, mammals are prone to conserve  $\text{Na}^+$  and eliminate the excesses, only if needed. This is why practically all the ingested  $\text{Na}^+$  gets absorbed. There is no conclusive scientific evidence for an estimated average requirement (EAR) of sodium hence only recommendations for an adequate intake (AI) exist. Sodium requirements increase with increased loss, such as heavy sweating, diarrhea or vomiting, and with increased demand (pregnancy, breastfeeding).

Salt ( $\text{NaCl}$ ) provides the major source of dietary  $\text{Na}^+$ . The average  $\text{NaCl}$  intake in the world is about 10–15 g/day (Powles et al., 2013; McCarron et al., 2013), which is way above the 5 g/day (2g/day of  $\text{Na}$ ) recommended by the World Health Organization (WHO) (World Health O, 2012). The WHO recommendation is based on evidence that an intake above this threshold is associated with an increase in blood pressure and adverse cardiovascular outcomes (Hunter et al., 2022). Various studies reported in part controversial outcomes of salt-intake on cardiovascular mortality. However, the two biggest metanalyses about this subject concluded that increased salt intake is associated with increased cardiovascular morbidity and mortality (Strazzullo et al., 2009; Ma et al., 2022).

Interestingly the main source of  $\text{Na}^+$  in the western diet are additives that are used in order to preserve food, making the individual effort to reduce salt intake difficult (Fig. 1). Population-based approaches might be more effective, as demonstrated in the UK and Finland, where government-based initiatives led to a reduction of salt consumption by 15% and 40%, respectively (He et al., 2014; Laatikainen et al., 2006). However, these kind of efforts are often seen as not cost-effective in the short term and some experts consider salt-reduction to be neither desirable, nor possible (McCarron et al., 2019).

The main sources of  $\text{Na}^+$  in the US are: breads and rolls, pizza, sandwiches, cold cuts and cured meats, soups, savoury snacks (chips, crackers, pop-corn etc), chicken, cheese, eggs and their derivatives (U.S. Department of Agriculture ARS, 2016). Vegetable contains in comparison far less salt, which is why evolutionary mechanisms led to a much more pronounced salt appetite in herbivores compared to carnivores. Some herbivores lick mineral salt in order to compensate the missing  $\text{Na}$ -intake coming from meat and animal products (Denton and Sabine, 1961). Of the five basic tastes: sweet, umami, sour, bitter and salty, the first two are attractive, the third and the fourth are repulsive and the salty taste is the only one which induces a biphasic reaction. It induces an appetitive reaction at concentrations <500 mM and an aversive one at concentrations > 500 mM (Oka et al., 2013). This might be one of the many evolutionary mechanisms protecting against a too low or to high  $\text{Na}^+$ -intake, which, if massive, might lead to emesis and death (Campbell and Train, 2017).

The absorption of  $\text{Na}^+$  takes place mainly in the small intestine and to a smaller extent in the colon. Sodium is absorbed by both passive and secondary active transport. The polarized intestinal cells express transport proteins, which allow movement of  $\text{Na}^+$  from the intestinal lumen into the enterocytes. On the basolateral side, the  $\text{Na}^+/\text{K}^+$ -ATPase (" $\text{Na}^+/\text{K}^+$  pump") actively pumps  $\text{Na}^+$  out of

**Fig. 1** Proportion of sodium intake from different sources in a typical Western diet. Modified from Harnack et al. (2017).

the enterocyte into the interstitium, from where it enters the circulation. This causes a sodium gradient, which drives secondary active transport processes. The main channel and transport molecules in the gut involved with sodium absorption are NHE (sodium/hydrogen exchanger) 3 and 2, SGLT1 (sodium glucose cotransporter 1),  $\text{Na}^+$ /amino acid cotransporters (e.g. Slc6, Slc38)  $\text{Na}^+$ /phosphate cotransporters and ENaC (epithelial sodium channel) in the colon. Parallel to  $\text{Na}^+$  absorption  $\text{H}_2\text{O}$  absorption occurs through a paracellular pathway.

Under normal conditions without significant sweating, total obligatory  $\text{Na}^+$  losses are minute and usually do not exceed eight mmol (0.18g) per day. Obligatory sodium loss occurs via urine ( $\sim 0.2\text{--}1.5$  mmol/d), skin ( $\sim 1.1$  mmol/d) and feces ( $\sim 0.4\text{--}5.4$  mmol/d) (Dahl, 1958).

### Role of the skin
