Ultra-processed foods also appear to increase the risk for type-2 diabetes. NutriNet-Sant  French prospective cohort verified the dietary consumption of more than 100,000 diabetes-free adults over six years (Srou et al., 2020). The risk for developing diabetes went up 13% for a 10%-point increase in the amount of UPF in the diet, even after several adjustments for metabolic comorbidities and diet quality. Recently, in the SUN Spanish cohort study (Llaver -Valero et al., 2021), participants who reported the highest consumption of ultra-processed foods had the highest risk of diabetes (HR: 1.53, 1.06–2.22). The same association has been found in a large-scale prospective study with UK adults (HR: 1.44, 1.04–2.02) (Levy et al., 2020).

### Cancer

A diet based on ultra-processed foods may lead to increased cancer incidence. The NutriNet-Sant  French cohort, researchers discovered that a 10% increase in consumption of ultra-processed foods was associated with a 12% higher risk for cancer in general and an 11% increased risk for breast cancer (Fiolet et al., 2018). Additionally, recent research observed that colorectal cancer was found to increase in proportion to the intake of ultra-processed foods in Spanish adults. Specifically, a 10% increase in the intake of ultra-processed foods and drinks was associated with an 11% increase in the risk of colorectal cancer (Romaguera et al., 2021).

### Mortality and aging

Eating ultra-processed foods may leave people more prone to accelerate biological aging and early death. In the SUN Spanish cohort study, higher consumption of ultra-processed foods, categorized by >4 servings daily, was independently associated with a 62% relatively increased hazard for all cause mortality (Rico-Camp  et al., 2019). Similar results have been found among US (Kim et al., 2019), Italian (Bonaccio et al., 2021) and French (Schnabel et al., 2019) adults. Analyzing the role of ultra-processed foods on DNA damage, a cross-sectional study analyzed the health data of around 900 people aged 55 or older in Spain (Alonso-Pedrero et al., 2020). Participants who consumed three or more servings per day of ultra-processed foods had an 82% chance of having shortened telomeres, a biomarker of an individual's biological age at a cellular level.

### Other diseases and risk factors

A higher intake of UPF has also been tied to increased other diseases and risk factors, such as early childhood caries (de Souza et al., 2021), depression (Zheng et al., 2020), and, frailty syndrome (Sandoval-Insausti et al., 2020). A recent systematic review and meta-analysis for the first time assessed the association between UPF consumption and health status (Pagliai et al., 2021). The pooled analysis confirmed that greater UPF consumption worse cardiometabolic risk profile (increased risk of overweight/obesity, elevated waist circumference, reduced HDL-cholesterol levels and increased risk of the metabolic syndrome), and greater risk of all-cause mortality, cardiovascular disease, cerebrovascular disease and depression. Finally, this section evidences the key role of UPF consumption in the development of chronic diseases.

### Ultra-processed foods and chronic diseases: potential mechanisms of action beyond nutritional quality

As outlined earlier, ultra-processed products are not modified foods, recognizable as such, but formulations of industrial sources of dietary energy and nutrients. While the association between UPF and an unbalanced nutritional composition is of great importance, current evidence suggests that ultra-processed foods may affect health through several complex mechanisms and interactions between many of their compounds and characteristics, which are not yet fully understood.

The high content of fat, salt, sugar, and artificial flavorings make ultra-processed foods hyper-palatable, for which endogenous satiety mechanisms may be altered and are sometimes even quasi-addictive (Schulte et al., 2015). Modifications to the food matrix by processes in the manufacture of ultra-processed foods are key players in health-damaged potential, even compared to minimally or non-ultra-processed foods with similar nutritional composition. The changes in the physical and structural characteristics of the original food can interfere with endogenous processes of satiety and control appetite. Evidence supports that ultra-processed foods are, on average, less satiating are more hyperglycemic than unprocessed or minimally processed foods (Fardet, 2016). The reason would that ultra-processed foods contains less satiating nutrients in their composition, such as fiber and protein, and many of these products are semi-solid or liquid, requiring less chewing, leaving a too short time for the complete stimulation of satiety hormones.

In addition, the consumption of ultra-processed foods can result in pathological eating behavior and may also enable greater energy intake in a shorter amount of time. Indeed, a study based on pooled data from five studies revealed that the average eating rate during the ultra-processed foods diet was two times higher than the unprocessed and minimally processed diet ( $69.4 \pm 3.1$  vs.  $35.5 \pm 4.4$  kcal/min) (Forde et al., 2020).

Ultra-processed foods are designed to be convenient, practical, and portable. Generally, they are developed to be consumed anywhere, any time, while working, in front of the television, walking or driving, or when using cell phones—and frequently do not require plates and cutlery. Most of the time, they are sold as snacks, drinks, or dishes ready-to-consume or heat up. Therefore, they can easily replace freshly made meals based on unprocessed or minimally processed foods. In addition, the portion size of ultra-processed foods, such as “fast foods”, has increased significantly in recent decades (Piernas and Popkin, 2011). Studies have demonstrated that energy intake is directly influenced by the size of the served portion, with larger portions resulting in notable increases in energy intake, which may play a role in weight gain (Steenhuis and Vermeer, 2009).

Other potential mechanisms for the link between ultra-processed diets and diseases may be related to the interaction of chemical foods additives on metabolic alterations on gut microbiota that have been linked to obesity and correlated conditions (Zinöcker and Lindseth, 2018). For example, Chassaing et al. in an experimental study, showed that carboxymethylcellulose and polysorbate-80 (P80), both emulsifiers largely used in ultra-processed foods manufacture, induced low-grade inflammation and obesity/metabolic syndrome in mice (Chassaing et al., 2015). In a recent study, polysorbate-80 (P80) has been shown to reduced microbiota diversity (Furuhashi et al., 2020). Furthermore, accumulating evidence suggests that low-calorie sweetener consumption interferes with the gut microbiota and plays a role in developing insulin resistance (Suez et al., 2014). It is worth note that human data on long term health impacts are still lacking, and potential effects remain largely unknown for most additives.

Regarding the packaging of ultra-processed foods, synthetic compounds like bisphenol A (BPA) are omnipresent in packages. Its exposition has been reported to disrupt several metabolic functions, including enhancing adipocyte cell differentiation (Heindel et al., 2015). A recent systematic review and meta-analysis, including the results of 10 studies, reported that BPA exposure increased the risk of obesity by 11% (Wu et al., 2020).

### Social determinants of ultra-processed foods consumption

The presentation and marketing of ultra-processed foods make these products preferable to unprocessed or minimally processed foods, promoting their overconsumption. Food companies have used many persuasive and aggressive marketing strategies in commercials and food package design to attract consumers' attention and drive their preferences, especially among children and young people (Mallarino et al., 2013). Marketing strategies commonly target at children include cartoon characters, photos of celebrities, bright colors, childish lettering, use of health statements and claims (Giménez et al., 2017; Pulker et al., 2018). These advertisements are intended to build upon children's positive affects toward a brand, and also create sensory and hedonic

expectations, impacting their food choices (Ares and Deliza, 2010; Folkvord et al., 2016). Thus, these mechanisms support that the marketing and the non-interpretation of food labeling increase the likelihood of consuming ultra-processed foods, potentially increasing the risk of obesity.

Strong policies, legislation, and frameworks on regulations of the marketing of ultra-processed foods are essential foundations for support better nutrition. As a model, since 2016, Chile has executed the world's most comprehensive regulatory efforts with actions for increasing people's awareness of unhealthy foods (Corvalán et al., 2019). Briefly, Chilean law of food labeling and advertising is a set of policies, including mandatory front-of-package warning-label system in foods that contain large amounts of critical nutrients (calories, saturated fat, sugar, and sodium) marketing restriction and banned sales of ultra-processed foods in schools. After a short period of the policy's implementation, a consumer survey has identified wide variations on household beverage purchases from before and 18 months after policy implementation (Taillie et al., 2020). Purchases of beverages high-in critical nutrients dropped nearly 24% during the period in Chile and similar reductions were observed across the different education levels of the population.

Lastly, implementing a multi-pronged integrated approach is an effective public strategy for reductions in unhealthy foods consumption. With proved and convincing evidence of the effectiveness of food regulation models, it should become a priority for government officials and civil society groups to define national policies and regulations.

## NOVA in use

In the past decade, the food classification system based on the degree of processing has been increasingly recognized in reports and comments from the Pan American Health Organization (PAHO, 2015) and the UN Food and Agriculture Organization (Monteiro et al., 2019a). The classification has also been used to orient the nutrient profile model developed by the PAHO for the region of the Americas.

In Brazil, the level of food processing was addressed to the official Dietary Guidelines in 2014, which did Brazil pioneering in adopting the NOVA classification for its food recommendations (Brazil, 2014). The main four recommendations and "golden rule" of the Brazilian guidelines are:

1. "Make unprocessed or minimally processed foods the basis of your diet."
2. "Use processed culinary ingredients in small amounts for seasoning and cooking foods and to create culinary preparations."
3. "Limit the use of processed foods, consuming them in small amounts as components of culinary preparations or as part of meals based on natural or minimally processed foods."
4. "Avoid ultra-processed products" **And the golden rule:** "Always prefer natural or minimally processed foods and freshly made dishes and meals to ultra-processed products."

The significance of food processing, more importantly, limiting the consumption of ultra-processed food, is now also adopted in dietary recommendations in several countries, including Uruguay, Ecuador, Peru, Canada, France, and Israel.

## Conclusion

Given that most foods are processed to some extent, the understanding of food processing, as proposed by the NOVA, a classification of foods based on their degree and purpose of industrial food processing, is crucial. There is a clear consistency in the data that the industrial processing in the fourth group of NOVA, the UPF group, is the issue. As ultra-processed products are becoming dominant in the global food supplies, the focus on food and the general quality of the diet instead of isolated nutrients, as proposed by the classification system, can improve the understanding of the role of ultra-processed foods in diet quality, besides providing information to assess and monitor dietary patterns of the population. In addition, with established and clear criteria, NOVA classification can be applied in all countries all over the world.

Perhaps more important than these broad changes in dietary patterns is the impact of ultra-processed foods as a risk factor for chronic non-communicable diseases. It has become clear that the dramatic increase in epidemics of overweight and obesity, type 2 diabetes, and cardiovascular diseases are associated with increased consumption of ultra-processed foods. There is strong evidence provided by several studies that ultra-processed foods may affect health through many biological, social, and environmental mechanisms, beyond the traditionally recognized individual nutrients.

There is an urgent need for double and triple duty actions focused on minimizing the overall consumption of ultra-processed foods and reduce the health risk provided by these products. In order to reduce the consumption of ultra-processed food, this requires the implementation of a set of fiscal policies and regulations of ultra-processed product labeling, promotion, and advertising. Policy makers should consider actions to make unprocessed and minimally processed foods more valued, and more available, and affordable. In the mean time, the solid data leads governments to recommend prioritizing the consumption of unprocessed/minimally processed foods, and avoiding the consumption of UPF in order to promote the public health.

### Key points

- To review current vegetarian eating patterns and practices in Western countries and their health effects.
- To define and describe different vegetarian eating patterns.
- To differentiate between vegetarian eating and vegetarianism.
- To understand nutritional benefits and the key nutrients of concern for followers of vegetarian eating patterns.

### Introduction

Vegetarian eating patterns are the norm in many parts of the world, while in Western countries they are still the exception but are gaining in popularity. This article examines the healthfulness of those vegetarian eating patterns and practices, and their benefits and risks. Vegetarian patterns in other countries, such as India, Southeast Asia and some low-income developing countries, are quite different and are not reviewed here. Currently, approximately 5% of adults in the US and 4% of adults in Canada report that they follow some sort of self-described vegetarian diet, and a far lesser percent claim to eat no animal foods at all. Approximately a fifth of American adults report that they do without animal protein at more than four main meals a week (NHANES, 2009–2010).

**Table 1** describes common vegetarian eating styles in Western countries by use of animal foods. However, those patterns also often differ in many other ways that have nutritional and health implications, and so some of the other differences are noted as well.

### History

Vegetarian diets have been eaten for millennia and continue to be popular for cultural and economic reasons in many parts of the world. In contrast, in Western countries, until 50 years ago, these patterns were uncommon. The vegetarian eating styles tended to be largely among individuals or groups with philosophical, religious or moral motivations for their consumption or among immigrants with vegetarian cultural traditions. The dominant vegetarian eating pattern was lacto-ovo, with avoidance of animal flesh (meat and poultry) at a minimum. In those days, categorization of vegetarian patterns was relatively straightforward and consisted simply of differentiating between those who ate no animal foods at all (vegan vegetarians), those who consumed only milk and milk products (lacto vegetarians), and those who ate eggs as well (lacto-ovo vegetarians). This simple categorization scheme broke down in the 1960s and 1970s when new patterns of vegetarian eating emerged as a result of Westerners' greater exposure to the cuisines of other cultures, the influence of new variants of Eastern religions and philosophical systems with a vegetarian tradition, growing popularity of economic, environmental, and sustainability arguments for eating fewer animal foods, and evidence that some vegetarian eating patterns were associated with decreased risks of certain chronic degenerative diseases. Consumers are

**Table 1** Common types of vegetarian dietary patterns in the western countries categorized by animal food use.

<i>Pattern</i>	<i>Animal food use and other characteristics</i>
Omnivorous	All culturally acceptable and economically available animal foods are consumed with no specific prohibitions on any food group.
Plant-based diet	A plant-based diet is usually defined as an eating pattern that focuses the consumption of foods primarily from plant sources (i.e., fruits, vegetables, nuts, seeds, whole grains, legumes, and beans). Meat, poultry, fish, and dairy products are still consumed but in limited quantities. However, the term is variously defined and thus confusing. According to the US Department of Agriculture's Economic Research Service, 70% of calories in US diets are from plant-based foods, 17% from meat, poultry and fish, and 13% from eggs and dairy.
DASH diet	The Dietary approaches to Stop Hypertension (DASH) diet is a plant-based diet high in low-fat-milk (2–3 servings per day), low in lean meat, poultry, fish (6 oz total per day), eggs, and very limited in red meat. It is high in fruits, vegetables, whole grains, nuts, and legumes, and limited in sugar-sweetened foods and beverages, sodium, added fats, and saturated/trans fats. DASH is one of the recommended eating patterns in the Dietary Guidelines for Americans 2020.
“Flexitarian” diet	“Flexitarian” patterns are plant-based and include meat, dairy, eggs, poultry, and fish/seafood on occasion or only in small quantities. Other food groups are rarely avoided entirely, but specific foods (e.g., those high in “added sugars”, sodium, trans fat, saturated fat, or those considered “processed”, “ultra-processed”, “nonorganic”, or that contain “chemical sounding” or certain specific ingredients etc.) may be avoided by some flexitarians.
Meat avoiding, meatless, or semi-vegetarian	Semi-vegetarians limit or avoid red meat and other flesh foods and may also restrict poultry, fish, and seafood. Diets are similar in most other respects to nonvegetarian diets.
Lacto-ovo vegetarian	Lacto-ovo vegetarians avoid all meat, poultry, and often fish, but milk products (especially low-fat products) and eggs are consumed. Iron, vitamin D, vitamin E, and choline may be limiting but are available from fortified cereals or supplements if those are eaten.
Lacto vegetarian	Lacto-vegetarians avoid all meat, fish, poultry, and eggs. Iron and choline may be low in these patterns.
Macrobiotic	Numerous restrictions include avoidance of all meat, poultry, milk, and eggs, with fish sometimes consumed in small amounts. Sugar, other refined sweeteners, members of the nightshade family (peppers, eggplant, tomatoes, and potatoes), and tropical fruits are avoided on some macrobiotic patterns. Current versions of the diet are possibly less restrictive than those of 40 years ago, but deficiencies of energy, iron, calcium, vitamin B <sub>12</sub> , vitamin D, choline, omega 3 fatty acids and other nutrients may still arise in weanlings, pregnant women, young children, and adolescents during the growth spurt especially if diets are nutritionally unplanned and nutrient containing dietary supplements and fortified foods are avoided.
Vegan	Vegans' avoidances include all animal products including meat, fish, poultry, eggs, and dairy products. Some may also refuse to use animal products (leather, fur, lipstick) in daily life. Without careful planning, energy, vitamins B <sub>12</sub> and D, choline, essential fatty acids, and bioavailable sources of iron and zinc may be low. Concentrated sources of energy-dense foods, such as sugars and fats are helpful for increasing energy intakes. Vitamins B <sub>12</sub> , D and calcium are available in fortified soymilk, fortified cereals, and dietary supplements of these nutrients. Usually, protein is adequate as long as a variety of protein sources is consumed in sufficient amounts.
Vegetarian	The term refers to a range of different dietary patterns, all of which include avoidance of some or all animal foods to varying degrees, with or without additional restrictions, additions, or prohibitions on other foods or ingredients. Depending on their composition, vegetarian diets may be poor sources of protein of high biological value, highly bioavailable iron, vitamins A, D, B <sub>2</sub> , B <sub>6</sub> , and B <sub>12</sub> , zinc, omega-3 fatty acids, choline, calcium, and sometimes iodine.
Vegetarianism	A larger belief system that is reflected not only in the eating pattern but also encompassing many other aspects of lifestyle and thought. Vegetarianism involves philosophy, values, beliefs, or religious convictions rather than simply food choices. Its adherents often hold strong, deeply held convictions about the moral, metaphysical, ethical, religious, or political appropriateness of vegetarian eating.
“Healthy vegetarian diet”	Healthy vegetarian diet is a term that refers to the food pattern recommended in the 2015 and 2020 Dietary Guidelines for Americans. In essence, it is a lacto-ovo vegetarian dietary pattern created by computer modeling using all foods in their most nutrient dense, lean or lower-fat forms, with recipes prepared using a minimal amount of added fats, sugars, refined starch, and sodium. Iron, vitamin D, vitamin E, and choline are somewhat limited but approach the levels suggested in the Recommended Dietary Allowances of the National Academies of Science, Engineering and Medicine.
Whole food	No regulatory definition of “whole food” exists but the term is often used to refer to foods that are minimally processed with no added ingredients, or any food that appears close to its original form.
Other patterns	Raw food eaters and “living food” eaters avoid animal foods and eat raw plant foods (fruits, vegetables, nuts, legumes, and cereals). They may also consume special foods that they believe to be especially healthful, such as wheatgrass or carrot juice. Fruitarians consume diets mostly of fruits, nuts, honey, and olive oil. Rastafarians eat a near-vegan diet and avoid alcohol, salt-preserved foods, and additives. Yogic groups (Transcendental Meditation, Hare Krishna, Bab Ram Das, etc.) vary in their eating patterns but are often lacto vegetarian.

now much better informed and concerned about nutrition than they were years ago. Those who follow vegetarian patterns today have complex and varied rationales that involve food preferences, environmental, economic, sustainability, and health concerns rather than solely religious or ethical reasons for adopting vegetarian eating patterns. Partial or semi-vegetarians often initially adopt a vegetarian diet for health or environmental sustainability reasons and in some instances their commitments then broaden or are augmented by other reasons for sustaining or further restricting their diets. Their eating patterns also include additions and restrictions on other foods and ingredients beyond animal foods alone, making it difficult to easily categorize either motivations or diets from the standpoints of their plant or animal constituents.

Many authoritative bodies now suggest that “plant-based” diets confer a health advantage, although the term “plant based” is rarely defined quantitatively. For example, evidence from large observational studies suggests that plant-based eating patterns rich in vegetables, beans, nuts, whole grains, fish, and plant oils have cardiovascular benefits. The mass media provides much favorable publicity about phytochemicals such as polyphenols, glucosinolates and other non-nutrient phytochemical bioactives in plant foods that supposedly have beneficial health effects on health, but evidence is still limited except for dietary fiber. At the same time, fears and concerns about the healthfulness of animal foods were retriggered in the late 20th century by the presence of an outbreak of bovine spongiform encephalopathy (BSE) in the United Kingdom and Europe, epidemics of hoof and mouth disease in cattle, and more recently severe acute respiratory syndrome (SARS), swine influenza, and today the COVID 19 epidemic that originated in animals and spread to people. Massive outbreaks of animal food borne illnesses, such as Salmonellosis caused by contamination of shell eggs and others, such as listeriosis, campylobacteriosis and *Escherichia coli* O157:H7 infections also stoke consumer concerns about animal foods (Richardson et al., 2021). What often goes unrecognized today is that many food borne illnesses including those caused by Salmonella, *E. coli*, Listeria and many viral illnesses can be contacted through contamination and failure to wash and store raw fruits and vegetables, as recent outbreaks of disease associated with sprouts and other raw foods have shown. Worries are also rife that “Western” diets rich in red meat, milk products, eggs and other animal foods contain saturated fat and cholesterol that increase risks of coronary artery disease, and that other components of animal foods cause certain cancers, type 2 diabetes, and other diseases. Over the past decade there has also been a growing emphasis in the mass media and by governments to pay more attention to environmental sustainability of national and global food supplies, and to the contributions of animal production agriculture to global warming. Such health and environmental concerns have probably also contributed to the increased prevalence of semi vegetarian and vegetarian eating styles. As a result of these influences, not only plant-based, but also meatless and vegetarian eating patterns have grown in popularity. Although “plant-based” diets do not conform strictly to the definition of a vegetarian diet, they are clearly different from usual intake patterns in that the type and amount of animal foods is substantially decreased (especially red meat) (especially red meat) and many who eat them now consider themselves to be “vegetarians”.

## Vegetarian patterns and practices

The term “vegetarian diet” does not fully describe the variety in dietary and nutrient intakes and associated health status of followers of such eating patterns in Western countries. Today, myriad vegetarian eating patterns exist that are not easily described by focusing on a single dimension, such as animal food intake (see Table 1). The impact of these patterns on nutritional status and health requires more complete characterization of diet and other aspects of lifestyle than a simple description of which animal foods are left over to eat after others have been omitted from the diet. It is also important to characterize what other foods are eaten in greater detail if one is to obtain an accurate profile of the diet’s nutrient adequacy. Traditionally, vegetarian diets were poor sources of energy, protein of high biological value, vitamins A, D, B<sub>2</sub>, B<sub>6</sub>, and B<sub>12</sub>, zinc, bioavailable iron, omega-3 fatty acids, choline, calcium, and sometimes iodine. Today a wide variety of plant foods are available year around in most Western countries, along with fortified foods and nutrient containing dietary supplements as well as meat, poultry, milk and egg analogs that can fill these nutrient gaps. However, for a variety of reasons not all vegetarians are willing to use these products, and so risks of inadequacy still remain for some individuals.

## Differences between vegetarian eating and vegetarianism

A vegetarian *eating style or pattern* is often confused with vegetarianism. In the world as a whole, most vegetarians have eating styles that are dictated chiefly by culture, habit, economic, food preferences, health cost, taste and environmental concerns rather than solely moral philosophical, religious, or ethics reasons. A small minority of vegetarians also subscribe to *vegetarianism*, consisting of one of many larger belief systems that are reflected in their eating pattern but that also encompass many other aspects of lifestyle and thought. Vegetarianism involves a variety of philosophies, values, beliefs, or religious convictions rather than simply food choices. Its adherents often hold strong, deeply held convictions about the moral, metaphysical, ethical, religious, or political appropriateness of vegetarian eating. Often those with the most restrictive avoidances of animal and other foods, such as vegans, have the most deeply held views. Advocates of vegetarianism have become more militant in recent years in Western countries. Some adherents, such as some but not all yogic groups, simply hope to enlist additional followers to what they believe is the optimal diet from their ethical, religious, health, and/or environmental standpoints. Those who adhere to the Seventh Day Adventist faith as well as to faiths such as Hinduism, Buddhism, and Jainism often follow vegetarian dietary patterns for religious reasons as well. Hinduism emulates non-violence and the cow is regarded as sacred, and so many Hindus are lacto-vegetarians and if meat is eaten

particular slaughtering methods must be used. Some Jains living in Western countries are vegans and also restrict root vegetables and tubers for religious reasons. The various Buddhist sects vary in their views on vegetarian eating although the religion emphasizes non-violence; some Buddhists are lactovegetarians, others vegan and still others are flexible and consume meat. Other adherents of vegetarianism are more vocal, strident, and occasionally violent advocates who proselytize broader agendas, including animal rights, anti-vivisection, reform of agricultural and animal husbandry practices, and nonuse of experimental animals in addition to health and environmental concerns. In the US these latter groups include People for the Ethical Treatment of Animals (PETA), the PETA foundation, the Animal Liberation Front, and the Physicians' Committee for Responsible Medicine (PCRM). They finance advertising, journal articles, and educational efforts to encourage adoption of their views. Extensive efforts are directed toward youth. Similar groups are also active in other countries.

### Nutritional features of well-planned vegetarian diets

There are four dimensions of food and nutrition security that need to be considered when planning diets. The International Covenant on Economic, Social and Cultural Rights acknowledges having adequate food, and being free from hunger as rights of all human beings. However, adequate nutrition requires a combination of nutrients rather than simply enough food energy. Very few plant-based foods contain all the essential nutrients needed for survival. Therefore, the consumption of a variety of foods is important. Secondly, the cost and affordability of food can impact one's availability to food despite a food item being physically available for purchase. In the development of healthy diet recommendations, nutrition economics must be at the forefront. Third, healthy dietary recommendations need to be culturally accepted. And lastly, it is increasingly viewed as important to take the impact on the environment into consideration (Godfray et al., 2018). All of these desiderata apply to vegetarian as well as other eating patterns (Dwyer and Drewnowski, 2017).

The nutritional benefits of vegetarian diets on health are several. Plant foods are generally nutrient dense without being calorically dense, at least in their unprocessed state. They are good sources of vitamins B, E, C, potassium, magnesium, copper, manganese, dietary fiber, omega 6 polyunsaturated and monounsaturated fat, and complex carbohydrates. They are also rich in plant sterols and several other phytochemicals, such as the flavonoids, lignans, glucosinolates, and isothiocyanates, and possibly also compounds, such as those in curcumin and other spices that some vegetarians use in large amounts. Those bioactives may have beneficial health effects, although as yet there is not compelling evidence that they do. In addition to plant foods providing these potentially beneficial compounds, the foods in vegetarian diets are generally low in saturated and trans-fats and in cholesterol. These are all positive attributes from the health standpoint.

However, there are some limitations. While some plant foods such as legumes are high in protein, others are low or incomplete by themselves and so they need to be combined with each other to fill all the human body's needs for amino acids and nitrogen (Fussell et al., 2021). Although some of the proteins in single plant foods, such as cassava, are "incomplete" (that is, their amino acid profiles alone cannot meet human amino acid needs), combinations of different plant protein sources or small amounts of animal protein with the plant protein foods can complement each other, supply missing amino acids, and meet amino acid and nitrogen needs. Since most vegetarian diets in Western countries contain a number of different plant protein sources and they are usually available in generous amounts, adequacy or quality of protein is rarely a problem even on vegan diets if due care is paid to making wise dietary choices. Potentially some vegetarian diets may fall short in vitamins D, B<sub>12</sub>, zinc, bioavailable iron and zinc, omega 3 fatty acids, choline, and iodine. Vitamin B<sub>12</sub> is bound to proteins in food and is naturally present in foods of animal origin. It is not found in plant foods unless the product is fortified. Breakfast cereals and nutritional yeasts are common foods that are fortified with vitamin B<sub>12</sub>. The bioavailability of vitamin B<sub>12</sub> is dependent on dosage. The vitamin must bind with intrinsic factor, a protein secreted by the stomach, for it to be absorbed. Only a few foods naturally contain vitamin D. Fatty fish such as trout, salmon, tuna, and mackerel, and fish liver oils are the best sources of vitamin D. However, the animal's diet affects the amount of vitamin D that are in their tissues. In the US the milk supply is fortified with vitamin D. In addition to fatty fish, and fortified products, vitamin D can be obtained through sun exposure, especially below approximately 40 degree N latitude where exposure to sunlight is likely to be sufficient to fulfill bodily needs. Similar to vitamin D, the omega-3 fatty acids are found in fish (salmon, mackerel, tuna, sardines, bass, tilapia, cod, trout, shrimp, and lobster) and are in small amounts in beef and chicken. Some omega-3 fatty acids are found in a variety of plant foods and oils (flaxseed oil, chia seeds, walnuts, soybean oil, edamame, kidney beans, eggs, and milk). Zinc is found in a variety of foods; that in plants is not highly bioavailable. Oysters contain more zinc per serving than any other food. Other sources of zinc include beef, crab, lobster, pork and chicken. Zinc is found in whole grains, fortified breakfast cereals, dairy products, baked beans, and some nuts. Choline is an essential nutrient found most commonly in animal foods (i.e., beef, eggs, chicken, and milk). Although it is present as well in small amounts in soybeans, potatoes, wheat germ, and cruciferous vegetables. Iodine is a nutrient that may be lacking in a vegetarian's diet because most fruits and vegetables are poor sources of iodine, and the iodine that they contain depends on the soil, fertilizer, and irrigation practices used. Seaweed and kelp are highly variable in their iodine content. Ocean fish, other seafood, eggs, and iodized table salt are good sources of iodine. Milk is highly variable in iodine; today, with the decline in the use of iodophors in milking equipment, the amounts are much lower in cow milk than they were in the past. However, today it is easy for vegans and vegetarians to obtain nutrients that might otherwise be low or lacking in their diets. A wide variety of plant foods is at their disposal (Kyriakopoulou et al., 2021). There is also widespread availability of various soy, nut and other meat alternatives and meat analogs, and of fortified plant foods, including soy milks (with added vitamins B<sub>12</sub> and D, as well as highly bioavailable calcium), calcium-fortified orange juice, and highly fortified breakfast cereals. Over the past several years, the availability of plant-based products has expanded in major grocery stores, and even the

major fast-food chains offer plant-based burger options. Milk alternatives have also increased and now include almond, soy, oat, pea, and rice milk. Dairy-free yogurts, cheeses, and ice creams are widely available. Meat alternatives now include breakfast sausage, bacon, chicken, hot dogs, burgers, and others. Although these products are easily accessible, some consumers may object to them because they eschew “processed” or “ultra-processed” foods as well as animal foods. Also, it should be noted that the nutrient profiles and costs of these products are often quite different and may not compare favorably to the nutrients in the animal products they substitute for. For example, some of the “plant milks” like soy have similar nutrient profiles to cow milk, while others such as rice milk, are quite different. Dietary supplements offer another alternative for remedying shortfalls in the micronutrients.

Some but not all of the dietary differences between the health of vegetarians and nonvegetarians are due to the types and amounts of essential nutrients in what they eat or avoid. There is less evidence supporting attributing the healthful aspects of vegetarian diets with respect to the bioactive constituents other than the nutrients that the diets contain or lack. For example, vegetarian diets are often claimed to be evolutionarily more in line with dietary patterns of Paleolithic times than are “Western” diets and therefore better suited to human genes. However, very little morphologic, bone, or artifactual evidence is available on the actual diets of early humans (Agouluniket al., 2021; Karlse et al., 2021). Most early hominids died young of infectious or other diseases rather than living into middle and old age when the chronic degenerative diseases so common today occur. What is clear is that the advent of farming and agriculture led to rapid population growth, and at least initially to increase in morbidity and mortality because of crowding, changes in patterns of disease transmission, and many other factors including diet, but not solely due to that.

Another rationale for vegetarian eating is that animal foods, particularly meat, increase risks of many infectious and chronic diseases. This is discussed elsewhere in this article. A third contention is that it is the synergy of foods that are plentiful in vegetarian diets and particularly in fruits and vegetables working together as a “package” (e.g., abundant fruits, vegetables, legumes, nuts, and other plant foods) that confers a special and added health advantage. Generally, Western vegetarian diets eaten today tend to be low in saturated fat and cholesterol and high in polyunsaturated fats, complex carbohydrates, dietary fiber, and contain a variety of plant proteins, which complement each other well and provide a protein mixture of good biological value, along with some animal protein as well as magnesium, potassium, folic acid, and antioxidant nutrients, such as vitamin E and selenium. Compared to common omnivorous patterns, the healthier vegetarian patterns also tend to be relatively low in food energy and relatively high in some of the nonnutritive phytochemical bioactives (phytosterols, flavonoids, and isothiocyanates) that may provide health benefits. Comparisons between a low-fat fast food nonvegetarian diet matched on type of fat, macronutrients, and dietary cholesterol, found that serum low-density lipoprotein (LDL) cholesterol levels were lower among those eating a vegetarian diet, suggesting that other components in the vegetarian diet might also have positive effects on this intermediary marker of coronary heart disease. However, the hypothesis that “food synergy” (e.g., the combined effects of plant foods and constituents working together in the vegetarian pattern) provides very large additional benefits over the health effects of each constituent alone or with other foods requires further verification. Finally, it must be remembered that many vegetarians also differ from nonvegetarians in other ways that may contribute to good health, including leading physically active lives, nonsmoking, and abstinence from alcohol and other illicit drugs.

The Dietary Guidelines for American’s updated its’ Healthy Vegetarian Diet in 2020 to provide an example of a nutritionally adequate lacto-ovo vegetarian eating pattern for those over age 2 years, and it is available at various calorie levels. Even with extensive modeling using foods alone, several nutrients still did not quite meet the Recommended Dietary Allowances (RDA) or adequate intake (AI) for several age and gender groups (iron, vitamins D, E, and choline. Also, the patterns did not consider cultural variation, and assumed that all foods chosen were the most nutrient-dense, lean. Low-fat versions prepared with recipes using minimal added fats, sugars, refined starches, and sodium. These considerations highlight the utility of dietary supplements or fortified foods that fill nutrient gaps and nutritional counseling by a registered dietitian/nutritionist who can personalize diets to eaters without sacrificing dietary adequacy and avoiding excess. **Table 2** provides some strategies that might be considered by vegetarians to prevent inadequacy.

### Morbidity and mortality on vegetarian versus omnivorous diets

Well-planned vegetarian diets have nutritional profiles that are in line with recent expert recommendations. These patterns, if sustained, may reduce diet-related risks of some chronic degenerative diseases (coronary artery disease, hypertension, type 2 diabetes) and obesity associated with caloric excess (Laouli et al., 2021). The differences between vegetarians and omnivores in diet but also in other lifestyle characteristics that affect disease risk play a role in the varied patterns of illness and disease between them. For example, many vegetarians are health conscious, eschew tobacco, alcohol, and recreational drugs, avoid overexposure to the sun, and lead physically active lives, and so risk factors for diseases that are influenced by those factors are decreased. Other less likely differences that may be residual confounders of the differences between them are lesser exposure to second-hand smoke, excessive amounts of food energy and refined sugars along with increased consumption of whole grains, nuts, and legumes that are possibly protective.

In the past few decades, some but not all observational studies have found that vegetarians are healthier or live longer than nonvegetarians. While some of the differences, such as those in lung cancer, are likely due largely to the lesser use of tobacco among vegetarians, other differences favoring lower prevalence of disease may be attributable to the diet itself. Since those dietary factors or other differences between vegetarians and nonvegetarians influence disease risk they, rather than solely the use or nonuse of animal foods, are potentially responsible for some of the positive health effects (Mihirshai et al., 2017; Palacios and Maki, 2019). Therefore, the effects of all these factors need to be accounted for. With respect to morbidity, the mishandling of animal foods during

Nutrient	Dietary strategies	RDA/AI	
		Male	Female
Vitamin B <sub>2</sub> (riboflavin)	Increase consumption of green vegetables such as asparagus, broccoli, and spinach. Eat riboflavin fortified cereals, bread, and grains and whole grain products. Supplements: most multivitamin-mineral supplements, B-complex vitamins, or as a single nutrient.	9–13 years: 0.9 mg 14+ years: 1.3 mg	9–13 years: 0.9 mg 14–18 years: 1.0 mg 19+ years: 1.1 mg
Vitamin B <sub>12</sub> (cobalamin)	Eat B <sub>12</sub> fortified breakfast cereals, nutritional yeasts, and other fortified products. Supplements: most multivitamins-mineral supplements such as B-complex vitamin products contain B <sub>12</sub> , and a single product contain vitamin B <sub>12</sub> higher levels in the form of cyanocobalamin. Other common forms include adenosylcobalamin, methylcobalamin, and hydroxycobalamin.	9–13 years: 1.8 mcg 14+ years: 2.4 mcg	9–13 years: 1.8 mcg 14+ years: 2.4 mcg
Vitamin D	Drink cow milk or plant milks fortified with vitamin D. Increase intake of vitamin D irradiated mushrooms. Consume vitamin D fortified breakfast cereals, orange juice, and milk substitutes. Supplements: most multivitamin-mineral supplements or as a single nutrient vitamin in the form of D <sub>2</sub> (ergocalciferol) and D <sub>3</sub> (cholecalciferol). * Vitamin D is more readily absorbed when consumed with a meal or snack that contains fat.	9–70 years: 15 mcg (600 IU) 70+ years: 20 mcg (800 IU)	9–70 years: 15 mcg (600 IU) 70+ years: 20 mcg (800 IU)
Zinc	Increase consumption of beans and nuts by adding them to meals and salads. Consume whole grains and zinc fortified breakfast cereals. Supplements: Most multivitamin-mineral supplements, combined with calcium, magnesium, or other nutrients, or as a single nutrient vitamin. Forms of zinc found in supplements include zinc gluconate, zinc sulfate, and zinc acetate.	9–13 years: 8 mg 14+ years: 11 mg	9–13 years: 8 mg 14–18 years: 9 mg 19+ years: 8 mg

preparation and storage increases risks of food-borne illness, and historically caused many types of food-borne illness (Salmonellosis, Campylobacter food borne disease, Brucellosis, various worms, and other parasites) posed major risks in animal foods and could be avoided by not eating them. Now that animal food handling and preparation practices are more advanced, the dangers of these diseases have decreased, although continued vigilance is necessary.

Some conditions and disease risks are clearly lower in vegetarians; for example, constipation is less of a problem in vegetarians (especially vegans) than in omnivores, perhaps due to their much higher intakes of dietary fiber and more active lifestyles. Vegetarians and especially vegans generally tend to have lower body mass indices (BMIs) than do nonvegetarians, and consequently they have lower risks of the chronic diseases for which obesity is a risk factor, such as type 2 diabetes. There are now several epidemiological reports of effects of various animal foods, and particularly meat, on type 2 diabetes, although some studies implicate all meats, others only do so for processed meats (World Cancer Research Foundation, 2020; Zeraatkar et al., 2019). Whether meat is still associated with risk when the comparison group consists of healthy and weight conscious nonvegetarians remains to be determined.

Animal foods and especially red and other meats (saturated fats and cholesterol), poultry (unless lean and skinned), eggs, crustaceans like shrimp and lobster (rich in cholesterol), and whole fat dairy products (high in saturated and total fat) have been indicted as increasing risks of coronary artery disease. The foods' ill effects appear to stem primarily from their content of saturated fat, cholesterol, and particularly the high amounts of food energy that they contribute to the diets of eaters and increase risks. Also, meat eaters tend to have low intakes of nuts, fruits and vegetables, plant sterols, dietary fiber, and other dietary components that may contain other bioactives that lessen coronary artery disease risk. Total serum cholesterol and LDL cholesterol tend to be lower. Ischemic and coronary heart disease are often decreased among vegetarians, particularly among vegans compared to carnivores (Key

et al., 2019). Blood pressure and hypertension are also generally somewhat lower among vegetarians, likely due to their lower weights, lesser sodium, higher potassium and perhaps their higher nitrate rich vegetable intakes (Van der Voort et al., 2021).

Excessive food energy, alcohol, and possibly fat pose greater risks of some cancers than do other constituents of Western diets, and vegetarian diets low in the former might have beneficial effects. Cancer morbidity is lower in some vegetarians, such as Seventh-Day Adventists but it is primarily in the smoking and alcohol-related cancers, as might be expected because many vegetarians of that faith also do not use tobacco or drink alcohol. Modest (<10%) protection against some cancers seems to be associated with decreased weight. Western diets contain a great deal more meat than do those in many other parts of the world. The human data are mixed but some substances in certain forms of meat are carcinogenic at least in experimental animals. Processed and red meat have recently been singled out as a risk factor for colon cancer because its composition (often high fat, high saturated fat, high salt, and high in heme iron), preservation methods (forming N nitroso compounds or interacting with heme to form carcinogens), and styles of preparation (such as benzo(a)pyrene, heterocyclic amines and polycyclic aromatic compounds, adducts, and other possible carcinogens produced in meats broiled and fried at high temperatures) may expose eaters to carcinogens or cancer promoters. The World Cancer Research Foundation in 2018 concluded that intakes of red meat should be limited, and processed meat should be avoided based largely on epidemiological evidence (World Cancer Research Foundation, 2018). It suggested that meat, especially preserved and processed meat, had a modest effect on some cancers, particularly colorectal cancers. That conclusion has been criticized and more recent studies are mixed. One very large prospective study of older Americans suggested a modest association between meat intake and mortality while effects on breast cancer were not apparent. Trimethylamine N-oxide (TMAO), a molecule generated from choline, betaine, and carnitine via gut microbial metabolism contains constituents also present in meat. More and better studies are needed to definitively rule out meat, or specific types of meat, as one of the culprits in these cancers. The notion that dairy products and particularly milk contain sufficient estrogens or other cancer promoters continues to be debated, but the human and experimental animal evidence of such effects is weak. There is mixed evidence that osteoporosis and fracture risks are greater in vegans, perhaps due to their low calcium and vitamin D intakes but their more active lifestyles may often compensate for those risks (Thorpe et al., 2021). The associations between animal food intakes and other illnesses, including diverticular disease of the colon, gallbladder disease, and appendicitis are more speculative.

Fewer studies are available on specific and all-cause mortality and longevity among vegetarians. Smoking-related mortality is lower among groups of vegetarians who do not use tobacco, but most of these effects do not appear to be diet related. Obesity-related mortality is also reduced. Once these factors have been accounted for, other differences between vegetarians and nonvegetarians or between vegetarians who differ in the degree to which they restrict animal foods in mortality or longevity are not dramatic.

At present the evidence is insufficient to conclude that well-planned meatless or vegetarian diets have distinct health advantages over well-planned plant-based dietary patterns that include animal foods. Causal inference is difficult in making comparisons between vegetarians and nonvegetarians: residual confounding in diet and the many existing differences between vegetarians and health-conscious omnivores, including education, lifestyles, and many other health related behaviors, cannot all be controlled for in observational studies. However, it is abundantly clear that most Western vegetarians who subsist on well-planned regimens appear to be at least as healthy as their omnivorous counterparts, and that many omnivores eat diets that do not conform to expert recommendations and that contribute to ill health. Whether vegetarians have an advantage over health conscious nonvegetarians is still uncertain, but regardless vegetarians may prefer these patterns for many other reasons.

## Nutritional adequacy

In English-speaking North America, dietary reference intake (DRI) standards that embody what is known about nutrient requirements have been issued by the Food and Nutrition Board of the National Academy of Sciences Engineering and Medicine and Health Canada. Similar but not identical reference standards are available in other Western countries to assess and plan nutritious diets. Nutritional adequacy is defined as meeting nutrient needs, such as the Recommended Dietary Allowances (RDAs) or the adequate intakes, while avoiding excess and staying below the tolerable upper levels of nutrient intakes (UL) and keeping within the acceptable macronutrient distribution ranges (AMDR) specified by expert groups (in the US, fat 20–35%, protein 10–35%, and carbohydrate 45–65% of calories). Most vegetarians have little difficulty in meeting these standards with a little planning.

From the nutritional standpoint the animal food groups (e.g., meat, fish/seafood, poultry/fowl, eggs, milk, and milk products) are generally nutrient-dense foods high in several micronutrients that are low or lacking in plant foods. In traditional vegetarian diets, depending on the particular animal food group under consideration, these nutrients that might fall short included protein of high biological value, highly bioavailable iron, zinc, calcium, vitamins A, D, B<sub>2</sub>, B<sub>6</sub>, and B<sub>12</sub>, choline, omega 3 fatty acids, calcium, and iodine. If animal food groups are entirely eliminated, intakes of these nutrients often become deficient. Today, the widespread availability of special foods fortified with these nutrients and appropriate micronutrient-containing dietary supplements provide options that can help to make up the slack. Although dietary diversity defined as the number of food groups consumed is less among vegetarians, diversity within the remaining food groups (such as fruits, vegetables, nuts, and legumes) is often considerable among vegetarians and with careful choice this may suffice to provide adequate amounts of some of these nutrients. However, when vegetarians use dietary supplements as an option, they must make sure that the nutrients they obtain are those that are low in their diets, rather than employing a “shotgun” approach of a little more of many nutrients, and that the nutrient dose in the product is sufficient to meet nutrient needs. For example, for an older woman, a single glass of calcium-fortified orange juice and a serving of spinach, or a multivitamin-mineral supplement does not contain enough calcium to meet her nutrient needs, and a specific

combined calcium and vitamin D supplement might be more appropriate. Also, many vegetarians prefer food-based solutions and are reluctant to use dietary supplements because the source of the vitamin or the capsule is of animal origin. In some instances, such as among infants who are breastfed for several months with no other source of vitamin D, a dietary supplement of water-miscible vitamin D may be acceptable and it protects the infant from vitamin D deficiency.

Eating patterns appear to be more closely associated with health outcomes than are intakes of nutrients alone, perhaps because of the synergistic effects of nutrients working with each other or because other bioactives, such as phytochemicals, also have health effects. Vegetarians' intakes of bioactives rich in fruits and vegetables, such as the flavonoids, antioxidants, and dietary fiber are often much higher than those of omnivores. If these substances prove to have beneficial effects on health, such increased intakes may be important. However, to date only a few effects have been demonstrated.

From the nutritional standpoint there are some beneficial trade-offs from vegetarians' limited intakes of animal foods. In Western diets, animal foods are the major sources of dietary constituents that are excessive in Western diets, such as calories, fat, saturated and trans-fat, cholesterol, and sodium, and they are low in polyunsaturated fats and dietary fiber. Consumption of fewer animal foods, especially if it leads to lesser intakes of these constituents and greater intakes of other nutrients and bioactives, may have positive effects on overall nutritional status. The beneficial effects of vegetarian eating patterns on nutritional status vary, however, depending on the food group(s) avoided, the degree of limitation, substitutions of other rich food sources, use of fortified foods and dietary supplements containing the lacking nutrients, and other changes in dietary intake or lifestyles that occur at the same time. The nutritional goal in planning a vegetarian diet is to personalize the eating pattern to the individual's preferences and beliefs while maximizing the benefits and minimizing the health risks by a judicious choice of the type and amount of animal foods or other sources of needed nutrients that are acceptable to the eater.

### Adequate vegetarian dietary patterns

Dietary practices among vegetarians are highly variable. Most vegetarians living in Western countries are at little or no risk of dietary inadequacy from their eating patterns and they do not merit special assessment although they may benefit from general dietary advice adopted to their eating preferences. For example, neither a man who regards himself as a semi-vegetarian (also referred to as a meat avoider) because he avoids red meat most of the time nor a lacto-ovo vegetarian woman with no other major dietary avoidances are likely to need further dietary assessment. In contrast, those at risk of, or whoever suffer from a chronic degenerative disease that requires dietary modification often benefit from counseling from a registered dietitian or other health professional with expertise in the dietary modifications needed ([Jardine et al 2021](#)).

Some characteristics of sound and adequate vegetarian diet patterns include the following:

- Limited animal food avoidances, only sporadic avoidances, or abstinence rather than complete animal food avoidance.
- Consumption of a wide variety of animal food groups and a wide variety of foods within each group.
- Use of a nutritionally sound food guide for diet planning; sound vegan, and vegetarian food guides available that ensure that nutrient needs are adequate, balanced, and moderate
- If an individual follows a vegan pattern, or has multiple food avoidances, the regular use of foods fortified with nutrients likely to fall short in the diet and vitamin or mineral supplements in RDA (or Daily Reference Value (DRV or DV) on food labels) amounts to meet nutrient needs plus use of a nutritionally sound food guide
- Membership in a group (such as Seventh Day Adventists) or a family with a long cultural or religious tradition of adherence to healthy vegetarian eating styles and attitudes toward health, and use of fortified foods or micronutrient containing dietary supplements.

### Possibly inadequate vegetarian dietary patterns

For vegetarians who are likely to be at high risk of dietary inadequacy, further and more complete dietary assessment and planning from a nutrition professional may be needed. The entire pattern of intake (including avoidances, substitutions, and additions of foods, and use of dietary supplements) must be examined by the counselor to obtain a full profile of nutrient adequacy or inadequacy. The presence or absence of other lifestyle practices with potentially beneficial health impacts (nonsmoking, abstinence from alcohol, high levels of physical activity) can also have impacts on health. Individual assessment is recommended for those at special risk in nutritionally vulnerable physiological groups [due to age, life stage (pregnancy, lactation, infancy, toddlerhood, pubertal growth spurt), or illness] or because they adhere to very limited patterns [such as avoiding many animal food groups (vegans) and other food groups, or have multiple other food avoidances (e.g., all "processed", "ultra-processed", nonorganic, cooked, or canned foods, "nonwhite" foods, "foods with chemical ingredients" and "non-natural" foods)] so that only "whole", "non-processed", "organic" and "natural" foods are acceptable, further limiting options for planning an acceptable diet.

Characteristics that may indicate inadequate or unbalanced vegetarian diets and the need for further assessment include:

- Entire or very extensive avoidance of animal food groups.
- Refusal to eat fortified plant foods containing micronutrients likely to be low in vegetarian diets or to use micronutrient-containing dietary supplements, or processed foods.
- Refusal to eat "processed" or "nonorganic" foods.

- Frequent fasting, vomiting, purging, or drastically altered diet during illness.
- Lack or avoidance of conventional health and medical care (e.g., prescribed medications, vaccinations, mental, or dental health visits), use of only alternative medical care.
- Nutritional vulnerability due to age or physiological condition (infancy, weaning and toddlerhood, rapid growth, puberty, pregnancy, lactation, chronic illness, or recovery from illness, old age, frailty).
- Low weight for height, body mass index (BMI)  $< 18.5 \text{ kg m}^{-2}$ ,  $> 4\text{--}7 \text{ kg}$  (10–15 lb.) unintentional weight loss, or rapid unintentional weight loss of  $> 5\%$  in a month.
- Deeply held beliefs in alternative philosophical or religious systems that rigidly restrict food choice and prescribe vegetarian diets that fail to meet the DRIs.

### Special nutritional concerns for vegetarians

Of particular concern with respect to risk of inadequacy for vegetarians and especially vegans and others with extreme dietary restrictions are energy, vitamins B<sub>12</sub> and D, riboflavin, omega 3 fatty acids, calcium, iron, zinc, choline, and iodine. Vegetarians of all types can meet current recommendations for these nutrients if they are willing to use nutrient sources in fortified foods (e.g., highly fortified cereals, calcium and vitamin D fortified soy milk or fruit juices, vitamin B<sub>12</sub> fortified yeast, vitamin A fortified margarine) or specific micronutrient supplements containing enough of the micronutrient that is falling short. However, some vegetarians are unwilling to use these options, increasing risks of deficiency, and making dietary planning more difficult. With respect to macronutrients, vegetarian and particularly vegan diets tend to be low in energy, total fat, saturated fat, cholesterol, and sodium. If processed foods are avoided, added sugars are also low but the naturally occurring sources of sugars may still be quite high. Current recommendations for acceptable macronutrient distribution ranges (AMDR) in the US are for fat 20–55% of calories and for protein 10–35% of calories, with added sugars no more than 10% of calories and preferably lower, and the remainder from other carbohydrates.

### Key nutrients for vegetarians over the life cycle

Well-planned vegan and vegetarian diets can meet nutritional needs at all stages of the life cycle including pregnancy, lactation, infancy, childhood, and adolescence (Melina et al., 2016). There are very few longitudinal studies of individuals on the more restrictive vegetarian diets; the notable exception is a Dutch cohort of macrobiotic vegetarians who were followed from birth to adolescence, and who showed very poor growth and continue to have some health problems (Salomé et al., 2019). More studies are needed so that long-lasting effects of diet early in life can be better ascertained.

Some vegetarian parents inadvertently feed their children with diets that are inadequate. The problem is not that nutritionally adequate diets cannot be planned, but that the eater's or cook's ideologies and concerns may get in the way (Bivi et al., 2021). Under such circumstances health problems have arisen and continue to do so, especially among infants and children on vegan diets that are limited in other foods as well.

Vegan diets present more problems of micronutrient adequacy than do other vegetarian diets all across the life cycle and particularly in infants and children because more food groups are eliminated, sources of vitamins B<sub>12</sub>, D, choline and bioavailable iron, calcium, and zinc as well as omega 3 fatty acids may be lacking, the caloric density of the diet is lower, but bulk is higher and weaning from the breast is often very late. Vegan diets may also be low in calcium, iron, and zinc, and the forms of these minerals may not be highly bioavailable. Sources of riboflavin and choline also need to be identified.

Vegetarian infants are usually breastfed. They generally thrive until 4–6 months of age, and continue to do so if they remain at the breast and receive complementary feedings of nutritionally complete heat-treated cow's milk-based or fortified soy formulas, or other developmentally appropriate feedings that are high in nutrients, sufficient in energy, and low in bulk. Soy or other plant milks are not appropriate under 1 year of age. In countries where home prepared or commercial infant formulas and weaning foods do not provide adequate amounts of micronutrients, certain dietary supplements such as iron, choline, or vitamins B<sub>12</sub> and D may be needed (Cofnas, 2019). Today, more fortified vegan foods are available for infants and other groups than in the past. Good food or supplemental sources of vitamin B<sub>12</sub> and D (especially above approximately 40 degree N latitude where exposure to sunlight is not likely to be sufficient), linolenic acid (an omega 3 fatty acid to ensure that docosahexaenoic acid (DHA) intakes are satisfactory), riboflavin, calcium, choline and bioavailable forms of iron, and zinc must be included in the diets of weanlings and young children. Protein intakes are usually adequate if many different plant proteins are fed and energy intakes are sufficient (Salomé et al., 2020). Growth monitoring is helpful to ensure that the diet is supportive of good growth. When soy milk is used later in childhood, especially if the child is a vegan, it should be fortified with vitamins D, B<sub>12</sub>, and calcium (Eaton et al., 2019). Other plant milks should be as well, but rarely are. For children during the pubertal growth spurt, energy, calcium, iron, vitamins D and B<sub>12</sub>, as well as iron are of particular concern with respect to dietary adequacy. Pregnant and lactating vegetarian women have increased nutrient needs for these and other nutrients that can usually be dealt with by dietary planning. Choline and omega 3 fatty acid intakes as well as iron and vitamin B<sub>12</sub> deserve particular attention. Older adults who are vegetarians may have problems meeting micronutrient needs because they have low energy requirements owing to physical inactivity, whereas their needs for calcium, vitamin D, and vitamins B<sub>6</sub> and B<sub>12</sub> increase. Also, they may suffer from chronic diseases that alter nutrient metabolism. One example is atrophic gastritis in older persons, which affects absorption of vitamin B<sub>12</sub>.

## Conclusions

Vegetarian diets should be planned in accordance with the DRI or other authoritative nutritional recommendations so that they are healthful and nutritionally adequate. When vegetarian diets are unplanned, the nutrients that are likely to fall short usually differ somewhat from those on unplanned omnivorous diets. In some cases, these deficits can be easily remedied by dietary counseling and appropriate food choices. In others, differences between ideologies about life, diet, and nutrient needs are such that acceptable dietary strategies are difficult to achieve. Nutrition scientists and healthcare practitioners can help vegetarians who seek their advice by screening for nutritional status to identify high-risk individuals, by identifying acceptable food sources of specific nutrients that may be low in the diet for the eater, by suggesting dietary modifications that may be necessary to meet individual needs when intakes fall short, and by monitoring the vegetarian's progress.

## Key points

- Although whole grains themselves are clearly defined, there has been variation in the definition of whole grain foods, recommendations, and health claims across different countries and organizations.
- Whole grains have been associated with lower risk of chronic diseases, including cardiovascular disease, type 2 diabetes, and cancers.
- Whole grains have also been associated with intermediate risk factors for chronic disease such as adiposity, hypertension, and inflammation.
- Components of whole grain including fiber, antioxidants, and phytochemicals may facilitate the health benefits of whole grains

## Glossary

**Bran** Outer protective coat of a cereal grain that protects the seed from the environment. Rich in dietary fiber, micronutrients, and phytochemicals. 5–15% of grain weight depending on species

**Endosperm** Energy source for the growing seed. Contains carbohydrate in the form of starches and other oligosaccharides. Protein is found in the extracellular matrix. Source of B-vitamins. 60–85% of grain weight depending on species

<sup>1</sup>Dr. Bhupathiraju is a scientific consultant for LayerIV for work outside the submitted manuscript.

**Germ** The embryo of the seed, rich in protein, oils, fat soluble vitamins, micronutrients, and phytochemicals. 2–4% of grain weight depending on species

**Phytochemicals** Non-nutrient bioactive chemicals naturally found in fruits, vegetables, nuts, legumes, and grains that may have a positive impact on health

**Whole grains** Intact, ground, cracked, or flaked kernel after removal of inedible parts such as the hull and the husk. The starchy endosperm, bran, and germ are present in the same relative proportions as they were in the intact kernel

## Introduction

It is universally accepted that eating whole grains is beneficial to health. Whole grains are nutrient-dense foods that, in addition to being dominant sources of carbohydrate and protein in the diet, contain a wealth of beneficial nutrients and phytochemicals. Consuming whole grains, whole grain food products, and foods prepared from whole grain flours is, therefore, recommended by government and health promotion agencies. Evidence demonstrating the health benefits of whole grains has come from a range of study designs, predominantly observational cohorts, but in more recent years there has been a growing number of intervention studies as well. This article provides an overview of this evidence, focusing on the association between whole grain intake and lower risk of morbidity and mortality from cardiovascular disease, type 2 diabetes, and cancer. Possible mechanisms of action including effects on intermediate risk factors such as body weight, blood pressure, inflammation, and the gut microbiota are described.

## Structural components and composition of grains

Cereal grains are the seeds of the *Poaceae* (or *Gramineae*) family of grasses which are also referred to as kernels or grains. Cereal grains are a staple of many diets worldwide, with the dominant grains consumed being wheat, rice, maize, barley, rye, and oats. Other minor grains common in some countries include millet, sorghum, teff, triticale, and wild rice (Table 1). Although not part of the grass family, the “pseudocereals” amaranth, quinoa, and buckwheat are included in most definitions of cereal grains because they are similar in structure, nutrient composition, and in the way they are consumed as foods.

Cereal grains have three principle anatomical components, which relate to their function within the seed. Each component is complex and carries a unique nutrient profile (Fig. 1).

**Table 1** Common grains that are considered whole grains.

Cereal type	Scientific name
<b>Cereals</b>	
Wheat, including spelt, emmer, faro, einkorn, kamut, durum	<i>Triticum</i> spp.
Rice	<i>Oryza sativa</i>
Maize (corn)	<i>Zea mays</i>
Barley, including hull-less or naked varieties but excluding pearled barley	<i>Hordeum</i> spp.
Rye, including hull-less or naked varieties	<i>Secale</i> spp.
Oats	<i>Avena</i> spp.
Millet	<i>Brachiaria</i> spp.; <i>Pennisetum</i> spp.; <i>Panicum</i> spp.; <i>Setaria</i> spp.; <i>Paspalum</i> spp.; <i>Eleusine</i> spp.; <i>Echinochloa</i> spp.
Sorghum	<i>Sorghum</i> spp.
Teff	<i>Eragrostis</i> spp.
Triticale	<i>Triticale</i> spp.
Canary seed	<i>Phalaris arundinacea</i> and <i>P. Canariensis</i>
Job's tears	<i>Coix lacryma-jobi</i>
Fonio, Black fonio and Asian millet	<i>Digitaria</i> spp.
Wild rice	<i>Zizania aquatic</i>
<b>Pseudocereals</b>	
Amaranth	<i>Amaranthus cordatus</i>
Quinoa	<i>Chenopodium quinoa</i>
Buckwheat	<i>Faopyrum</i> spp.

Dry processes to develop wheat fractions and products with enhanced nutritional quality. *J. Cereal Sci.* 46(3): 327–347.

### Bran

The bran is a tough outer layer that functions as a physical barrier to protect the seed. The bran is often referred to as a single component of the grain, but as Fig. 1 shows, there are several distinct layers including the pericarp and aleurone layers, which are each further subdivided. Modern milling techniques can be used to sequentially remove these layers. Removal of the bran is a vigorous, abrasive process known as de-hulling, pearling, or peeling. The principal nutrient in bran is dietary fiber, which is predominantly insoluble, although there can be significant quantities of soluble fibers such as arabinoxylan found in wheat and rye and beta-glucan in oats and barley. The bran layers are also a principal source of phytochemicals and contribute to the antioxidant potential of grain.

### Endosperm

Quantitatively, the biggest part of the grain is the endosperm which comprises approximately 60–85% of the cereal grain dry weight, depending on species. The endosperm provides the necessary energy for the growing embryo. Nutritionally, the endosperm is mainly carbohydrate in the form of starches and other oligosaccharides such as fructans. Some protein is found in the extracellular matrix, as well as some B vitamins including pantothenic acid and riboflavin.

### Germ

The germ is the smallest fraction of the grain at approximately 2.5% of the grain weight. The germ is the plant embryo which would form the new plant if germinated and is characterized by high lipid and protein content. The germ is also a rich source of minerals, particularly potassium, calcium, magnesium, and zinc, and both water- and fat-soluble vitamins including vitamin A, tocopherols, and tocotrienols. The oil content of the germ is prone to oxidation, which reduces the storage time for whole grain flours.

### Definition of whole grains and health claims

Various definitions of “whole grain” exist and are largely based on the first definition proposed by the American Association of Cereal Chemists International (AACCI) in 1999:

Whole grains consist of the intact, ground, cracked or flaked caryopsis (kernel) after the removal of inedible parts such as the hull and husk. The principal anatomical components—the starchy endosperm, germ, and bran—are present in the same relative proportions as they exist in the intact kernel.

More recently, to achieve consensus with respect to the definition of whole grains used in the European Union (EU), the HEALTHGRAIN Forum developed a similar definition in 2010 which additionally accounted for small losses (<2% of the grain or 10% of the bran) that can happen in modern industrial milling processes. This small loss is meant to account for the removal of the outermost layers of the bran, which is commonly done to eliminate mycotoxins, pesticides, or other contaminants that can be found in these layers. Intact whole grains must be processed before consumption to increase digestibility and improve the texture, flavor, and cooking characteristics of the products. During modern milling, the anatomical components of the grain are fractionated and recombined later to produce whole meal flour. Besides milling, less destructive processes such as rolling, flaking, and cracking of grains are also used. Intact whole grains are used in small quantities to add texture to some foods. Processing of the grains will, inevitably, result in changes to the gross morphology of the product and most likely the chemical composition. Although there is no evidence that recombined flours are nutritionally different than traditional stone-ground flours (where the grains are crushed without separation of the component fractions), the metabolic consequences of consuming whole grain foods prepared from heavily processed reconstituted flours compared to crushed, minimally processed flours have not been extensively investigated. Another characteristic known to change is the glycemic index (GI), which is higher in foods prepared from finely ground flours. This is because flours have a larger surface area for digestive enzymes to act on, thereby rapidly increasing blood glucose concentration.

Although there is general consensus for the definition of whole grains, defining whole grain *foods* becomes much more complex, particularly when a whole grain food contains additional ingredients including varying amounts of refined grain. There has been variation across countries and organizations regarding what should qualify as a whole grain food. In the US, the Food & Drug Administration (FDA) defines a whole grain food as a product containing 51% whole grain by weight per reference amount customarily consumed (RACC) per day, while the Whole Grain Council considers a product with 16 g of whole grain per serving eligible for a “100% Whole Grain” stamp. In Sweden, Norway, Denmark, the UK, and Taiwan, similar criteria of >50% of ingredients as whole grain have been used. In the Netherlands, 100% of the grain ingredients must be whole grain in breads, and in Germany more than 90% of ingredients must be whole grain. Others, such as Indonesia and Malaysia, allow certain whole grain or partial whole grain claims at lower amounts, around a minimum of 25%. Recently, the Whole Grain Initiative, consisting of global representatives from academia, government agencies, and industry, proposed a consensus definition:

A whole-grain food shall contain at least 50% whole-grain ingredients based on dry weight. Foods containing 25–50% whole-grain ingredients based on dry weight, may make a front-of-pack claim on the presence of whole grain but cannot be designated “whole grain” in the product name.

The criteria for defining a whole grain food are important in determining what products can make whole grain related health claims. Since 1999, the FDA allows products meeting the 51% criteria to carry the statement “Diets rich in whole grain foods and other plant foods and low in total fat, saturated fat, and cholesterol may reduce the risk of heart disease and some cancers.” Similar, equally cumbersome, claims in the UK and Europe followed. For example, the Swedish claim certified by the Swedish Nutrition Foundation states: “A healthy lifestyle and a well-balanced diet rich in whole grain products reduces the risk for (coronary) heart disease. The product X is rich in whole-grains (contains Y% of whole grain).” However, since 2010 the European Food Safety Authority made the decision to no longer approve whole grain health claims on the grounds that whole grain was “insufficiently characterized,” particularly when the term was used to refer to all grains rather than a specific type of grain (i.e., wholegrain wheat or wholegrain rye).

### Recommendations for whole grain consumption and consumption patterns

Many countries recommend or encourage greater intake of whole grains. Most provide qualitative statements such as “choose whole grains whenever possible,” but only a few provide specific, quantitative recommendations. Since 2000, the US Dietary Guidelines have recommended that at least half of total grain-food intake should be as whole grains which, for those over 9 years of age, is a *minimum* of approximately 3 ounce-equivalents or 48 g per day. In Denmark, where there is already a stronger tradition of eating whole grain foods, the target level for consumption is 75 g of whole grain per 10 MJ (about 2400 kcal) energy consumed. Sweden has a similar recommendation, and in the Netherlands 90 g/day of brown bread or other whole grain products is recommended. However, most individuals consume amounts much lower than these recommendations. In the USA, for example, Americans consume a mean intake of <1 ounce-equivalent (or 16 g) of whole grains per day, according to data from the National Health and Nutrition Examination Survey (NHANES) (Shan et al., 2019). Mean consumption is of a similar magnitude in other major countries, such as France (14 g/d), Italy (16 g/d), the UK (20 g/d), and Australia (21 g/d) (Miller, 2020). Even in some Scandinavian countries, where whole grains are integral to traditional diets, mean consumption is still below their national recommendations, at around 55 g/d.

### Biomarkers of whole grain consumption

Estimation of whole grain intake at the population level is necessary for development of public health initiatives and for exploring the health consequences of whole grain intake. However, methods for measuring whole grain intake vary and are prone to

measurement error. For example, in many earlier studies, dark bread was assumed to be whole grain bread, which may not be the case. Studies that collected data in the early 1990s were not originally designed to investigate whole grain intake (as it was not a focus of research interest at that time), and most research relied on the use of food frequency questionnaires to collect data on dietary intake. Some studies have reported intake in grams of whole grain per day, whereas others have reported intake as servings or as grams of whole grain food product, requiring additional assumptions on definitions of servings or whole grain foods. This creates a challenge for researchers attempting to estimate absolute whole grain intake and can confound observed associations, particularly when whole grain products contain a mixture of whole and refined grain. Although the estimation of absolute intake may vary depending on the method of measurement, relative associations observed between the highest and lowest consumers with chronic disease risk have been consistent.

More recently, there have been growing efforts to identify and utilize biomarkers of whole grain intake. Alkylresorcinols and their metabolites were the first proposed and are the most studied biomarkers specifically for whole grain wheat and rye intake (Ross, 2012; Sang, 2018). Other proposed biomarkers include benzoxazinoids (also for whole grain wheat, rye and sourdough rye), avenanthramides and avenacosides for whole grain oat intake, and enterolactone for total whole grain or cereal fiber intake (Landberg et al., 2019; Sang, 2018). New advances in targeted and untargeted metabolomic methods, which aim to identify and quantify metabolites in biological systems, are being used to study potential biomarkers for other grain varieties as well. These methods are also being utilized to identify potential mechanistic pathways by which whole grains may impact health. For example, in one randomized cross-over trial, untargeted metabolomics identified 15 metabolites associated with rye intake, including significantly lower plasma serotonin, which may be linked to metabolic control (Keski-Rahkonen et al., 2019).

## Whole grain consumption and disease risk

### Cardiovascular disease

Approximately one-third of global deaths can be attributed to cardiovascular disease (CVD), and morbidities associated with CVD account for significant proportions of health care costs. The inverse relationship between higher whole grain intake and lower risk of CVD has been documented in numerous observational studies, and for all types of CVD. Much of this data has been generated from large observational cohort studies carried out in North America and Europe. Meta-analyses that include data from multiple observational studies show significant and marked lowering of CVD risk (20–30%) between the lowest and highest consumers of whole grain intake. One meta-analysis estimated that 11.6% of all CVD mortality could be attributed to low whole grain intake (intake below the recommended amount) (Zong et al., 2016). Conversely, positive relationships between higher refined grain intake and higher risk of CVD have been observed in some observational studies, although others have found no significant association. These discrepancies may be due to differences in study design, background diet, or study population. It is important to note that higher whole grain intake is associated with many other indicators of a healthy lifestyle, such as lower smoking status, higher physical activity, use of nutritional supplements and generally higher household income. Therefore, the relationships observed with whole grain intake may be due to other components of a generally healthier lifestyle. However, after mitigating these confounding factors through statistical adjustment, the inverse relationships between whole grain intake and CVD risk continue to remain significant. Fig. 2 summarizes some of these data, using fully adjusted models from some of the large cohort studies investigating CVD incidence or mortality as endpoints. The range of lower risk, estimated by either hazards ratios or relative risk of incident CVD or CVD mortality, remains large—between 5% and 30%. Most of these analyses use data from large US cohort studies, including the Health Professionals Follow-up ( $n = 42,850$ ); Nurses' Health Study ( $n = 75,521$ ); Iowa Women's Health Study ( $n = 34,491$ ); and Atherosclerosis Risk in Communities Study ( $n = 15,972$ ). Other studies have also evaluated intermediate CVD risk factors in relation to whole grain intake. In a meta-analysis of 25 randomized controlled trials (RCTs), researchers observed improved total cholesterol (standardized mean difference [SMD] =  $-0.54$ , 95% CI  $-0.95$  to  $-0.12$ ) and LDL =  $-0.57$ , 95% CI  $-0.84$  to  $-0.31$ ), hemoglobin A1c (SMD =  $-0.33$ , 95% CI  $-0.61$  to  $-0.04$ ) and C-reactive protein (SMD =  $-0.22$ , 95% CI  $-0.44$  to  $-0.00$ ) with whole grain (all types) intake (Marshall et al., 2020). Functional measures of cardiac health are few but in one prospective cohort study involving postmenopausal women ( $n = 229$ ), smaller reductions in minimum coronary artery diameter and a trend toward lower progression in mean percent stenosis with higher whole grain intake have been reported (Erkkilä et al., 2005).

### Type 2 diabetes

Incidence of type 2 diabetes (T2D) has increased dramatically in line with the rise in obesity worldwide, and consequences of the epidemic represent a major challenge for health services. The etiology of the disease is complex, including interactions between genes, diet, and lifestyle. The underlying pathology is the development of insulin resistance, which has been linked to high intake of refined carbohydrates, along with low intake of dietary fiber. Many of the large cohorts used to examine the relationship between whole grain intake and CVD risk have also been used to explore similar relationships for T2D (Fig. 3). These observational studies suggest an inverse relationship between whole grain intake and risk of T2D (with a lower risk, ranging between 11% and 43%), as well as lower concentrations of glucose and insulin, where these measures are available. Prospective data from the National Institutes of Health (NIH)-AARP Diet and Health Study, which followed 367,442 participants for an average

**Fig. 2** Observational cohort studies on whole grain intake and cardiovascular disease (CVD). All models presented are the most fully adjusted unless otherwise stated. CHD = coronary heart disease, HR = hazard ratio, MI = myocardial infarction, RR = relative risk.

of 14 years with 46,067 total deaths, showed that the highest intake of whole grain (1.20 oz eq/day) vs. the lowest (0.13 oz eq/day) was associated with 43% lower risk of death from diabetes (HR 0.57 95% CI 0.37–0.89) after adjustment for potential confounders, including BMI (Huang et al., 2015). More recently, in a pooled analysis of 3 large cohorts with data from 158,259 women and 36,525 men (Nurses' Health Study I and II and Health Professionals Follow-up Study), with an average follow-up time of 24 years, and 18,629 incident cases of T2D, 29% lower risk of T2D was observed among those in the highest vs lowest category of whole grain intake (Hu et al., 2020). The greatest lowering of risk was observed at 2 servings (about 32 g) per day, after which further lowering of risk seemed to plateau.

A meta-analysis of 45 prospective cohort studies showed that, compared with people who never or rarely ate whole grain, those consuming 48–80 g/d (~3–5 servings/d) had ~26% lower risk of developing T2D [RR = 0.74 (95% CI: 0.69, 0.80)] (Ye et al., 2012). These authors also conducted a meta-analysis of 21 RCTs and observed that those whole grain interventions resulted in a weighted mean difference in fasting glucose of  $-0.93$  mmol/L (95% CI:  $-1.65$ ,  $-0.21$ ) compared to control groups. However, many intervention studies investigating the effect of whole grain consumption on blood glucose and insulin resistance/sensitivity have yielded conflicting results. For example, in a meta-analysis of 14 RCTs, significant associations were observed between whole grain foods and acute changes in post-prandial glucose [iAUC (0–120 min) by  $-29.71$  mmol min/L (95% CI:  $-43.57$ ,  $-15.85$  mmol min/L)] and insulin [iAUC (0–120 min) by  $-2.01$  nmol min/L (95% CI:  $-2.88$ ,  $-1.14$  nmol min/L)] (Marventano et al., 2017). However, when the same study looked at 16 RCTs of medium or long duration, no significant effect was observed on fasting glucose, insulin, or insulin resistance. The discrepancies in these results may be due to differences in study populations, baseline disease risk, or the background diet that the study participants consumed.

## Cancer

Unhealthy diet patterns are a major contributor to cancer, partially due to their direct and indirect effects on adiposity. On the other hand, consistent evidence from scientific literature shows that whole grains may protect against various types of cancer. In a 2020 meta-analysis of both case-control and cohort studies, whole grain consumption was associated with lower risk of total cancer mortality (Gaesser, 2020). Seven meta-analyses of prospective cohort studies indicated that whole grain intake was associated

**Fig. 3** Observational cohort studies on whole grain intake and Type 2 diabetes (T2D). All models presented are the most adjusted unless otherwise stated. HR = hazard ratio, RR = relative risk.

with 6%–12% lower risk of cancer mortality, when comparing highest vs. lowest intake groups. In dose-response analyses, each 30 g/day intake of whole grains was associated with ~7% lower risk of cancer mortality. For site-specific cancers, greater whole grain intake was associated with lower colorectal, gastric, pancreatic, and esophageal cancers (Table 2). The largest body of epidemiological evidence is for whole grain intake and risk of incident colorectal and breast cancers (Table 3).

### Colorectal cancer (CRC)

In 2020, an estimated 1.9 million individuals were diagnosed with CRC, the second leading cause of cancer and the third leading cause of cancer death worldwide. Case-control studies, in particular, show lower risk of CRC with greater whole grain consumption; however, evidence from prospective studies is limited and inconsistent, with some studies showing protective associations between whole grain intake and CRC and others showing a null association. A meta-analysis of data from 10 individual prospective cohorts (Schwingshackl et al., 2018), reported 5% lower risk per 30 g serving of whole grains per day—translating into 20% lower CRC risk with whole grain intakes up to 120 g/day. More recently, two umbrella reviews graded the evidence from published meta-analyses of observational studies on the association of whole grain intake and incidence of CRC, and determined that the evidence was “possible/suggestive” for a protective impact of risk with higher intakes (Schwingshackl et al., 2018; Tieri et al., 2020). Estimates of whole grain intakes in servings per day or grams of whole grain products, rather than grams of whole grain ingredients, led to insufficient dose-response data. In addition, there was limited data on the impact of different sources of whole grains. Inconsistencies in associations may be due to a few incident cases, low habitual intake of whole grains in the sample, different lengths of follow-up, or lack of repeated measures to capture usual or long-term dietary intake. In addition to absolute whole grain intake, the source of whole grain and degree of processing may be important to consider with respect to CRC risk.

Total and individual whole grain *product* consumption among Danish men and women in the Diet, Cancer, and Health cohort were examined in relation to incident risk of colon and rectal cancer over a median follow-up of 10.6 years (Egeberg et al., 2010). Among 26,630 men, there were 461 incident cases of colon cancer and the incident relative risk (IRR) per 50 g of whole grain intake was 0.85 (95% CI 0.77, 0.94). There were 283 incident cases of rectal cancer with an IRR of 0.90 (95% CI 0.80, 1.01). There were no consistent associations between total or individual whole grain consumption and colon or rectal cancer risk among women. In men, whole grain wheat bread was the only whole grain food significantly associated with lower risk of colon cancer, where every 25 g per

day was associated with 11% lower risk of colon cancer (IRR 0.89; 95% CI 0.82, 0.97). Although not significant, a slight lowering in colon cancer risk was also observed for rye bread (IRR 0.94; 95% CI 0.88, 1.01). This response is interesting because intake of rye bread was approximately twice that of the wheat bread (63 g/day compared with 31 g/day), and rye was shown to lower colon cancer risk in women from the Swedish Mammography Cohort (Larsson et al., 2005).

Data from the Health Professionals Follow-up Study demonstrated that higher intake of whole grain and dietary fiber attributed to whole grain (i.e., cereal fiber) were associated with 25–27% lower CRC risk in men. However, no significant lowering of risk was observed in women in the Nurses' Health Study, which may be due to the lower intake of whole grains in women (He et al., 2019). More recently, the association between whole grains and fiber sources on risk of CRC, was examined in the largest cohort to date—478,994 US adults, 51–70 years of age, in the NIH-AARP Diet and Health Study (Hullings et al., 2020). Compared to those in the lowest quintile category of whole grain intake (daily median intake 0.2 servings per 1000 kcal), those in the highest quintile (1.3 servings per 1000 kcal) had 16% and 24% lower risk of developing CRC and rectal cancer, respectively. Interestingly, these associations remained statistically significant after adjustment for two mediating nutritional attributes of whole grains: dietary fiber and folate. This would suggest that other nutritional constituents of the whole grain may be responsible for the association. In this same analysis, of all potential fiber sources, only fiber from grains demonstrated a significant linear inverse association with CRC among those in the highest category of cereal fiber intake. There was no evidence that associations differed by sex. The most recent 2018 WCRF/AIRC Continuous Update Project concluded that there is strong evidence that consuming whole grains help protects against colorectal cancer.

### Breast cancer

Based on data from the WHO in 2020, 2.3 million women were diagnosed with breast cancer and 685,000 died from the disease globally, with a large proportion of deaths being attributed to obesity and lifestyle related factors, including diet. However, evidence suggesting that a higher intake of whole grains is protective against breast cancer risk has been inconsistent.

Some observational studies show small but modest benefits of whole grain consumption (Adzersen et al., 2003; Chatenoud et al., 1998; Mourouti et al., 2016; Sonestedt et al., 2008; Tajaddini et al., 2015; Yun et al., 2010), but others show either no benefit (Egeberg et al., 2009; Farvid et al., 2016; La Vecchia et al., 1987; Levi et al., 1993) or, unexpectedly, higher risk in breast cancer risk (Nicodemus et al., 2001). The latter study used data from the Iowa Women's Health Study and was the first prospective cohort to consider grain sources on breast cancer among post-menopausal women in the United States. After multivariable adjustment, the

Adapted from Gaesser (2020).

risk of incident breast cancer was 20% *higher* for women with the highest, vs. lowest whole grain intake. However, when the data were further examined, it appeared that the incidence of breast cancer was not higher among women who had not undergone screening mammography before follow-up. This suggests that increasing whole grain intake was associated with more health-conscious behaviors such as attending cancer screening, thus increasing the detection rate in whole grain consumers. In a cohort of Danish post-menopausal women, no protective association was observed between whole grain intake and breast cancer risk, including all estrogen and progesterone receptor disease subtypes. It is possible that hormone replacement therapy may interfere with the mechanisms of lignans/enterolactone with higher whole grain intake.

A 2018 meta-analysis of data from 11 published studies (4 cohort and 7 case-control) suggested that, compared to the lowest intake, those with the highest whole grain intake had 16% lower risk of breast cancer (pooled RR 0.84, 95% CI: 0.74–0.96,  $P = 0.009$ ) (Gaesser, 2020). When stratified by study design, the observed relationships were stronger for case-control than for cohort studies and, in some studies, sample size was cited as a potential limitation. Therefore, it remains inconclusive as to whether higher intake of whole grains is linked to a lower risk of breast cancer.

### Other cancers

Research on whole grains and other cancers is limited. With respect to prostate cancer, results are mixed (Egeberg et al., 2011; Nimptsch et al., 2011). In one nested case-control study in Swedish men, no evidence of a protective association was observed

with the blood biomarker, plasma alkylresorcinol, and incident prostate cancer (Drake et al., 2014). The association between whole grain intake and other cancers such as endometrial (Aarestrup et al., 2012; Kasum et al., 2001), pancreatic (Lei et al., 2016), and stomach (McCullough et al., 2001) are limited to a few prospective cohort studies, with mixed findings and, thus, inconclusive evidence.

### Intermediate risk factors of disease and potential mechanisms of action

There are various potential mechanistic pathways, many yet to be fully understood, by which whole grain consumption may lower chronic disease risk. When compared to refined grains, whole grains are higher in several nutrients and many potentially protective bioactive compounds found in the bran and germ layers, which are lost during the milling process. These include dietary fiber, magnesium, potassium, vitamin K, vitamin E, antioxidants, and other phytochemicals, all of which have been linked to cardiometabolic health. For example, dietary fiber and magnesium may reduce insulin resistance, and potassium has been associated with lower blood pressure. Although different grains have similar nutritional composition, they vary in type and amounts of specific nutrients and other bioactive components, which can lead to differential health benefits. For example, oats have a stronger favorable association with triglyceride, LDL, and total cholesterol compared to whole wheat or mixed grains (Holl nder et al., 2015), likely because oats are higher in soluble fiber, whereas wheat is higher in insoluble fiber. Emerging research utilizing metabolomics methods aim to identify metabolites that may further link whole grain intake to health benefits.

### Whole grains and adiposity

A contributing factor in the development of many chronic diseases is excess body fat. Higher adiposity has been linked to greater risk of T2D, CVD, and cancer. In several observational studies, higher whole grain consumption was associated with lower body weight, BMI, and waist circumference (a measure of abdominal or central obesity), which may contribute to the observed protective association observed with greater whole grain intake in chronic disease development. Prospective analyses that measure change in weight over many years suggest that, although individuals tend to gain weight with age, those with higher whole grain intake gain less weight over time than those with lower intake. One recent dose-response meta-analysis of five prospective cohort studies found that for every additional 30 g/d of whole grain intake, the risk of overweight or obesity was 7% lower. In three other prospective cohorts, the risk of weight gain (>2 kg over 4 years) was  $\geq 17\%$  lower among the highest, vs. lowest whole grain consumers (Schlesinger et al., 2019). Similar results have been observed in the Nurses' Health Study (Liu et al., 2003) and Health Professionals Follow-up Study (Mozaffarian et al., 2011), as well as in the Black Women's Health Study (Boggs et al., 2013) cohorts from Spain (PREDIMED (Bautista-Casta o et al., 2013), and SUN (de la Fuente-Arillaga et al., 2014)), and Australia (ALSWH (Quatela et al., 2017)).

Evidence from RCTs has been less consistent. One meta-analysis, that included both prospective cohorts and RCTs, found a significant association between higher whole grain intake and less weight gain over time among the cohort studies; however, no association with body weight was observed in the RCTs (Maki et al., 2019). Another recent meta-analysis of 21 RCTs, ranging from 2 to 24 weeks, also found no significant association between whole grain intake and body weight, BMI, body fat percentage, or other measures of obesity (Sadeghi et al., 2020). Conversely, another meta-analysis of 11 RCTs, ranging from 3 weeks to 18 months, found 0.62 kg lower weight among the highest, vs. lowest, whole grain consumers (Reynolds et al., 2019). There is heterogeneity across RCT designs, and each meta-analysis had different inclusion and exclusion criteria, possibly contributing to their different conclusions.

Emerging research shows that even among individuals with similar BMI, variability in body fat distribution may differentially impact metabolic disease risk. In particular, excess abdominal obesity, most easily measured by waist circumference, has been linked to higher risk of metabolic syndrome, T2D, and CVD, independent of overall BMI (Casanueva et al., 2010; M ller et al., 2012). Observational data support a potential beneficial association between whole grain intake and lower waist circumference. A recent analysis with 3121 participants of the Framingham Heart Study found that higher whole grain intake was significantly associated with less increase in waist circumference over time. Those in the highest quartile of whole grain intake had an increase of only 1.4 cm per 4-year period compared to a 3.0 cm increase in the lowest quartile (Sawicki et al., 2021). This seemingly small difference adds up over time, and even small increases in risk factors such as waist circumference have been shown to impact disease risk.

When specific adipose tissues are considered separately, visceral adipose tissue (VAT), the fat that surrounds organs, is more strongly related to metabolic risk than subcutaneous adipose tissue (SAT), the fat that lies under the skin. Greater VAT has been linked to insulin resistance, dyslipidemia, inflammation, and oxidative stress, all of which increase the risk of cardiometabolic diseases (Fox et al., 2007). Data from the Framingham Heart Study demonstrate that those in the highest whole grain consumption group had less SAT and less VAT. In contrast, those from the highest refined grain consumption group had more of both types of abdominal fat, especially VAT (McKeown et al., 2010). When SAT and VAT were mutually adjusted, only VAT remained significantly associated with whole and refined grain. More recently, a randomized, controlled 12-week intervention with 49 overweight participants in Japan reported that those randomized to a whole grain diet group lost a mean of 4 cm<sup>3</sup> in VAT, compared to no significant

change in the refined grain group (Kikuchi et al., 2018). However, other RCTs have not found a significant association between whole grain and VAT. A systematic review and meta-analysis of randomized controlled trials of whole grain and body weight changes concluded that whole grain may have a small beneficial effect on body fat, but not overall body weight, and that short duration and heterogeneity among study designs may contribute to the conflicting evidence (Pol et al., 2013).

### Whole grains and hypertension

A small number of observational studies have shown an inverse relationship between hypertension and whole grain intake. A meta-analysis of 4 prospective observational studies reported that, for every 30 g/d higher whole grain intake, the risk of hypertension was lower by 8%. No significant association was observed with refined grain (Schwingshackl et al., 2017). It should be noted that two of the 4 included studies were in men only. A more recent prospective study in the Framingham Offspring Cohort found that high, vs. lower, whole grain intake was associated with smaller increases in systolic, but not diastolic, blood pressure over time (Sawicki et al., 2021). The effects of whole grain consumption on blood pressure have also been measured in intervention studies with varying results. A double-blind RCT with 33 overweight or obese men and women found that, after 8 weeks on a whole grain diet (50 g whole grain/1000 kcal per day) diastolic blood pressure decreased by 5.8 mm Hg (95% CI: -7.7, -4.0 mm Hg,  $P = 0.01$  compared to control diet) (Kirwan et al., 2016). One RCT from the UK with more than 200 healthy volunteers, showed that consuming three servings per day of whole grain wheat or a 50:50 mix of whole grain wheat and whole grain oats for 12 weeks led to a significant reduction of 6 mmHg in systolic blood pressure and 3 mmHg in pulse pressure (Tighe et al., 2010). In another RCT of similar size, however, volunteers consumed either three servings of mixed whole grains per day for 16 weeks or three servings per day for 8 weeks followed by six servings per day for a further 8 weeks, with no changes in blood pressure (Brownlee et al., 2010). Heterogeneity of trials is emphasized by a meta-analysis that included 8 RCTs and did not show a statistically significant effect of WG on systolic blood pressure (Reynolds et al., 2019).

### Whole grains and inflammatory status

It is now recognized that chronic subclinical inflammation is central in the progression of many diseases such as CVD and T2D. In several studies, relationships between whole grain consumption and markers of inflammatory status such as high-sensitivity C-reactive protein (hsCRP), tumor necrosis factor receptor-2 (TNF-R2), fibrinogen, plasminogen activator inhibitor-1 (PAI-1), or interleukin-6 (IL-6) have been investigated. For some, higher whole grain consumption was associated with lower inflammatory marker concentrations. In one cohort study of 259 healthy premenopausal women, participants who ate small amounts of whole grain (<one serving per day) for 2 years had lower hsCRP concentration (average 11.5%) than those who ate no whole grain at all (Gaskins et al., 2010). For women eating one or more servings of whole grain, hsCRP concentration was 12.3% lower. A more recent RCT showed improvement in IL-6 and CRP after 8 weeks on a whole grain intervention, compared to a refined grain control (Roager et al., 2017). Similar associations were found in two meta-analyses of RCTs (Hajihashemi and Haghighatdoost, 2019; Xu et al., 2018). While the underlying mechanisms are not completely understood, whole grains are rich in antioxidants and phytochemicals that may play a role in inflammatory pathways. Additionally, the fiber in whole grain may reduce postprandial hyperglycemia, thus reducing the formation of advanced glycation end products which are known to induce oxidative stress and inflammation.

### Whole grain, dietary fiber, and fermentable carbohydrates

Whole grains are considered “complex carbohydrates” because they are good sources of dietary fiber. The variety of fibers, or non-starch polysaccharides, derived from cereal grains include cellulose, hemicellulose, arabinoxylans, lignin, fructans, such as inulin, and resistant starch. In many of the observational studies described above, health benefits associated with higher whole grain intake were similarly correlated with cereal fiber intake. The myriad of physiological effects of dietary fiber in the digestive tract have been linked to health benefits that may contribute to the reduction in disease risk associated with whole grain intake (McRorie and McKeown, 2017). These include direct effects on digestive characteristics such as viscosity, flow rate/transit time, and bulking. These changes then affect digestive processes, such as reducing stomach emptying, increasing satiety, reducing rates of carbohydrate and lipid digestion, blunting the postprandial glucose and insulin response, and lowering glycemic index/glycemic load. These effects may contribute to the observed associations between whole grain or cereal fiber and lower adiposity and better glycemic/insulinemic maintenance. Some dietary fiber may also bind and help remove bile acids in the small intestine, interrupting the enterohepatic circulation of cholesterol and lowering blood lipid concentrations. Similarly, dietary fiber may potentially reduce endogenous estrogen levels by binding estrogen and facilitating their fecal excretion.

The dietary fibers in whole grains also provide fermentable carbohydrates to the gut microbiota in the large intestine. The potential prebiotic effects of nondigestible oligosaccharides, such as fructans and arabinoxylan fractions, have also been suggested. Emerging research suggests that modulation of the gut microbiome composition can have physiological effects. Some, but not all, RCTs have shown that higher abundance of *Bifidobacterium* and *Lactobacillus* spp., promoted by fructans and galacto-oligosaccharides, is associated with improved metabolic health (So et al., 2018). In a recent RCT, healthy overweight adults with *Prevotella* abundance lost more body weight on an ad-libitum whole grain diet compared to refined grain diet, whereas those with low *Prevotella* abundance did not lose weight (Christensen et al., 2019). Fermentation of dietary fiber by the microbiota present

in the colon can also produce short-chain fatty acids (SCFAs), which are absorbed into the blood stream and can activate fatty acid oxidation and inhibit *de novo* synthesis and fat storage. SCFAs may also stimulate the production of gastrointestinal hormones that play a role in satiety and glucose metabolism, including PYY and GLP-1.

### Whole grains, antioxidants, and phytochemicals

Phytochemicals are bioactive non-nutrient plant compounds in fruits, vegetables, whole grains, and other plant foods that have been associated with a lower risk of major chronic diseases. The most studied phytochemicals found in grains are phenolics. Phenolics are compounds with one or more aromatic rings and one or more hydroxyl groups, such as phenolic acids, plant lignans, alkylresorcinols, and flavonoids. Phenolics exist in cereal grains in two forms: soluble free and insoluble bound; the latter include compounds esterified to macromolecules which, as a result, may escape digestion in the upper gastrointestinal tract. It has been suggested that as much as 74% of phenolic compounds in wheat, maize, oats, and barley are found in the insoluble bound fraction. Phenolic compounds exist mainly as glycosides linked to various sugar moieties or as other complexes linked to organic acids, amines, lipids, carbohydrates, and other phenols.

These fractions may be released during the processing of the grain and be available in the small intestine, or they may be released during bacterial fermentation in the large intestine. Thus, there is potential for local effects in different parts of the gut or systemic effects once the compounds are absorbed. Phenolics and other compounds found in cereal grains can act as antioxidants because they can donate hydrogen atoms to free radicals. In principle, the higher the phenolics and other antioxidant compounds in cereal grains, the greater their potential antioxidant capacity, and this has been well documented *in vitro* using a variety of assays. However, their potential to affect antioxidant status *in vivo* is less certain, and the mechanisms by which antioxidants that cross the intestinal barrier protect the body remain unclear. Of note are lignans, a group of dietary phytoestrogen compounds found in the bran of cereals that have strong antioxidant capacity *in vitro* and may impact endogenous estrogen and/or sex hormones by binding or inhibiting enzymes involved in steroid hormone physiology that may promote health benefits, such as susceptibility to hormone-related cancers.

### Conclusion

Evidence shows that whole grains contribute to a healthy diet. They have been linked to reduced risk of several chronic diseases, through diverse potential mechanistic pathways that are still active areas of research. Currently, most countries report that whole grain intake is below recommendations. Given increasing evidence for their health benefits, global efforts to increase whole grain intake are warranted.

## CONTENTS OF VOLUME 3

---

<i>Contributors to Volume 3</i>	<i>ix</i>
<i>Editor Biographies</i>	<i>xv</i>
<i>Preface</i>	<i>xix</i>

### DISORDERS DIRECTLY RELATED TO INADEQUATE NUTRIENT INTAKE

Biochemical indices	1
<i>CM Pfeiffer, RL Schleicher, and KL Caldwell</i>	
Body composition	20
<i>M Ashby-Thompson, S Chung, and D Gallagher</i>	
Clinical examination	35
<i>B Caballero</i>	
Dietary intake measurement: Methodology	39
<i>AA Welch and AA Mulligan</i>	
Doubly labeled water	52
<i>Michele N Ravelli, Timothy C Shriver, and Dale A Schoeller</i>	
Food choice: Behavioral aspects	62
<i>Barbara J Rolls, Kathleen L Keller, John E Hayes, and Travis D Masterson</i>	
Glucose: Metabolism and homeostasis	70
<i>Julie Miller Jones</i>	
Nutritional aspects of bone	79
<i>AR Bournot, SA Lanham-New, M Alghamdi, and J Jalal</i>	
Nutritional assessment: Anthropometry	87
<i>J Eaton-Evans</i>	

### NUTRITION IN DISEASE STATES

Adipose tissue: Structure, function and metabolism	94
<i>G Frühbeck and J Gómez-Ambrosi</i>	
Arthritis	109
<i>F Cuesta Triana</i>	

Brain and nervous system: Biology, metabolism, and nutritional requirements <i>JD Fernstrom and MH Fenstrom</i>	118
Cancer: Carcinogenic substances in food <i>AI Prieto, AM Troncoso, and AM Cameán</i>	125
Cancer: Dietary management <i>Victoria Nelson and Louise Henry</i>	136
Cancer: Epidemiology and associations between diet and cancer <i>Graham A Colditz and Hank Dart</i>	146
Cancer: Epidemiology of lung cancer <i>Anthony J Alberg, Rajat Das Gupta, and Maxwell Akonde</i>	154
Celiac disease <i>Balakrishnan S Ramakrishna</i>	162
Cerebral palsy: Nutritional aspects <i>Patricia Miller</i>	171
Colon: Structure, function, and disorders <i>Asim Maqbool</i>	184
Cystic fibrosis <i>J Dowsett and O Tully</i>	207
Dehydration <i>Shashank S Dhareshwar</i>	216
Diabetes mellitus: Diagnosis and heterogeneity <i>Ram Jagannathan, Kosuke Tamura, and Priyathama Vellanki</i>	227
Diabetes mellitus: Dietary management <i>M Lu, SJ Pilla, and SH Oh</i>	234
Diabetes mellitus: Etiology and epidemiology <i>Yara S Beyh and KM Venkat Narayan</i>	252
Diarrheal diseases <i>Phoebe Hodges and Paul Kelly</i>	263
Diet and oral health <i>Anja Heilmann, Yanela Aravena Rivas, and Richard G Watt</i>	272
Down's syndrome: Nutritional aspects <i>A Lavery</i>	283
Eating disorders: Anorexia nervosa <i>Meredith Kells and Jennifer E Wildes</i>	290
Eating disorders: Binge eating <i>MA Kalarchian and MD Marcus</i>	296
Eating disorders: Bulimia nervosa <i>Heather A Davis and Jennifer E Wildes</i>	304
Energy balance <i>Yves Schutz</i>	314

Enteral and parenteral nutrition	324
<i>Kent Aje, Sara Yacyshyn, Lindsay Dowhan, and Lisa Reitz</i>	
Food allergies: Diagnosis and management	337
<i>TJ David</i>	
Food intolerance	345
<i>B Caballero</i>	
Hyperactivity: Nutritional aspects	353
<i>Klaus W Lange</i>	
Hyperlipidemia	361
<i>Penny M Kris-Etherton, Lisa Sanders, Olivia Lawler, Terrence Riley, and Kevin Maki</i>	
Hyperlipidemia: Nutritional prevention and management	380
<i>AH Lichtenstein</i>	
Hypertension: Dietary factors	391
<i>LJ Appel</i>	
Hypoglycemia	401
<i>RA Sulaiman, R Gama, and V Marks</i>	
Inborn errors of metabolism: Classification and biochemical aspects	412
<i>DL Marsden</i>	
Inborn errors of metabolism: Nutrition management of phenylketonuria	424
<i>DL Marsden, B Reineking, and FJ Rohr</i>	
Ketosis	432
<i>DH Williamson</i>	
Lactose intolerance	441
<i>DM Paige</i>	
Liver disorders: Nutritional management	449
<i>Jenifer Thompson and Wikrom Karnsakul</i>	
Lung diseases	463
<i>SA Unger</i>	
Malabsorption syndromes: Nutritional management	477
<i>PM Tsai and C Duggan</i>	
Malnutrition	484
<i>Joy Ngo and Lluís Serra-Majem</i>	
Malnutrition: Secondary, diagnosis and management	507
<i>LH Allen</i>	
Nutrition and asthma	513
<i>Charles B Stephensen and Nicholas J Kenyon</i>	
Nutrition and burn injury – manuscript	522
<i>Marc G Jeschke, Sophie Brosset, and Anna Van Osch</i>	
Nutrition and HIV/AIDS	535
<i>S Filteau and D Manno</i>	

Nutrition and parasitism	541
<i>Olga P García, Gerardo A Zavala, Maiza Campos-Ponce, and Katja Polman</i>	
Nutrition and susceptibility to tuberculosis	549
<i>Pranay Sinha and J Peter Cegielski</i>	
Nutritional support: Adults, enteral	556
<i>Berkeley Limketkai, Octavia Pickett Blakely, and Gerard E Mullin</i>	
Nutritional support: In the home setting	564
<i>M Elia and TR Smith</i>	
Nutritional support: Infants and children, parenteral	574
<i>S Collier and C Lo</i>	
Obesity: Childhood obesity	580
<i>G Bueno-Lozano and LA Moreno Aznar</i>	
Obesity: Complications	590
<i>RL Atkinson</i>	
Obesity: Definition, etiology, and assessment	599
<i>S Hawkesworth</i>	
Obesity: Prevention	604
<i>TP Gill</i>	
Osteoporosis nutritional factors	612
<i>Alexa Barad and Kimberly O O'Brien</i>	
Pediatric feeding disorders: Feeding children who can't or won't eat	622
<i>Sarah E Fleet and Ryan D Davidson</i>	
Sarcopenia: Molecular mechanism and current nutritional approach	633
<i>Kunihiro Sakuma, Akihiko Yamaguchi, and Muneshige Shimizu</i>	
Starvation and fasting: Biochemical aspects	645
<i>Kathleen H McGrath, Wolfram Haller, and Julie E Bines</i>	
Stroke nutritional management	657
<i>L Perry</i>	
The role of nutrition in inflammatory bowel disease: Disease associations, management of active disease and maintenance of remission	669
<i>Gabrielle Wark, Dorit Samocha-Bonet, Simon Ghaly, and Mark Danta</i>	
Tuberculosis: Nutritional management	698
<i>Pranay Sinha and J Peter Cegielski</i>	
Water security and nutrition	706
<i>Joshua D Miller and Sera L Young</i>	
Weight management: Weight cycling	717
<i>L Lissner and BL Heitmann</i>	
Weight management: Weight maintenance	724
<i>Lauren A Griffiths, Anna M Jackson, Elizabeth T Anderson Steeves, and Hollie A Raynor</i>	

## CONTRIBUTORS TO VOLUME 3

---

Kent Aje

*The Cleveland Clinic Foundation, Cleveland, OH,  
United States*

Maxwell Akonde

*Department of Epidemiology and Biostatistics, Arnold  
School of Public Health, University of South Carolina,  
Columbia, SC, United States*

Anthony J Alberg

*Department of Epidemiology and Biostatistics, Arnold  
School of Public Health, University of South Carolina,  
Columbia, SC, United States*

M Alghamdi

*Joint Supervision Programme, King Abdulaziz  
University, Jeddah, Saudi Arabia*

LH Allen

*University of California, Davis, CA, USA*

Elizabeth T Anderson Steeves

*Department of Nutrition, University of Tennessee  
Knoxville, Knoxville, TN, United States*

LJ Appel

*Johns Hopkins University, Baltimore, MD, United States*

Yanela Aravena Rivas

*University College London, London, United Kingdom*

M Ashby-Thompson

*Columbia University, New York, NY, United States*

RL Atkinson

*Virginia Commonwealth University, VA, USA*

Alexa Barad

*Cornell University, Division of Nutritional Sciences,

## EDITOR BIOGRAPHIES

---

### Editor in Chief

#### Professor Benjamin Caballero

*Emeritus Professor, Bloomberg School of Public Health and School of Medicine, Johns Hopkins University, Baltimore, MD, United States.*

Dr. Caballero is Professor Emeritus at the Department of International Health, Bloomberg School of Public Health, with joint appointment at the Department of Pediatrics, School of Medicine, Johns Hopkins University. He obtained his MD from the University of Buenos Aires, Argentina, and his PhD (in neuroendocrine regulation) from MIT, in Cambridge, Massachusetts. He started his academic career at Boston Children's Hospital, Harvard Medical School, and subsequently became the Founding Director of the Center for Human Nutrition at Johns Hopkins University.

Dr. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries.

He is currently a member of the Council of the International Union of Nutritional Sciences. He has served on the Food and Nutrition Board of the US National Academy of Medicine and on a number of expert panels, including the Dietary Reference Intakes Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the U.S. Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration, and of advisory committees of the National Institutes of

Health and the Department of Agriculture. He is a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK), and a member of the Spanish Academy of Nutritional Sciences.

He is the Editor-in-Chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption, and biological effects. He is also Editor-in-Chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. He also co-edited a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

### Section 1: *The Foundations of Human Nutrition*

#### Professor Angel Gil

Honorary President of the Iberoamerican Nutrition Foundation (FINUT), Emeritus Professor, Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology, Centre of Biomedical Research, University of Granada, Campus de la Salud, Avda. del Conocimiento, 18100 Armilla, Granada, Spain.

**Angel Gil** is an Emeritus Professor at the University of Granada and a Full Professor in the Department of Biochemistry and Molecular Biology. He is Doctor Honoris Causa at the Autonomous University of Nuevo León, Monterrey, México, and a visitant Professor of the University of Chile, Santiago de Chile, and University of San Miguel de Tucumán, Argentina. He got a major degree in Biology (1973) and PhD in Biochemistry and Molecular Biology (1978).

Prof. Gil is an internationally recognized authority in Food and Nutrition: His expertise extends from the study of human milk composition to the molecular effects of food bioactive compounds and probiotics and the design and development of novel products for infant and clinical nutrition. He conducted pioneering and innovative research, leading 7 international, 27 national, and more than 50 projects and 120 contracts; he has taught since 1981, supervising more than 50 PhD students.

Prof. Gil has several areas of interest that include evaluating the role of dietary nucleotides in early life and the development of infant nutrition products. Besides, the isolation, identification, and description of the mechanism of action of probiotics and the metabolic, molecular, and genetic factors involved in obesity and the early onset of metabolic syndrome (MS) in childhood; and the design, development, and evaluation of enteral clinical nutrition products. What describes Prof. Gil best is the variety of fields

and problems he has faced during his professional carrier and his significant ability to combine his knowledge and expertise in Food Science and Human Biochemistry. This has allowed him to design, develop, innovate, and evaluate exclusive products for Human Nutrition, which are demonstrated in his published articles and his patents' impact.

The multi- and interdisciplinary nature of his work is reflected in the variety of international journals in which he has published 546 articles. Also, he has published 28 books and about 180 book chapters. His five volumes *Treatise of Nutrition*, 3rd Edition, Ed. Medica Panamericana, 2017, with more than 3500 pages, is the "bedside" book for the study of Nutritional Sciences in Spain and all Latin American countries.

He has also been the Chairman of the International Union of Nutritional Sciences (IUNS) 21st International Congress of Nutrition (2013) and the Executive Director of the 23rd International Congress of Nutrition (2017) and has been engaged in the organization of other renowned international congresses. He is a member of prestigious international and national nutrition societies and Honorary President of the Iberoamerican Nutrition Foundation (FINUT), a nonprofit organization promoted by the IUNS, in which the main goal is to contribute to the formation of young scientists in Food and Nutrition in the setting of Iberoamerica. He has received 42 National and International Awards for his contribution to Nutrition and Food Science, among them, the Class Fellow 2022 of the American Society of Nutrition; the Sir David Cuthbertson Lecture Award of the European Society of Clinical Nutrition and Metabolism for scientific achievement in clinical nutrition on 2021; the Award "Granada, City of Science and Innovation" 2021 to the Scientific Career; the Gregorio Marañón Award 2018 to the best Spanish Scientist in the field of Food Science and Nutrition; the Institute Danone Spain Award 2017; the Award of the Spanish Federation of Dairy Industries, 2015; the Nutra Excellence Award 2014, Nutra India Summit; the UIB Honorary Award of 2013; and the NAOS Strategy Prize 2012, Special recognition for his extensive professional experience in the field of nutrition and obesity, Spanish Ministry of Health, Social Services and Equality (AESAN).

### Section 2: *Molecular Mechanisms for the Interaction of Nutrients and Health*

#### Dr. Noel W. Solomons

Center for the Studies of Sensory Impairment, Aging, and Metabolism (CeSSIAM), Guatemala City, Guatemala, Guatemala

**Noel W. Solomons** was Assistant and Associate Professor from 1977 to 1984 in the former Department of Nutrition and Food Science of MIT. A resident of Guatemala since 1975, he cofounded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) in 1985, where he has been Scientific Director ever since. He is an Adjunct Professor at Tufts University in both the Friedman School of Nutrition Science and Policy and the Department of Public Health and Community Medicine.

Dr. Solomons received his MD degree from Harvard Medical School and subsequently undertook clinical and research training in infectious diseases and in gastroenterology and clinical nutrition at the Universities of Pennsylvania and University of Chicago, respectively. He was Editor-in-Chief of the *Food and Nutrition Bulletin* from 2016–2020. He has 364 publications indexed on PUBMED. In addition, he has edited 2 books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection. Also, he has supervised doctoral dissertations for 12 PhD candidates from the USA, Canada, Germany, Spain, the UK and the Netherlands through CeSSIAM.

## Section 3: Diet Composition

**Professor Anura Kurpad**

Department of Physiology, St John's Medical College, Bengaluru, India

**Anura Kurpad** works at St. John's Medical College, Bengaluru. He received his MBBS and MD from St. John's, and his PhD from Bangalore University in 1992. He was a Postdoctoral Fellow at the Rowett Research Institute and at Cambridge University, UK, and a visiting Scientist at MIT, Cambridge, United States. He is an elected Fellow of the Royal College of Physicians (London), Fellow of the Indian National Academy of Medical Sciences, Indian Academy of Sciences, and International Union of Nutritional Sciences. His interests are in human, clinical, and public health aspects of nutrition, applied throughout the life cycle. His research focuses on the physiology and clinical aspects of human energy and protein requirements and metabolism, with more recent interests in micronutrient status and metabolism. He is an Associate Editor of *The American Journal of Clinical Nutrition*. He was the President of the Nutrition Society of India from 2012 to 2016 and is the current President of the Asia Pacific Clinical Nutrition Society. He has been, and is, on many national and international advisory bodies, including being the Chair of the Indian Nutrient Requirements Committee.

## Section 4: Disorders Directly Related to Inadequate Nutrient Intake

**Dr. Katherine L. Tucker**

Department of Biomedical and Nutritional Sciences, Center for Population Health, University of Massachusetts Lowell, Lowell, MA, United States

**Katherine L. Tucker**, PhD, is University Distinguished Professor of Nutritional Epidemiology in the Department of Biomedical and Nutritional Sciences, and Director of the Center for Population Health, at the University of Massachusetts Lowell. She holds an adjunct appointment at the University of Massachusetts Medical School. She received her PhD from Cornell University and her undergraduate degree from the University of Connecticut, both in nutritional sciences. Between these degrees, she spent 2 years as a Peace Corps volunteer in the Philippines. Before joining UMass Lowell, she was at the USDA Human Nutrition Research Center on Aging at Tufts University, and McGill University. Dr. Tucker has contributed to more than 450 articles in scientific journals. Her research focuses on dietary intake and risk of chronic disease, including osteoporosis, cognitive decline, obesity, metabolic syndrome, and heart disease, with an emphasis on health disparities. She is the PI of the Boston Puerto Rican Health Study, an ongoing cohort study, to examine the roles of diet, health behaviors, stress, and genetic predisposition in relation to chronic conditions, including heart disease, cognitive decline, and bone health; and is actively involved as a scientific advisor for the NHLBI Jackson Heart Study. She served two terms on the Food and Nutrition Board of the National Academies of Science and Engineering. She is a Fellow of the American Society for Nutrition (ASN), the Gerontological Society of America, and the American Society for Bone Mineral Research and is

currently the Editor-in-Chief of *Advances in Nutrition*, the international review journal of the ASN, and Senior Editor of the forthcoming 12th edition of the textbook, *Modern Nutrition in Health and Disease*.

## Section 5: Nutrition in Disease States

**Dr. Paolo M. Suter**

Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital, Zurich, Switzerland.

**Paolo M. Suter**, MD, MS, is a Professor of Medicine presently affiliated with the Department of Endocrinology, Diabetology and Clinical Nutrition at the University Hospital Zurich (Switzerland). He received his MD at the University of Zurich and an MS in Nutrition at Tufts University (Boston, USA). He specialized in Internal Medicine and was a Faculty Member at the Medical Polyclinic of the University Hospital Zurich, where he was directing the well-known Hypertension and Obesity Outpatient Consultation. His research activities focused on vitamin nutriture in the elderly, alcohol metabolism and obesity, blood pressure and hypertension, as well as nutrition and lifestyle in non-communicable disease prevention. During his clinical work he focused on the ideal combination of pharmacological therapy with nonpharmacological strategies and on the therapy and prevention of diseases especially hypertension and obesity. Besides many research publications and review articles he authored a widely used textbook entitled *Checkliste Ernährung (Checklist Nutrition)*. He served on different national and international boards in the area of his expertise.

Section 6: *Nutrition in the Life Cycle***Professor Lawrence J. Cheskin**

*Department of Nutrition and Food Studies, George Mason University, Fairfax, VA, United States*

*And*

*Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD, United States*

**Lawrence J. Cheskin, MD, FACP, FTOS**, is Professor and Chair of the Department of Nutrition and Food Studies at George Mason University in Fairfax, VA, and an Adjunct Faculty Member of the Department of Medicine at the Johns Hopkins School of Medicine in Baltimore, MD, United States. He received his medical degree from Dartmouth and was a Postdoctoral Fellow in gastroenterology and liver diseases at Yale University-New Haven Hospital. Dr. Cheskin's work is at the intersection of public health nutrition and clinical medicine and has dedicated his career to research, education, and program building in the service of combating obesity, through both treatment and prevention. He founded the Johns Hopkins Weight Management Center, a multidisciplinary clinical research and treatment program. He was also Director of Clinical Research of the Global Obesity Prevention Center at Johns Hopkins and directed its Pilot Studies Core, which evaluated systems-focused proposals worldwide to study such areas as school policies and the built environment in preventing childhood obesity. He is co-PI of the Mason Cohort Study of entering college freshmen and has authored over 240 peer-reviewed journal articles and 8 books. He is committed to mentoring the next generation of public health and clinical scholars dedicated to nutrition and obesity.

Section 7: *Nutrition Epidemiology***Dr. Manuel Franco**

*Associate Professor at the Department of Surgery, Medical and Social Sciences, University of Alcalá, Madrid, Spain, and adjunct faculty at the Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

**Manuel Franco, MD, PhD**, Epidemiologist, is an Associate Faculty at the University of Alcalá and an Adjunct Faculty at the Johns Hopkins Bloomberg School of Public Health.

He is the Principal Investigator of the European Research Council Starting Grant Heart Healthy Hoods (<http://www.hhhproject.es>) studying urban characteristics in relation to eating patterns, physical activity levels, smoking, and alcohol consumption. He is also the PI of the Participatory Project on food in the cities: Photovoice Villaverde (<https://youtu.be/VliFggKzVas>).

Manuel Franco trained in Medicine both in Madrid and Berlin. As a Fulbright Scholar he joined the Johns Hopkins Bloomberg School of Public Health Department of Epidemiology to obtain his PhD and Postdoctoral Fellowship in the fields of social epidemiology and urban health.

His work focuses on the prevention of chronic diseases and their major risk factors as nutrition. He has published 94 international peer-reviewed articles and has led 15 studies as PI raising over 2.9 million € in competitive international research bids. His methodological interests include the measurement of urban characteristics related to chronic diseases and nutrition, the use of mixed methods, and the conduction of participatory action research methods.

Section 8: *Global aspects of Human Nutrition***Professor Daniel J. Hoffman**

*Department of Nutritional Sciences and director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States*

**Daniel J. Hoffman, PhD**, is a Professor in the Department of Nutritional Sciences and Director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States. He graduated from St. John's University, Collegeville, MN, United States, and received his PhD in Human Nutrition from the Tufts University Friedman School of Nutrition Science and Policy, Boston, MA, United States. For his doctoral training, Dr. Hoffman studied the metabolism of children living in the shantytowns of São Paulo, Brazil. He then completed a Postdoctoral Fellowship at Columbia University, New York, NY, United States, before joining the faculty at Rutgers University.

Dr. Hoffman's research focuses on the long-term impact of undernutrition early in life on body composition and metabolism later in life. This work is complemented by research on sustainable methods to improve diet and growth in lower- and middle-income countries, including Brazil, Mexico, Kenya, South Sudan, and Vietnam. He also directs the Center for Childhood Nutrition Research at the New Jersey Institute for Food, Nutrition, and Health where members conduct interdisciplinary research on childhood growth and development. Dr. Hoffman is an Associate Editor of the *Food and Nutrition Bulletin* and a Section Editor for the *Annals of Human Biology*. His other responsibilities include serving on the editorial board of the *Journal of Nutrition*, serving in leadership positions for the American Society for Nutrition, and advising international and national agencies on matters related to childhood nutrition. Aside from his

academic life, Dr. Hoffman is a published documentary photographer whose portfolio includes work on the life of Roma in Europe, urban landscape of São Paulo, Brazil, gentrification of Times Square in New York City, and punk music as the "American Mosaic."

## PREFACE

---

By the middle of last century, the science of nutrition had identified most of the essential nutrients and had provided evidence to propose specific dietary intake recommendations for many diet constituents, with the practical aim of preventing nutrient deficiencies. As chronic, noncommunicable diseases such as cardiovascular disease, cancer, etc., began to emerge as an important causal factor for disability and early death, scientists turned their attention to the potential effects of nutrients and diet patterns on chronic disease risk. Pioneering studies by Burkitt, Keys, Breslow, and others were followed by a large number of studies on the role of dietary patterns and constituents on certain chronic diseases. Many important studies were completed over the second part of the century, providing the evidence to support specific dietary recommendations to reduce disease risk.

The 21st century ushered the next transition in nutrition science, this time centered on the interrelationships between nutrients, dietary patterns, and the human genome. Over the past few decades, advances in our understanding of the human genome and on the molecular tools to explore it have permitted to probe those interactions in increasing detail. In turn, findings from nutrient–gene interaction studies have informed population-wide and clinical and metabolic studies, further advancing our understanding of the effects of diets on human health at the molecular level. This understanding of the links between genotype, phenotype, and nutrient/dietary intake became a key contributor to the emerging area of personalized nutrition/precision medicine.

All those phases of research emphasis, to different degree, continue to exist today and result in a vast, multidisciplinary, ever-expanding amount of information reaching the peer-reviewed literature. This massive amount of information needs to be organized and summarized in a way that makes it accessible to experts, teachers, and, as much as possible, the general public. This has been and continues to be the goal of the *Encyclopedia of Human Nutrition* since its first edition, over 20 years ago.

Such an ambitious task can only be achieved by the collective work of many people. We all have experienced the challenge of writing an article that combines focus and relevance with conciseness, so we are very appreciative of the work of our contributors. Their effort was backed up by an excellent editorial board, which reviewed and provided feedback on every manuscript. Finally, we must acknowledge the outstanding support of the Major Reference Works division at Elsevier. A publication like this *Encyclopedia* has a lot of moving parts, and it is a great privilege to be able to concentrate on the content, knowing that the other parts of the process are in the hands of excellent professionals.

We hope that this book will help satisfy the need for accurate and concise information to the many students and professionals who are committed to use nutrition science as a tool to improve people's quality of life.

Benjamin Caballero, MD, PhD  
Editor In Chief

### Glossary

**Acute phase response** Various physiological processes occurring soon after the onset of infection, trauma, inflammatory processes, and some malignant conditions; an increase or decrease in acute phase proteins in serum, fever, increased vascular permeability, and metabolic and pathologic changes are part of an acute phase response.

**Biochemical test** Laboratory test that measures the level of an analyte or metabolite in, for e.g., serum, blood or urine.

**Chromatography assay** Laboratory technique that separates a compound of interest from other compounds by either passing a liquid or a gas in which the compound of interest is dissolved (mobile phase) through a stationary phase; this process separates the compound of interest from other compounds in the mixture based on differential partitioning between the mobile and stationary phases.

**Cutoff point** A concentration or quantity that is selected in clinical practice for quantitative diagnostic tests and maximizes the specificity and sensitivity of the diagnostic test.

**Immunoassay** Laboratory assay that typically measures analytes in biological liquids such as serum and urine; the technique is based on the unique ability of an antibody to bind with high specificity to one or a very limited group of molecules, representing the antigen.

**Nutritional deficiency** Progression throughout various stages from adequate to inadequate nutritional body stores, leading to disturbances in metabolism and ultimately to clinical signs and symptoms.

## Introduction

Biochemical methods are considered to be the most objective measures for the assessment of nutritional status of individuals or communities. Ideally, the method employed should cover various cutoff points specific and sensitive to depletion of the nutrient body pool or tissue store.

The pathophysiology of deficiency for most nutrients, particularly vitamins, progresses in successive stages. The first stage of deficiency is when nutrient body stores begin to be depleted; in this stage, urinary excretion of the nutrient decreases, whereas homeostatic regulation ensures that the level of nutrient in the blood or tissues does not change. In the next stage, depletion is more marked; nutrient excretion via urine continues to decrease and blood and other tissue concentrations are reduced. Evidence of an increase in compensatory or dependent metabolites or enzymes tends to characterize the third stage. In the last stage, morphological or functional disturbances are present, first reversible, then irreversible, which can manifest as clinical signs and symptoms when these biochemical effects accrue or worsen.

The static and functional tests most commonly used in nutritional status assessment in humans are discussed here. Static tests measure the content of nutrients, their active or inactive metabolites, or other related components in tissues or fluids. Functional tests measure the behavioral, physiological, or biochemical functions of the organism that are dependent on the adequate availability of a nutrient, or the organism's responses to the processes to maintain body stores or homeostasis. The availability of specific and reliable chromatography-based methods in recent times has allowed for more frequent use of static compared to functional tests. The choice of tissue or fluid depends on the information required (long-term status or short-term, body pool or tissue store), operational characteristics of the biochemical test, and on the condition of the subject.

Various factors influence biochemical test results. Some are related to the individual, such as age, sex, genetics, physiological, and hormonal status; others are environmental or situational, such as seasonality, elevation, and latitude and thus cannot be eliminated; still others are behavioral and more easily modified (e.g., alcohol intake, smoking habits, and use of medicines). Major factors influencing biochemical indicators are presented in [Table 1](#). In addition, infection and inflammation are known to have confounding effects on several laboratory tests and this is discussed as part of each nutrient status section. Different approaches have been investigated to account for infection and inflammation in nutrition surveys (e.g., exclusion of participants with infection, adjustment of biomarker levels in those with infection). Although no consensus exists on the best approach, the concurrent serum determination of acute phase proteins such as C-reactive protein (CRP) and  $\alpha$ 1-acid glycoprotein (AGP) is highly recommended. Influential factors of a technical nature can usually be reduced or eliminated by adherence to standardized sample handling protocols. [Table 2](#) provides information on preanalytical factors (e.g., fasting, storage stability, freeze/thaw stability) that influence biochemical indicators used to assess nutritional status.

## Protein Nutritional Status

Several serum or plasma proteins can be used to roughly measure the adequacy of protein intake and metabolism, including albumin and several transport proteins (transthyretin (TTR) involved in thyroid hormone transport and formerly called prealbumin, transferrin (TF), and retinol binding protein (RBP)). These proteins will decrease during acute phase response. Reduction of albumin levels may indicate a catabolic state, but is more common in chronic liver disorders. Serum albumin, easily measured by automated clinical analyzers, has a large body pool and a long half-life; it is therefore a less sensitive index of immediate nutritional status. TTR, complexed with RBP in the carriage of vitamin A, TF, and RBP have smaller pool sizes and shorter half-life than serum albumin, however, their specificity as an index of protein status is low and they are confounded by some nutritional deficiencies (vitamin A deficiency for RBP, iron deficiency for TF) and disease states. Serum transport proteins are measured by radial immunodiffusion or immunoassay including nephelometry and turbidimetry. Serum insulin-like growth factor I, or somatomedin C, is a regulator of anabolic properties. It has been proposed as a more sensitive indicator to changes in protein status than other serum proteins. It can be measured by immunoassay techniques.

Urinary creatinine, derived from the catabolism of creatine phosphate which is present mainly in muscle, can be used as a biochemical marker of muscle mass after adjustment for body mass, race, and gender. It is measured by direct colorimetric and enzymatic methods and available on automated clinical analyzers. A major difficulty in estimating urine creatinine excretion is ensuring that 24-h urine collections are complete. Various assumptions are required when estimating the muscle mass from urinary creatinine and influencing factors have to be taken into consideration. In the clinical setting, the creatinine/height index is used to assess the degree of depletion of muscle mass in children with the marasmic form of protein-energy malnutrition and to monitor the effects of long-term nutritional intervention on repletion of lean body mass in hospital patients. Measurement of the amino acid 3-methylhistidine in urine is used as an indicator of muscle protein turnover, however, available data on various populations is limited.

Metabolic changes that occur in protein-energy malnutrition are sometimes used as less specific indices of protein status. These relate to changes in free amino acid profiles in plasma, reduced urinary hydroxyproline excretion and increased urinary nitrogen excretion. Functional indices of protein status include muscle function, handgrip strength, and immunological testing.

**Table 1** Factors known to influence biochemical indicators

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Influencing factors</i>
Protein	Serum albumin	<ul style="list-style-type: none"> <li>↑ ↓ Age, sex</li> <li>↑ Dehydration</li> <li>↓ Acute phase infection and chronic inflammation, catabolic states, protein-losing diseases, hemodilution, zinc depletion</li> </ul>
	Serum transport proteins: TTR, TF and RBP	<ul style="list-style-type: none"> <li>↑ Chronic renal failure (for TTR and RBP), when estrogen is increased (for TF)</li> <li>↓ Infection, protein-losing diseases, hemodilution, zinc depletion, vitamin A deficiency (for RBP), iron deficiency (for TF)</li> </ul>
	Urinary creatinine	<ul style="list-style-type: none"> <li>↑ ↓ Age, sex, diet, diurnal and day-to-day variations</li> <li>↑ Intensive exercise, pregnancy, catabolic states, hypothyroidism</li> <li>↓ Chronic renal failure, hyperthyroidism, diseases with decreased muscle mass</li> </ul>
	Urinary 3-methylhistidine	<ul style="list-style-type: none"> <li>↑ ↓ Age, sex, diet</li> <li>↑ Intensive exercise, catabolic states</li> <li>↓ Chronic renal failure</li> </ul>
	Serum IGF-I	<ul style="list-style-type: none"> <li>↓ Stress, hormonal diseases, hepatocellular diseases</li> </ul>
Fatty acids	Plasma fatty acids	<ul style="list-style-type: none"> <li>↑ ↓ Smoking, exercise, stress, pregnancy, estrogens, obesity, alcohol, diabetes, renal disease</li> <li>↑ Age</li> <li>↓ Fat malabsorption, catabolic states, depression</li> </ul>
Vitamin A	Serum retinol, RBP, RDR and MRDR	<ul style="list-style-type: none"> <li>↑ ↓ Sex, race</li> <li>↑ Age, chronic renal disease, estrogens</li> <li>↓ Protein–energy malnutrition, fat malabsorption, catabolic states, zinc deficiency, liver disorders</li> </ul>
Carotenoids	Serum carotenes, cryptoxanthin, lutein, zeaxanthin, lycopene	<ul style="list-style-type: none"> <li>↑ ↓ Age, sex, race, season, smoking, alcohol, BMI</li> <li>↓ Fat malabsorption</li> <li>Diet and season, sex and age, infection, smoking, and drinking habits and circulating lipids are determinants of carotenoid concentrations.</li> </ul>
Vitamin D	Serum 25OHD	<ul style="list-style-type: none"> <li>↑ ↓ Season/latitude, age, sex, race</li> <li>↑ Sun exposure, dairy consumption, estrogens</li> <li>↓ Skin pigmentation, liver or renal diseases, smoking, drugs, fat malabsorption, obesity</li> </ul>
Vitamin E	Serum $\alpha$ -tocopherol	<ul style="list-style-type: none"> <li>↑ ↓ Race</li> <li>↑ Age, hyperlipidemia, pregnancy</li> <li>↓ Fat malabsorption, abetalipoproteinemia, premature infants</li> </ul>
Vitamin K	Serum phyloquinone (K <sub>1</sub> ), menaquinones (K <sub>2</sub> )	<ul style="list-style-type: none"> <li>↑ ↓ Age, sex, season</li> <li>↑ Plasma triglyceride levels</li> <li>↓ Fat malabsorption, osteoporosis, liver disease, hemorrhagic disease of newborn, antibiotics and other drugs</li> </ul>
Thiamin	Erythrocyte TDP	↓ Hemodialysis, storage of specimen
	Serum thiamin	↓ Alcoholism
	Urinary thiamin	↓ Starvation
	Erythrocyte EKT-AC	↑ Alcoholism, pernicious anemia
Riboflavin	Erythrocyte or serum FAD, FMN	↓ Diabetes mellitus, polyneuritis, storage of specimen
	Urinary riboflavin	↓ Alcoholism, hypothyroidism, anorexia
		↑ Negative nitrogen balance, infection, drugs
	Erythrocyte EGR-AC	↓ Starvation
Niacin Vitamin B <sub>6</sub>	Urinary methylated niacin metabolites	↑ Alcoholism, heterozygous beta thalassemia, iron-deficiency anemia, severe uremia, liver cirrhosis
	Serum PLP	↓ Glucose-6-phosphate dehydrogenase deficiency, pyridoxine deficiency, storage of specimen
		↓ Drugs, alcoholism
		↑ ↓ Age, sex
		↑ Prolonged fasting
		↓ Drugs, alcohol intake, smoking, malnutrition, pregnancy, various disease states
	Urinary 4-PA	↑ ↓ Drugs
	Erythrocyte EAST-AC	↑ ↓ Drugs and diseases that affect the liver and heart
		↓ Alcohol intake, pregnancy

(Continued)

**Table 1** Factors known to influence biochemical indicators—cont'd

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Influencing factors</i>
Folate	Serum folate	↑ ↓ Age, sex, race ↑ Hemolysis ↓ Pregnancy, smoking, alcoholism, antifolate drugs, malnutrition, malabsorption, storage of specimen
	RBC folate	↑ ↓ Age, sex, race ↑ Iron deficiency ↓ Pregnancy, smoking, malnutrition, malabsorption, vitamin B <sub>12</sub> deficiency
	Plasma tHcy	↑ ↓ Age, sex, race, diet ↑ Deficiencies in B <sub>2</sub> , B <sub>6</sub> , and B <sub>12</sub> , impaired renal function, smoking, alcohol intake, lack of exercise, various disease states, drugs, inborn errors affecting enzymes involved in lowering tHcy level, delayed processing of blood specimen ↓ Pregnancy
Vitamin B <sub>12</sub>	Serum B <sub>12</sub>	↑ ↓ Age ↑ Chronic renal failure, severe congestive heart failure, diabetes, organic diseases ↓ Drugs, alcoholism, pregnancy, smoking, vegetarianism, folate deficiency, bacterial overgrowth, disease states associated with alterations in the levels of vitamin B <sub>12</sub> -binding proteins, malabsorption, worm infestation
	Serum MMA	↑ Impaired renal function, bacterial overgrowth, cobalamin genetic defects, classical methylmalonic acidemia
Vitamin C	Serum total ascorbic acid	↑ ↓ Age, sex, race ↓ Smoking, low socioeconomic status, catabolic states, obesity, improper specimen handling
Sodium and potassium	Urinary sodium, potassium	↑ ↓ Age, sex ↑ Renal disease, conditions in which urine is alkaline ↓ Renal diseases with decreased urine flow, diarrhea, or excessive sweating
Calcium	Serum ionized calcium	↑ ↓ Age ↑ Hyperparathyroidism, functional hypercalcemia, hemodialysis ↓ Hypoparathyroidism, vitamin D-deficient rickets
Magnesium	Serum magnesium	↑ ↓ Age, sex, race, diurnal variation, hypo-/hyperalbuminemia ↑ Renal failure, hemolysis, drugs (antacids, cathartics) ↓ Pregnancy, strenuous exercise, osteoporosis, drugs (diuretics, antibiotics), GI and renal disease
Iron	Serum ferritin	↑ ↓ Age, sex, race ↑ Acute phase infection and chronic inflammation, liver disorders, malignant diseases, acute leukemia, Hodgkin's disease, rheumatoid arthritis, thalassemia major, alcohol intake
	Serum sTfR	↑ ↓ Age, sex, race ↑ Autoimmune hemolytic anemia, sickle cell anemia, folate, or vitamin B <sub>12</sub> deficiency ↓ Chronic renal failure
	Serum iron, TIBC, TS	↑ ↓ Age (mainly for iron), biological variation (mainly for iron) Chronic disease states with infection, inflammation (decrease in iron and TIBC, TS low) Decreased erythropoiesis due to folate or vitamin B <sub>12</sub> deficiency (increase in iron, decrease in TIBC, TS high) Increased erythropoiesis in response to vitamin B <sub>12</sub> and folate therapy, in hemolysis, in polycythemia (decrease in iron, increase in TIBC, TS low)
	Erythrocyte zinc protoporphyrin	↑ ↓ Age, sex ↑ Chronic disease states with infection, inflammation and some neoplastic diseases, lead poisoning, porphyrin disorders
	Hemoglobin	↑ ↓ Age, sex, race, biological variation ↑ Polycythemia, dehydration

**Table 1** Factors known to influence biochemical indicators—cont'd

Nutritional status	Biochemical indicator	Influencing factors
Zinc	Serum zinc	↓ Pregnancy, iron-deficiency anemia, deficiencies of vitamin A, B <sub>2</sub> , B <sub>6</sub> , B <sub>12</sub> , folate and copper, parasitic infections, chronic infection and inflammation, chronic diseases that cause overhydration or plasma volume expansion, smoking
		↑ ↓ Age, sex, diurnal variation, fasting
Copper	Serum copper and ceruloplasmin	↑ Hemolysis, delayed separation of serum from red cells
		↓ Pregnancy, acute infection and inflammation, estrogen-containing preparations, malabsorption syndromes, chronic disease states resulting from hypoalbuminemia
Selenium	Serum selenium	↑ ↓ Age, sex, diurnal variation, certain disease states
		↑ Pregnancy, estrogen-containing preparations, smoking, acute phase infection, chronic inflammation, stress, delayed separation of serum from red cells
Iodine	Urinary iodine	↓ Malabsorption syndromes
		↑ ↓ Age, diet
	Serum or whole blood TSH	↓ Prematurity, pregnancy and lactation, smoking, genetic defects (maple sirup urine disease, PKU), certain disease states (disorders of digestive tract, muscle disorders, neurological diseases, inflammatory diseases, chronic renal failure, cancer, CVD)
		↑ ↓ Diurnal variation
		↓ Pregnancy
		↑ Congenital hypothyroidism, exposure to iodine-containing antiseptics

## Essential Fatty Acid Status

Essential fatty acids are those fatty acids that are not synthesized by the body but are vital for proper growth and development; linoleic and linolenic acids are essential and must be obtained through dietary sources. Fatty acids can be measured in plasma or serum, in the phospholipid fraction of plasma, in red blood cell membranes, in whole blood, or in tissues. *In vivo*, fatty acids are almost always combined with sterols, glycerol, or phospholipids although free fatty acids circulate bound to albumin (1 mol albumin: 20 mol fatty acids) and the flux of free fatty acids through the plasma is very large and varies with metabolic demands. Fatty acid data are expressed either as concentration or as a percentage of total fatty acids. Capillary gas chromatography (GC) is the technique most frequently used to separate fatty acids for quantitative analysis. Detection methods include flame ionization or electron capture negative chemical ionization mass spectrometry. Internal standards are used to correct for losses during sample preparation and improve the accuracy and precision of measurements. Most often, the diagnosis of essential fatty acid deficiency is made from clinical findings but deficiency may be detected weeks to months before clinical manifestations are present using fatty acid profiling. Unusual or large changes in total or individual plasma fatty acids are due to underlying disease states (liver disorders), medications, or inborn errors of metabolism. General fatty acid deficiency can be detected when values of linoleic and alpha-linolenic acids are low based on total plasma fatty acids or phospholipid extracts of plasma. In addition, the ratio of triene to tetraene fatty acids is the most common laboratory indicator of essential fatty acid deficiency (Holman index). The omega-3 (n-3) index, a measure of the amount of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in red blood cell membranes as a proportion of total fatty acids, has been suggested to be a marker of risk for sudden cardiac death.

## Vitamin Nutritional Status

### Vitamin A

Vitamin A (retinol) status can be assessed by testing liver, plasma, or serum. The best way to determine inadequate status is through hepatic biopsy but this procedure is invasive and unsuitable in population studies. Serum or plasma retinol is usually measured using high performance liquid chromatography (HPLC) with ultraviolet (UV) detection after separation from its carrier RBP. Serum retinol values do not always reflect total body status because of homeostatic control and therefore are often not useful for assessing the vitamin A status of individuals. Additional tests may be required to confirm vitamin A deficiency when  $0.70 \mu\text{mol l}^{-1}$  is used as

**Table 2** Preanalytical factors influencing biochemical indicators for nutritional status assessment

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Specimen collection requirements</i>	<i>Storage stability</i>	<i>Freeze/thaw stability</i>
Protein	Serum albumin	Fasting not required	Stable for a few days refrigerated; stable for several months frozen	Minimize freeze/thawing
	Urinary creatinine	Fasting not required; 24-h collection recommended (ideally for 3 consecutive days)	Stable for a few days at RT; stable for weeks refrigerated; stable for years frozen	Stable for at least 5 cycles
	Urinary 3-methylhistidine	Fasting not required; 24-h collection essential (ideally for 3 consecutive days)	Stable for a few days refrigerated; stable for several months frozen	No information
Fatty acids	Plasma fatty acids	Fasting essential	Stable for several years at $-70^{\circ}\text{C}$	Stable for at least 4 cycles
	RBC fatty acids	Fasting not required	Stable for 7 days at RT for an omega-3 index assessment; stable for at least 4 years at $-80^{\circ}\text{C}$	No information
Vitamin A	Serum retinol	Fasting not required	Stable for years at $-70^{\circ}\text{C}$ ; stable for weeks refrigerated	Little deterioration for at least 3 cycles
	Serum RBP	Fasting not required	Reported to be as or more stable than retinol	
Carotenoids	Serum carotenes, cryptoxanthin, lutein, zeaxanthin, lycopene	Fasting recommended	Stable for years at $-70^{\circ}\text{C}$ ; stable for weeks refrigerated	Little deterioration for at least 3 cycles
Vitamin D	Serum 25OHD	Fasting not required	Stable for years at $-70^{\circ}\text{C}$ ; stable for weeks at $37^{\circ}\text{C}$	Little deterioration for at least 5 cycles
Vitamin E	Serum $\alpha$ - and $\gamma$ -tocopherol	Fasting recommended; alternatively, normalization to cholesterol or lipids content	Stable for years at $-70^{\circ}\text{C}$ ; stable for weeks refrigerated	Little deterioration for at least 3 cycles
Vitamin K	Serum phyloquinone ( $K_1$ ), menaquinones ( $K_2$ )	Fasting recommended; abstain from alcohol for 1 day before blood draw	Protect from light; stable for 6 months frozen	No information
Thiamin	Erythrocyte or whole blood TDP	Fasting not required; measure Hb when whole blood is used to correct for cell volume variability	Protect from light; transport frozen to avoid loss of TDP; whole blood stable at RT up to 2 days; hemolyzed erythrocytes and whole blood stable for at least 6 months at $-70^{\circ}\text{C}$	Stable for 3 cycles (whole blood hemolysates)
	Serum thiamin	Fasting not required	Protect from light; stable for 1 year frozen	No information
	Urinary thiamin	Fasting not required; 24-h collection recommended	No information	No information
	Erythrocyte ETK-AC	Fasting not required; packed erythrocytes must be washed and buffy coat removed	Rapid enzyme inactivation within 2 weeks stored at $-20^{\circ}\text{C}$ ; hemolysate is stable for 1 year at $-70^{\circ}\text{C}$	Avoid freeze/thawing
Riboflavin	Erythrocyte, whole blood or serum FAD, FMN	Fasting not required	Protect from light; stable for at least 5 h at RT in whole blood; endogenous vitamers stable for 14 days at RT in EDTA plasma (supplemented FAD is less stable); serum vitamers stable for 1 year frozen	No information
	Urinary riboflavin	Fasting not required; 24-h collection recommended	Protect from light; little deterioration when specimen in amber glass vial is exposed to fluorescent light at RT for up to 3 days; stable for up to 6 months refrigerated or frozen at $-20^{\circ}\text{C}$	No information
	Erythrocyte EGR-AC	Fasting not required; packed erythrocytes must be washed	If assay is not performed immediately, hemolysate has to be frozen and is stable for 1 year at $-70^{\circ}\text{C}$	No information
Niacin	Urinary methylated metabolites	Fasting not required; 24-h collection recommended; acidify with HCl	No information	No information

**Table 2** Preanalytical factors influencing biochemical indicators for nutritional status assessment—cont'd

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Specimen collection requirements</i>	<i>Storage stability</i>	<i>Freeze/thaw stability</i>
Vitamin B6	Serum PLP	Fasting not required	Protect from light; stable for several hours at RT in the dark; stable for 1 month at $-20^{\circ}\text{C}$ ; stable for years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
	Urinary 4-PA	Fasting not required (morning fasting urine preferred)	Protect from light; stability of 4-PA in serum exceeds that of PLP and stability of 4-PA in urine is expected to be very good	No information
	Erythrocyte AST-AC	Fasting not required; packed erythrocytes must be washed	Hemolysate is stable for a few months at $-70^{\circ}\text{C}$	No information
Folate	Serum folate	Fasting essential for individual but probably not for population	Protect from light; stable for 1 week refrigerated; stable for a few years at $-70^{\circ}\text{C}$ ; ascorbic acid can be added (0.5% w/v) before storage to improve stability	Little deterioration for at least 3 cycles
	RBC folate	Fasting not required; measure Hct to correct for packed cells; use of serum folate level in calculation of RBC folate level preferred	Protect from light; whole blood stable for several days refrigerated; hemolysate with ascorbic acid (1% w/v) stable for several years at $-70^{\circ}\text{C}$	Little deterioration for at least 3 cycles
	Plasma tHcy	Fasting not required; separate plasma from red cells within an hour of collection to avoid artificial increase in tHcy	Stable for days at RT; stable for weeks refrigerated; stable for years frozen	Excellent stability
Vitamin B <sub>12</sub>	Serum B <sub>12</sub>	Fasting not required; avoid ascorbic acid	Protect from light; stable for several days refrigerated; stable for several years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
	Serum MMA	Fasting not required	Stable for days at RT; stable for weeks refrigerated; stable for years frozen	Excellent stability
Vitamin C	Serum total ascorbic acid	Fasting recommended; blood must be promptly processed and serum must be acidified (metaphosphoric acid) to stabilize ascorbic acid	Acidified serum is stable for at least 10 years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
Calcium	Serum free calcium	Fasting recommended; avoid heparin, triethanolamine, trypsin as they bind calcium; calcium standard should contain sodium and chloride at same level as test samples	Changes in pH of blood may alter measurement; adjust to pH 7.4 with CO <sub>2</sub> before measurement; perform measurement as soon as possible; serum can be stored anaerobically refrigerated for several days or at $-20^{\circ}\text{C}$ for 6 months	No information
Magnesium	Serum magnesium	Fasting recommended; avoid hemolysis; collect in metal-free container; separate red cells immediately	Serum stable for several days if refrigerated; stable for months if frozen	No information
Iron	Serum ferritin	Fasting not required	Stable for years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
	Serum sTfR	Fasting not required	Stable for years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
	Serum iron/TIBC	Fasting not required	Stable for at least 10 years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles
	Erythrocyte zinc protoporphyrin	Fasting not required; avoid hemolysis	Stable for several days if refrigerated	Do not freeze
Zinc	Serum zinc	Fasting not required; collect in prescreened metal-free container; avoid contact with rubber stopper; avoid hemolysis; remove serum promptly from red cells	Stable for years at $-70^{\circ}\text{C}$	Stable for multiple cycles

(Continued)

**Table 2** Preanalytical factors influencing biochemical indicators for nutritional status assessment—cont'd

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Specimen collection requirements</i>	<i>Storage stability</i>	<i>Freeze/thaw stability</i>
Copper	Serum copper	Fasting not required; collect in prescreened metal-free container; remove serum promptly from red cells	Stable for years at $-70^{\circ}\text{C}$	Stable for multiple cycles
Selenium	Serum selenium	Fasting not required; collect in prescreened metal-free container	Stable for years at $-70^{\circ}\text{C}$	Stable for multiple cycles
Iodine	Urinary iodine	Fasting not required; 24-h collection recommended for individual; measurement of urinary creatinine allows for adjustment in casual samples but could be problematic in malnutrition; avoid contamination	Stable for months if refrigerated; stable at least 10 years at $-70^{\circ}\text{C}$	Stable for at least 3 cycles

25OHD, 25-hydroxyvitamin D; 4-PA, 4-pyridoxic acid; AST-AC, erythrocyte aspartate aminotransferase activation coefficient; CRP, C-reactive protein; EGR-AC, erythrocyte glutathione reductase activation coefficient; ETK-AC, erythrocyte transketolase activation coefficient; FAD, flavinadeninucleotide; FMN, flavinmononucleotide; Hct, hematocrit; MMA, methylmalonic acid; PLP, pyridoxal-5'-phosphate; RBC, red blood cells; RBP, retinol binding protein; RT, room temperature; sTfR, soluble transferrin receptor; TDP, thiamin diphosphate; tHcy, total homocysteine; TIBC, total iron binding capacity.

a cutoff. The distribution of serum retinol values in a population together with the prevalence of individuals with serum retinol values below a given cutoff point provide important information about the vitamin A status of a population. WHO recommends using the prevalence of serum retinol  $\leq 0.70 \mu\text{mol l}^{-1}$  to define public health problems involving vitamin A deficiency as mild (2–9%), moderate (10–19%) or severe ( $\geq 20\%$ ). In the case of infection or inflammation, the degree of depression of circulating retinol can be roughly quantified by assessing the concentration of certain acute phase proteins such as CRP and AGP. Misclassification of vitamin A status is likely to occur unless subjects undergoing an acute phase response from infection, trauma, or a chronic inflammatory condition are identified and adjustments are made to account for this phenomenon.

RBP is a well-regulated transport protein for retinol. Nearly all circulating retinol is bound to a soluble RBP-transferrin (TTR) complex in equimolar amounts. Because retinol is closely correlated with RBP, the measurement of this transport protein using enzyme-linked immunosorbent assay (ELISA) has been used to assess vitamin A status. In most populations, serum RBP has been shown to be a suitable surrogate for retinol. The molar ratio of RBP to TTR was introduced to detect vitamin A deficiency in the presence of inflammation but is rarely used nowadays because of unsatisfactory results in several population groups.

The deuterated-retinol-dilution (DRD) technique is used to indirectly assess total body vitamin A reserves. In this test, a dose of deuterium-labeled retinyl acetate is given orally. After allowing time to reach equilibration (3–21 days), deuterated and nondeuterated serum retinol levels are measured using GC with mass spectrometric detection (GC-MS) and this ratio is used to estimate total body stores of vitamin A. Because of technical requirements, this method is used mostly in research. In inflammation, the release of RBP from the liver is reduced, so the test is also unreliable during the acute phase response.

The provitamin (carotenes and cryptoxanthins) and nonprovitamin (lutein, zeaxanthin, and lycopene) compounds of vitamin A, the carotenoids, need consideration due to their independent and specific role in good health by preventing oxidation. Serum levels of carotenoids are correlated with vegetable and fruit intake. Lutein is the best indicator of green leafy vegetable consumption. Lycopene is a good measure of tomato-based product consumption.  $\beta$ -Carotene in industrialized countries is probably a biomarker of carrot consumption and in West Africa a good marker of red palm oil consumption. Serum or plasma levels of carotenoids are measured by HPLC-UV/vis; it is possible to measure in a single assay a panel of about a dozen fat-soluble micronutrients including several forms of vitamins A and E, and individual carotenoids.

Several functional tests have been developed to assess vitamin A reserves in the liver. These tests are based on the accumulation of unbound RBP within the liver when vitamin A intake is low and reserves of retinyl esters are depleted. Once retinol becomes available as a result of uptake from food or supplements or biosynthesis from carotenoids, it is released from the liver bound to RBP within hours of availability. Vitamin A functional tests, the relative dose-response (RDR) and the modified relative dose-response (MRDR) test, take advantage of this immediate release.

Other functional testing protocols involving dark adaptometry have been used to assess night vision as an indicator of vitamin A status. In the rapid dark adaptation test, the subject is light adapted and then while working in dim light, usually takes  $<10$  min to correctly sort colored disks while adapting to darkness. The time required to achieve a perfect score is recorded. A simpler functional test is one in which pupillary dark adaptation is assessed; it requires minimal cooperation and is suitable for very young children

( $\geq 2$  years) who are most likely to be vitamin A deficient. The pupillary threshold test measures the tendency of the pupil to constrict in response to illumination. An impaired response is seen when vitamin A stores are depleted even if overt clinical signs of deficiency are absent.

### Vitamin D

Vitamin D status is routinely assessed by measurement of serum or plasma 25-hydroxyvitamin D (25OHD). Typical methods are either antibody-based (e.g., radioisotope-, enzyme-linked- or chemiluminescence immunoassay), or chemistry-based (e.g., HPLC separation with UV or tandem mass spectrometry [MS/MS] detection). GC-MS has also been employed. Studies have shown that the chemistry-based methods are equivalent but that antibody-based methods may show significant bias compared to chemistry-based methods. Genetic variants near genes involved in cholesterol synthesis, hydroxylation, and vitamin D transport affect vitamin D status.

Several vitamin D functional tests have been suggested such as the measure of: (1) circulating parathyroid hormone (PTH); (2) bone resorption markers such as serum alkaline phosphatase activity, serum C-terminal telopeptide of type I collagen, urinary cross-linked N-telopeptides of type I collagen, and urinary deoxypyridinoline; (3) bone mineral density (BMD); and (4) intestinal calcium absorption. PTH appears to be a useful marker of vitamin D status when vitamin D is given without calcium but not with calcium. Markers of bone resorption are not good functional markers of vitamin D status, due in part to high inter-subject variability; however, bone resorption using a more sensitive calcium radioisotope method may prove to be useful. Increased BMD of some sites appears to be useful as a functional response to vitamin D supplementation in older persons but not adolescents. Intestinal calcium absorption has been shown to be responsive to vitamin D status.

### Vitamin E

Vitamin E status can be assessed in serum, plasma, erythrocytes, platelets, and adipose tissue. The most common and practical measure is  $\alpha$ -tocopherol in serum or plasma using HPLC with UV detection. Because  $\alpha$ -tocopherol is bound to lipoproteins, circulating  $\alpha$ -tocopherol is often expressed relative to serum cholesterol. The determination of  $\alpha$ -tocopherol in adipose tissue biopsy provides information on long-term nutritional status, but this test is too invasive.

Vitamin E functional tests consist of the following assays: erythrocyte hemolysis, erythrocyte malondialdehyde (MDA) release, breath pentane or ethane, susceptibility of low density lipoprotein (LDL) to oxidation using diene conjugate second derivatives, and isoprostane formation. Susceptibility to erythrocyte hemolysis is inversely correlated with  $\alpha$ -tocopherol concentration. *In vivo*, hemolysis ( $>20\%$ ) occurs when  $\alpha$ -tocopherol concentration is  $<4.6\text{--}11.6\ \mu\text{mol l}^{-1}$ . MDA is a breakdown product of lipid peroxidation and is measured colorimetrically. These two *in vitro* erythrocyte assays are the primary vitamin E functional tests; methodological limitations including the need for freshly prepared red blood cells make them disadvantageous.

Volatile hydrocarbons (pentane and ethane) in breath, generated from oxidized lipids, and the susceptibility of LDL to oxidation are general markers of oxidative stress and also have been investigated as functional tests of vitamin E deficiency, but technical difficulties, lack of specificity, and inconsistent findings were some of the problems. More recently, vitamin E has been shown to decrease isoprostane F2 in individuals with moderate hypercholesterolemia who exhibited oxidative stress. F2-isoprostanes are formed by free radical-mediated peroxidation of arachidonic acid, an omega-6 polyunsaturated fatty acid. Plasma concentrations of F2-isoprostanes were suppressed in these patients by 35–50% in a dose-dependent manner with maximum suppression at vitamin E intake of 1600–3200 IU d<sup>-1</sup>.

### Vitamin K

Vitamin K status assessment is usually performed in response to abnormal bleeding. Static tests are used to measure circulating concentrations of vitamins K<sub>1</sub> (phylloquinone) and K<sub>2</sub> (menaquinone). Serum or plasma vitamin K<sub>1</sub> is measured using HPLC with postcolumn chemical reduction followed by fluorometric detection or with electrochemical detection. Hemolysis should be avoided when the detection method is fluorescence. Measurement of K<sub>1</sub> has also been performed using GC-MS or HPLC-MS/MS. It has been suggested, although not yet commonly implemented, that K<sub>1</sub> concentration should be expressed as a ratio of the triglyceride concentration.

Determination of the serum undercarboxylated form of prothrombin (PIVKA-II) by ELISA and urinary  $\gamma$ -carboxyglutamic acid by HPLC with fluorometric detection have been proposed for assessment of vitamin K status. A vitamin K functional test that has been more widely used in recent years is the determination of serum undercarboxylated osteocalcin. This test is well correlated with other indicators of vitamin K status. A number of commercial ELISA kits are available.

### Thiamin (vitamin B<sub>1</sub>)

Thiamin status can be assessed through measurement of thiamin diphosphate (TDP) – also known as thiamin pyrophosphate (TPP) – in whole blood or erythrocytes by HPLC (preferably after postcolumn derivatization and fluorometric detection). TDP is the primary active form of vitamin B<sub>1</sub> and approximately 90% of thiamin in whole blood is present as TDP. Thiamin concentration in serum or plasma is small compared to that in erythrocytes and reflects recent intake rather than body stores. Urinary

thiamin excretion (preferably as 24-h urine samples) under basal conditions or after thiamin loading also reflects recent dietary intake, but the within-subject variation is high. Owing to limited body stores of thiamin, deficiencies can develop within a few weeks if intake is restricted. The response to thiamin therapy is usually rapid and a reliable test for thiamin deficiency. Infections that prevent normal absorption (diarrhea and dysentery) or increase the requirement (fever) can confound tests for thiamin status.

The erythrocyte transketolase activation coefficient (ETK-AC) test is a functional test that reflects the adequacy of body stores and is sensitive to marginal thiamin deficiency. It is measured by spectrophotometry. Because transketolase is a thiamin-dependent enzyme with a specific role in the glucose oxidative pathway, decreased enzyme activity is presumed to be due to the decrease of thiamin. However, the test is somewhat nonspecific, as factors other than thiamin status, such as genetic defects, may influence the enzyme activity and thus the test results. The ETK-AC test also suffers from imprecision problems and rapid loss of enzyme activity during frozen storage and repeated freezing and thawing. There is some debate whether the ETK-AC test – due to its slower response compared to the increase of TDP in whole blood – is a better biomarker to follow thiamin supplementation.

### Riboflavin (vitamin B<sub>2</sub>)

Riboflavin status can be assessed by urinary excretion of the vitamin in fasting, random, 24-h specimens (preferable), or by loading test, and by whole blood, erythrocyte, plasma, or serum flavin concentration. Riboflavin urinary excretion is indicative of recent dietary intake and is measured by HPLC using fluorometric detection, taking advantage of the inherent fluorescent properties of flavins. Erythrocytes are considered to be a more useful sample than plasma or serum because the riboflavin cofactors flavinadenine dinucleotide (FAD) and flavinmononucleotide (FMN) are concentrated in erythrocytes. They can be measured by HPLC with fluorometric detection. Whole blood FAD is considered a reliable indicator of long-term nutritional status, whereas FMN responds more quickly to changes in riboflavin intake. The light-sensitivity of riboflavin in particular and most B vitamins in general requires careful sample handling.

A riboflavin functional test that is commonly used is the erythrocyte glutathione reductase activation coefficient (EGR-AC) test measured by spectrophotometry. Because glutathione reductase is a flavoenzyme with FAD as a prosthetic group, the EGR-AC test is an indirect measure of FAD concentration in the erythrocytes and is considered a sensitive and robust index of riboflavin deficiency, but is less suitable for the assessment of riboflavin status at high riboflavin intake.

### Niacin (vitamin B<sub>3</sub>)

Niacin intake status can be assessed by measuring the excretion of methylated metabolites in urine by HPLC. Such metabolites are N'-methylnicotinamide (N'MN) and N'-methyl-2-pyridone-5-carboxamine (2-Py). Other biochemical markers include erythrocyte pyridine nucleotides, oral dose uptake tests, and plasma 2-pyridone derivative after an oral niacin load. Plasma concentrations of other niacin metabolites and of niacin are not useful markers of niacin status. The most reliable test for niacin deficiency is the patient's response to niacin therapy.

Niacin used as a drug has seen a sudden surge in popularity for treatment of lipid disorders and other associated clinical conditions for the prevention of cardiovascular risk. To clarify the role of metabolic pathways and evaluate pharmacokinetic studies, HPLC-MS/MS assays have recently been developed to measure the levels of niacin and its metabolites in various biological matrices.

### Vitamin B<sub>6</sub>

Vitamin B<sub>6</sub> status is typically assessed by measuring the level of one or more of the B<sub>6</sub> vitamers in serum or plasma. Serum pyridoxal-5'-phosphate (PLP) is generally viewed as the best single indicator of status. PLP is the active coenzyme form of vitamin B<sub>6</sub>, reflects both dietary intake and tissue stores, and changes slowly in response to changes in dietary intake. 4-Pyridoxic acid (4 PA) is the end product of vitamin B<sub>6</sub> catabolism. 4 PA can be measured in serum, plasma, or urine and reflects recent intake. PLP and the B<sub>6</sub> vitamers are most commonly measured by HPLC using fluorescence detection. Chemical derivatization (sample, online, or post-column) is almost always used to enhance PLP fluorescence. HPLC-MS/MS methods for measuring B<sub>6</sub> vitamers are emerging. Plasma PLP can also be measured enzymatically, either by radioactive or nonradioactive assays.

Vitamin B<sub>6</sub> functional tests, such as the erythrocyte aspartate aminotransferase activation coefficient (AST-AC) test and the tryptophan load test, have been used more frequently in the past. Plasma total homocysteine (tHcy) in the absence of folate and vitamin B<sub>12</sub> deficiencies can be considered indicative of vitamin B<sub>6</sub> status. For its determination, see the following discussion of folate functional tests.

### Folate

Folate status can be assessed by serum or plasma folate, which provides information on recent intake, and erythrocyte folate, indicative of body folate stores and long-term nutritional status. Traditionally, folate has been measured by microbiologic assay, however, in clinical settings where high throughput is needed, commercial protein-binding assays on automated clinical analyzers are used. If folate vitamers are of interest, for e.g., the measurement of free folic acid in serum or the measurement of various methyl- and nonmethyl-folate forms in erythrocytes depending on MTHFR C677T genotype, chromatography-based separation techniques need to be employed. Nowadays, they are often coupled to mass spectrometry (HPLC-MS/MS), because this detection method

offers superior sensitivity, specificity, and selectivity compared to other detection methods such as fluorometric or electrochemical detection. Although the comparability of serum folate methods has been somewhat improved recently because serum-based standard reference materials have become available, diagnostic kits are not yet sufficiently standardized and no progress has yet been made in improving the comparability of assays for erythrocyte folate. Folate is the least stable of the B vitamins; careful sample handling and use of antioxidants are required to maintain sample integrity. Dried blood spots can also be used to measure folate by microbiologic assay. This presents a field-friendly alternative when prompt specimen processing cannot be performed or blood collection is limited to a finger stick.

In the absence of vitamin B<sub>12</sub> and B<sub>6</sub> deficiencies, measurement of plasma tHcy is a sensitive functional test for folate status. Because an elevated plasma tHcy concentration is associated with an increased risk of cardiovascular diseases, the determination of this amino acid in plasma has become very common. Various methods are available for tHcy determination, but the most commonly used research methods are HPLC with fluorescence detection or coupled to mass spectrometry. They allow simultaneous measurement of other thiols in the same sample. Many fully-automated commercial kits are available on the basis of immunoassay and enzymatic methods. Prompt separation of the plasma from the red cells needs to be ensured to avoid artificial elevation of tHcy. Urinary formiminoglutamic acid (FIGLU) and lymphocyte deoxyuridine (dU) suppression assays are older functional tests for folate status that are no longer used routinely. Hypersegmentation of neutrophilic granulocytes are sometimes seen as a functional indicator during the examination of blood smears following routine cellular blood counts.

### Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub> status can be assessed by measuring serum or plasma total cobalamins and serum holo-transcobalamin II. The level of plasma vitamin B<sub>12</sub> falls relatively late in depletion, limiting the utility of an isolated vitamin B<sub>12</sub> measurement. Serum or plasma total cobalamins are commonly determined by competitive protein-binding assay, but microbiologic assays have also been used earlier. Holotranscobalamin II (holo TC) is the transport protein of absorbed cobalamin and has been considered as an early indicator of vitamin B<sub>12</sub> deficiency and possibly a marker of cobalamin malabsorption. The availability of the holo TC assay is currently limited and only recently have reliable and sensitive methods for estimating holo TC become available. A new microparticle enzyme immunoassay is available on an automated immunoassay analyzer and can measure holoTC directly without sample pretreatment.

Vitamin B<sub>12</sub> functional tests are the urinary or serum methylmalonic acid (MMA) and the plasma tHcy. MMA increases in vitamin B<sub>12</sub> deficiency; the loading with valine or isoleucine produces a marked increase in both urine and serum. MMA is measured by GC-MS or HPLC-MS/MS. In the absence of folate and vitamin B<sub>6</sub> deficiencies, tHcy in plasma increases in vitamin B<sub>12</sub> deficiency and decreases with B<sub>12</sub> administration. For tHcy determination, see the discussion of folate functional tests.

### Biotin

Biotin status has been assessed traditionally with bioassays and microbiologic assays. Modern methods rely upon the binding of biotin by either the protein avidin or streptavidin as part of competitive binding assays. To minimize the influence of interfering substances, prior separation and purification of biotin and its metabolites can be performed by HPLC. A low plasma biotin concentration is not a sensitive indicator of inadequate biotin intake. Urinary biotin excretion, particularly when extended to the excretion of its metabolites (that is, 3-hydroxyisovaleric acid [3-HIA] and 3-methylcrotonylglycine) is a more sensitive indicator of biotin status. Biotin is abnormally decreased, whereas 3-HIA is abnormally increased in urine in deficiency. The resolution of the signs and symptoms of deficiency in response to biotin supplementation is also important in the diagnosis of biotin deficiency.

### Pantothenic Acid

Pantothenic acid intake status can be assessed by measuring whole blood concentrations or urinary excretion. The widespread occurrence of releasable pantothenic acid in food however makes a dietary deficiency unlikely.

### Vitamin C

Vitamin C status can be assessed by measuring total ascorbic acid (oxidized and reduced) in serum or plasma, buffy-coat, or leukocytes. Ascorbic acid in plasma is considered as an index of the circulating vitamin available to tissues, and in leukocytes (particularly polymorphonuclear) it is believed to be a good indicator of tissue stores. Concentrations in leukocytes are much higher than in serum or plasma (14-fold). Isolation of specific cells is technically challenging limiting its usefulness. The urinary excretion of ascorbic acid is an index of recent intake; but because of instability of the collected sample, the determination is limited to special cases. Serum or plasma vitamin C is the most practical indicator of vitamin C status, however preanalytical requirements must be followed to promptly generate an acidified serum sample to stabilize ascorbic acid. Ascorbic acid is measured using HPLC coupled with electrochemical detectors. Newer methods have incorporated internal standards to improve accuracy and precision. Acute and chronic infections can depress markedly the serum ascorbic acid level due to a decrease in vitamin C reserves.

There are no reliable functional tests for vitamin C status.

## Essential Mineral and Trace Element Nutritional Status

### Sodium and Potassium

Sodium, potassium, and chloride in serum have little meaning in nutritional terms because they are tightly regulated. However, the excretion of sodium, potassium, and chloride in urine are a good indicator of intake. A 24-h specimen is needed to interpret concentrations in a person. Equations are available to calculate estimated electrolyte excretion from measured spot urine concentrations of electrolytes and creatinine. Electrolyte concentrations in serum and urine are typically measured by ion-selective electrodes (ISE), often available as add-ons to chemistry analyzers.

### Calcium

Calcium intake cannot be assessed satisfactorily on a routine basis. Serum calcium concentrations (free plus bound calcium) are strongly homeostatically controlled and remain constant under most conditions. Serum or plasma free calcium (a.k.a., ionized calcium), the physiologically active form, is increasingly used to assess disturbances in calcium metabolism and is the most promising index of calcium status. It is measured by a calcium-selective electrode. Because one of the major roles of calcium is to be a structural component in bone and soft tissues, measurement of biochemical markers of bone remodeling (serum bone-specific alkaline phosphatase and osteocalcin; urine pyridinoline and deoxypyridinoline) or measurement of bone mass and bone density are indirect ways to assess calcium status.

### Magnesium

Magnesium status can be assessed by measuring magnesium in serum, erythrocytes, leukocytes, and urine. Serum is the matrix most commonly used, mainly because of the ease of measurement by colorimetric methods or atomic absorption spectroscopy (AAS). Serum magnesium concentrations decrease rapidly in developing deficiency, followed by a slower decline of magnesium concentrations in erythrocytes. The validity of leukocyte magnesium concentrations as a biomarker of total body magnesium status is still under investigation. Urinary magnesium has been used as an indicator of magnesium status, primarily in association with a magnesium load test. However, this test is invasive and cumbersome and the protocol requires standardization. Measurement of serum ionized magnesium concentrations using ISE is promising, but its use in clinical disease states requires more investigation.

### Iron

Iron status is assessed in relation to three stages of development of iron-deficiency anemia. In the first stage, to evaluate the size of body iron stores, serum ferritin can be measured using immunological methods (immunoturbidity, immunonephelometry, chemiluminescence, or ELISA). Commercial kits are available for most clinical analyzers. In the second stage, to determine the adequacy of iron supply to the erythroid marrow, the following biochemical indicators can be measured: serum iron (colorimetric methods, available as commercial kits), erythrocyte protoporphyrin (specific hematofluorometer), and serum soluble transferrin receptor (sTfR) (immunological methods, available as commercial kits). The transferrin saturation (TS) is calculated as the ratio of serum iron/TIBC (expressed as a percentage). In the third stage, iron-deficiency anemia develops, for which hemoglobin (Hb, spectrophotometry or automated with an electronic counter) is the most common indicator. Infection is an important confounder for iron status markers. Serum ferritin and erythrocyte protoporphyrin levels increase, whereas serum iron, serum iron binding capacity and Hb decrease.

Multiple indicators should be used to assess iron deficiency. The ferritin model has been used extensively in the past. It defines iron deficiency as an abnormal value for at least two of three indicators (serum ferritin, erythrocyte protoporphyrin, and TS). An approach for estimating body iron was developed more recently. It uses two indicators, serum ferritin and sTfR, and allows the full range of the iron status to be evaluated. Furthermore, sTfR is generally not influenced by infection, inflammation, and chronic diseases. This body iron model is currently applied to the National Health and Nutrition Examination Survey (NHANES) to assess the iron status of the US population.

### Zinc

In healthy individuals, plasma or serum zinc are reliable markers of zinc status, mainly reflecting zinc intake. Because the effective regulation of zinc homeostasis buffers the functional response to dietary deficiency and excess, plasma zinc levels are generally considered a poor measure of marginal zinc deficiency. Urinary zinc excretion (24-h) and hair zinc can provide useful information on zinc status in zinc-supplemented persons, but whether these reflect zinc status in depleted persons is not clear. Zinc levels are typically measured by inductively coupled plasma mass spectrometry (ICP-MS), however, they can be assessed using AAS as well. Many precautions are required during sample collection, preparation, and storage to avoid contamination of the specimen (environmental exposure and hemolysis). Newer evidence suggests that platelet, mononuclear, and polymorphonuclear cell, and erythrocyte zinc levels are ineffective as biomarkers of zinc status.

Zinc functional tests are serum or plasma alkaline phosphatase, erythrocyte metallothionein (MT), monocyte metallothionein mRNA (MTmRNA), and serum thymulin assays. Alkaline phosphatase is a zinc metalloenzyme; rather than being indicative of zinc

**Table 3** Biochemical indicators and analytical methods used in NHANES to assess the nutritional status of the US population during some or all years of 1999–2010

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Analytical method</i>
Protein	Serum albumin	Colorimetric on analyzer
	Urinary creatinine	Colorimetric Jaffé reaction on analyzer
Infection/inflammation	Serum CRP	Immunonephelometry on analyzer
Lipids	Serum total cholesterol, triglycerides, HDL and LDL cholesterol (calculated)	Enzymatic and colorimetric on analyzer
Fatty acid	Plasma or serum fatty acids	GC-MS
Vitamin A	Serum retinol and retinyl esters	HPLC-UV/VIS
Carotenoids	Serum carotenes, cryptoxanthin, lutein, zeaxanthin, lycopene	HPLC-UV/VIS
Vitamin D	Serum 25OHD	Radioimmunoassay (2000–2006)
	Serum 25OHD <sub>2</sub> , 25OHD <sub>3</sub> , epi-25OHD <sub>3</sub>	LC-MS/MS (2007–2010)
Vitamin E	Serum $\alpha$ - and $\gamma$ -tocopherol	HPLC-UV/VIS
Vitamin B6	Serum PLP	Enzymatic (2003–2004)
	Serum PLP and 4-PA	HPLC-FD (2005–2010)
Folate	Serum folate (total)	Radio protein binding assay (1999–2006)
	Serum folate (total)	Microbiologic assay (2007–2010)
	Serum folate (species)	LC-MS/MS (2007–2008)
	RBC folate (total)	Radio protein binding assay (1999–2006)
	RBC folate (total)	Microbiologic assay (2007–2010)
	Plasma tHcy	FPIA on analyzer
Vitamin B <sub>12</sub>	Serum B12	Radio protein binding assay
	Serum MMA	GC-MS
Vitamin C	Serum total ascorbic acid	HPLC-ED
Sodium, potassium	Serum sodium and potassium	ISE on analyzer
Calcium	Serum total calcium	ISE on analyzer
Iron	Serum ferritin	Radioimmunoassay (1999–2002)
		Immunoturbidity on analyzer (2003–2010)
	Serum iron, TIBC, TS (calculated)	Colorimetric manual (1999–2002)
	Serum iron, UIBC, TS (calculated)	Colorimetric on analyzer (2003–2010); iron only (2007–2010)
	Serum sTfR	Immunoturbidity on analyzer
	Erythrocyte protoporphyrin	Fluorometric manual
Selenium	Serum selenium	ICP-MS
Iodine	Urinary iodine	ICP-MS

25OHD, 25-hydroxyvitamin D; 25OHD<sub>2</sub>, 25-hydroxyvitamin D<sub>2</sub>; 25OHD<sub>3</sub>, 25-hydroxyvitamin D<sub>3</sub>; 4-PA, 4-pyridoxic acid; CRP, C-reactive protein; epi-25OHD<sub>3</sub>, 3-epimer-25-hydroxyvitamin D<sub>3</sub>; FPIA, fluorescence polarization immunoassay; GC-MS, gas chromatography with mass spectrometry detection; HDL, high-density lipoprotein; HPLC-ED, high performance liquid chromatography with electrochemical detection; HPLC-FD, HPLC with fluorometric detection; HPLC-UV/VIS, HPLC with UV and visible detection; ICP-MS, inductively coupled plasma with mass spectrometry detection; ISE, ion selective electrode; LDL, low-density lipoprotein; LC-MS/MS, liquid chromatography with tandem mass spectrometry detection; MMA, methylmalonic acid; NHANES, National Health and Nutrition Examination Survey; PLP, pyridoxal-5'-phosphate; RBC, red blood cells; sTfR, soluble transferrin receptor; tHcy, total homocysteine; TIBC, total iron binding capacity; TS, transferrin saturation; UIBC, unbound iron binding capacity.

deficiency, it is considered to be of value after zinc supplementation but with contrasting results. A commercial kit is available for plasma alkaline phosphatase determination. Alkaline phosphatase activity has low specificity and is subject to many pathophysiological conditions. Erythrocyte MT decreases in moderate and severe zinc depletion and changes in response to elevated dietary zinc intake. Erythrocyte MT is measured by sandwich ELISA assay. MTmRNA is a new approach to zinc status assessment. It responds more rapidly to zinc supplements than erythrocyte MT. MTmRNA is measured in monocytes by competitive reserve transcriptase-polymerase chain reaction. An improvement of this method is the determination of MTmRNA on blood samples spotted onto filter paper. Confounding effects are limited to infection. MT and MTmRNA assays are very promising; further studies are needed because of the difficulty in their determination. Serum thymulin activity is decreased in zinc deficiency because it requires zinc to maintain its structure. There are some indications that erythrocytes, PMNCs, mononuclear cells, platelet zinc, and plasma alkaline phosphatase are not useful biomarkers of zinc status.

## Copper

Serum copper is the most useful marker of copper status, effective in both replete and depleted persons. The tight homeostatic regulation of copper levels in circulation generally restricts major perturbations in levels to the extremes of dietary intake. Serum copper

**Table 4** Available reference materials and external quality assessment programs for biochemical indicators of nutritional status

<i>Nutritional status</i>	<i>Biochemical indicator</i>	<i>Reference materials</i>	<i>Selected list of external quality assessment programs</i>
Protein	Serum albumin and transport proteins (TTR, TS and RBP)	ERM-DA470 (human serum, freeze-dried; one level; consensus value)	CAP General Chemistry Survey and Cal V/L Survey
Infection/ inflammation	Serum CRP	ERM-DA472 (human serum, frozen; one level; consensus value)	CAP CRP-Immunology Survey and Cal V/L Survey
	Serum AGP	ERM-DA470 (human serum, freeze-dried; one level; consensus value)	Not available at this time
Fatty acids	Fatty acids	NIST SRM 1950 (human plasma, frozen; one level; certified values for selected fatty acids)	Not available at this time
Vitamin A	Serum retinol	NIST SRM 968e (human serum, frozen; three levels; certified values)	NIST MMQAP; UK NEQAS
Carotenoids	Serum carotenes, cryptoxanthin, lutein, zeaxanthin, lycopene	NIST SRM 968e (human serum, frozen; three levels; certified values)	NIST MMQAP; UK NEQAS
Vitamin D	Serum 25OHD <sub>2</sub> , 25OHD <sub>3</sub> and epi-25OHD <sub>3</sub>	NIST SRM 972 (human serum, frozen; four levels; certified values for 25OHD <sub>2</sub> , 25OHD <sub>3</sub> , and epi-25OHD <sub>3</sub> ); NIST SRM 2972 (solvent-based; certified values for 25OHD <sub>2</sub> and 25OHD <sub>3</sub> )	UK DEQAS; CAP Bone and Growth Survey and ABVD Survey; and NIST/NIH VitDQAP
Vitamin E	Serum $\alpha$ - and $\gamma$ -tocopherol	NIST SRM 968e (human serum, frozen; three levels; certified values)	NIST MMQAP; UK NEQAS
Vitamin K	Serum phyloquinone (K <sub>1</sub> )	UK KEQAS SRM-001 (human plasma; one level; consensus value)	UK KEQAS; NIST MMQAP
Vitamin B <sub>6</sub>	Serum PLP	NIST SRM 3950 (human serum, frozen; two levels; certified values)	Not available at this time
Folate	Serum folate species	NIST SRM 1955 (human plasma, frozen; three levels; certified values for 5MTHF, reference values for FA, information values for TFOL and 5FTHF); NIBSC RM 03/178 (human serum, freeze-dried; one level; certified values for 5MTHF, FA, 5FTHF and TFOL)	CAP Ligand Assay General Survey and Cal V/L Survey for TFOL; UK NEQAS for TFOL
	Whole blood folate	NIBSC RM 95/528 (human whole blood hemolysate, freeze-dried; one level; consensus value)	CAP Ligand Assay General Survey and Cal V/L Survey for TFOL; UK NEQAS for TFOL
	Plasma tHcy	NIST SRM 1955 (plasma, frozen; three levels; certified values)	CAP Homocysteine Survey and Cal V/L Survey; DEKS
Vitamin B <sub>12</sub>	Serum B12	NIBSC RM 03/178 (human serum, freeze-dried; one level; consensus values); NIBSC RM 81/563 (serum, freeze-dried; one level; consensus values)	CAP Ligand Assay General Survey and Cal V/L Survey; UK NEQAS
	Serum MMA	NIST SRM 1950 (human plasma, frozen; one level; certified value)	DEKS
Vitamin C	Serum total ascorbic acid	NIST SRM 970 (human serum, frozen; four levels; certified values)	NIST MMQAP
Sodium and potassium	Serum and urine sodium and potassium	NIST SRM 2201 (NaCl standard) and 2202 (KCl standard)	CAP General Chemistry Survey and Cal V/L Survey; CAP Urine Chemistry Survey and Cal V/L Survey
Calcium	Serum total calcium	NIST SRM 956c (human serum, frozen; three levels; certified value)	CAP General Chemistry Survey and Cal V/L Survey
		NIST SRM 956c (human serum, frozen; three levels; certified value)	
Magnesium	Serum magnesium	NIST SRM 956c (human serum, frozen; three levels; certified value)	Center de Toxicology Quebec
Iron	Serum ferritin	NIBSC RM 94/572 (human plasma, freeze-dried; one level; consensus value)	CAP Chemistry Survey and Cal V/L Survey; UK NEQAS
	Serum sTfR	NIBSC RR 07/202 (human serum, freeze-dried; one level; gravimetric/spectrophotometric value assignment)	Not available at this time

is frequently measured by ICP-MS, although AAS is a common alternative. Levels of copper in other tissues or fluids are difficult to assess or are not considered valid indices of copper status.

Different copper functional tests are available: serum ceruloplasmin, erythrocyte superoxide dismutase (SOD), and leukocyte/platelet cytochrome c oxidase assays. Serum ceruloplasmin can be measured for its oxidase activity on various substrates or by radial immunodiffusion. The majority of serum copper is bound to ceruloplasmin, resulting in a similar response for these two markers. However, ceruloplasmin is not a useful marker in copper-replete adults and levels can be affected by a range of nondietary factors, mainly by infection because this is an acute phase reactant protein. Cu/Zn SOD is a cytosolic metalloprotein that catalyzes the reduction of superoxide to hydrogen peroxide and oxygen. Newer evidence suggests that it is not a useful marker of copper status. Cytochrome c oxidase activity in platelets or leukocytes is another marker under investigation, but the paucity of data does not allow any firm conclusions about its usefulness yet.

## Selenium

Short-term selenium status is usually assessed by measuring plasma or serum selenium by ICP-MS or by AAS, a more commonly-available measurement procedure. Long-term selenium status is assessed by measuring selenium in whole blood or erythrocytes. Urinary selenium has been shown to be a reliable marker for recent selenium intake rather than a robust marker for selenium status. Insufficient data currently exist that would allow for the prediction of a health effect from the concentration of selenium in hair or nails. Also the presence of selenium in hair or nails may indicate both external and internal exposures and there is a lack of reference or background ranges to help frame the interpretation of the results.

Selenium functional tests are plasma, whole blood, and platelet glutathione peroxidase activity (GSH-px) assays. The plasma GSH-px is a useful marker of selenium status in populations with low selenium intake; it responds rapidly to supplementation. Erythrocyte GSH-px has a plateau above which it is independent of selenium status. In addition, erythrocyte GSH-px responds slowly to depletion and supplementation. Platelet GSH-px responds rapidly to selenium dietary changes, accordingly, it is considered to be a sensitive indicator of changing selenium status. GSH-px can be measured with an enzyme assay or ELISA; commercial kits are available. The determination of selenoprotein P, which accounts for 50% of selenium in blood, is also a useful and sensitive test for selenium status, at least in populations with relatively low-to-moderate selenium intakes. Selenoprotein P can be detected by isolating the protein with chromatography followed by detection of selenium with ICP-MS.

## Iodine

Iodine status is most commonly assessed by measuring urinary iodine using highly specific ICP-MS methods or technically simpler spectrophotometric methods. Urinary iodine reflects iodine intake within the past few days, but the marker is generally not useful to

**Table 5** Tentative cutoff points for interpretation of biochemical laboratory indices

Nutritional status	Biochemical indicator	Deficiency	Excess
Protein	Serum albumin <sup>a</sup>	<30 g l <sup>-1</sup>	
	Serum TTR <sup>a</sup>	<0.11 g l <sup>-1</sup> (severe) 0.11–0.16 g l <sup>-1</sup> (moderate)	
	Serum TF <sup>a</sup>	<1.0 g l <sup>-1</sup> (severe) 1.5–2.0 g l <sup>-1</sup> (mild)	
	Serum RBP <sup>a</sup>	<25 mg l <sup>-1</sup>	
Fatty acids	Plasma essential fatty acids Holman Index <sup>b</sup>	>0.2 (ratio of triene [C20:3n–9 mead acid] to tetraene [C20:4n–6 arachidonic acid] fatty acids)	
	RBC membrane fatty acids Omega-3 Index <sup>c</sup> (marker of risk for sudden cardiac death)	Amount of EPA and DHA as a proportion of total fatty acids: <4% (high risk) 4–8% (intermediate risk) >8% (low risk)	
Vitamin A	Serum retinol <sup>a</sup>	<0.35 µmol l <sup>-1</sup> (severe) <0.70 µmol l <sup>-1</sup> (moderate) <1.05 µmol l <sup>-1</sup> (suboptimal)	
	Serum retinyl esters <sup>a</sup>		>10% of total vitamin A (fasting) (potential hypervitaminosis A)
	Serum RBP <sup>a</sup>	<0.70 µmol l <sup>-1</sup> ; validation in different populations needed	
	Serum RDR <sup>a</sup>	>20% (marginal status)	
Vitamin D	Serum MRDR <sup>a</sup>	>0.060 (marginal status)	
	Serum 25OHD <sup>d</sup>	<30 nmol l <sup>-1</sup> (deficient)	>125 nmol l <sup>-1</sup> (reason for concern, possibility of hypervitaminosis D)
Vitamin E	Serum α-tocopherol <sup>a</sup>	30–50 nmol l <sup>-1</sup> (inadequate) <11.6 µmol l <sup>-1</sup>	
Thiamin	Erythrocyte TDP <sup>a</sup>	<120 nmol l <sup>-1</sup> (high risk) 120–150 nmol l <sup>-1</sup> (marginal)	
	Urinary thiamin <sup>a</sup>	<27 µg g <sup>-1</sup> creat (high risk) 27–65 µg g <sup>-1</sup> creat (medium risk)	
Riboflavin	Erythrocyte EKT-AC <sup>a</sup>	>1.25	
	Erythrocyte FAD <sup>e</sup>	<270 nmol l <sup>-1</sup> RBC	
	Urinary riboflavin <sup>a</sup>	<27 µg g <sup>-1</sup> creat (high risk) 27–79 µg g <sup>-1</sup> creat (medium risk)	
Niacin	Erythrocyte EGR-AC <sup>a</sup>	>1.40 (high risk) 1.2–1.4 (medium risk)	
	Urinary N'MN, 2-Py <sup>a</sup>	<0.5 mg g <sup>-1</sup> creat	
Vitamin B <sub>6</sub>	Serum PLP <sup>a</sup>	<20 nmol l <sup>-1</sup>	
	Erythrocyte EAST-AC <sup>a</sup>	>1.85 (deficient) 1.70–1.85 (marginal)	
Folate	Serum folate <sup>a</sup>	<6.8 nmol l <sup>-1</sup> (negative balance)	
	RBC folate <sup>a</sup>	<317 nmol l <sup>-1</sup> (used frequently)	
Vitamin B <sub>12</sub>	Plasma tHcy <sup>a</sup>	>12–14 µmol l <sup>-1</sup> (used frequently)	
	Serum B12 <sup>a</sup>	<74 pmol l <sup>-1</sup> (deficient) 100–150 pmol l <sup>-1</sup> (moderate) 100–300 pmol l <sup>-1</sup> (low-to-normal)	
Vitamin C	Serum MMA <sup>f</sup>	>271 nmol l <sup>-1</sup>	
	Serum total ascorbic acid <sup>a</sup>	<11.4 µmol l <sup>-1</sup> (deficient) 11.4–23 µmol l <sup>-1</sup> (low levels)	
Iron	Serum ferritin <sup>g</sup>	<12 µg l <sup>-1</sup> (<5 years) <12 µg l <sup>-1</sup> (≥5 years)	>150 µg l <sup>-1</sup> (females) >200 µg l <sup>-1</sup> (males)
	Serum sTfR <sup>a</sup>	Assay specific cutoff values	
	Serum TS <sup>a</sup>	<16%	>70%
	Erythrocyte protoporphyrin <sup>a</sup>	>80 µmol/mol heme (severe) 60–80 µmol/mol heme (moderate)	
	Hemoglobin <sup>a</sup>	<110 g l <sup>-1</sup> (6–59 months) <115 g l <sup>-1</sup> (5–11 years) <120 g l <sup>-1</sup> (12–14 years)	

**Table 5** Tentative cutoff points for interpretation of biochemical laboratory indices—cont'd

Nutritional status	Biochemical indicator	Deficiency	Excess
Zinc	Serum zinc <sup>a</sup>	$<120 \text{ g l}^{-1}$ (nonpregnant women) $<110 \text{ g l}^{-1}$ (pregnant women) $<130 \text{ g l}^{-1}$ (men) Children $<10$ years: $9.9 \text{ } \mu\text{mol l}^{-1}$ (collected AM) $8.7 \text{ } \mu\text{mol l}^{-1}$ (collected PM) Males $\geq 10$ years: $11.3 \text{ } \mu\text{mol l}^{-1}$ (collected AM fasting) $10.7 \text{ } \mu\text{mol l}^{-1}$ (collected AM other) $9.3 \text{ } \mu\text{mol l}^{-1}$ (collected PM) Females $\geq 10$ years: $10.7 \text{ } \mu\text{mol l}^{-1}$ (collected AM fasting) $10.1 \text{ } \mu\text{mol l}^{-1}$ (collected AM other) $9.0 \text{ } \mu\text{mol l}^{-1}$ (collected PM)

classify intake sufficiency or deficiency in a person, but rather to define the risk of a population. If 24-h urine cannot be collected, iodine excretion can be expressed per gram of creatinine but only in areas with very low inter and intraindividual variation in urinary creatinine. In clinical settings, the measurement of uptake of radioactive iodine is used.

Iodine functional tests relate to its impact on thyroid function. The measurement of thyroid hormones and of thyroglobulin – a key precursor in the production of thyroid hormones – is performed by specific competitive radioimmunoassay or immunofluorimetric methods. When thyroid disease is not present, serum thyroxine (T<sub>4</sub>) can be a useful marker of iodine status in most age groups, whereas serum pituitary thyroid-stimulating hormone (TSH) is a good marker in pregnant and lactating women, but not useful in children and adolescents. Serum 3,5,3'-triiodothyroxine (T<sub>3</sub>) is not a useful biomarker for iodine status. Serum thyroglobulin is a useful marker in children and adolescents, but not useful during pregnancy and lactation. Infection has a confounding effect on iodine status because the synthesis of TTR – a thyroid hormone transporter – is markedly suppressed.

## Choice of Laboratory Tests

The choice of laboratory tests depends on the type of study to be carried out. In field nutritional epidemiology studies, particularly in developing countries, the number and type of tests will be mainly limited by the specimen volume, the local laboratory infrastructure, and the availability of skilled personnel and financial resources. The lowest complexity profile of testing achievable with a spot urine sample and an EDTA whole blood sample from a finger stick covers representatives of iodine, iron, vitamin A, and folate

status, including parameters of infection and inflammation: urinary iodine (spectrophotometric method), Hb (portable point-of-care instrument), serum ferritin/sTfR/RBP/CRP/AGP (ELISA), and RBC folate (microbiologic assay). The measurement of additional vitamins and biochemical indicators generally requires a larger volume of blood that can only be obtained through venipuncture and requires the availability of more complex laboratory tests.

In population studies carried out in developed countries with high-level laboratory facilities, the selection of laboratory tests depends on the purpose of the study, specimen volume, and financial resources. Because certain plasma proteins and urine creatinine are part of standard biochemical profiles on fully-automated clinical analyzers, they can be easily determined. Fatty acid distribution profiles are rarely assessed in population studies. However, serum cholesterol, triacylglycerols and lipoprotein fractions are typically measured. These tests are available on fully automated clinical analyzers, have been largely standardized and are sometimes required for normalization of lipophilic compounds. The selection of micronutrient tests can be determined by the suspected deficiencies from previous dietary surveys and by the need to assess the impact of nutritional interventions such as fortification. A representation of micronutrients covered by the recent NHANES can be found in [Table 3](#). Several analytical methods evolved in the last few years from less specific immunoassays to highly specific mass spectrometry-based techniques.

In a hospital setting, the selection of laboratory tests depends on the clinical condition of the patient at admission and during the subsequent course of injury or illness. Among hospital and institutionalized patients, deficiencies in proteins, vitamins, and trace elements are common due to underlying medical disease; suspicion of deficiency is based on history and physical examination.

Regardless of the setting, two other considerations deserve mention. First, the precision of the laboratory test largely influences the minimum detectable difference on repeat measurements or the ability to distinguish between healthy and diseased individuals or populations. It is therefore desirable to select laboratory tests with the highest achievable precision. Second, most biochemical indices do not have the required sensitivity and specificity to be used solely in the diagnosis of an abnormality. It is therefore recommended to combine findings from dietary intake assessment with static biochemical indices and functional tests whenever possible.

Most methods used to assess nutritional status have not been standardized yet which can lead to considerable differences among laboratories and methods. Where available, the selection of high-order reference methods should be favored or, in their absence, carefully validated methods with regards to sample collection, processing, and analysis should be used. An appropriate quality control (QC) system with internal and external verifications should be in place throughout the entire study. Particularly for longitudinal studies, large batches of in-house prepared QC pools are preferred to commercial QC samples where frequent lot changes can be expected. It is suggested to prepare two or three levels of QC pools and to analyze them in every assay together with the patient samples. Participation in external quality assessment programs or interlaboratory cross-comparisons as well as the regular use of reference materials for calibration verification is highly recommended. [Table 4](#) provides information on currently available international reference materials and gives a selected list of external quality assessment programs. The Centers for Disease Control and Prevention (CDC) also maintains an inventory of external quality assessment programs by country, some of which pertain to nutritional status indicators.

## Evaluation of Laboratory Indices

In general, reference values are population specific; accordingly, each major laboratory in homogenous areas has to derive them from a clinically healthy reference population selected with very specific criteria. These values should preferably be given in percentiles. The National Report on Biochemical Indicators of Diet and Nutrition in the US Population 1999–2002 is a comprehensive CDC publication that offers nationally representative reference information for 27 nutritional indicators derived from NHANES. A second edition of the report, providing reference information for 58 nutritional indicators from NHANES 2003–2006, as well as information on prevalence of nutritional deficiencies for selected indicators, is released in 2012.

Ideally, cutoff points are derived by determining the biochemical values that correspond to the earliest determinable physiological, metabolic, functional, and morphological alterations. Because such an approach has been followed only in very few cases, most cutoff points have been derived statistically from reference values and should therefore be considered as tentative. [Table 5](#) presents a list of tentative cutoff points for interpretation of nutritional status tests. In some cases, different cutoff points are used for children, pregnant and lactating women, and the elderly. These values can be found in reference texts. It is important to remember that cutoff points as well as reference intervals can vary with the method used to measure the biochemical indices. Continued efforts to standardize methods are therefore needed.

## Conclusions and Future Directions

Over the last few years, scientific and public health agencies initiated renewed efforts to better define biomarkers of nutritional status, to focus on analytical method standardization for accurate and precise measurement of biomarkers, and to develop systematic processes for the evaluation of biomarkers and surrogate endpoints. The Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health is leading an effort to build a consensus around biomarkers of nutrition for development (BOND). The goal of BOND is to promote the discovery, development, and use of biomarkers across a range of applications and to harmonize the global health community's decision-making about what biomarkers are best suited

for a given use under specific conditions and settings. In collaboration with CDC and NIH, the National Institute of Standards and Technology (NIST) has developed over the last several years reference methods and materials for nutritional biomarkers that are essential to enhance and promote high quality laboratory measurements. The development and validation of new dietary biomarkers are also constantly evolving. The emerging field of nutritional metabonomics – the study of metabolic responses – is receiving increasing attention as an analytical method to assess metabolic profiles as measures of dietary exposures and indicators of dietary patterns, dietary changes, or effectiveness of dietary interventions.

Yet, with all these efforts ongoing, the findings of the EURRECA project to assess potential biomarkers of micronutrient status by using a systematic review methodology were that far as fewer studies were available for biomarker assessment than initially predicted, and the risk of bias of included studies was greater than expected. The authors concluded that further research is needed to assess the usefulness of many potential biomarkers and that we still have to overcome gaps in our understanding of how well a biomarker works in particular population groups or in people with different baseline micronutrient status.

## Introduction

Historically, the measurement of the body and its components centered around cadaver analyses where specific tissues and organs were extracted from the body for inspection (Forbes, 1987). The extraction of tissue samples from the living body was a step forward in allowing for the analyses of tissue morphology in a state more closely resembling the *in vivo* state. However, both cadaver and *in vitro* tissue analyses are subject to inaccuracies when extrapolations are being made to the living body. Nevertheless, much of our understanding of human body composition in both children and adults has roots in these approaches. During the twentieth century, significant advances were made in the development of *in vivo* methods of body composition analysis thanks to the disciplines of Physics, Engineering, and Medicine. Methodologies with minimal or no risk to the participant have allowed for the assessment of body composition in growth and development, aging, and disease. Refinements of existing methodologies continue now in the 21st century as do efforts to show linkages between the non-invasive quantification of adipose tissue depots and infiltration into tissues, skeletal muscle quality and quantity with metabolic health and with diseases rooted in metabolic dysregulation.

The physiological significance of knowing the composition of the body greatly depends on the question of interest. Common applications involving medical/clinical diagnoses include osteopenia/osteoporosis; muscle wasting; sarcopenia; lipodystrophy; altered states of hydration; malnutrition; obesity. There are also metabolic consequences (for example, insulin resistance) associated with high and low levels of body fat and where the fat is distributed. From a nutritional perspective, the interest in body composition has increased multifold with the global increase in the prevalence of obesity and its complications. This article will focus on our current state of body composition knowledge and how this knowledge was determined with the available most advanced methodologies.

## Body composition determination

There is no single gold standard for body composition measurements *in vivo*. All methods incorporate assumptions that do not apply in all individuals and the more accurate models are derived using a combination of measurements, thereby reducing the importance of each assumption. The most commonly used technique today with good reproducibility in children and adults is dual-energy X-ray absorptiometry.

## DXA

The DXA method evolved from earlier single and dual photon absorptiometry methods for evaluating bone mineral. DXA systems share in common an X-ray source that, after appropriate filtration, emits two photon energy peaks. The attenuation of the two energy peaks relative to each other depends on the elemental content of tissues through which the photons pass. Bone, fat, and lean soft tissues are relatively rich in calcium/phosphorus, carbon, and oxygen, respectively. DXA systems are designed to separate pixels, based on appropriate models and relative attenuation, into these three components. There are no known factors, including hydration effects that significantly influence the validity of DXA fat and bone mineral estimates. Excessive or reduced fluid volume would be interpreted as changes in lean soft tissue. The radiation exposure is minimal and can be used in children and adults of all ages. DXA measures in persons who fit within the DXA field-of-view have good reproducibility for total body and regional components. A method using half-body scans to measure persons whose body dimensions fall outside the DXA field-of-view has been described (Tataranni and Ravussin, 1995). In studies evaluating adults with obesity, significant differences between whole- and half-body scans were found for percentage fat mass and bone mineral content (BMC) (Lundqvist et al., 2009; Tataranni and Ravussin, 1995; Rothney et al., 2009). In one study comparing whole- and half-body scans to ADP before and after weight loss, whole- and half-body scans measured percent body fat differently compared to ADP before weight loss for percent body fat, however, that difference did not persist after weight loss when the participants fit entirely within the DXA field-of-view (Lundqvist et al., 2009). Among children and adolescents (ages 7–18 years) with obesity, there were no significant differences in percent fat, total mass, fat mass, lean mass and BMC when comparing whole- and half-body scans (Breithaupt et al., 2011). Among children and adolescents ages 4–20 years with wide BMI range and considering Tanner Stage, half-body scans produced very small differences for bone mineral density and bone mineral content (Ferreira et al., 2019). The difference was not considered clinically meaningful. Half-body scans have not been validated in normal weight adults. From three studies that compared scans from the right compared to the left side of the body, one study reported a difference in percent fat, fat mass, fat free mass and BMC (Ravussin and Bogardus,

1989); the second reported differences only in BMC (Rothney et al., 2009) and the third found no differences between the sides (Ferreira et al., 2019). The authors concluded that the differences were not large enough to affect accuracy and that the use of half-body scans could introduce bias, depending on whether scans of the right half versus the left half of the body is scanned. They agree that in theory, true anatomical differences between right and left side (lateral distribution and physical characteristics of visceral organs) may lead to bias.

Advancements in DXA analysis software has allowed for the estimation of visceral adipose tissue (VAT) from a whole-body DXA scan; versions are available from the major DXA manufacturers. Estimating VAT by DXA has the advantage of faster scan and analysis time, lower cost, less radiation exposure and the ability to accommodate a wider range of individuals compared to MRI or CT, the standards for measuring VAT. Presently, the tool produces variable results—underestimating at lower VAT volumes and overestimating at higher volumes among adults and adolescents with normal weight, overweight or obesity and overestimating volumes in children with normal weight, overweight and obesity. There is a lack of validity for measuring change in VAT.

### Hydrodensitometry/air plethysmography

One of the oldest methods of measuring body composition, the determination of body volume by water displacement (Archimedes principle) allows for the estimation of fat-free mass (FFM) density (where an assumption is made that densities of fat and FFM are constant) from which percent body fat is calculated using a two-compartment body composition model. Today there are a number of additional methods for measuring body volume, including air displacement plethysmography. Limitations with this approach include the assumptions of stable densities of fat and FFM across the age range where this may not be true in older individuals and across race/ethnic groups (Schutte et al., 1984).

### Dilution techniques

As fat is relatively anhydrous, the body's water is found primarily in the body's FFM compartment where approximately 73% of a healthy nonobese adults FFM compartment is water. The body's water pool can be measured using tracers which after administration, dilute throughout the body. Basic assumptions involved with tracer dilution for body composition determination include equal distribution throughout the pool of interest and dilution is complete within a specific period of time without any loss. Examples of commonly used tracers include deuterium oxide for total body water and sodium bromide for extracellular water. These isotope dilution techniques allow for the evaluation of fat and FFM without making the assumption that the hydration of FFM is constant and therefore stable.

### Whole-body counting

A small constant percentage of total body potassium (TBK) is radioactive ( $^{40}\text{K}$ ) and emits a g-ray. With appropriate shielding from background, this g-ray can be counted using scintillation detectors. As the ratio of  $^{40}\text{K}$ – $^{39}\text{K}$  is known and constant,  $^{39}\text{K}$  or “total body potassium” can be estimated accordingly. All of the body's potassium is within the FFM compartment and the proportion of the body FFM compartment TBK/FFM ratio is relatively stable in the same subject over time and between different subjects. However, with increasing age or when comparing young versus elderly, the TBK to FFM ratio decreases. Although the specific mechanism(s) associated with this decrease in the TBK to FFM ratio with increasing age is/are unclear, it could be explained by a small but consistent increase in extracellular fluid compared to intracellular fluid.

### Magnetic resonance imaging (MRI)

The use of MRI has resulted in important advances in body composition phenotyping. MRI studies are safe and instruments are available in most hospital or related facilities. Expense is a limiting factor. The importance of MRI is that this method acquires cross-sectional images of the body at predefined anatomic locations. Image analysis software then allows estimation of the adipose tissue, skeletal muscle, and organs based on pixel intensity. Acquiring images at predefined intervals and integrating the area between slices allows reconstruction of an entire organ of interest such as skeletal muscle mass. A significant advancement made possible by these imaging methods has been the characterization of a tissue distribution, such as adipose tissue where it is now possible to quantify visceral, subcutaneous, and intermuscular depots at the regional and whole-body level.

### Quantitative magnetic resonance (QMR)

QMR (EchoMRI-AH; Echo Medical Systems, Houston, TX) is a non-imaging system that relies on proton nuclear magnetic resonance to measure human body composition (Gallagher et al., 2010). Using various pulse sequences, the QMR system provides estimates of fat mass, lean tissue mass, free water, and total body water. The QMR approach has important advantages over currently

available methods as it provides body composition estimates with high precision and without the use of ionizing radiation. The system for infants enables measurements in subjects from birth up to 12 kg, while the adolescent system optimizes measurement of subjects up to 80 kg. The adult system, moreover, can accommodate subjects up to 250 kg, almost double that of the widely used DXA approach. Human validation studies revealed systematic differences in body-fat estimates between the QMR and other available research methods (Napolitano et al., 2008; Gallagher et al., 2010; Andres et al., 2011). A validation study in infants found small differences between measured weights and fat, free water, and total water measured by QMR (Toro-Ramos et al., 2017). Further exploration is needed to identify these sources of and potential correction approaches for these differences. QMR accurately detected small changes in simulated body composition, and did not differ from deuterium dilution estimate of TBW.

### Bioimpedance analysis (BIA)

BIA is a simple, inexpensive, and noninvasive body composition measurement method. BIA is based on the electrical conductive properties of the human body. Measures of bioelectrical conductivity are proportional to total body water and the body compartments with high water concentrations such as fat free and skeletal muscle mass. BIA assumes that the body consists of two compartments, fat and FFM (Body weight = Fat + FFM). Single frequency BIA (50 kHz) allows the estimation of TBW from which FM and percent body fat are derived. Single frequency BIA has also been used for estimating skeletal muscle mass. Multifrequency BIA uses different frequencies, ranging from low (1 kHz) to high (1000 kHz) to estimate TBW, FFM, FM, and intracellular water (detected by frequencies >50 kHz) and extracellular water (detected by frequencies 1–5 kHz) compartments. The equations developed to estimate body composition by any BIA system are population specific such that they are most valid in populations similar to the population in which a specific equation was developed. The validity of BIA in persons with severe obesity is questioned as TBW and extracellular water relative to TBW are both greater in subjects with obesity compared with normal-weight individuals.

### Anthropometry

For routine clinical use, anthropometric measurements (circumference measures and skinfold thickness) have been preferred due to ease of measurement and low cost. Waist circumference and the waist-hip ratio measurements are commonly used surrogates of fat distribution, especially in epidemiology studies. Waist circumference is highly correlated with visceral fat and was recently included as a clinical risk factor in the definition of the metabolic syndrome. Specifically, waist circumferences greater than 102 cm (40 in) in men and greater than 88 cm (35 in) in women are suggestive of elevated risk.

Skinfold thicknesses which estimate the thickness of the subcutaneous fat layer are highly correlated with percent body fat. Because the subcutaneous fat layer varies in thickness throughout the body, a combination of site measures is recommended, reflecting upper and lower body distributions. Predictive percent body fat equations based on skinfold measures are age and sex specific in adults and children.

### Body mass index (BMI)

The body mass index ( $\text{BMI} = \text{weight (kg)} / \text{height (m)}^2$ ) continues to be the most commonly used index of weight status, where normal weight is a BMI 18.5–25.9  $\text{kg m}^{-2}$ ; overweight is a BMI 25.0–29.9  $\text{kg m}^{-2}$ ; obese a BMI > 30.0  $\text{kg m}^{-2}$ . BMI is a commonly used index of fatness due to the high correlation between BMI and percent body fat in children and adults. The prediction of percent body fat is dependent on age (higher in older persons), sex (higher in males), and race (higher in Asian compared to African American and Caucasian).

### *In Vivo* neutron activation

Nitrogen, carbon, hydrogen, phosphorus, sodium, chlorine, calcium, and oxygen are all measurable *in vivo* by method known as neutron activation analysis. A source emits a neutron stream that interacts with body tissues. The resulting decay products of activated elements can be counted by detectors and elemental mass established. Carbon, nitrogen, and calcium can be used to estimate total body fat, protein, and bone mineral mass using established equations. Neutron activation analysis is uniquely valuable in body composition research as there are no known age or sex effects of currently applied equations. However, facilities that provide these techniques are limited.

### Three-dimensional photonic scanner (3DPS)

3DPS is noninvasive optical method used to generate a 3-dimensional (3-D) photonic image of an object. High-resolution 3DPS systems have four photonic image production units or cameras mounted on four corner poles (Ashby-Thompson et al., 2020). Each

unit has an eye-safe class-1 laser-light source (664 nm) and a high-speed, high-resolution digital camera. The scan field is 200 cm high, 100 cm wide, and 60 cm deep, generating over 2 million data points. Subjects must wear a tight-fitting cap to minimize air spaces between the hair and skull and well-fitting underwear that cling to the skin surface during scan acquisition. Subjects are positioned in a standardized position such that arms are abducted from the trunk, and no contact between the legs and must remain motionless during the 10 s of scan. 3DPS can generate hundreds of body circumferences, segment lengths, total and regional body volumes, total and regional body surface areas with high precision. High-resolution 3DPS systems have limited availability due to cost. Advances in technology and demand for personalized health assessment have resulted in a growth of laser-based imaging technologies and associated applications. These technologies show promise but cannot yet replace the high-resolution models.

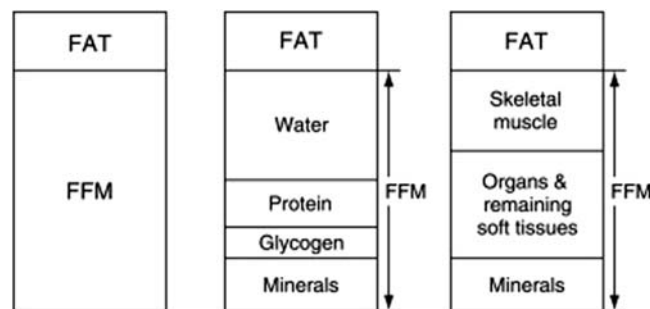

## Models in body composition

The use of models in the assessment of body composition allows for the indirect assessment of compartments in the body. Typically, a compartment is homogenous in composition (e.g., fat), however, the simpler the model the greater the assumptions made and the greater the likelihood of error. The sum of components in each model is equivalent to body weight (Fig. 1). These models make assessments at the whole-body level and do not provide for regional or specific organ/tissue assessments.

The basic two-compartment (2C) model (Table 1) is derived from measuring the density of FFM by hydrodensitometry and subtracting FFM from total body weight thereby deriving fat mass (body weight – FFM = fat mass). FFM is a heterogeneous compartment consisting of numerous tissues and organs. A 2C approach becomes inadequate when the tissue of interest is included within the FFM compartment. Nevertheless, the 2C model is routinely and regularly used to calculate fat mass from hydrodensitometry, total body water, and total body potassium.

A three-compartment (3C) model consists of fat, fat-free solids, and water. The water content of FFM is assumed to be between 70% and 76% for most species and results from cross-sectional studies in adult humans show no evidence of differences in the hydration of FFM with age. The fat-free solids component of FFM refers to minerals (including bone) and proteins. The 3C approach involves the measurement of body density (usually by hydrodensitometry) and total body water by an isotope dilution technique. Assumptions are made that both the hydration of FFM and the solids portion of FFM are constant. Because bone mineral content is known to decrease with age, the 3C approach is limited in its accuracy in persons or populations where these assumptions are incorrect.

A four-compartment (4C) model involves the measurement of body density (for fat), total body water, bone mineral content by DXA, and residual (residual = body weight – (fat + water + bone)). This model allows for the assessment of several assumptions that are central to the 2C model. The 4C approach is frequently used as the criterion method against which new body composition methods are compared in both children and adults.

**Fig. 1** Three different models for characterizing body composition compartments. Components are as labeled: FFM, fat-free body mass.

**Table 1** Multicompartment body composition models.

Model	Equations for % fat	References
2C	$100 \times (4.971/D_b - 4.519)$	(Behnke et al., 1995)
3C	$100 \times (2.118/D_b - 0.78 \times (TBW/W) - 1.354)$	(Siri, 1961)
4C	$100 \times (2.747/D_b - 0.727 \times (TBW/W) + 1.146 \times (BMC/W) - 2.0503)$	(Boileau et al., 1985)
6C	$100 \times (2.513/D_b - 0.739 \times (TBW/W) + 0.947 \times (TBBM/W) - 1.79)$	(Heymsfield et al., 1996)

Db, body density; TBW, total body water; W, body weight; BMC, bone mineral content; TBBM, total body bone mineral.

The more complex 4C model involves neutron activation methods for the measurement of total body nitrogen and total body calcium, where total body fat = body weight – (total body protein (from total body nitrogen) + total body water (dilution volume) + total body ash (from total body calcium)). A six-compartment model is calculated as follows: fat mass (measured from total body carbon) = body weight – (total body protein + total body water + bone mineral + soft tissue mineral (from a combination of total body potassium, total body nitrogen, total body chloride, total body calcium) + glycogen (total body nitrogen) + unmeasured residuals). However, the availability of neutron activation facilities is limited and therefore the latter models are not readily obtainable by most researchers.

At the organizational level, a five-level model was developed where the body can be characterized at five levels (Wang et al., 1992). The following are the levels and their constituents: atomic = oxygen, carbon, hydrogen, and other (level 1); molecular = water, lipid, protein, and other (level 2); cellular = cell mass, extracellular fluid, and extracellular solids (level 3); tissue-system level = skeletal muscle, adipose tissue, bone, blood, and other (level 4); whole body (level 5).

## Tissues and organs

The aforementioned models do not allow for subregion or specific organ and tissue measurements. For example, skeletal muscle mass (SM) is contained within the FFM compartment. SM represents the single largest tissue in the adult body and is equivalent to ~40% of body weight in young adults, decreasing to ~30% of young values at elderly ages. SM is one of the more difficult components to quantify. Estimates of SM are commonly derived from anthropometry, total body potassium, and DXA using modeling approaches previously described. The use of MRI in body composition research has allowed for a good estimation of SM, adipose tissue (AT), and select organs *in vivo*, in all age groups with no risk to the participant (Fig. 2). Moreover, AT distribution, including subcutaneous adipose tissue (SAT), visceral adipose tissue (VAT), and intermuscular adipose tissue (IMAT) is also measurable using a whole-body multislice MRI protocol (Fig. 3). In studies relating body composition to energy expenditure, high metabolic rate organs including liver, kidneys, heart, spleen, and brain are also measurable using MRI.

Bone mineral content and bone mineral density of specific body sites (for example, radius, hip, lumbar spine) are most commonly measured using DXA. Bone mass and microarchitecture are important determinants of bone strength, with microarchitectural deterioration being one of the specific changes associated with osteoporosis. Using high-resolution microcomputed tomography (micro-CT) and computer software, detailed analysis of three-dimensional (3D) architecture is feasible and allows microstructural 3D bone information to be collected.

## Body composition applications during growth

As many health and disease outcomes have origins in early childhood, measurement of body composition during infancy can provide important insights into the longitudinal associations between body composition, physiologic and metabolic processes and these health and disease outcomes throughout the lifespan. Body composition methods at this age include anthropometry (recumbent length, stature, weight, circumferences and skinfold thicknesses), BIA, MRI, multicompartiment models including TBW by isotope dilution, body density by air-displacement plethysmography (ADP) and BMC by DXA. Limitations which may impact accuracy of these measurements in infancy have been identified and include population-specific prediction equations (anthropometry and BIA), movement during testing (ADP or MRI) and significant technical examiner expertise (MRI) (Gallagher et al., 2020). Emerging areas of relevance for measuring body composition in infancy include the use of metabolomics (interrogating relationships between maternal metabolome to newborn size and body composition), discovery-based genetics studies (to define the genetic architecture of body composition during childhood and the development of polygenic risk scores or other

**Fig. 2** 3D reconstructed image of whole-body scan (from MRI). Skeletal muscle (red); adipose tissue (green); bone, organs, and residual (yellow); intermuscular adipose tissue (pink).

**Fig. 3** Cross-sectional images from (A) upper arm, (B) trunk (L4–L5 level), (C) mid-thigh, and (D) mid-calf in an elderly female volunteer. IMAT, intermuscular adipose tissue (pink); SM, skeletal muscle (red); SAT, subcutaneous adipose tissue (green); VAT, visceral adipose tissue (blue).

approaches at birth to predict subsequent body composition and to identify children at risk for greater adiposity), epigenetics, and D3-creatine dilution as an index of muscle mass.

Skeletal muscle mass has a central role in intermediary metabolism, aerobic power, and strength. Its mass increases as a portion of body weight during growth, accounting for 21% at birth and 36% at adolescence. The essential role of skeletal muscle in many physiologic processes throughout the lifespan makes understanding of factors affecting it significant. The greater incidence of type 2 diabetes mellitus in adolescents in the US (particularly in girls from minority populations) and in Japan makes evaluation of race and sex differences in pediatric skeletal muscle mass (and adipose tissue or fat mass) especially important. Identification and characterization of differences could form the basis for further investigation of the associated metabolic implications.

Race differences in SM are known to exist as early as birth (Paley et al., 2016). African-Americans have greater limb lean tissue mass compared to Asian and Caucasian children, although Caucasian children have greater amounts than Asians throughout Tanner stages 1–5 (Song et al., 2002). Race differences in total body bone mineral content adjusted for total body bone area, age, height, and weight have been reported in prepubertal African-American, Asian, and Caucasian females and males. African-American children had greater total body bone mineral content than Asian and Caucasian children, although differences between Asian and Caucasian children are less clear. Collectively, these findings suggest that the proportions of specific FFM subcomponents may differ by race. Although mechanisms leading to bone and skeletal muscle differences between races are not well understood, endocrine factors may be involved.

Sex differences in FFM have been reported from birth throughout childhood with females having smaller amounts than males (Song et al., 2002). Total body bone mineral content is less in Tanner 1 females compared to males in African-Americans, Asians, and Caucasians. The mechanism for this sex difference is unclear. Gonadal steroids are significant mediators of adult sexual dimorphism of body composition, including fat-free soft tissues. Prepubertal females have higher concentrations of circulating estradiol than prepubertal males, and gonadotropin and gonadal steroids increase gradually in both males and females from the age of 5 years. Thus, prepuberty is a period with sex differences in circulating concentrations of sex steroids and of changes in these concentrations with advancing age. The earlier skeletal maturation of females, for example, has been attributed to the greater estradiol level in females compared to males. However, nonhormonal (possibly genetic) mechanisms may also play a role.

Fat or adipose tissue distribution is recognized as a risk factor for cardiovascular disease in both adults and children. An android or male fat pattern, with relatively greater fat in the upper body region, is associated with negative metabolic predictors whereas a gynoid or female fat pattern, with relatively greater fat in the hip and thigh areas, is associated with less metabolic risk. More and more studies are showing that the metabolic syndrome develops during childhood and is highly prevalent among overweight

children and adolescents. Although the concept of the metabolic syndrome referred initially to the presence of combined risk factors including VAT, dyslipidemia, hypertension, and insulin resistance in adults, it is now known to exist in children, especially where obesity and/or higher levels of VAT are present. Although sex-specific patterns of fat distribution had previously been thought to emerge during puberty, sex and race differences in fat distribution are now known to exist in prepubertal children. The implications are that a specific body composition pattern may differ by sex and race. An example is the relationship of blood pressure to central fat distribution in boys compared to girls where a significant positive relationship between trunk fat and blood pressure was reported in boys but not girls, and was independent of race, height, weight, and total body fat (He et al., 2002). Understanding the predictors of blood pressure in children is important because childhood blood pressure has been shown to track into adulthood in longitudinal studies. Children whose blood pressure levels were in the highest quintile, were two times more likely to be in the highest quintile 15 years later. Identification of clinically useful body composition measures would allow for the identification of children at increased risk for hypertension, who could benefit from monitoring.

Race differences in fat distribution among prepubertal Asians, African-Americans, and Caucasians also exist (He et al., 2004). Previous reports in adolescents have suggested significantly smaller hip circumferences in Asian females at all pubertal stages compared to Caucasians and Hispanics and greater trunk subcutaneous fat in Asian females compared to Caucasians. Differences in subcutaneous fat mass and fat distribution in Asian compared to Caucasian adults have also been described (Hoffman et al., 2005). Understanding the sex- and race-specific effects of puberty on regional body composition may help delineate the developmental timing of specific health risk associations.

### Body composition applications during aging

During the adult life span, body weight generally increases slowly and progressively until about the seventh decade of life, and thereafter, declines into old age. An increased incidence of physical disabilities and comorbidities is likely linked to aging-associated body composition changes. Characterization of the aging processes has identified what is now considered a muscle disease (muscle failure), characterized by low muscle strength and associated with low muscle quantity and quality and collectively defined as “sarcopenia” (Cruz-Jentoft et al., 2019). This new definition places low muscle strength as the principal determinant because it is expected to facilitate prompt diagnosis and intervention in clinical practice and to better predict adverse outcomes. Low muscle quantity and quality remain the focus in research settings, however, there are differences in how these concepts are operationalized and they are difficult to measure accurately. Muscle quantity or mass can be estimated by MRI, CT, DXA, and BIA. Muscle quality, a relatively new term, refers to micro- and macroscopic changes in muscle structure and composition, and to muscle function delivered per unit of muscle mass. Imaging techniques such as MRI and CT and BIA phase angle measurements have been used to assess muscle quality. Muscle quality has also been defined by ratios of muscle strength to appendicular skeletal muscle mass or muscle volume.

Little is known about the overall rate at which sarcopenia develops in otherwise healthy elderly subjects, if this rate of progression differs between women and men, and the underlying mechanisms responsible for age-related sarcopenia. Peak SM mass is attained in the young adulthood years and slowly declines thereafter. During the latter adult years, SM decreases more rapidly as body fat becomes more centralized. Anthropometric equations have been developed for predicting appendicular skeletal muscle (ASM = SM of the limbs) in the elderly where sarcopenia was defined as ASM (kg)/height<sup>2</sup> (m<sup>2</sup>) less than two standard deviations below the mean of the young reference group (Baumgartner et al., 1998). In the elderly men, the mean ASM/height<sup>2</sup> was approximately 87% of the young group. The corresponding value in women was approximately 80%. Table 2 shows the estimated prevalences of sarcopenia in the same survey sample for each ethnic group, by age and sex. The same authors have reported that obese and sarcopenic persons have worse outcomes than those who are nonobese and sarcopenic.

Even in healthy, weight-stable elderly persons, changes in body composition over a 2-year period can include decreases in SM mass and bone mineral content with corresponding increases in IMAT and VAT, after adjusting for their baseline values, despite no detectable changes in physical function or food intake (Gallagher et al., 2000).

In adults, excess abdominal or VAT is recognized as an important risk factor in the development of coronary heart disease and noninsulin dependent diabetes mellitus. Waist circumference and the waist:hip ratio are commonly used to predict visceral fat

**Table 2** Prevalence (%) of sarcopenia<sup>a</sup> in the New Mexico Elder Health Survey, by age, sex, and ethnicity, 1993–1995.

Age group (years)	Men		Women	
	Hispanic (n = 221)	Non-hispanic whites (n = 205)	Hispanics (n = 209)	Non-hispanic whites (n = 173)
<70	16.9	13.5	24.1	23.1
70–74	18.3	19.8	35.1	33.3
75–80	36.4	26.7	35.3	35.9
>80	57.5	52.6	60.0	43.2

<sup>a</sup>Appendicular skeletal muscle mass/height<sup>2</sup> (kg/m<sup>2</sup>) less than two standard deviations below the mean value for the young adults from Gallagher et al. (1997), with permission from APS and OUP.

accumulation in epidemiological studies. However, waist circumference is unable to differentiate VAT from SAT. As a result, persons with similar waist circumferences could have markedly different quantities of VAT and abdominal SAT. Skinfold thickness has been used as a continuous variable grading adiposity or adipose tissue distribution within study populations.

The most accurate measurement of VAT requires imaging techniques (MRI and computed tomography (CT)), which are expensive and not readily available in many clinical settings. Fig. 3B shows an MRI-derived cross-sectional image at the L4–L5 level with adipose tissue depots identified. The AT located between muscle bundles (IMAT; Fig. 3) and visible by MRI and CT may be negatively associated with insulin sensitivity. In the elderly, greater IMAT (as suggested by lower skeletal muscle attenuation by CT) is associated with lower specific force production. Currently, there is no simple or clinic-based method to measure adipose tissue located between the muscle groups, defined in our laboratory as intermuscular adipose tissue (IMAT). IMAT has been reported to be significantly negatively correlated with insulin sensitivity and higher in type 2 diabetic women compared to nondiabetic women (Song et al., 2004).

Sex and race differences in body composition are well established in adults. Men acquire higher peak SM mass than women and some evidence exists suggesting that men may lose SM faster than women with age. Moreover, it is well established that women have a larger amount of total body fat or total adipose tissue than men. Among races, African-American adult men and women have larger amounts of SM than Asian and Caucasians even after adjusting for differences in body weight, height, age, and skeletal limb lengths (Gallagher et al., 1997).

Efforts are ongoing to better understand variations in IMAT as a function of age, race, and level of fatness. IMAT deposits appear comparable in size in adult African-Americans, Asians, and Caucasians at low levels of adiposity but accumulate as a greater proportion of TAT in African-Americans compared to Caucasians and Asians subjects (58 g IMAT/kg TAT in African-Americans; 46 g IMAT/kg TAT in Caucasians; 44 g IMAT/kg TAT in Asians) (Gallagher et al., 2005). Across race groups, VAT deposits also appear comparable in size at low levels of adiposity but with increasing adiposity VAT accumulates more in Asians and Caucasians compared to IMAT, although accumulation rates for IMAT and VAT do not differ in African-Americans (Gallagher et al., 2005). Although the association between greater amounts of abdominal or VAT and increased insulin resistance and the metabolic syndrome is well established compared to the peripherally located SAT, the role of the IMAT compartment in the metabolic alterations leading to the development of insulin resistance warrants further investigation, especially as it may influence race/ethnicity differences in dysglycemia. Collectively, sex and race differences exist in body composition in children and adults.

## Physiological application: two examples

### Example 1

Expressing heat production relative to body mass is required when comparing energy expenditure rates between individuals that differ in size. Age and gender-specific resting energy expenditure (REE) norms based on body weight and stature-derived were developed in the early 1900s by Kleiber and showed that adult mammals differing widely in body size had similar metabolic rates relative to body weight raised to the 0.75 power (Kleiber, 1961). Two components are usually considered as representative of whole-body metabolically active tissue, body cell mass (BCM), and FFM. BCM is typically estimated as the exchangeable potassium space that can be measured by total body potassium. The FFM component can be measured using two-component body composition methods.

In studies assessing REE, FFM is considered the principal contributor to energy requirements, and is commonly used as a surrogate for metabolically active tissue. However, this practice is inherently flawed as it pools together numerous organs and tissues that differ significantly in metabolic rate (Gallagher et al., 1998). The brain, liver, heart, and kidneys alone account for approximately 60% of REE in adults although their combined weight is less than 6% of total body weight or 7% of FFM. The skeletal muscle component of FFM comprises 40–50% of total body weight (or 51% of FFM) and accounts for only 18–25% of REE. REE varies in relation to body size across mammalian species. Within humans, REE per kg of body weight or FFM is highest in newborns ( $\sim 56 \text{ kcal kg}^{-1} \text{ day}^{-1}$ ), declines sharply until 4 years, and slowly thereafter reaching adult values ( $\sim 25 \text{ kcal kg}^{-1} \text{ day}^{-1}$ ). Among adults, REE is lower in the later adult years, to an extent beyond that explained by changes in body composition. That is, the loss of FFM cannot fully explain the decrease (5–25%) in REE in healthy elderly persons.

Recent attention has been given to modeling REE based on available information on organ- and tissue-specific metabolic rates combined (Table 3) with the mass of these tissues as determined by MRI. Whole-body REE can be calculated from organ-tissue mass ( $\text{REE}_c$ ) and then compared to REE measured using indirect calorimetry ( $\text{REE}_m$ ) for individuals or groups. REE (in  $\text{kJ day}^{-1}$ ) of each organ-tissue component (subscript  $i$ ) can be calculated using the following equation:

$$\text{REE}_i = \text{OMR}_i M_i \quad (1)$$

where (OMR) (organ metabolic rate) is the metabolic rate constant (in  $\text{kJ per kg per day}$ ) for each organ-tissue component (Table 3) and  $M$  is the mass of the corresponding organ/tissue (kg). Whole-body REE (in  $\text{kJ per day}$ ) is calculated as the sum of the seven individual organ-tissue REE:

$$\text{REE}_c = \sum_{i=1}^7 (\text{REE}_i) \quad (2)$$

**Table 3** Organ and tissue coefficients used in developing models.

	Weight (kg) <sup>a</sup>	Density (kg L <sup>-1</sup> ) <sup>a</sup>	Metabolic rate (kJ kg <sup>-1</sup> day <sup>-1</sup> ) <sup>b</sup>
Skeletal muscle	28.0	1.04	55
Adipose tissue	15.0	0.92	19
Liver	1.8	1.05	840
Brain	1.4	1.03	1008
Heart	0.3	1.03	1848
Kidneys	0.3	1.05	1848
Residual	23.2	–	50

Residual mass was not assigned a density but was calculated as body mass minus sum of other measured mass components.

<sup>a</sup>Snyder et al. (1975), with permission from OUP and LWW.

<sup>b</sup>Ella (1992), with permission from OUP and LWW.

The whole-body REE equation is

$$REE_C = 1008M_{\text{brain}} + 840M_{\text{liver}} + 1848M_{\text{heart}} + 1848M_{\text{kidneys}} + 55M_{\text{SM}} + 19M_{\text{AT}} + 50M_{\text{residual}}$$

This approach has allowed for the hypothesis to be tested that the proportion of FFM as certain high metabolic rate organs, specifically liver and brain, is greater in children compared to young adults (Fig. 4). Findings thus far have shown that after accounting for this disproportion, the specific organ/tissue metabolic constants available in the literature (Table 3) are not adequate to account for REE in children. These results therefore imply that the decline in REE per kilogram body weight (or per kilogram FFM) during the growth years is likely due to both changes in body composition and changes in the metabolic rate of individual organs/tissues. When this approach was applied to young adults ( $31.2 \pm 7.2$  years),  $REE_C$  and  $REE_m$  were highly correlated, with no significant differences between them. When this approach was applied to persons over 70 years, both older men and women had significantly lower  $REE_m$  compared to  $REE_C$ , and the magnitude of the differences were 13% and 9.5%, respectively, for men and women. These findings suggest that even after adjustment for age-related organ and tissue atrophy in the elderly, whole body REE by indirect calorimetry continues to be lower than expected. The latter suggests that the metabolic rate constants used (Table 3) for specific organs and tissues may not be appropriate in the elderly.

At the individual or clinic level, the measurement of REE by indirect calorimetry is frequently unavailable. An alternate approach has been to estimate REE based on body weight, height, age, and sex. Many studies have examined the association between these basic and easily acquired measures and REE. A small number of studies have included FFM in their REE prediction equations. Table 4 lists published equations for the prediction of REE in healthy individuals.

**Fig. 4** Proportional contribution of each organ/tissue to Adipose Tissue Free Mass (ATFM). Liver ( ), brain ( ), heart ( ), kidneys ( ), skeletal muscle mass ( ), residual mass ( ), \*  $p < 0.01$  and \*\*  $p < 0.001$  for children vs. adults. Reproduced from Hsu, A., Heshka, S., Janumala, I., et al., 2003. Larger mass of high-metabolic-rate organs does not explain higher resting energy expenditure in children. *Am. J. Clin. ## Example 2

Prenatal exposures may increase long-term risk of developing obesity and related cardiometabolic diseases. Interventions to reduce adverse exposures in utero may impact risk of developing these conditions. Excessive maternal gestational weight gain (GWG) is one such exposure. A randomized controlled trial was developed to evaluate whether an intervention designed to prevent excessive GWG in women with overweight or obesity has a measurable effect on offspring body composition in the offspring at birth (less FM, greater FFM) (Gallagher et al., 2018).

Considerations for selection of measures depend on the resources available to the research team as well as parental preferences and concerns; however, the method(s) need to be sufficiently sensitive to detect small differences in FM and FFM between the intervention group and usual care group. In most studies, length and weight were most commonly measured because they are the least intrusive; generally require little skill, training, and equipment; and can be conducted quickly with minimal costs. However, length and weight and their relative indices such as weight-for-length and weight-for-age percentiles do not provide information on body

composition, specifically FM or FFM. Such indices assume that a higher percentile reflects additional or excess FM and fail to consider the contribution of the FFM compartment to weight. Skinfold thicknesses of the triceps, subscapular, and iliac crest can be used to assess between group differences in subcutaneous fat, a proxy for total body fat. While these methods are noninvasive and often acceptable to parents, they require skilled data collectors to conduct and additional time to acquire and can be burdensome to the parent and child.

Validated methods for measures of whole-body FM and FFM with high precision in the newborn are ADP (PEA POD), DXA and QMR. These instruments have higher cost, require trained/technical staff, and require more time to complete. ADP and DXA require that the infant be as still as possible during testing; movement is not an issue for QMR. For DXA, the infant is measured swaddled in a blanket. For ADP, the infant must be naked in a chamber where air temperature is comfortable. DXA also involves a small amount of radiation. Ultimately, ADP (PEA POD) was selected for measurement of the primary outcome, FM, and QMR for secondary outcomes FM, LM and TBW. Skinfold thicknesses at four sites, head circumference, length, and body weight and their indices (weigh-for-length and weight-for-age) were also collected as secondary measures to facilitate comparisons between other studies. Outcomes data were collected between 1 and 4 days after birth.

Results at baseline showed no between group differences in maternal characteristics (mean ( $\pm$ SD)): age 33.8 ( $\pm$ 4.3) years, weight 81.9 ( $\pm$ 13.7) kg, BMI 30.4 ( $\pm$ 4.5) kg/m<sup>2</sup>, gestational age at randomization 14.9 ( $\pm$ 0.8) wk. GWG was less in the lifestyle intervention (LI) group by 1.79 kg ( $p = 0.003$ ) or 0.0501 kg/wk ( $p = 0.002$ ). Body weight and its lean component were significantly increased in LI measured by two independent methods. Compared to usual care (UC) group, LI infants had greater weight ( $131 \pm 59$  g;  $p = 0.03$ ), FFM ( $98 \pm 45$  g;  $p = 0.03$ ) by PEAPOD, and lean mass ( $105 \pm 38$  g;  $p = 0.006$ ) by QMR. FM and percentage fat were not significantly different. Head circumference, an index of greater brain growth, was similarly greater in LI. The QMR also measured greater total body water in the LI group.

This trial demonstrated that reliance only on infant body weight, length, and ponderal index would have resulted in an interpretation that LI produced larger and heavier babies, falsely presuming them to have greater adiposity and less lean mass per body weight. This rigorously controlled RCT highlights the importance of designing newborn trials with sensitive body composition measurement methods for adiposity and lean tissues.

## Conclusion

The measurement of body composition allows for the estimation of body tissues, organs, and their distributions in living persons without inflicting harm. It is important to recognize that there is no single measurement method in existence that allows for the measurement of all tissues and organs and no method is error free. Furthermore, bias can be introduced if a measurement method makes assumptions related to body composition proportions and characteristics that are inaccurate across different populations. The clinical significance of the body compartment to be measured should first be determined before a measurement method is selected because the more advanced techniques are less accessible and more costly.

### Glossary

**Beriberi** Clinical syndrome resulting from thiamin (vitamin B-1) deficiency.

**Keratomalacia** Corneal lesion characteristic of vitamin A deficiency.

**Kwashiorkor** Undernutrition syndrome in young children characterized by severe protein depletion (edema, skin and hair changes, etc.).

**Pellagra** Clinical syndrome caused by niacin deficiency.

### Introduction

The two most common settings for a clinical examination are the hospital (inpatient or outpatient) and the field health care unit. In the first situation, the physician or examiner may have access to resources that are usually not available in the field. Because of this and other constraints, the assessment of nutritional status in the field is frequently more narrowly aimed at identifying a specific clinical condition or set of signs and symptoms. In either case, it is essential that information on history and physical findings be collected in a standardized manner in terms of both format and procedures. The former is usually best achieved by the use of preprinted or computerized forms. Electronic forms can be programmed to perform immediate range checking as values are entered, thus alerting the operator when values out of range are entered. Procedures for examination must be clearly defined in writing, and any health worker should be able to follow the instructions and perform an acceptable measurement. Although many components of the examination are subjective, it is important to standardize as much as possible terms such as 'minor', 'average', and 'large' within the group of examining persons, attributing a numeric value whenever possible. If data entry requires selection from a numeric scale, they should also be standardized by cross-validation with experienced personnel or by means of photographs or models.

The two components of the clinical assessment are the medical history and the physical examination (Table 1).

### Medical History

The medical history for nutritional assessment is no different from a general medical history, in which familial and past and present environmental factors and their possible association with specific diseases or disease risk are considered. For the purpose of nutritional assessment, this information will be used to determine if any nutritional finding or complaint may be caused by an underlying medical condition, particularly one that remains unrecognized at the time of the examination. Additionally, specific medical conditions and their current status are important factors altering nutrient requirements and dietary prescriptions.

One specific focus of medical history in a nutritional assessment context is the exploration of gastrointestinal function. Conditions such as chronic diarrhea, gastroesophageal reflux, and colonic disorders may be associated with reduced nutrient absorption or food avoidance that result in impaired nutritional status. Past history of gastrointestinal problems or surgery may also point to current alterations in nutrient digestion or absorption. Other important components of the medical history are history of weight loss or gain, past and present use of medications, use of special foods or formulas, changes in taste or smell, and food allergies and intolerances.

In children and adolescents, the medical history must also obtain information on neurodevelopmental stages, history of behavioral problems, and overall school performance. Food preferences must be noted, particularly in adolescence, when adoption of unconventional dietary practices is more likely to occur.

**Table 1** Major components of a nutrition-oriented medical history*Medical history*

History of weight loss or gain  
 Gastrointestinal symptoms (nausea, diarrhea, flatulence, pain, etc.)  
 History of changes in color or texture of skin, hair, conjunctiva, buccal mucosa  
 Use of medications  
 Physical activity level (work-related, leisure)  
 History of fatigue, shortness of breath, muscle cramps  
 Other lifestyle practices  
 Places of residence, travel (exposure to toxins, sunlight, food contaminants)  
 In children and adolescents  
 – Growth history  
 – Neurodevelopmental history  
 – General school performance  
 – Parental and siblings' body size (body mass index)  
 – Pubertal stage  
 – Food preferences, fads

*Dietary history*

Habitual dietary intake and preferences  
 Past diet history  
 Alcohol consumption  
 Food allergies and intolerances  
 Assessment of dietary intake  
 – 24-hour recall  
 – Food frequency questionnaire

A special component of the nutritional history is the assessment of habitual dietary intake. There are several approaches, all of them requiring substantial experience and standardization. These procedures, such as 24-hour dietary recall, or food frequency questionnaires, are discussed in detail elsewhere.

## Physical Examination

As noted previously, anthropometric measurements are a key component of the physical examination. Measurement of weight and height is perhaps one of the most frequently performed nutritional measurements. Although its value is limited with regard to identifying specific nutrient deficiencies, it is invaluable to evaluate growth and adequacy of past and present diets in infants, children, and adolescents and to identify undernutrition and obesity in adults. Measurements should be done by trained personnel and following standard protocols. In addition to anthropometry, the physical examination focuses on signs of nutrient deficiency or excess. These signs usually appear only when the deficiency is advanced and are not to be expected in marginal deficiencies. Furthermore, the time that it takes for a deficient intake of a given nutrient to cause clinical manifestation of deficiency varies considerably, depending on whether the nutrient is stored in the body and on the initial status of the reserves. Typical signs for selected nutritional deficiencies are presented in [Table 2](#). Virtually none of these signs, with the exception of Bitot's spots, are pathognomonic for one specific deficiency. However, they are useful in indicating a specific nutrient impairment and prompting further evaluation.

The physical examination should start with a general visual assessment of the patient. In children, state of alertness, willingness to engage in play, or resisting examination are important clues to energy level and physical strength. A generalized loss of fat depots, or excess adiposity as in the obese, is readily identifiable in most circumstances. A general overview can also identify pallor, loss of muscle mass, and skin changes.

Numerous signs of nutritional deficiencies can be identified in the skin and hair. Because skin exhibits a relatively rapid turnover, impairments in protein synthesis can result in fragile, flaky, and discolored skin. Vitamin A deficiency typically causes a dry, hyperkeratotic skin. The dermatitis of pellagra consists of patchy areas of hypo- or hyperpigmentations, usually in sun-exposed body regions, eventually progressing to hardened, broken surfaces. In protein–energy malnutrition, hair may become brittle, thin, and easily pluckable. Fluctuations in the rate of synthesis of hair protein may result in band discoloration, where pale and normal colors alternate, resulting in the 'banner sign', typical of kwashiorkor. Petechiae or hematomas may result from protein–energy malnutrition or vitamin K or vitamin E (in the newborn) deficiencies.

One of the most specific signs of nutritional deficiency can be identified in the eye. Vitamin A deficiency produces a series of alterations in the conjunctiva and the cornea that not only indicate a deficiency of this nutrient but also help grade its severity.

**Table 2** Typical clinical signs of selected nutritional deficiencies

<i>Deficiency</i>	<i>Signs</i>
Protein–energy malnutrition	Hair: depigmentation, thinning, pluckability Edema in lower extremities (generalized in severe cases) Muscle wasting Decreased subcutaneous fat Skin: diffuse depigmentation, flaky dermatosis Liver enlargement
Vitamin A	Bitot's spot Conjunctival xerosis Corneal xerosis Keratomalacia Night blindness
Riboflavin	Angular stomatitis Cheilosis Scrotal (vulvar) dermatosis Red tongue Corneal vascularization
Thiamin	Edema Hyporeflexia Muscle tenderness Cardiac enlargement Tachycardia
Niacin	Pellagroid dermatosis Scarlet, raw, fissured tongue Malar and supraorbital pigmentation
Vitamin C	Bleeding, spongy gums Petechiae Ecchymoses Epiphyseal enlargement Atrophy of lingual papillae Follicular hyperkeratosis
Vitamin D	Active rickets: rib beading, epiphyseal enlargement, persistently open fontanelle, craniotabes, hypotonia Residual rickets: frontal or parietal bossing, bowlegs, knock-knees, thorax deformities
Iron	Pale conjunctiva Atrophy of lingual papillae Koilonychia
Folic acid, B <sub>12</sub>	Usually associated with pallor of anemia Peripheral neuropathy (B <sub>12</sub> )
Iodine	Thyroid enlargement

The most commonly used classification of vitamin A deficiency is primarily based on eye findings, from Bitot's spots to perforated keratomalacia. Conjunctival pallor has been a classic sign of anemia, but its sensitivity varies substantially depending on ethnicity, ambient lighting, and experience of the observer.

The mouth and tongue are also areas where typical manifestations of deficiency can be detected. A red tongue is a classic sign of riboflavin deficiency but has also been associated with niacin deficiency; the latter may also include fissures. Conversely, a pale tongue may indicate iron deficiency. Glossitis, with or without color changes, has been linked to pyridoxine deficiency. A similar condition, including pain and intense red color, has been associated with biotin deficiency. Angular stomatitis and ulcerations and other lip lesions are associated with riboflavin or ascorbic acid deficiencies. In the latter, extensive involvement of the gums (swelling and bleeding) is also typical. Atrophy of the papillae occurs in vitamin B<sub>12</sub>, niacin, and folate deficiencies. Excess vitamin A intake may result in discoloration of the gingival mucosa.

Rib beading (also known as rickets rosary) is a typical sign of vitamin D deficiency in children, but a similar manifestation may appear in vitamin C deficiency (scurvy). Epiphyseal enlargement and bowlegs are other classic signs of rickets. A distended abdomen is characteristic of protein–energy malnutrition in children. In the lower limbs, inspection must ascertain the presence of edema, which is also associated with protein–energy malnutrition.

Peripheral neuropathies such as those associated with beriberi or vitamin B<sub>12</sub> deficiencies may result in visible impairment of limb movements, such as the ‘foot drop’ of dry beriberi.

In preadolescents and adolescents, assessment of sexual maturation (usually following the Tanner staging) is an important component of the physical examination, although it is not always feasible due to cultural and practical reasons. Alternatively, more limited information may be obtained in girls by self-reported menarcheal status. Self-assessment of Tanner stage by comparison with photographs is another useful alternative, but use of these photographs with children may not be acceptable in some communities.

To obtain a unified rating of a person's nutritional status, it is desirable to integrate clinical, laboratory, and functional data into a single scoring system. Several approaches to achieve this have been proposed, and their use will depend primarily on the target population and the intended use of the score. The Subjective Global Assessment is an approach that relies primarily on data from the physical examination and thus can be readily performed after this examination has been completed. Other scoring systems, such as the Prognostic Nutritional Index or the Instant Nutritional Index, rely to variable degrees on combinations of clinical and laboratory data.

**Key points**

- Measuring dietary intake can be achieved using a number of different methods
- Dietary intake may be measured using direct methods of dietary assessment or using biomarkers of nutrition
- Measurement error can occur when measuring dietary intake
- Validation and calibration methods can be used to account for measurement error that occurs when measuring dietary intake

**Glossary**

**Calibration** A method of adjusting for systematic error. An example would be to use a more precise measure of dietary intake or a biomarker to adjust for measurement error with a less precise dietary method

**Measurement error** Error that can occur when measuring information in studies. An example would be error that occurred when estimating dietary intake of an individual

**Qualitative analysis** A technique for less structured or unstructured information and uses more open ended information such as open-ended survey responses or other non-numerical information such as photographs

**Quantitative analysis** A technique of analyzing numerical information or data and is used in statistical techniques that provide numerical outcomes

**Validation** A method of identifying the type and scale of measurement error. An example would be to use a biological marker such as plasma vitamin C to compare with dietary intake of vitamin C

**Introduction**

Dietary intake measurements are used to assess food, nutrient, or bioactive intake of individuals, groups, or populations. They may also be used to assess dietary patterns, such as the Mediterranean diet, or to study dietary behaviors, such as skipping breakfast. The purpose of collection of measurements varies from individual assessments in clinical situations (nutrition screening) or the adequacy of intake of population groups (nutrition surveillance) to use in research relating diet to health status, particularly in epidemiology. Measurements are also used to establish exposure to food-borne contaminants, in the evaluation of nutritional intervention programs, and to develop nutritional guidelines for governmental health policy. This article describes the dietary intake measurements available, issues associated with data collection, conversion to nutrients and food types, measurement error when using dietary intake methods, validation and calibration of dietary methods, and future developments. Dietary assessment methods can be broadly grouped into two categories, objective and subjective. Objective methods independently record the diet and do not rely on input from an individual. Direct observation, the analysis of duplicate diets and the use of nutritional biomarkers are the main types of objective methods. Subjective methods rely on the dietary information provided by an individual, with the aim of obtaining data that is as accurate as possible, by minimizing bias. Weighed and estimated food records, 24-h recalls, FFQs, diet checklists and diet histories are all types of subjective methods.

**Dietary intake measurements**

**Table 1** describes the advantages and limitations of the main types of dietary methods, which are suitable for different purposes.

In all methods, “foods” refers to consumption of foods, beverages, and snacks both inside and outside of the home.

Of the individual methods, weighed records, estimated food records, 24-h recalls (24-HR), and dietary histories are more intensive. The quantity of food consumed may be weighed directly or estimated using household measures such as cups and spoons, photographs, standard units, or average portions (see **Table 2**). More recent methods in development utilize photographs of portion size recorded with mobile phone or digital camera technology. For all methods, the amount consumed can be measured or described either including or excluding wastage material usually discarded during food preparation, e.g., outer leaves and peel from vegetables or bones from cuts of meat.

Data should be derived from weighed intakes, government surveys, and research groups in populations similar to the one to be studied.

Some considerations when choosing a dietary method are shown in **Table 3**.

**Table 1** Names and characteristics of dietary methods used for estimating food and nutrient intake.

<i>Name of method</i>		<i>Advantages</i>	<i>Limitations</i>
<b>National level</b>			
Food balance sheets		Available for 200 countries; suitable for monitoring change	Per caput not individual intake derived from estimates of use of commodities within a country or region; intake overestimated as nutrient losses during storage and preparation not accounted for; should not be used to provide estimates of nutritional adequacy of particular regions
<b>Household level</b>			
Food account method		Low respondent burden; relatively inexpensive	No estimates of change in larger stocks; measurements confined to food brought into the home (unless method modified to measure food consumed outside the home, which can be quite large); consumption of confectionery, alcoholic, and soft drinks excluded
Inventory method		Low respondent burden; relatively inexpensive	Consumption of confectionery, alcoholic, and soft drinks excluded
Household record		Suitable for populations with high proportion of homemade foods; useful if literacy levels are low; provides direct measure of food available for consumption	High input from field workers or interviewers
List recall methods		Relatively rapid and inexpensive; only one interview required; suitable for populations with higher proportion of purchased than home-produced food	Advance warning of interview may distort food consumption patterns; subject may fail to record items from memory; no record of foods eaten outside the home
<b>Individual level</b>			
Retrospective methods	24-hour recall (24-HR) (single or multiple days)	If interviewed, respondent literacy not important; not reliant on long-term memory; providing not forewarned, individuals do not alter food consumption; interview length 20–45 min	Single 24-HR should not be used for estimating intake of individuals but can be used for group assessments
	Diet history	Respondent literacy not required	Report of past intake is influenced by current diet; trained interviewers required; average interview length 1–1.5 h; high processing costs
	Food frequency questionnaire (FFQ) (if includes portion estimates termed semiquantitative FFQ)	Useful for large numbers; relatively straightforward to complete; administration simpler and less costly than other individual methods; more rapid data processing	Needs to be developed for specific population group to ensure important food items are covered and requires updating to accommodate changes to supply of foods; less flexible for later analysis as food lists are fixed; responses governed by cognitive, numeric, and literacy abilities of respondents also by length and complexity of the food list
Current methods	Weighed food record (weighed inventory technique)	No requirement for memory retrieval as it records current intake; food intake weighed so estimates of quantity consumed not required	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record; high processing costs
	Food record with estimated weights	No requirement for memory retrieval as it records current intake	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record; necessary to find values for estimates of quantity of food consumed; high processing costs

(Continued)

**Table 1** Names and characteristics of dietary methods used for estimating food and nutrient intake.—cont'd

<i>Name of method</i>	<i>Advantages</i>	<i>Limitations</i>
Duplicate analysis	Greater accuracy	Highly labor intensive; requires laboratory to do food composition analysis; limited applicability in population studies
Records using electronic equipment e.g., mobile phones, digital cameras	Visual records of foods. Avoids need for paper records. Data can be sent to investigators electronically	Currently involves labor intensive programmes to convert to useable data i.e., quantities and types of foods, although systems are in development to deal with this Limited use in older people who experience difficulties with using newer technology

**Table 2** Types of portion used for methods using estimated portions.

<i>Portion types</i>
Average or small, medium, large portions, weights – available from studies of weighed intake
Photographs (ideally there should be five or more representing the population range of intake)
Household measures (spoons, cups, mugs, liquid measures)
Standard units (1 apple, 1 banana)
Food models/replicas (three-dimensional models representing foods)

**Table 3** Factors determining choice or suitability of method.

Size and scale of the data collection
Screening, clinical, research, surveillance purposes?
Literacy or numeracy of the population
Age of the individual or population (the very young or very old may need assistance with completion)
Intended or potential use of the data (immediate short-term assessment vs. prospective research)
Requirement for group or individual estimates for nutrient intake
Requirements from the data for nutrients, food groups, or bioactive nutrients
Detail and comprehensiveness of the information to be extracted for analysis (if information only required for particular nutrient or food type, shortened questionnaires may be administered)
Has repeatability of the method been assessed?
Have previous validation studies been performed on the method by other researchers in similar population groups to the one being studied?
Availability of resources for interviewers, including training
Availability of suitable coding and/or processing program (record and recall methods require greater resources than frequency methods but frequency programs are more complex to develop)

## Methods for measuring food consumption at the national level

### Food balance sheets

The Food and Agriculture Organization (FAO) publishes food balance sheets (FBSs) for approximately 200 countries. FBSs present a comprehensive picture of the pattern of a country's food supply during a specified reference period. Food balance sheets may also be termed national food accounts, food moving into consumption, food consumption statistics, food disappearance data, and consumption level estimates, reflecting differences in the method of calculation but providing similar information.

The supply available during a period is calculated from the total quantity of foodstuffs produced in a country, added to the total quantity imported and modified for any change in stocks that may have occurred. Calculation of quantities used for purposes other than human consumption (exports, livestock, used for seed, nonfood uses) and losses during storage and transportation are made. The per capita supply of each food item available for human consumption is calculated by dividing the total of available food by the number of the population actually consuming it and expressed in terms of quantity and nutrients. Estimates from FBSs include household wastage material, plate waste, and food fed to pets. Nutrient losses during storage, preparation, and cooking are not calculated and so figures for available food are greater than those reported by individual dietary surveys.

Food balance sheets can be used to formulate agricultural policies concerned with production, distribution, and consumption of foods and as a basis for monitoring changes and forecasting food consumption patterns, as well as to provide inter-country comparisons of available supplies.

### Methods for estimating dietary intake at the household level: household budget surveys

Techniques for estimating intake at the household level include the food account method, the inventory method, the household record, and the list recall method. These methods measure all foods and beverages available for consumption by a household or family group during a specified time period of between 1 and 4 weeks, although some last for 2–3 months. Wastage factors are sometimes applied. Household surveys provide data for per capita consumption of foods or nutrients, not intake for specific individuals. Data are calculated irrespective of the age and gender distribution in the household. These methods provide population data for annual mean food consumption and selection patterns and are used for analyzing trends in intake. Household budget surveys are used more widely in Europe than elsewhere. As countries may not produce compatible data, the Data Food Networking Project (DAFNE) has developed the methodology to allow the data from 11 European countries to be combined and compared.

#### Food account method

A record is made by a respondent of details of all quantities of food entering the household (purchased, home grown, or received), usually over a period of 7 days. Changes in larger stocks are not estimated, as on average, some households will gain and some will use up stocks. Estimates of losses and wastage during preparation are made. This method is used for Living Costs and Food (LCF) module of the Integrated Household Survey (IHS) (until 2001 the LCF was called the National Food Survey and from 2001 to 2008 the UK Expenditure and Food Survey), and has included consumption of food, confectionery, soft drinks, and alcohol outside the home since 1992. As consumption outside the home now accounts for a substantial proportion of dietary intake in the UK the method was modified in 2001 to include the use of till receipts and individual 2-week diaries for each household member aged 7 years or older. This method can be used to measure seasonal variation in intake over 1 year.

#### Inventory method

The inventory method is similar to the food account method and respondents record all foods coming into the household. A wastage factor is often applied and a larger inventory is included at the beginning and end of the survey period.

#### Household record

Foods available for consumption (either raw or processed) are weighed or estimated. Foods for each meal are recorded separately to give a total for the household. Waste is measured directly or estimated. Interviewers visit the household early in the day to determine the quantity of food used to prepare the first meal and the number of individuals who consumed it. The midday meal may be weighed or recorded using estimated measures. A further interview is required later in the day. This method is appropriate for use in preindustrial societies where literacy is low and units for buying foods not standardized.

#### List recall methods

The respondent is asked by a trained interviewer to recall the amount and cost of food obtained for household use over a period, usually of 1 week. The method takes into account food use, purchases, and acquired food, but not waste. Quantities consumed are weighed or estimated using household measures. The interview can take up to 2.5 h. Response rates are usually high. Information on the age and sex of people in the household and the number of meals eaten both in and outside the home, income, and other socioeconomic characteristics may be collected. It is helpful to notify the respondent in advance so that records of purchases can be kept before the interview. This method was used by the United States Department of Agriculture (USDA) National Food Consumption Survey between 1931 and 1988.

#### Individual dietary intake methods

Many methods are available for estimating individual dietary intake measures and can be divided into two types: retrospective measures of intake such as 24-HR, dietary history or food frequency questionnaires (FFQs), or current measures of intake such as weighed or estimated food records. Qualitative information is available from all methods but quantitative estimates for nutrient

consumption are possible only if data for weighed or estimated portion weights are available. Most methods may be either self-completed or completed by a surrogate. Surrogates may be required if study individuals are too young, old, or infirm but data will be less reliable than when reported directly.

24-HR and FFQs may be self-completed or interview administered either face-to-face or by telephone and can be mailed. Data collection costs can be reduced if questionnaires can be self-completed or mailed.

The number of days of report required for adequate measures of nutrients using 24-HR, weighed, or estimated records varies depending on the day-to-day variability of nutrient consumption. The number of days is partly dependent on the variation in nutrient concentration in foodstuffs. The concentration of macronutrients such as protein and carbohydrate in foods varies less than micronutrients such as vitamin C or iron. The number of days required to classify individuals into the correct third of the percentage distribution for usual intake, for 80% of individuals, has been calculated in British and Swedish populations. Up to 7 days of recall would be required for energy, protein, sugars, and calcium. Nutrients with greater variability and requiring between 4 and 14 days of records were alcohol, vitamin C, riboflavin, and iron. More recent analysis for the number of days required to estimate energy intake, using doubly labeled water estimates of energy over 14 days as the reference, suggest that 3 days of record are optimal with no improvement with 4 or more days of records. Also, one of the 3 days of record should include a weekend day.

## 24-hour recalls

24-HRs determine intake during the preceding 24 h. Interviews can be recorded on paper or using interactive computerized software. The multiple pass approach has been developed in an effort to obtain a more accurate record of foods and drinks consumed over the previous day. The exact stages or passes may vary between tools. An example of a 5-stage approach is given below.

1. Quick list - to collect a list of foods and drinks consumed during the previous day
2. Forgotten foods - probe for any items that may have been forgotten during the quick list
3. Time and occasion - record the time and eating occasion for each item
4. Detail cycle - record detailed description, amount, cooking methods, use of condiments/associated foods, brands of shop-bought items, and any other information as a review of the day
5. Final probe - probe for anything else consumed, such as commonly forgotten items, e.g. drinks, fruit, biscuits, sauces

Day-to-day variability in nutrient intake is large and a single day will not categorize individuals correctly within a distribution of intake. Therefore, single 24-HR are better used for group assessments than estimates for individuals. However, multiple 24-HR can be used to overcome this problem. The sampling protocol for studies should include an equal proportion of all days of the week and coverage of all four seasons. Newer methods for on-line recording of 24-HR recalls currently exist and include ASA24 (<https://asa24.nci.nih.gov/>), myfood24 (<https://www.myfood24.org/>), Intake 24 (<https://intake24.co.uk/>) and the Oxford WebQ (<https://www.ceu.ox.ac.uk/research/oxford-webq>).

## Diet history

The diet history consists either of an interview administered 24-HR or establishing usual eating pattern over a 1-week period, followed by a frequency questionnaire to provide additional information. The dietary history provides a representative pattern of usual intake and is interview administered only.

## Food frequency questionnaires

FFQs consist of a list of specific foods or food types associated with frequency of consumption. They are termed semiquantitative if portions are included. Most questionnaires specify a frequency response in relation to an average or medium portion but some request records of specific portions. The period of record is usually the previous month or year. FFQs provide an indication of usual intake and can be used to obtain population estimates of frequency of consumption of food types. Guidance on the development, validation and use of FFQs for different study designs is available (Cade et al., 2002).

FFQs need to be developed for specific population groups otherwise important foods may be missed. FFQs may become outdated if the supply of foodstuffs changes. FFQs consist of a fixed food list, which may be a disadvantage for prospective studies as hypotheses to be tested are limited by the list. The FFQ EPIC Tool for Analysis (FETAs) is a tool to calculate nutrient and food group data from the EPIC-Norfolk FFQ (<https://www.epic-norfolk.org.uk/for-researchers/feta-download/>) but it has been designed so that it may be customized for different study populations. Factors that affect the response to FFQs are the literacy and numeracy of respondents, as some mathematical ability is necessary to calculate relative frequencies, the length and complexity of the food list, and the influence of current diet. Not all respondents will relate frequency to portion size accurately.

In the US, examples of FFQs are the Block and Willett questionnaires. In Europe, FFQs were developed for the European Prospective Investigations into Cancer and Nutrition (EPIC) study in the Netherlands, Germany, Greece, Italy, Denmark, France, and the UK.

A short FFQ, usually without portion size questions, may be used as a screening tool, to collect data about specific dietary components, such as intakes of fruits and vegetables, wholegrain foods, dairy foods or red/processed meats.

### **Weighed food record inventory and estimated food record**

For weighed food records (WRs) all food consumed over a period is weighed and recorded with details of food type and method of preparation, on preprinted forms or booklets, to obtain consumption over a period of days. Portable scales need to be supplied. WRs may include some estimated items eaten out of the home. Leftover food should be weighed and deducted. The recommended time period for records is 4–7 days or more, although the number of days depends on the nutrient of interest, study population, and objectives of the study. As some populations have different eating habits at weekends, weekend days should be included proportionately.

For estimated food records, all foods consumed over a period are recorded with details of food type, method of preparation, and estimated portions over a period of days (see [Table 2](#)). If recorded over 7 days, this may be called a “7-day diary.”

Both these methods have a high respondent burden and need cooperative, literate respondents. Respondents require training in the level of detail needed to describe foods. It is also possible that respondents will change usual eating patterns to simplify the process of the record. It is also beneficial to include a review of weighed records during the period of recording either after the first day or at the end.

### **Duplicate sample technique**

Duplicate samples of all foods consumed are made and the nutrient content analyzed. This method is used for metabolic studies and though providing greater accuracy than other methods, its use is not feasible for most purposes.

### **Further information**

Although nomenclature for dietary methodology is reasonably consistent, care should be taken when reading the literature as methods with the same name may have been applied differently. The final decision over which method to choose will depend on the aims of the study, the population for study, the potential burden on respondents, and the resources available. Household surveys and food balance sheets provide data for per caput but not individual intake. In general, individual and the more intensive methods are associated with higher costs and respondent burden, whereas household methods are more economical and have a lower respondent burden.

### **Clinical practice**

Dietary methodology for clinical practice requires rapid assessments of nutritional intake in order to prescribe dietary change or to improve nutritional status. Traditionally, 24-HR or “usual” intake or diet histories have been used for this purpose. Food frequency questionnaires and weighed or estimated food records are not generally used, due to the more intensive burden on respondents and on the resources required for coding and processing the data.

There is considerable discussion over the optimum method to use for establishing individual dietary intake and studies designed to measure the validity of methods suggest that those that are more intensive and detailed lead to greater measurement precision, justifying the greater cost. Confirmation of these findings is required. Despite these potential benefits, if resources are unavailable, less intensive methods tend to be used.

### **Factors affecting individual ability to report intake accurately**

Factors governing individual accuracy and quality of reports are respondent’s literacy and numeracy skills; preconceived ideas on the purpose of the inquiry and, for list-based methods, the interpretation and meaning of food names ([Smith, 1993](#)). Individuals may make errors when measuring and recording food weights or estimating weights of foods consumed. There is also respondent variation in the perception of the size of portions represented by photographs.

### **Interviewers**

The aim of using interviewers with dietary methods is to obtain a complete, accurate, and detailed record of what respondents eat. Therefore, it is important for interviewers to be well trained and have an awareness of food composition and preparation

techniques. Ideally, interviewers should be educated in nutrition (dietitians or nutritionists), although non-nutritionists can be trained to standardized techniques, and come from the same cultural or ethnic background as the study population. Interviewer protocols should be developed.

### **Computerized interview procedures**

Computerized interview systems can aid interviewers by prompting for specific questions to elicit sufficient and specific detail and reduce the burden on interviewers. Examples are the Minnesota Nutrition Data System and the EPIC-SOFT systems, used in the US and a number of European countries. Although computerized interviews have advantages in improving accuracy and standardization, and in saving time and effort when recording and coding data, interviewers do have to be competent with computers and the resources required to develop systems are high.

### **Using dietary methods in different populations**

Ethnic subpopulations may consume different food types than a main population and baseline surveys will be required to establish what types of foods and method of preparation are common. This information would be required before list-based methods such as the FFQ could be developed.

### **Recall of remote diet**

Investigators may wish to recall diet in the remote past, perhaps of many years. However, interpretation of remotely recalled dietary data is complex as recalled diet is heavily influenced by current dietary habit. Some studies have found that the correlations between recalled past diet and current diet were higher than the correlations between actual past diet and recall of past diet. The onset of diseases such as cancer may affect the appetite and dietary intake of study participants and as recall of remote diet is strongly related to current diet, may affect recall of remote diet. As diet before the onset of disease is the measure of interest, it is preferable to collect dietary information prospectively, that is before disease onset. Case-control studies in which the diet of cases with disease is compared with controls may be affected by altered perception of recalled diet, particularly by cases.

### **Reproducibility of dietary methods**

The reproducibility of a method may also be referred to as reliability, repeatability, or precision and is a measure of the extent to which the same results can be obtained when repeated under the same conditions. Repeated measures provide an estimate of the within-person variability of intake. However, interpretation of the repeatability of measures is difficult as a lack of consistency may be due to genuine change over a time period or a lack of sensitivity or specificity of the method used to measure intake.

### **Use of data and conversion of reported intake to nutrients and food types**

#### **Qualitative analysis**

Dietary method data can be used qualitatively, for instance during the process of reviewing nutritional intake for the purpose of dietary treatment as in clinical practice. Data on frequency of consumption may also be collected and analyzed by the FFQ method without conversion to nutrient intakes. However, even for qualitative analyses, it is likely that paper-based dietary methods will require conversion to an electronic format. The majority of uses of dietary methods are targeted toward quantitative analyses.

#### **Quantitative analysis**

The data collected by dietary methods are converted into food and nutrient consumption by calculating the amount of food eaten and linking this to a database with values for the nutrient composition of foods.

The databases of nutrient composition of foods are provided by the governments of many countries. They consist of nutrient composition data for the average composition of commonly consumed foodstuffs and are usually available as printed publications, computerized databases, or as part of software packages. Values in nutrient composition databases are expressed as either per 100 g of food or per common household measure. Nutrient databases vary in the coverage and comprehensiveness of the foods and nutrients. They are revised periodically to cover newer foods of different nutrient compositions or to modify or extend the nutrient coverage. Some issues concerning the choice of nutrient databases are shown in [Table 4](#). It is important to read the information distributed with the printed or electronic versions of databases to determine the uses and limitations of the data.

**Table 4** Factors to consider when choosing a nutrient database to calculate nutrient intakes.

---

Comprehensiveness of food item and beverage coverage?
Does the database contain entries for important foods consumed by the population to be studied?
How comprehensive is the coverage of nutrients?
Does the database contain data for mixed or multiple ingredient recipes or dishes?
What analytical techniques were used to derive nutrients in the database? (There can be differences in nutrients measured by different techniques.)
Are the data officially evaluated?
What compilation methods were used to construct the database?
Which conversion factors are used to calculate metabolizable energy content of foods for protein, fat, carbohydrate, and alcohol?
What proportion of missing values exists within the database? (Missing values are counted as zero in calculations and so result in systematic underestimates of intake.)
For international studies or comparisons, how do the analytical methods for determining nutrient composition and compilation techniques affect the resulting data?

---

Several steps are involved in calculating nutrient intake (also known as coding or processing). The first is to choose an item in the database, which corresponds most closely with the food consumed. If the food consumed is not in the database a suitable alternative can be chosen by considering food type, general characteristics, and likely nutrient profile. Once the food has been chosen, the nutrient composition of the food quoted in the database is multiplied by the amount of food eaten, e.g., for 60 g food the nutrients would be multiplied by 0.6 (where nutrients are expressed per 100 g of food).

To calculate daily intake for an individual, the contribution of each food is calculated and all the foods for a day summated. If more than one day's data have been collected, it is usual to calculate the average of the number of days recorded. Data from FFQs are usually computed to consumption per day but can also be computed per week.

Although it is possible to compute intake by hand, using a calculator and a printed copy of a nutrient database, this is very labor intensive and in practice for most purposes has been superseded by computerization.

The UK Nutrient Databank (UKNDB) (<https://beta.ukdataservice.ac.uk/datacatalogue/doi/?id=6533#!#7>), contains over 5600 foods. The UKNDB is commissioned by Public Health England as part of the National Diet and Nutrition Survey (NDNS), is available in electronic format as an integrated dataset, and contains up-to-date nutrient composition data. Data in the UKNDB are very similar to the UK McCance and Widdowson's food composition tables (<https://www.gov.uk/government/publications/composition-of-foods-integrated-dataset-cofid>) but the UKNDB includes a larger range of processed foods and composite dishes, and missing values have been replaced with plausible values. It is maintained as part of NDNS.

## Data processing and computing dietary intake

The same care as that invested in data collection should be applied to data processing as errors of great magnitude may be introduced.

## Estimated food quantities

To obtain quantitative information for nutrients or food groups, actual or estimated food weights are used. For methods using estimated food weights, values also need to be found for foods described, such as standard units, average portions, or household measures. Sources of data are national publications, surveys of weighed dietary intakes, and food manufacturers. Data may also be included in nutrient calculation programs. Portion weights need to be population specific and, if unavailable, studies to establish values will be needed. Intensive methods used for large-scale surveys will require databases of more than 20 000 values for portion weights.

## Data entry and nutrient calculation systems

A number of computerized data entry systems and nutrient calculation programs exist (Fitt et al., 2015; Welch et al., 2001); factors that need to be considered when choosing a system are given in Table 5. The features required depend on the intended use of the data but, as a minimum, should include a list of foods, weights of portions, and a nutrient composition database. Ideally, systems should enable entry of data in sufficient detail to fulfill hypotheses for investigation and include measures to ensure consistent entry by staff such as defaults for inadequately reported foods, portions, or mixed component foods. They should also include a method for entering newer foods with different nutrient composition from the existing nutrient database. This is particularly important, as the range of new foodstuffs and products with different nutritional characteristics is ever increasing.

**Table 5** Factors to consider when choosing a computerized entry or interviewing program.

---

Speed of the assessment
Requirements of the study for detailed or general data
Food composition database used
Food portion database used
Cost of the system
Facilities for organization of data
Ability to extract nutrients or food groups from the system
How up to date are the nutrient composition databases included in the system?
Commercial availability

---

Computerized systems and nutrient databases become outdated and for large-scale prospective studies, it is desirable to develop systems with a flexible approach to updating by using database technology.

### Data processing errors

Errors arising during the coding (data entry) and processing of individual dietary methods (24-HR, diet history, weighed and estimated records) need to be avoided. Misclassification can arise due to human error if incorrect foods are chosen during coding, for instance, if milk was consumed in the full-fat form but was coded for skimmed milk. This may also arise where a food has local or alternative food names, which may be unknown to the coder. It is important to have a qualified nutritionist available to develop a protocol for training staff, answering queries, and dealing with ambiguities. Coders should have knowledge of food composition and food preparation techniques. It is difficult to control entry of incorrectly matched foods but careful checking and staff training are crucial in preventing this. Other potential errors are entry of incorrect quantities or multiplication factors for portion weights and missed items, problems that can occur even with structured computer programs. So, systematic post-entry checks to identify extremes of portion weights or nutrient values and the verification and correction of data are necessary.

## Issues associated with measurement of dietary intake

### Measurement error

There is potential for the occurrence of measurement error with the measurement of any exposure such as when using dietary methods to measure nutritional intake. Errors may arise as a result of flaws in the design of the measurement instrument or during data collection or processing. Measurement error may also occur as a result of individual characteristics of participants in studies. Measurement error can be defined as the difference between the measured exposure (or measure of dietary intake) and the true exposure. All measurement of dietary exposures is subject to some degree of measurement error making it difficult to achieve measurements of true intake.

Efforts to reduce measurement error during data collection and processing should be introduced into the protocol of all studies, however, even if preventative measures are taken, it is impossible to eliminate it altogether. It is difficult to identify the type and structure of measurement error associated with dietary intake. Measurement error may occur because of inaccurate reporting by respondents. It may also vary according to dietary method, for instance, food items within record methods may be intentionally or unintentionally omitted and with FFQs, frequency of consumption may be inaccurately reported. Systematic bias, interviewer bias, recall bias, and social desirability bias have been identified but there are likely to be other sources of error. (Bias can be defined as the modification of a method of measurement by a factor, which influences the measurement in one or more directions.) Measurement error associated with dietary methods may consist of one or more types of error.

### Measurement error in data collection and processing

Self-report dietary assessment instruments are affected by two main types of error or bias, systematic and random error, which must be understood and addressed in order to avoid misleading results.

Random error can occur for a variety of reasons. Examples of random error relating to dietary assessment include unclear explanations from investigators, an individual's error in estimating portion size, dietary coding errors, or limitations with a food composition table. Random error causes the estimated values to deviate from the true intake, due to chance, affecting the reliability of a method. It may be reduced by increasing the number of days of dietary assessment, including quality control and assurance checks or carrying out pilot studies, especially when creating a new questionnaire.

### Systematic bias

Systematic bias is a systematic mismeasurement of data and can occur, for instance, if equipment such as weighing scales under- or overestimates values or if an interviewer consistently fails to use questions to probe for consumption of snacks and additional foods. If systematic bias can be identified, solutions can be found, for instance, by calibrating equipment or training and monitoring interviewers.

### Interviewer bias

The behavior of an interviewer can influence the response of interviewees leading to interviewer bias. The degree of rapport between interviewer and respondent also influences results. Bias may occur if interviewers omit responses or record them incorrectly. Trained interviewers should ask open-ended questions in a neutral or non-leading manner, and not imply that a food or beverage should or should not have been consumed and avoid value judgments.

### Social desirability bias

Social desirability bias can influence dietary measures as respondents strive to report what they think is required not what was actually consumed, for example, reporting less alcohol consumption than is the case or greater consumption of foods with perceived health benefits such as fish, fruit, or vegetables. This is likely to be the cause of misreporting, under-reporting, or low energy reporting, which occurs in certain respondents. It is possible to predict how much energy a respondent should report, as this is the amount required to maintain a stable weight. (Weight will be either gained or lost if more or less energy is consumed than required.) As energy intake should equate to energy expenditure, expenditure effectively measures intake. Techniques for measurement of energy expenditure such as whole body calorimetry and doubly labeled water can be used. Using these techniques, those individuals classified as low energy reporters are likely to be older, more overweight, and of lower educational and socioeconomic status than the rest of the population. Low energy reporters tend to have lower consumption of foods in certain food groups such as cookies, cakes, puddings, confectionery (candy), and sugary foods and, in some populations, lower consumption of spreads, cooking fats, and potato chips. Interviewers should be aware of low energy reporting, aim to be entirely nonjudgmental, and also request participants make complete records of food intake.

### Impact of measurement error

As the proportion of error within a measurement increases, the accuracy of the measurement decreases and the results using the measurement will become less interpretable. Hence, greater measurement error reduces the likelihood that the truth has been measured with accuracy and increases the likelihood that analyses relating diet to disease status will tend toward null results. The effect of measurement error is to misclassify an individual within a range of intake.

### Validation of dietary methods

Validation is used to quantify the measurement error that occurs when measuring dietary intake exposures. It requires two measures: a main measurement and a second measurement that is subject to less measurement error than the first. The errors of the two measurements should be independent. Validation is used to estimate the proportion of measurement error within the main method by modeling the differences between the main and the secondary measurements. It had been considered that dietary methods had errors independent of each other and that record methods such as 24-HR could be used, but it is now known that the errors are not independent as individuals report in the same way with different methods. Therefore, it is better to use biological variables measurable in blood or urine (also known as biomarkers) as the second measure for dietary validation ([Jenab et al., 2009](#); [Potischman and Freudenheim, 2003](#)).

Nutritional biomarkers may be classified using more than one method. This classification is comprised of four types: recovery, concentration, predictive and replacement biomarkers, although the classification is not mutually exclusive. Recovery biomarkers allow quantitative estimates of intake over a specific time period. Concentration biomarkers measure relative concentration across a distribution. Predictive biomarkers can be used to assess the validity of a dietary assessment method but have lower overall recovery. Replacement biomarkers are closely related to concentration biomarkers and often the distinction between them is difficult to make - their differentiating characteristic is that they refer specifically to compounds for which information in food composition databases is unsatisfactory or unavailable. Examples of recovery biomarkers are urinary excretion over 24 h of nitrogen, potassium and sodium ([Park et al., 2018](#)). Examples of concentration biomarkers are measures in blood of vitamins such as vitamin C and carotenoids, minerals, and individual fatty acids. Urinary sucrose ([Kuhnle et al., 2015](#)) and fructose are examples of predictive biomarkers. Examples of replacement biomarkers are some aflatoxins and phytoestrogens ([Grace et al., 2004](#)) and some of the recent biomarkers identified through metabolomics.

Examples of validation studies are those performed within EPIC-Europe and the Observing Protein and Energy Nutrition Study (OPEN) in the US. Work is ongoing to extend the number of biomarkers available and to define further and elicit the structure of measurement error. The doubly labeled water technique has been used to estimate total energy utilization in order to validate estimates of energy intake. However, this technique is extremely costly which reduces its use in large populations. Also, independent estimates of energy intake should be done in periods of weight stability.

Newer methods of identifying biomarkers have been developed recently. These include the use of metabolomic techniques (Brennan et al., 2015) which can identify and measure small molecules, called metabolites, which can provide detailed information on metabolic pathways and biological processes. The metabolome has been measured in biological samples of blood and urine and newer candidates for nutritional biomarkers identified. A recent study (Playdon et al., 2017) found strong associations between healthy eating patterns and biomarkers, identified using metabolomics, in blood. However, whether or not metabolomic biomarkers will enable us to achieve a more accurate self-reported assessment of dietary intake or proximates, such as carbohydrate or fat, remains to be seen. These techniques have so far identified components/metabolites on metabolic pathways of nutrient metabolism, which have mainly been specific to particular nutrients or bioactive compounds in foods. It is not possible to estimate intakes of foods from these methods, only to “validate” consumption of certain types of foods or not e.g. strawberries, citrus fruit.

### Use of calibration methods to adjust for measurement error

In contrast to validation, which attempts to identify the type and scale of measurement error, calibration is designed to adjust for systematic over- or under-estimation in dietary intakes within populations. It may also be used at the individual level, in an attempt to correct for attenuation bias (or dilution) in relative risk due to errors in dietary measurements. Calibration of data has been proposed for large multicenter nutritional studies that have used different dietary methods to capture population-specific diets. Calibration studies require a highly standardized second dietary measure to be used in a representative subsample from each cohort to form a common reference measurement across populations. An example of this approach has been used by the European EPIC Study using a computerized, standardized 24-HR in 10 countries (Slimani et al., 1999).

### Future developments

A number of technology-based tools which currently exist for the assessment of dietary intake have been evaluated (Eldridge et al., 2019; Vu et al., 2017). Future developments in methodology involve using computing, digital, and Internet technology, such as videos of food eaten and online programs for self-reported intake. Use of Dictaphones and combinations of weighing and other recording equipment are also possible. Development of statistical techniques to combine the optimal properties of different dietary methods is also ongoing and is a promising avenue for the future.

The number of foodstuffs available, particularly of manufactured foods and readymade meals, will continue to increase, presenting challenges for those attempting to estimate nutrient intake. Nutrient databases will continue to be expanded and updated to incorporate newer food items and nutrient measurements available using improved analytical techniques.

In some populations more than 40% of individuals have been shown to consume supplements and as very few comprehensive databases of vitamin and mineral supplements exist these need to be developed, as supplements can make a major contribution to nutrient intakes (Lentjes et al., 2011).

### Conclusion

A wide variety of methods for measuring dietary intake exists, categorized as subjective or objective. It is essential to understand their advantages and limitations, and how to deal with measurement error which may occur, both for use in clinical practice and research, and when reading and interpreting the scientific literature.

### Key points

- The DLW is an accurate (0.5%) and precise (8%) method to measure total daily energy expenditure and total body water.
- The method is based on the difference between the elimination rates of water labeled with two stable isotopes (<sup>2</sup>H and <sup>18</sup>O).
- The Doubly labeled water method was first validated and applied to measure the energy expenditure of wild animals and later validated in humans and utilized in hundreds of studies under free-living conditions.
- The DLW method revolutionized the study of energy metabolism through applications including energy requirements throughout the life-course, physical activity, weight management, and effects of disease and diet and lifestyle on energy expenditure.

### Glossary

**Body composition** Partitioning of body tissues into compartments. A common two-compartment model separates the body into fat and fat-free mass

**Doubly labeled water (DLW)** A tracer kinetic method to measure CO<sub>2</sub> production using a combination of two stable isotopes of water-i.e., deuterium and oxygen-18

**Indirect calorimetry** The measurement of respiratory gas exchange during the oxidation of fuel in the body producing CO<sub>2</sub> and consuming O<sub>2</sub> from which the heat released during that oxidation is calculated

**Respiratory exchange ratio (RER)** The ratio of CO<sub>2</sub> output, and O<sub>2</sub> consumption that occurs during respiration

**Total energy expenditure (TEE)** The sum of resting metabolic rate, the thermic effect of meals, and physical activity expenditure

### Introduction

Chemically defined, water is composed of one oxygen atom bonded to two hydrogen atoms. This molecule has unique physical and chemical properties that are vital to support life. The molecule is polar, having a slightly negative end and a slightly positive end. This characteristic allows water to easily dissolve other polar molecules and also creates surface tension, capillary action, and is a medium for electrical conductivity. From the largest mammal to the smallest bacteria, the existence of life on Earth depends on water. Water fills cells providing cell volume and intracellular structural support. Without water, organisms would not have a means to store genetic information as water's polarity is what facilitates DNA to form helical coils from which the genetic information can be translated into the synthesis of proteins. In multicellular organisms, water is a critical transport medium for polar molecules between cells whose membranes are lined with channels making them permeable to water. The metabolic processes taking place within cells in the form of photosynthesis or respiration require water as a chemical solvent and often also as a reactant or product. Water also provides the essential functions of lubrication and transport for nutrients and waste. Because of these roles and many others, water is central to life known on Earth.

Water is usually the largest component of the four basic molecular entities that together comprise the body: protein, lipid, mineral, and water. Because these are the only basic components, measurement of any of these can provide considerable insight into an individual's body composition. Moreover, nutritionists frequently combine protein, water, and mineral into a single compartment that is termed fat-free mass. This allows an investigator to describe the body in terms of fat and fat-free mass, which is useful in determining body energy stores and in assessing the health status of an individual in terms of malnutrition and obesity. Several methods are available to determine fat or fat-free mass. Dual-energy X-ray absorptiometry (DXA) uses X-rays to differentiate fat mass, fat-free mass, and bone mineral mass. Underwater weighing is a way to measure body volume by water displacement. This procedure helps to calculate body density or mass per unit volume, and from density, the body fat percentage can be estimated using based on the difference in density of fat and fat-free mass. Finally, one of the oldest and still commonly used methods of body composition analysis is to measure total body water (TBW). Water is found only in the fat-free compartment because fat is anhydrous. In humans and other mammals, TBW has been found to be relatively constant at approximately 73% of the body's fat-free mass. Thus, a measured TBW allows us to calculate  $\text{Fat mass} = \text{Body mass} - \left( \frac{\text{TBW}}{0.73} \right)$ .

The common method for measuring TBW is isotope dilution, which is based on the principle of dilution using a small amount of tracer with a known volume to measure a large unknown volume into which it is mixed. The principle of dilution can be illustrated by analogy. Consider a highly concentrated dye in a small volume will have a very dark appearance (high light absorbance). If this is diluted in a large beaker of water, the mixture will have a lighter color (Fig. 1). If the amount of the concentrated dye added into the small beaker is known and the concentration of the dye in the larger mixture is measured, then the volume of the diluting water in the larger beaker can be calculated. Isotope dilution uses the same principle, but instead of a dye, an isotopically labeled water is added to the water. Total body water, or more correctly, isotope dilution space (N), which is calculated as:

$$N = \frac{\text{Dose}}{\text{Isotope concentration}}$$

For this purpose, minor isotopes of interest in a water molecule typically include  $^2\text{H}$  (deuterium) and  $^{18}\text{O}$ , which are stable (nonradioactive) isotopes, and  $^3\text{H}$  (tritium), which is a radioactive isotope. Because stable isotopes do not undergo nuclear decay, they do not release harmful radiation; yet, as isotopes, they act very much like their more common isotope in chemical processes. These stable, minor isotopes occur in nature and make up a relatively constant percentage of the total pool of each element in nature. Because there is no risk to radiation, they constitute a safe option for use as tracer molecules, except for  $^2\text{H}$  in water which begins to cause some changes in biological reaction rates when the enrichments exceed 10–15% body water. These enrichments are more than 1000 times those employed in the doubly labeled water (DLW) method.

When a loading or pulse of isotope-labeled water is consumed, however, the tracer does not remain in body water after TBW is measured. Water is constantly being lost from the body. This loss, if unchecked, further demonstrates the importance of water for human life. A water loss ( $\sim 3\%$  of TBW) as little as 2% body mass will cause dry mouth, headaches, and decreased urine production. A water loss of 5% of body mass will further cause increased heart rate, respiration, fatigue, muscle cramps, and even further decreased urine production. Severe dehydration, a loss of 10% of body mass or more after several days without water

**Fig. 1** Adding a concentrated dye to a beaker of water is analogous to a person adding a small amount of isotopic tracer to their body's water pool. Adding water to the mixture created is analogous to that person then ingesting water over time and further diluting the mixture.

consumption, will cause seizures, loss of vision, high pulse, muscle spasms, and eventually death. Repletion through drinking and food moisture along with the required electrolytes replaces lost water. In normal daily living, this loss and replacement occur well before dehydration occurs and creates a dynamic state in which part of the human water pool turns over on a daily basis. This daily loss of labeled water and replacement with unlabeled water further dilutes the isotopically labeled body water. Returning to the analogy of the dye solution, the mixture's color will become lighter with each loss of labeled water and replacement with unlabeled water (Fig. 1B).

Because the method uses water labeled with two isotopes,  $^2\text{H}$  and  $^{18}\text{O}$ , hence the name DLW. After dosing these labeled water molecules readily mix with unlabeled water and can therefore follow or trace the physiological and biochemical pathways of water in the body. Lifson was the first who reported that the oxygen in body water exchanges and equilibrate with those in carbon dioxide (Speakman, 1997). Because of this, the two isotopes do not behave identically. The  $^2\text{H}$  is excreted as water, while the  $^{18}\text{O}$  is excreted as both water and carbon dioxide. The turnover rate of  $^{18}\text{O}$  is, therefore, greater than that of  $^2\text{H}$  and the difference between the turnover rates is a measure of the  $\text{CO}_2$  flux through the body (Fig. 2A). Because  $\text{CO}_2$  is an end product of energy metabolism, one can use the difference between the two turnover rates to measure  $\text{CO}_2$  production (Fig. 2B), and from that to calculate energy expenditure.

The DLW method is, therefore, a form of indirect calorimetry because it measures a product produced during the oxidation of fuel in the body and not a direct measure of the heat released during that oxidation. This form of indirect calorimetry has become the method of choice for the measurement of energy metabolism in free-living animals including humans. The isotope dilution allows for the dynamic measurement of each of the water isotopes over time. Because  $^2\text{H}$  exits the body almost exclusively as water, it is possible to calculate the water elimination rate ( $r\text{H}_2\text{O}$ ):

$$r\text{H}_2\text{O} = N_D k_D$$

where  $N_D$  is the deuterium dilution space and  $k_D$  is the fractional turnover rate of  $^2\text{H}_2\text{O}$ , which equals:

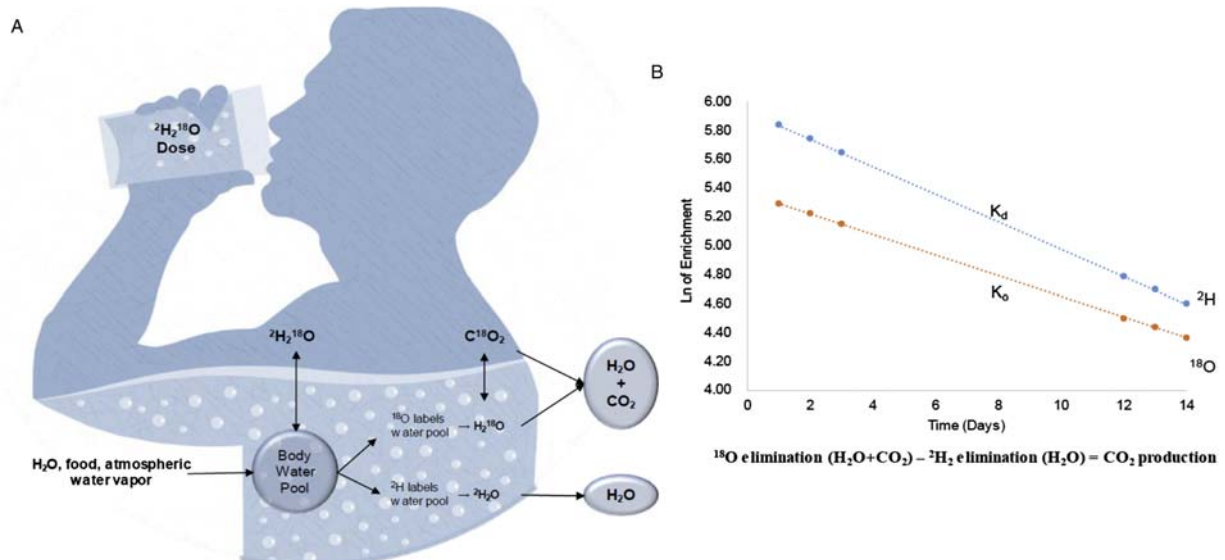

$$k_D = \frac{(\ln[D]_2 - \ln[D]_1)}{(t_2 - t_1)}$$

where the slope of deuterium enrichment is calculated by the difference between isotopic abundances ( $\ln[D]_2$  and  $\ln[D]_1$ ) in the samples across the time interval after the dose administration ( $t_2$  and  $t_1$ ). Similarly,  $^{18}\text{O}$ 's elimination rate ( $r\text{H}_2\text{O} + 2r\text{CO}_2$ ) can be calculated:

$$r\text{H}_2\text{O} + 2r\text{CO}_2 = N_O k_O$$

where  $N_O$  is the  $^{18}\text{O}$  dilution space and  $k_O$  is the fractional turnover rate of  $\text{H}_2^{18}\text{O}$ . However, note that provides us with two equations and two unknowns, which when combined allows us to solve for  $r\text{CO}_2$ :

$$r\text{CO}_2 = \frac{1}{2}(N_O k_O - N_D k_D)$$

**Fig. 2** Schematic image of the doubly labeled water method. (A) After ingesting the dose of DLW, the labeled compounds dilute in the body water pool and then equilibrate with the  $\text{H}_2\text{O}$  and  $\text{CO}_2$ . The washout kinetics of both isotopes and their concentrations decrease exponentially toward natural abundance levels due to the elimination of water and  $\text{CO}_2$ . (B) The difference in the turnover rates of  $^2\text{H}$  and  $^{18}\text{O}$  is proportional to  $\text{CO}_2$  production.

However, this equation is not exact because it does not take into account isotope fractionation. Fractionation occurs when one isotope is discriminated against during a change in state (liquid to water vapor) or exchange between molecules (water to  $\text{CO}_2$ ). The fractionation factor is  $<1$  when the heavy isotope is discriminated against,  $=1$  when there is no discrimination, or  $>1$  when the light isotope is discriminated against. At  $37^\circ\text{C}$ , the isotope fractionation factors are as follows: 0.946 for  $^2\text{H}$  and 0.991 for  $^{18}\text{O}$  between liquid to water vapor and 1.038 for  $^{18}\text{O}$  between water and  $\text{CO}_2$ .

In addition, to further increase the accuracy, this equation needs to take into account the difference between dilution spaces ( $N_D$  and  $N_O$ ) and TBW ( $N$ ) across the lifespan. With regard to the former, a small amount, which can vary slightly particularly during the first few years after birth, of both  $^2\text{H}$  ( $\sim 4.3\%$ ) and  $^{18}\text{O}$  ( $\sim 0.7\%$ ) exchange with nonaqueous compounds creating an isotope dilution space that is a little larger than the TBW pool.

Over the past 40 years, a classical equation proposed by Schoeller et al. (1986), has been presented with small slight variations (Coward and Prentice, 1985; Racette et al., 1994; Schoeller, 1988; Speakman, 1997; Speakman et al., 1993) in the combination of the four basic parameters to measure the isotope elimination rates and, subsequently,  $\text{CO}_2$  production, has been used in nutrition science studies. The variability on energy data using these slightly different equations is not relevant when results are compared within an investigation, however, it can significantly affect research outcomes when the TEE values are compared across studies, such as between cultures and lifestyles (Speakman et al., 2021).

To address these issues, a group of experts in stable isotopes and energy metabolism recently derived a new equation based on data of 6621 DLW measurements from 23 countries, which were compiled in the International Atomic Energy Agency (Speakman et al., 2019). This assessment aimed to obtain a more accurate estimative of energy expenditure values, besides promoting gathering and comparing data of future studies more efficiently (Speakman et al., 2021). To this end, the experts proposed a correction to the propagation of the isotope exchange variation with nonaqueous atoms, which even small, is another critical parameter that affected the  $\text{CO}_2$  calculation.

Two new approaches were derived and recommended for use in DLW future studies (Speakman et al., 2021). First, the original equation proposed by Schoeller et al. (Schoeller et al., 1986), was modified taking into account the constant of 1.036 as the average dilution space ratio ( $\text{DSR} = N_D/N_O$ ) to mitigate the potential error induced by the nonaqueous isotope exchange variation (Sagayama et al., 2016). This updated approach is indicated for individuals  $>2$  and  $<96$  years and achieved an accuracy of  $-0.4 \pm 7.6\%$  when compared to values from indirect calorimetry. The equation was simplified as follow, considering the isotope fractionation and exchange constants into it:

$$r\text{CO}_2 = 0.455 \times N \times [(1.007k_O) - (1.041k_D)]$$

Second, the experts' group validated a new equation for babies and infants under 2 years of age with a body mass of 0–10 kg, which accuracy of  $0.64 \pm 11.9\%$ . In this approach, the equation considered the weight dependency observed for the isotopes DSR, and then combined it to the new standard equation above, as simplified below:

$$r\text{CO}_2 = [0.45859 \times N \times (K_O - (\text{DSR} \times k_D))]$$

Where  $N = N_O$  and DSR is defined from an asymptotic exponential model, considering the body mass BM in kg, as follow:

$$\text{DSR} = 1.036 - 0.05 \times \exp(-0.5249 \times \text{BM})$$

Finally, the investigators (Speakman et al., 2021) provided a free-to-use website (<http://dlw.som.cuanschutz.edu/>) where investigators can input isotope data to obtain  $r\text{CO}_2$  and TEE using the recommended approaches.

## Methodology

The initial distribution and equilibration of the two isotopes across TBW after ingestion and subsequent elimination from the body provides the basis for the total energy expenditure calculation. Because the isotope analysis is for aqueous samples, various body fluids (urine, saliva, and plasma) can be used. Urine is the usual fluid of choice as it is easily acquired in sufficient quantities and requires minimal cleaning to prepare it for isotope ratio mass spectrometric analysis. The procedure starts with the participant in the fasted state and providing a baseline sample, after which the dose is administered. Three more samples are obtained typically over 3–6 h post-dosing depending on other requirements of the study protocol and specific population characteristics. At this point, the subject is free to leave the testing center and resume their normal lifestyle and experimental protocol. Urine samples are again required at the end of the measurement period. The measurement period is typically between 0.5 and 3 elimination half-lives of the  $^2\text{H}$  in body water. In most adults, this is between 3 days and 3 weeks, although to best account for the weekend and weekday behaviors, periods of 7 or 14 days after the dose was administered are recommended. The specimens should be collected at the same time of the day that the post-dose samples were obtained. The measurement is usually shortened under conditions of high water turnover, such as extreme physical activity, high ambient temperature, or infancy (Schoeller et al., 1986). This minimal sampling protocol is one of the attributes of the DLW method because it allows the subject to engage in the activities of their normal lifestyle. Unlike other methods of calorimetry that require frequent or continuous sample collection or monitoring.

This modest sampling requirement is possible because the DLW method transforms the human body into a metabolic recorder. By measuring the tracer concentrations in the body at the start and end of a 1- or 2-week metabolic period, the amount of tracer that left the body can be calculated and from that how much tracer was eliminated. This provides a measure of the total water flux and  $\text{CO}_2$  flux through the body during that period, which, when divided by the number of days, yields the average daily flux.

To calculate total energy expenditure (TEE), one more piece of information is needed. The respiratory exchange ratio (RER) is the ratio of CO<sub>2</sub> output and O<sub>2</sub> input that occurs during respiration. The RER is dependent on what type of substrate (fat vs. carbohydrate) is being used to produce energy on a cellular level. The RER can be estimated based on diet. For example, the typical Western diet of 30–35% of energy from fat yields a food quotient of approximately 0.86. When the subject is close to the energy balance, the RER is assumed to equal the food quotient and this is used as an estimate of the RER in the standard indirect calorimetric equations for calculating energy expenditure from CO<sub>2</sub> production. The following modified Weir equation is the simplest and thus the most commonly used:

$$TEE \text{ (kcal.day}^{-1}\text{)} = 22.26 \times r\text{CO}_2 \times (1.10 + 3.90 / RER)$$

Where 22.26 is the gas volume constant in l mole of CO<sub>2</sub>. The gas volume constant for CO<sub>2</sub> differs slightly from that of the perfect gas. The value for  $r\text{CO}_2$  is derived from the tracer measurements as discussed above, and RER is estimated from diet or diet plus any change in body fat and protein stores.

## Instrumentation

Unlike radioisotopes, which can be detected by the amount or the form of radiation products they produce, stable isotopes must be identified and differentiated on the basis of their mass. Several types of mass spectrometers are currently available that separate and measure isotope concentrations based on their mass-to-charge ratio ( $m/z$ ), where  $m$  is the mass of the ion and  $z$  is its charge. In basic terms, a sample is introduced into the instrument in the gas phase, ionized, separated by  $m/z$ , and then detected. Briefly, magnetic sector mass analyzers create and then accelerate ions through a magnetic field. Because all ions have equal initial kinetic energies, they are separated by their velocities through the tube as a lighter isotope will follow a more curved path than the heavier isotope. The quadrupole mass analyzer contains four parallel rods that use a combination of a direct current and an alternative current voltage at radio frequencies to guide ions of selected mass toward the detector. Ions in the sample whose  $m/z$  ratios are not selected by the detector simply collide with the rod and do not reach the detector. Although quadrupole instruments may be more compact and less expensive to purchase and operate, for the purposes of analyzing DLW, the isotope ratio mass spectrometer (IRMS) is used. This is a magnetic sector instrument that offers superior precision for isotope ratio analysis of the light elements like H and O. The use of IRMS allows investigators to use lower doses of isotopic tracer in their studies and thus reduces the cost of <sup>18</sup>O administered. Typically, 10% atom percent excess (APE) rather than 95–99% APE normalized <sup>18</sup>O is mixed with 99% APE <sup>2</sup>H<sub>2</sub>O for dosing, thus making the application of the DLW method more cost-efficient, typically between \$2.50 to \$3.50 per kg of body weight. In this context APE is the percentage of water molecules that contain the heavy stable isotope in excess of that present in natural water. This fact alone has led to the use of this type of analysis in human experimental trials than any other. The sample is introduced into the IRMS as a gas (CO<sub>2</sub> or H<sub>2</sub>) which is then ionized by electron impact under vacuum and accelerated from the source as an ion beam (Fig. 3). The ionized gas sample is then accelerated through an evacuated flight tube by an electrical gradient, during which the ions of different mass are separated by a magnetic field. The ion flight for each gas species is then terminated on impact with a faraday cup or collector. An array of these cups are configured to measure the current for each of the charged species of a gas and the isotope ratio is then measured for each sample and then compared with a reference of known isotope abundance, typically being either CO<sub>2</sub> or H<sub>2</sub>.

Traditionally the introduction of the sample is through a dual-inlet system. This allows an unknown specimen to be measured against a known reference pure gas and the isotope abundance expressed using the delta notation ( $\delta_i$ ) and permil unit (‰). The delta permil value is essentially the relative difference of the isotopic ratios for each of the two gases. Originally introduced by geochemists to express isotope abundances for natural samples collected from around the world, delta value in permil is calculated as follows:

$$\delta_i = \frac{(R_S - R_R)}{R_R} \times 1000, \text{‰}$$

Where  $R_S$  is the ratio of the minor (heavy) to the major (light) isotope for the sample and  $R_R$  is the same for the reference. For example, the isotope ratio for an unknown sample of carbon dioxide enriched with <sup>18</sup>O is calculated by measuring the mass-to-charge ratio of 46/44 (a molecule of <sup>12</sup>C–<sup>16</sup>O–<sup>18</sup>O<sup>+</sup>,  $m/z = 46$  over that of a molecule <sup>12</sup>C–<sup>16</sup>O–<sup>16</sup>O<sup>+</sup>,  $m/z = 44$ ). The reference is calibrated and reported relative to an international isotopic standard. Similarly, isotope ratios can be measured by introducing the gas sample into the IRMS via a continuous flow system. This method utilizes a noninterfering carrier gas (typically He) to transport the sample into an ion source. Once in the source, the sample with the carrier is subjected to the isotope ratio analyses. The detector selects the mass of the sample and therefore the carrier is not detected. Other analytical methods also exist that are used for the analysis of isotopically stable water. Fourier transform infrared spectrometry (FTIR) is a technique that utilizes the absorption of infrared light to measure the deuterium content of a water sample. Based on the absorption of light specific to the vibration energies of the <sup>18</sup>O and <sup>2</sup>H in the O–H bonds, the concentration of deuterium can be measured, but FTIR does not provide the same precision for isotope abundance measures and thus requires the use of a larger and more costly dose of DLW. A relatively new method, laser absorption spectroscopy, has an analytic precision close to that of IRMS, and costs less than IRMS, and is easier to operate. The cavity ring-down spectroscopy (CRDS) instruments measure the light remaining nanoseconds after a pulse of laser light

**Fig. 3** Schematic of an IRMS measuring CO<sub>2</sub> at the US Geological Survey ([https://en.wikipedia.org/wiki/Isotope-ratio\\_mass\\_spectrometry](https://en.wikipedia.org/wiki/Isotope-ratio_mass_spectrometry)).

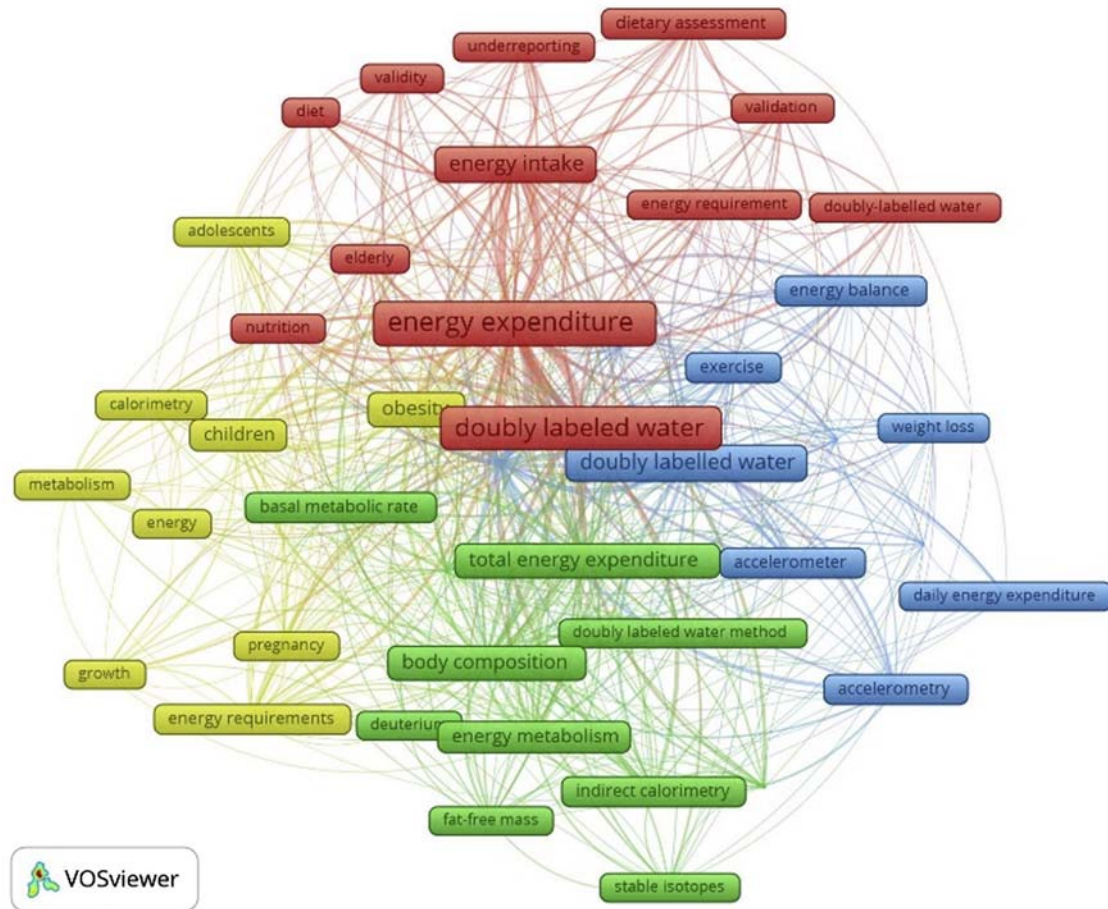

as it is absorbed by a gas sample in an optical cavity, while the off-axis integrated cavity output spectroscopy (OA-ICOS) devices provide a direct measurement of the absorbing substances, rather than only a cavity decay time, by scanning the laser light wavelength in the gas mixture. The better performance of the OA-ICOS is related to its non-dependence of hyper-critical optical alignment, making this new technology less vulnerable to vibrations, small physical shocks, and changes in temperature and pressure. An advantage of CRD and OA-ICOS is its ability to measure both <sup>2</sup>H<sub>2</sub>O and H<sub>2</sub><sup>18</sup>O simultaneously, potentially increasing user throughput and reducing operating costs.

### Uses for the doubly labeled water method

When introduced as a novel method more than 50 years ago, the DLW dosage was large, rendering the method as a novel, but expensive method to measure the total energy expenditure. Advances in measuring isotope abundances, however, have reduced the dose requirements and the DLW turned into a revolutionary tool in nutrition science, which is now used to measure energy expenditure in thousands of humans. Its reliability and accuracy in measuring the energy requirement in free-living conditions made it the method of choice against which others are validated. Therefore, the DLW technique is being largely used to answers questions related to TEE and its components, body composition, energy requirements at the different stages of life, and also under conditions of health, such as obesity or chronic disease, and to validate dietary assessment and physical activity instruments (Fig. 4).

Due to financial limitations and subject burdens, in the clinical assessment, clinical epidemiological investigations, often rely on the use of questionnaires for data collection. It is crucial that such self-reported energy intake and physical activity questionnaires provide accurate estimations to accurately assess the relationship between diet, physical activity, and chronic disease. Therefore, the validation of self-reported questionnaires is a common application of the DLW technique. Studies comparing such questionnaires against DLW revealed them to be subject to errors or misreporting (Burrows et al., 2019; Lee et al., 2011). A recent review of various dietary intake methods established that, regardless of the type of dietary survey instrument used, participants regularly underreported their caloric intake by anywhere from 15 to 34% (Park et al., 2018). Not dissimilarly physical activity monitors have been proposed as objective methods to assess physical activity energy expenditure to avoid the misreporting errors using questionnaires, however, have shown a high variability of results obtained by Jeran et al.(2016). For this reason data on relationships between diet or physical activity, from self-reported questionnaires and in some cases objective monitors such as accelerometers should be interpreted cautiously.

**Fig. 4** Cluster map based on bibliometric data of author keyword with a minimum of 15 occurrences. Four clusters, distinguished by colors, described the main fields of application of the DLW technique. The frames' size represents the frequency of the keywords' appearance, and the distance between them is related to their correlation strength. The analyses were conducted using original research articles indexed in the SCOPUS database to study the field of knowledge about the doubly labeled water method and energy metabolism. The results of the search were analyzed by the VOSviewer software (version 1.16.16) that generated a network map based on the co-occurrence matrix.

Historically, energy metabolism and its requisite recommendations have been based on dietary intake data provided largely by various self-report questionnaires, however, as indicated above, the DLW technique has proven that these tools are prone to misreporting (Ravelli and Schoeller, 2020) and thus, are not a reliable basis to establish the human energy requirement guideline. Therefore, one of the most significant roles DLW has played has been its influence in revising the dietary reference intake energy requirements for humans. Indeed, the most recent dietary reference standards for energy requirements were revised using DLW-measured energy requirements instead of dietary intake estimates, the energy requirements of healthy individuals were established by national and international organizations have been reassessed yielding higher values. Based on the DLW data, adult human energy intake requirements were increased by 10% compared with estimated energy requirements published before 1990. An exception is the energy requirement for infants and neonates during the first two years of life, which were decreased by 10–15%.

As obesity has taken on the epidemic and global status, it is not surprising that DLW has been essential in evaluating its impact and studying its etiology. Of particular interest was the finding that obese individuals had on average a higher TEE than their age- and height-matched lean counterparts (Fig. 5). This was contrary to the popular hypothesis of the 1990s that obesity developed in individuals due to low energy expenditure as compared with their corresponding age- and height-matched lean counterparts based on energy intake data. Another theory that was not supported by data from the DLW technique was that weight regain after an intentional weight loss was due to a metabolic adaptation leading to dramatically low energy expenditure among post-obese patients. After assessing changes in the TEE of participants with obesity who underwent bariatric surgery, and thus achieved substantial weight loss, researchers found that TEE was decreased at 6 months after surgery due to a combination of a metabolic adaptation and smaller body size. At one year after the procedure, however, the metabolic adaptation no longer existed (Ravelli et al., 2019; Wolfe et al., 2018). In a larger cross-sectional data analysis based on DLW assessment of energy expenditure, it was possible to conclude that the rapid increase in human obesity over the last 50 years was largely an effect of increases in dietary intake and not a product of lower energy expenditure (Swinburn et al., 2009).

**Fig. 5** Comparison of energy expenditure among men and women in individuals with healthy ( $18.5\text{--}24.9\text{ kg m}^{-2}$ ) vs obese ( $>30.0\text{ kg m}^{-2}$ ) BMI as measured by DLW. Data are from the International Atomic Energy Agency DLW database, with more than 3700 accumulated subjects in studies performed in 23 countries (Speakman et al., 2019).

In contrast to the application of DLW to studies to understand the obesity epidemic, DLW has also assessed humans' limits on human energy expenditure during conditions of extreme physical activity and endurance events. For example, cyclists during the Giro d'Italia (Plasqui et al., 2019), athletes over one athletic season (Silva et al., 2017), tri-athletes in international ironman competitions (Cuddy et al., 2010), and synchronized swimmers (Ebine et al., 2000) have all utilized DLW (Fig. 6). Additionally, this method has been used to define the energy and water requirements of those individuals who have participated in mountain climbing (Westerterp et al., 2000), Alaska hunting expeditions (Coker et al., 2018), as well as various military training exercises of the US Special Forces (Johnson et al., 2018; Margolis et al., 2014).

Not constrained to only a single physical event, nutritional epidemiologists have used DLW to track body composition changes and energy expenditures in groups of individuals across countries, continents, societies, and economic conditions. A meta-analysis of 4972 data from 98 studies, on which 14 were from low or middle human development index, investigated the differences of energy-expenditure variables between countries' development status and their populations' body composition (Dugas et al., 2011). Authors showed despite the differences in body sizes between populations living in developing and industrialized countries, no significant difference was observed between adjusted TEE for weight and age or physical activity level. These findings again suggest that diet rather than a decline in physical activity appears to be the main contributor to the current rapid rise in the prevalence of obesity in developed and developing countries. Additionally, the DLW technique can be

**Fig. 6** Energy expenditures of four high-endurance activities as measured by DLW.

**Fig. 7** Comparison between men and women of the effects of age on energy expenditure and body composition. Data are from the International Atomic Energy Agency DLW database, with more than 4800 accumulated subjects in studies performed in 23 countries (Speakman et al., 2019).

utilized *via* meta-analysis to corroborate or refute long-held hypotheses. Combining more than 5000 DLW study participants, the effects of age and sex on body composition and energy expenditure can now be analyzed using the recently compiled IAEA DLW database (Speakman et al., 2019). These data show the interactions between age, fatness, and energy expenditure for men and women (see Fig. 7).

The DLW method has been an important tool for researchers in a wide range of applications and has made an impact on the understanding of the human body. As obesity continues to increase globally, the use of DLW to measure body composition and energy metabolism will become even more paramount to health-related research in the future. In countries subjected to the dual burden of obesity and undernutrition, the DLW method has also become an important tool in the study of undernutrition and repletion.

## Conclusion

After an analytical improvement of isotopic ratio mass spectrometry over the last 60 years, the application of the doubly labeled water method went from those in small animals to humans with high accuracy (0.5%) and precision (8%). It still has limited availability due to the moderate cost per measurement and the limited number of quality analytical laboratories. The high quality of results, and low burden to the subjects, however, have been instrumental in the development of accurate human energy requirements in countries across the globe. It is recognized as a revolutionary method to study energy metabolism, the DLW is an important tool in understanding the causes and treatment of obesity and malnutrition, and other aspects of human bioenergetics.

### Key points/objectives

- The goal of this review is to provide an understanding of the competing factors that influence an individual's food choices
- A summary is provided of methods used to understand psychological, cognitive, and biological factors that influence food choices
- The effects of taste, liking, wanting and motivation on food choices are described
- Consideration is given to techniques used by food producers to understand consumer needs and food choices
- Advances in technology for the study of food choice behavior are described

### Introduction

Determinants of food choice are broad and span multiple levels of the socioecological model (Contento, 2008). At the outermost level, food choices are influenced by policies, prices, accessibility, and regulatory practices. Working from this level, food choices are influenced by settings and context (e.g., restaurants and workplaces), as well as by interpersonal factors, including family, cultural, and peer groups (Leng et al., 2017). Each of these factors plays a role in determining both the types and amounts of foods chosen. For a comprehensive picture, the reader is directed to a systematic review by (Chen et al., 2020), which includes available conceptual models on food choice and summarizes consistencies across models on the role of food-related influences, individual differences, and societal factors. The focus of the present review is to provide an overview of various methods used to understand psychological, cognitive, and biological factors that influence food choices at the individual level so that strategies for improving diet quality can be developed and improved.

A recent conceptual analysis, meant to reach consensus on terms used in the study of dietary behavior, defined food choice as an "umbrella term for behaviors and other factors occurring before food actually reaches the mouth" (Stok et al., 2018). Some behaviors included within this definition include monetary aspects (i.e., purchasing, share of income, and willingness to pay), food preparation, intended use, and overall food preferences. However, as such decisions are made prior to consumption, they may not reflect the foods chosen or the amounts of foods consumed once eating commences. Even if a specific food is highly liked by an individual, this does not necessarily mean that they will eat that food when presented with multiple competing foods at a meal or snack. While pre-meal decisions certainly play a key role in determining the types and amounts of foods selected, food choices during consumption of a multi-item meal evolve as the hedonic appeal of foods changes and biological mechanisms engage. Therefore, in this review, behavioral aspects of food choice will include those occurring both before and during consumption.

At the population or community level, standard methods include sophisticated demographically weighted surveys such as The National Health and Nutrition Examination Survey (NHANES) that ask a large number of individuals to record their intake over

several days (Ahluwalia et al., 2016). Such tools, even with problems of inaccurate reporting, can provide a general understanding of the average food choices of various groups of people and can be used to develop broad policies and recommendations to improve diet quality. To understand individual behavioral determinants of food choices, more controlled and specific methods are required.

### Questionnaires to assess an individual's motives for food choices

While questionnaires to assess aspects of food choice such as those related to attitudes and beliefs had been used previously, the first psychometrically validated instrument specifically designed to assess motives for food choices came in 1995 with The Food Choice Questionnaire (FCQ) (Stephens et al., 1995). This questionnaire consists of 37 items separated into nine factors. Four of the nine factors – sensory appeal, health, convenience, and price – emerged as most important for understanding food choice. The other five factors – weight control, familiarity, mood, natural content, and ethical concern – were reported less frequently. The FCQ remains a standard method for measuring motives for food choices and has been extended to include additional dimensions such as those related to culture, ethical concerns, and sustainability (Onwezen et al., 2019).

While there have been extensions of the original FCQ, a recent study sought to facilitate broader use and reduce participant burden by shortening it. The shortened FCQ retains the original nine factors but includes a single question for each. This short instrument was shown to have comparable predictive validity to the original FCQ and can be used to understand context-specific motives for food choices such as those in home versus restaurant settings (Onwezen et al., 2019). To investigate individual differences in food choice motives, the most suitable version of the FCQ can be administered along with anthropometric measures and other validated questionnaires such as the Three Factor Eating Questionnaire (Stunkard and Messick, 1985). While these questionnaires provide an overview of the motives that typically underlie an individual's food choices, additional measures are needed to provide insight into the types and nutritional characteristics of foods individuals choose.

### The assessment of food choices

In addition to the questionnaires that have been developed to assess food choice motives, there are instruments that assess the types of foods individuals say they prefer, along with frequency of consumption. For example, the Fat Preference Questionnaire is a validated instrument used previously to show that the reported preference for high-fat foods declined after participation in a weight loss trial emphasizing fat reduction (Ledikwe et al., 2007). Validation of this instrument was done by comparing responses on the questionnaire to self-reported intake in a free-living cohort, and in participants in a weight-loss trial. Responses on the questionnaire were also compared over two days to foods selected and consumed from lab-based buffets offering foods similar to those on the survey. More generally, buffets that offer participants an array of foods provide a simple and frequently used method to assess food choice. While the number of foods that can be offered in buffet paradigms is limited by cost and logistics, the selection can be tailored to answer specific questions related to food choice. For example, if the goal is to determine whether consumption of a high-fat preload (first course) leads to a shift away from other high-fat foods at a subsequent course, a buffet offered for that course would provide a variety of foods varying in fat content (Hetherington and Rolls, 2018). An advantage of such paradigms is that food intake can be directly measured along with food selection, thus providing broader insight into eating behavior than questionnaires.

As buffet studies with real foods can be costly and labor-intensive, investigators may instead choose to use alternatives, such as a Fake Food Buffet (Bucher et al., 2012). In this paradigm, food replicas are offered to participants who are asked to select a plate of food or snacks that would represent what they would typically eat within a given context. While this results in a food selection paradigm similar to the use of real foods, the use of fake food precludes assessment of actual intake. Similar to buffets with real foods, only a limited set of food options can be presented to participants; however, the use of fake foods does reduce food and labor costs as well as food waste.

When the ability to conduct in-person studies is limited, or other study demands make assessment in the laboratory impractical, remote assessment of food choice can be useful. For example, the Fake Food Buffet has been adapted to a Web Buffet, in which participants are asked to choose the types and amounts of foods they would like for a meal from a set of images (Bucher and Keller, 2015). Other web-based tools have been developed such as the Food Choice Task. This task presents individuals with a series of images and asks them to select one. A benefit of this type of task is that it allows for easy calculation of scores related to an individual's food preferences, such as a fat preference score, based on the types of foods selected during the task (Foerde et al., 2018). While easy to use, it remains unclear how representative these tools are of actual food choices or intake. However, another computer task, The Multiple Food Test, has been shown to be related to actual food choices (Schreiber et al., 2020). The development of additional computerized tools that have validity to predict both real food choices and intake will facilitate the collection of more reproducible food choice data in the future.

This section is not meant to be comprehensive; rather, it is intended to illustrate the types of tasks that have been used to assess food choices. One caveat is that the tasks discussed here were developed and tested primarily with industrialized Western diets. They could, however, be adapted and validated to fit a variety of cultures and contexts. It is also important to note that such controlled studies may not reflect habitual diets, but are instead intended to test specific hypotheses about contextual and individual influences on food choice.

## Sensory-specific satiety: an example of the utility of laboratory-based studies

Controlled laboratory-based studies can be used to extend findings from observational studies to gain a deeper understanding of robust influences on both food selection and food intake. For example, while the pleasantness or liking of a food has been shown to be a key determinant of food choice (Hayes, 2020), the degree to which a food is liked is not stable across contexts, or even within a meal. As a food is eaten, the pleasantness evoked by its sensory properties – including taste, texture, appearance, and odor – declines while the pleasantness of other uneaten foods generally remains unchanged. This decrease in the palatability of a food as it is eaten, relative to other foods, is termed sensory-specific satiety (Rolls, 1986). Behaviorally, sensory-specific satiety leads to the termination of consumption of the specific food being eaten and promotes switching to other foods, especially those with different sensory properties. Thus, sensory-specific satiety promotes the selection of a wider variety of foods and can help to ensure that a balance of nutrients is consumed; however, it can also lead to greater intake if multiple types of energy dense foods are available (Raynor and Vadiveloo, 2018; Rolls, 1986). Sensory-specific satiety helps to explain the excess energy intake associated with the availability of variety of tasty, energy dense foods at a restaurant buffet (Johnson and Wardle, 2014). These studies demonstrate why the assessments of food choice should not be limited to pre-consumption measures, and should also consider objectively assessed food intake.

## Taste as a driver of food choice

According to the Food Choice Process Model, taste is one of the five factors that influences the decision to consume a food (Furst et al., 1996). In consumer surveys, taste is reliably the most important driver of food choice for most individuals (IFIC, 2020). Therefore, genetically influenced variations in taste perception likely play a role in food choice. Some taste preferences, such as liking for sweetness and disliking of bitterness and sourness, are innate (Desor and Lawrence, 1977; Mennella and Beauchamp, 1996). Evidence on salty taste is more mixed: while it is widely claimed infants do not acquire a preference for saltiness until a few months after birth (Bernstein, 1990), other data indicate some newborns may prefer salty stimuli within a few days of birth (Zinner et al., 2002). Preferences for fat, on the other hand, are learned in childhood (Birch, 2009). These biologically driven preferences are thought to guide humans toward food sources that provide them with energy and protect them from ingesting potentially toxic substances (which are often bitter in taste). What this means for food choice, is that some foods, like bitter fruits and vegetables, are harder to learn to like than others. However, with repeated exposure individuals can learn to like most foods, making experience a critical factor that shapes food choice (Cines and Rozin, 1982).

There are also genetically driven differences in taste receptors that have implications for food choice, food consumption, and even chronic disease risk. The best studied of these phenotypes is the ability to taste bitter thiourea compounds, like phenylthiocarbamide (PTC) and 6-n-propylthiouracil (PROP). Individuals who are less sensitive to the taste of PTC and PROP typically show increased acceptance of bitter and strong-tasting foods. In a recent meta-analysis, variants of *TAS2R38* (the gene responsible for the ability to taste PTC and PROP) (Kim et al., 2003), were associated with perceived bitterness of vegetables, berries, and wine, as well as preferences for sweet taste (Diószegi et al., 2019), consistent with earlier reports (Duffy et al., 2010). However, *TAS2R38* is only one of 25 bitter receptor genes in humans, some of which have been shown to influence bitterness perception, and potentially food choices. For example, variation in the *TAS2R31* gene is associated with perception of bitter side tastes in some sweeteners and with liking for grapefruit juice (Hayes et al., 2015). In addition to genes implicated in bitter perception, there is also convincing evidence that polymorphisms in the *CD36* gene, a fatty acid translocase, are related to the perception of fat and preferences for certain high-fat foods (Keller et al., 2012; Pepino et al., 2012; Sayed et al., 2015). For additional discussion of chemosensory gene variants and food choices, the reader is directed to (Nolden and Feeney, 2020).

## The influence of liking, wanting, and motivation on food choice

While innate predispositions for specific tastes clearly exist, the extent to which a food is liked is modified by learning via prior experiences (Prescott, 2020). Liking plays a key role in determining whether a food is chosen or avoided (Hayes, 2020). However, in the late 1990s, Berridge and Robinson challenged the presumed importance of hedonic responses by differentiating between the concepts of liking and wanting. In their framework, “liking” is an affective reaction to a food based on a combination of prior experience, sensory properties, and internal physiological state, while “wanting” refers to one’s drive and motivation to get a food at a given time (Berridge, 1996). Because wanting relates to how motivated someone is to receive a food, it is arguably a more important driver of food choice than liking. Liking is thought to be a more stable hedonic response to a food but wanting varies due to both internal (e.g., hunger, satiety) and external (e.g., advertising, environment) stimuli. For example, one might have a high liking for spaghetti Bolognese, but the motivation to consume this dish (i.e., “wanting”) first thing in the morning is probably quite low.

A variety of methods have been used to measure liking and wanting. For example, explicit measures ask participants to report on scales the extent to which they both like and want to eat a particular food item (Pool et al., 2016). However, to improve the ability to differentiate these constructs, some studies have developed implicit association tasks. For example (Finlayson et al., 2007), developed a computer-based paradigm where participants choose which of a pair of foods with different sensory properties (e.g., low-fat, savory, sweet) they would “most like to eat right now.” By asking the individual to make choices in response to the same food

multiple times, paired with different foods on each presentation, a relative ranking of wanting can be determined. These types of rankings can be used to make inferences about the foods someone would choose in a variety of situations. For example, a systematic review from (Oustric et al., 2021) suggested liking and wanting for high-fat, energy-dense foods tended to decrease with weight loss, regardless of the type of intervention (e.g., pharmacological, behavioral, surgical). Although the relationship of liking and wanting to weight outcomes needs confirmation, these approaches will allow investigators to develop more targeted interventions in the future.

In addition to liking and wanting, the value placed on a food also depends on the availability of other foods or activities. For example, peanut butter cookies might be highly liked, but if given the choice of a peanut butter cookie and premium Belgian chocolate, the chocolate might ultimately be chosen. In order to assess the relative motivation to obtain a food, one can measure how hard someone will work to gain access to it. Epstein and colleagues adapted methods from Behavioral Economics to develop the Relative Reinforcing Value of food task (RRV task) to operationally measure how hard someone will work to obtain a food relative to some other food or activity (e.g., watching TV, exercise) (Epstein et al., 2007). In the RRV task, “work” is measured as the number of times participants will press a keyboard key to obtain portions of a desired snack relative to an alternative (either another food or activity). The number of key presses required to obtain a desired food increases on a progressive ratio with each portion earned. By comparing foods that vary in sensory or nutritional qualities, one can determine how hard someone will work to obtain a food, and from this, can infer food choice under a variety of physiological and context-related situations.

Because food choices are not constant and are influenced by both the context and the other types of foods available, environmental settings can be engineered to optimally affect dietary behaviors. These manipulations in choice architecture can be used to nudge consumers into making healthier food choices (Szasz et al., 2017). For example, by creating environments where fruits and vegetables are easily accessible, and identifying appropriate nonfood reinforcers to substitute for high-energy dense foods (e.g., music, reading), one can engineer environments that are optimally suited for making healthier choices (Epstein, 2020). The long-term goal of these nudge strategies is to develop more personalized approaches to improve chronic health.

## Techniques used by food producers to understand consumer needs and food choices

Substantial research on food choice is performed by food and beverage companies that make high volume, low margin products like snacks, soft drinks, candy, breakfast cereals, and ready to eat meals. The majority of this work is not reported publicly, as the results are proprietary and are seen as a competitive advantage. The methods used can be divided into those meant to assist in product optimization (i.e., classic sensory evaluation techniques, including blind tests with naïve consumers) and those meant to understand the broader needs of the consumer (i.e., consumer insights). These methods are reviewed in this section, along with their implications for understanding food choice.

One mainstay technique for product optimization – the 9-point hedonic scale – was first developed by researchers focused on testing military rations (e.g. (Meiselman and Schutz, 2003)). As they noted in 1955, “Even foods that are extremely well-liked, but by only a small proportion of the consumers, are unsuited for military use (Jones et al., 1955).” The 9-point hedonic scale, which was developed seven decades ago, is still widely used in the food industry, in part due to its simplicity for both investigators and consumers. Ratings from this category scale can be used in food preference surveys (to determine which foods are most liked by a group, as in the original ration selection studies), or to quantitatively compare the degree of liking for foods and beverages prepared/processed in different ways (Hayes et al., 2014), or to allow investigators to understand the optimal preferences of the consumer (Wang et al., 2018).

However, industrial research by food and beverage producers is not limited to blind taste tests with naïve consumers, as it also includes qualitative and quantitative methods that are used to understand food choices, and the motivations that underlie those choices. Many of these techniques are borrowed from the social sciences (e.g., ethnography, focus groups, and semi-structured interviews) or market research and experimental economics (e.g., surveys, conjoint analysis, non-hypothetical auctions). Critically, such studies are not conducted blind, as they are focused on the interaction of the participant with the food product as well as information about the food (e.g., nutritional information, food labeling). Participants are usually given some relevant details about the product (e.g., “low in fat”, “a protein-rich food”), and perhaps the context in which the product will be consumed. For example, rather than giving a participant two beer samples and simply asking which they prefer, as in a blind taste test, participants might be prompted to imagine they are at a boardwalk café after a long day at the beach, and asked to evaluate which beer is more thirst quenching. In this way, industrial researchers are able to look beyond simple blind tastings to better assess consumer needs and wants.

Qualitative techniques like focus groups may provide key insights when performed by an experienced moderator. For example, in one such study, a canned food manufacturer was interested in a label change to highlight that vegetables in the can were grown locally. Over several focus groups, it quickly became clear consumers did not care if the vegetables were grown in-state or several states away; rather, they cared that farmers who grew the vegetables had been working with the canner for 2, 3, or even 4 generations. Likewise, academic researchers have used focus groups and semi-structured interviews to better understand beliefs and attitudes about salt use and sodium intake in a high-risk rural population (Smith et al., 2006). They found food lacking salt was seen as “fresh”, and critically in this usage, the descriptor “fresh” was in fact pejorative, as “fresh” also implied bland and flavorless to their participants. Use of a traditional quantitative survey to assess beliefs about salt would have missed this key insight.

A method developed by market researchers in the 1970s with substantial value in assessing food choice, particularly when considering competing tradeoffs between product attributes, is conjoint analysis. This technique has become increasingly popular recently for internet-based research. The use of online conjoint analysis has substantially reduced the cost of collecting large samples required for more generalized and informative data. Multiple variants of conjoint analysis exist but, in general, product attributes are grouped into silos, and individual elements within the silo are varied. For example, Brodock and colleagues (Brodock et al., 2021) explored how sweetener type, added sugar, protein content, and fat level, influenced product choices for chocolate milk in adults. In this case, within a specific silo, such as added sugar, the stated amount of sugar was varied across choices. By systematically varying elements from each silo, an exhaustive set of product vignettes was generated and presented to participants and specific product aspects that play a role in consumer food choice were quantified. This provided insight into factors that influence food choice, even when participants were not aware of why they preferred one food over another. From this example, Brodock and colleagues were able to identify three distinct groups of consumers with respect to chocolate milk preferences (Brodock et al., 2021). Notably, these groups, formed solely based on product choices, also differed in measures of several health related behaviors. This type of convergent validity (i.e., revealed preferences in a choice task, and psychometrically validated eating behavior questionnaires) supports the view that such online tasks can provide valid and useful insights into food choices.

In summary, industrial research is not limited to blinded tests with consumers to optimize products, but also includes research on the interaction of consumers with products within a specific context or use case to better understand consumer needs, under the presumption that better understanding of such needs and wants will provide a competitive advantage in the market.

### Food choices in the “real world”

Outside of the laboratory setting, food choices can be monitored in environments like grocery stores or restaurants to assess the array of contextual variables that can influence selection. These approaches are useful for the study of consumer behavior in response to environmental manipulations such as menu labels, portion size, and the variety of available choices. However, collecting data in these settings is less useful when trying to determine how food choices relate to individual characteristics of consumers. The collection of personal data on individuals requires informed consent and obtaining such consent largely compromises the ecological validity of such studies.

To simulate a “real-world” experience while still offering the control afforded by the laboratory, some investigators have established test restaurants or supermarkets that allow food selection to be observed in an ecologically relevant setting. In such facilities, a combination of food photography and weighing the foods selected can be used to answer questions as to how food choices vary with both individual and food characteristics (Hinton et al., 2013). However, such simulation of the “real-world” can be expensive and not practical for widespread application. A more sustainable approach could be to incorporate hypothesis-driven studies related to food choice into the food development and testing done, for example, at institutes for culinary training, some of which include an experimental restaurant or partnerships with restaurants, school canteens, or bars in a variety of locations (dos Santos et al., 2020; Miele et al., 2021).

### Technology and innovation in the study of food choice behavior

Computerized tools can extend the assessment of food choice beyond the laboratory. Tools such as the Web Buffet (Bucher et al., 2012), the Food Choice Task (Foerde et al., 2018; Masterson et al., 2019; Hare et al., 2009), or the Multiple Food Test (Schreiber et al., 2020) provide participants with a variety of food choice situations. These paradigms allow for multiple comparisons to be made within a short period of time. Additionally, specific food comparisons (e.g., low-vs. high-energy dense foods) can be tested to better understand the sensory and nutritional characteristics that drive food choice. An advantage of these online tools is that they can be administered to large numbers of participants at a low cost. Such large-scale data collection can aid in the identification of individual variability related to food choice (e.g., (Brodock et al., 2021)), and this could be used to develop tailored interventions to improve dietary intake.

One method originally developed by addiction researchers to study behavior in a participant’s usual environment, Ecological Momentary Assessment (EMA), has promise for the study of food choice. Broadly, EMA allows intensive data collection about a participant’s behavior to be collected in real time during their daily routine (Shiffman et al., 2008). The evaluation of real-world food choices via EMA helps to minimize recall and response biases (Shiffman et al., 2008). Further, computerized food choice tools inherently provide quantitative metrics (e.g., reaction time) that may give additional insight into the cognitive processes underlying food choice (Masterson et al., 2019). For example, one study that used a Food Choice Task in combination with functional magnetic resonance imaging (fMRI) demonstrated that weight conscious women with higher self-control were able to make choices more quickly between healthy and palatable, energy dense foods (Sullivan et al., 2015). Additionally, using the same task, it has been shown that individuals demonstrating higher levels of dietary restraint make healthier food choices, and they do so more quickly, than those with lower levels of restraint. Use of these digital food choice assessments alongside EMA paradigms may provide further insight into how external (e.g., food marketing exposure) and internal factors (e.g., emotional state) can modify dietary self-control and affect food choice over the course of a day. Overall, these digital tools can provide investigators increased flexibility, insight, and potential to understand food choice in the real world.

Hand-held devices and smartphones also show promise for deploying and monitoring interventions designed to help individuals make better food choices. For example, these devices have been used to deliver personalized interventions and educational materials that positively modify individuals' food choices (see (Chen et al., 2020) for a detailed review). Specifically, personalized programs have been shown to increase the intake of fruit, vegetables, and dairy, as well as decrease the intake of dietary fat and total energy intake (Acharya et al., 2011; Ambeba et al., 2015; Atienza et al., 2008; Burke et al., 2011; Olson et al., 2008). Additionally, dietary and physical activity self-monitoring applications on smartphones can help users focus on their daily food choices, leading them to modify their intake to achieve dietary goals (Duncan et al., 2014; Ipjian and Johnston, 2017; Mummah et al., 2017). Future use of these applications will provide interventionists and participants more precise and immediate feedback on the participant's cognitive state (i.e., current level of dietary restraint) and how that may influence their food choices in the moment.

Another emerging technology with promise for studying food choice is immersive virtual reality (iVR). Using Immersive iVR, an individual can enter a computer-generated environment where they can physically move around and interact with objects like foods and plates. Recent computational improvements provide a sense of realism not possible previously, improving the ecological relevance of data that are collected (Parsons and Rizzo, 2008). Additionally, researchers can control and manipulate environmental factors that potentially influence decision making within the iVR environment, holding these variables constant across individuals (Cheah et al., 2020; Cheah et al., 2019). Also, behavioral variables are measured continuously and automatically. Such measurements include the order, timing, and amount of food selected, along with psychophysiological variables of interest (e.g., eye movement, brain response, etc.) (Marcum et al., 2018). Additionally, these variables can be collected and analyzed without the need to record and manually annotate videos. Recent studies have demonstrated the utility of iVR food buffets. For example, food selections made in iVR were similar to those made in fake food buffets (Ung et al., 2018) and actual food buffets (Cheah et al., 2020; Persky et al., 2018), and the method is also being used to examine food choice in virtual supermarkets (Ruppert, 2011). In addition to making similar food choices to real world situations, participants in these studies also report that the iVR environment feels natural and that decisions made during these paradigms represent their real-world behavior (Lombart et al., 2019; Ruppert, 2011; Siegrist et al., 2019). Additionally, recent work has shown that physiological responses to food in iVR environments are similar to responses observed when participants are viewing food pictures or actual foods (Gorini et al., 2010; Ledoux et al., 2013; van der Waal et al., 2021).

While techniques like EMA and iVR have only recently been adapted for food choice research, they show promise to increase understanding of factors that drive food choices. These technologies provide new ways to investigate food choice behavior under conditions that allow for greater flexibility and reach than traditional laboratory studies. Specifically, they can provide information about a wide range of foods tested under a variety of conditions, and with participants that span the globe. A goal for these methods is that they will expand understanding of the influences on food choice under ecologically relevant conditions.

## Summary: changing food choices to improve nutrition and health

This review has covered a variety of tools and methods that can be applied to help investigators understand food choice behavior. Validated questionnaires are widely used to characterize an individual's food choices in a variety of contexts and the motives for making these choices. Such instruments can be administered online or by electronic devices, making it feasible to collect data on large numbers of individuals in a wide variety of contexts. Data derived from large-scale data collection procedures can be integrated with traditional controlled laboratory studies to test specific hypotheses related to how food choice behavior affects food intake. Overall, the practical goal of most studies on food choice in academic settings is to improve diets and nutrition-related health. Similarly industrial researchers frequently focus on improved nutritional profiles for food products (i.e., reduction in added sugar or salt), but this must be balanced against a need to make and sell products that remain liked by consumers to be competitive with alternatives.

Many strategies have been used to encourage healthier food choices. Environmental approaches involve making healthy foods taste better, be more accessible, and more affordable. Behavioral nudges that remind consumers to choose healthier options are becoming easier to test with technological and methodological advances (Stuber et al., 2021). An umbrella review of systematic reviews on food choice found that nutrition education is the most common strategy used to alter food choices, followed by nutrition labels (Perez-Cueto, 2019). However, nutrition education alone has limited impact on food choices, suggesting that newer methods are needed to help individuals improve their food choices. Many opportunities exist to test the effectiveness of integrated approaches that involve methods discussed in this review. An understanding of the competing factors that influence an individual's food choices, from basic biology to interactions with the food environment, will facilitate a personalized approach to improving food choices.

## Key points

- The glucose body pool and blood glucose homeostasis mechanisms are discussed.
- Metabolic reactions that involve the breakdown of glucose to produce energy through aerobic and anaerobic glycolysis and its related pathways are delineated.
- The metabolic and hormonal response to high and low blood sugar, including storage of extra energy as glycogen and fat, and the production of glucose when energy is needed.
- The synthesis and storage of glycogen by glycogenesis and its breakdown in glycogenolysis, and the synthesis of glucose from precursors such as amino acids and lactic acid in gluconeogenesis are explored.
- The various hormones that regulate and impact blood glucose are introduced and the interrelationships between them, various tissue sensors and levels of metabolites are discussed.

## Glossary

**Cephalic phase** The start of the digestive process which begins gastric secretion even before food enters the stomach. It results from thoughts, aroma, sight, or taste of food

**Glucagon** A polypeptide hormone, secreted by pancreatic  $\alpha$ -cells in the islets of Langerhans, that raises the concentration of glucose in the bloodstream by stimulating liver glycogenolysis. It also stimulates insulin secretion

**Glucose** A ubiquitous monosaccharide that provides 60–80% of dietary energy as the *simple sugar*, combined with fructose or *galactose* in the form of sucrose and lactose, respectively, or predominantly as its polymer, starch

**Gluconeogenesis** The process by which simple precursors such as lactic acid and glycerol can be built up to produce new glucose molecules in the liver

**Glucose pool** An expression of the amount of glucose in the body to which glucose molecules can be added from the food after eating and from the liver during fasting and removed into the tissues under the influence of insulin

**GLUT4** The principal glucose transporter protein mediating glucose uptake and playing a pivotal role in regulating glucose homeostasis

**Glycogenesis** The enzymatic process by which glycogen is formed from glucose

**Glycogenin** The center of a glycogen molecule

**Glycogenolysis** The breakdown of polymeric storage form of glucose, glycogen, to produce glucose that is released into the bloodstream in times of glucose need

**Homeostasis** The concept explains how the body maintains vital functions such as temperature, blood sodium, and glucose concentration within narrow ranges despite large changes in the environment

**Incretin** One of several hormones released by glandular cells in the intestinal mucosa in response to the ingestion of food that stimulate insulin secretion only in the presence of a higher than fasting blood glucose concentration

**Insulin** A protein hormone secreted by the *B*-cells of the pancreatic islets of Langerhans necessary for glucose entry into insulin-sensitive cells. It is antagonistic to glucagon secretion

**Insulin-like growth factor I (IGF-I)** A polypeptide hormone structurally similar to insulin that can bind to insulin receptors and can stimulate glucose transport and with growth hormone promotes normal growth

## Introduction

Glucose is the primary energy source of human cells; therefore, glucose must reach all tissues when they need it. Despite wide variation in glucose supply and demand, glucose in the bloodstream and body pool must not fluctuate wildly. Glucose homeostasis is controlled by a complex, carefully balanced integration of nervous impulses, counterregulatory hormones, and metabolic signals that activate and inhibit glucose movement, breakdown, storage and mobilization. Three pathways maintain blood glucose: (1) the breakdown of absorbed dietary carbohydrate through glycolysis; (2) the release of glycogen from stores in the liver or muscle through glycogenolysis; and (3) the endogenous synthesis of glucose from glucogenic amino acids and other carbohydrate sources through gluconeogenesis.

The brain modulates blood glucose by controlling various aspects of metabolism, such as food intake, energy expenditure, insulin secretion, hepatic glucose production and glucose/fatty acid metabolism in adipose tissue and skeletal muscle. Any defects in signal pathways between the brain and organs charged with supplying energy and maintaining glucose homeostasis may contribute to development chronic disease. This entry will highlight the metabolism of absorbed dietary carbohydrates by following the delivery of glucose to various tissue and breakdown for energy production by glycolysis. Energy storage of glucose as glycogen and generation of glucose via gluconeogenesis and glucose metabolism by the brain and other various tissues under aerobic and anaerobic conditions will be explored. The complicated interplay of control sensors in the brain and gut, and various hormones and rate-limiting enzymes and metabolites that control glucose movement, breakdown, synthesis and storage to maintain glucose homeostasis will be outlined.

## Glucose in the body

Dietary carbohydrates are the primary source of glucose. Therefore, carbohydrate intakes are recommended to range between 45 and 65% of energy (E). While these percentages far exceed minimum carbohydrate requirement, which is based on energy needs of tissues that depend on ATP generated from glycolysis (Sünram-Lea and Owen, 2017), the brain prefers glucose as its fuel and needs at least 50–100 g d<sup>-1</sup> of glucose. Thus, the Institute of Medicine of the US National Academy of Sciences (2005) recommends ~130 g d<sup>-1</sup> of glucose (200–500 kcal d<sup>-1</sup>). While the brain can use alternative fuels such as lactate and ketone bodies, their transfer through the blood brain barrier and ability to substitute for all glucose functions is limited (Bentsen et al., 2019). Thus, glucose remains the preferred fuel.

Blood glucose results from digestion of dietary carbohydrate. Three main pathways maintain blood glucose concentration: (1) the movement of glucose into tissues for energy production by glycolysis or energy storage as glycogen or as part of lipid synthesis; (2) the release glucose from glycogen stores by glycogenolysis; and (3) the endogenous synthesis of glucose from glucogenic amino acids and carbohydrate sources such as lactic acid through gluconeogenesis.

The glucose hungry brain is only 2% of body weight but consumes half of the body's glucose at rest. More is required during challenging mental tasks. The average adult needs ~110 g d<sup>-1</sup> of glucose and ~75 g d<sup>-1</sup> in young children. Glucose adequacy in the brain is so important that when supplies are low, the brain blocks glucose entry and utilization by other organs. For some brain regions, small glucose drops not only impair cognition, but also may damage tissue. During fasting or very low carbohydrate diets, the brain is forced to shift and metabolize  $\beta$ -hydroxybutyrate and other ketones in place of glucose (The benefits and drawbacks of diets promoting ketones as fuel for dieting, brain functioning, and exercise performance are subjects of much research and debate).

The testes, renal medulla, and erythrocytes are also totally dependent for correct functioning on a steady glucose supply to generate ATP from glycolysis. These tissues are incapable of utilizing ketones. The marrow uses glucose but relies on fat as its primary fuel.

## Body pool

The total amount of glucose in blood and body fluids comprises “the body pool of glucose”. In adults, this ranges from 8 to 28 g and corresponds to blood glucose concentrations of 3.5–5 mmol L<sup>-1</sup>. The body pool stays within this narrow range despite enormous

fluctuations in glucose supply and demand. For example, ingestion of a large, carbohydrate-rich meal may raise blood glucose concentration as high as  $10 \text{ mmol L}^{-1}$ , but the glucose body pool changes little, due to carefully orchestrated interactions among multiple hormones, sensors, and metabolites. Further this produces only small perturbations in blood glucose in normal individuals because the rate of glucose removal from the pool rises to match glucose input. During an overnight fast in a normal adult,  $\sim 9 \text{ g}$  of glucose enter and leave the body pool every hour. This marks the only way glucose leaves the pool in healthy individuals. However, in situations where blood glucose remains high, excess glucose is forced into the urine causing polyuria and measurable urinary glucose, which are classic symptoms of type 2 diabetes or impaired glucose tolerance. Glucose in the urine is usually followed up in the clinic with the oral glucose tolerance test (OGTT) described in **Box 1**.

### Glucose: breakdown, storage and synthesis

Glucose, the product of carbohydrate digestion, is absorbed by the intestinal enterocyte and enters portal blood for delivery to the liver. The liver retains about 30% of the glucose for further metabolism. The remaining 70% travels to various tissues to provide energy. For most cell types, particularly muscle and adipose, insulin is required for glucose uptake and initiation of energy production by glycolysis. However, some tissues, such as brain, kidney and red blood cells do not require insulin.

*Glycolysis* is a multistep pathway key to energy production not only in body tissues, but also in organisms populating the microbiome. If energy is needed, insulin stimulates enzymes of glycolysis. The first step requires the addition of a high-energy phosphate group from ADP to glucose by a hexokinase. The result is glucose-6-phosphate (G-6-P). This is the “currency” needed to enter further metabolism or transfer to other tissues. G-6-P is then isomerized to fructose-6-phosphate, then phosphofructokinase adds a second high-energy phosphate group to make fructose-1,6-bisphosphate. This energy-rich, 6-carbon sugar is then split into two 3-carbon entities, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. These both can be converted to glyceraldehyde-3-phosphate (or may serve as the glycerol backbone for triglyceride synthesis if energy is not needed immediately). These 3-carbon carbohydrates undergo another phosphorylation to form two 1,3-bisphosphoglycerate. These compounds then transfer their energy-rich phosphate compounds to ADP to yield 2 ATPs and pyruvate. Thus, the glycolysis of a single glucose molecule utilizes two high-energy phosphates but generates four, creating a net energy gain.

The pyruvate produced continues to generate energy as it undergoes further metabolism. However, both the amount of energy produced, and reactions involved, depend on the level of oxygen available. Under aerobic conditions, each pyruvate enters the mitochondria and joins with coenzyme A to yield one acetyl CoA, one  $\text{CO}_2$ , and one reduced niacin (NADH). The high-energy electrons held in NADH can enter the electron transport chain. Acetyl CoA continues through the citric acid cycle (CAC) interacting with various carbohydrate intermediates crucial to continuation of the cycle. However, these intermediates may also be used in a variety of important metabolic reactions and used for gluconeogenesis. Under conditions of reduced or limited oxygen, as occurs during heavy exercise, pyruvate cannot follow the aerobic pathway through CAC and electron transport. Instead, pyruvate is converted to lactic acid by lactate dehydrogenase using NADH. Lactate is shuttled to the liver for conversion back to glucose in gluconeogenesis.

Mitochondria are necessary for aerobic glycolysis, but erythrocytes have none, so their energy needs are supplied through the pentose phosphate pathway (PPP). Glucose-6-phosphate produced in the first step of glycolysis is shunted to PPP. In PPP’s anaerobic phase, sugars such as fructose and pentoses (ribose-5-phosphate), vital for building nucleic acids, are produced. In its aerobic phase, it generates NADPH, a biologically active niacin, and provides both the energy and reducing power for synthesizing nucleotides, fatty acids, sterols, and non-essential amino acids. Further, NADPH can react with glutathione to protect cells from reactive oxygen species. Thus, PPP is pivotal for both redox homeostasis and glucose metabolism.

### Glucose breakdown to alcohol during fermentation reactions

Ethyl alcohol is the main product of carbohydrate fermentation in food. Specifically, microbial fermentation of foods such as yeast-leavened doughs or mashes for wine and beer, produces  $\text{CO}_2$  and ethyl alcohol.

However, only in extremely rare instances does this reaction occur in the human body. If it occurs, it follows a course of strong antibiotics that fosters conditions for fungal overgrowth, (usually candida), called “auto-brewery syndrome”. Despite its rare

#### Box 1 The oral glucose tolerance test (OGTT)

Clinically the OGTT follows glucose uptake and delivery to the tissues, e.g., rise and fall of blood glucose, and is used to identify those with abnormal glucose tolerance and diabetes. After an 8 h fast, the subject drinks a test syrup containing 75 g of glucose. Blood glucose is measured during the postprandial (usually 2 h) period. In healthy individuals, blood glucose stays in the range of  $60\text{--}140 \text{ mg dL}^{-1}$  and returns to fasting levels within 2 h.

The same tool is used as in research to aid the understanding of glucose absorption and utilization from daily meal patterns. However, the disposition of glucose absorbed after a carbohydrate-rich meal by healthy subjects varies widely from individual to individual, depending not only on the glucose tolerance of the individual, but also many characteristics and composition of the “eating event”, even previous ones. Thus, the actual rate and pattern of glucose utilization after a carbohydrate-rich meal can be hard to accurately predict.

occurrence, some writers justify their claims that ingestion of sugars and carbohydrates is addictive by erroneously citing that alcohol is produced.

## Glycogen

Humans do store glucose, but capacity is capped. The storage molecule glycogen is structurally like its plant cousin amylopectin, but is more branched, compact, and smaller, with only 2000–60,000 glucose units. The main role of liver glycogen is to maintain blood glucose concentration and supply all tissues with glucose, whereas muscle glycogen supplies energy the needs of cardiac and skeletal muscles only.

Liver glycogen has more glucose units than that in muscle glycogen and occupies 5–6% of the liver's cell volume. In muscle, glycogen occupies only 1–2% of muscle cell volume, but total muscle glycogen is four times higher than that found in liver because of large total muscle mass. Skeletal muscle glycogen is distributed in defined pools, which vary depending on factors such as exercise intensity, degree of training or immobilization, and fiber phenotype (Ørtenblad and Nielsen, 2015).

Glycogen is also found in small amounts in kidney, adipose, and erythrocytes, and even smaller amounts in white blood cells and brain. In brain, glycogen plays a role in memory formation, learning, and other cognitive functions, and serves as an emergency cerebral energy source (Duran et al., 2019). Active glycogen metabolism appears allow some tolerance to hypoxia and help brain functioning.

## Glycogen synthesis

In the fed state, when current body energy needs are satisfied, insulin upregulates multiple enzymes involved in hepatic glycogen synthesis including glycogen synthase and glycogen branching enzyme. Glycogen synthesis requires cooperative actions using the glycogenin core. The rate-controlling step glucokinase phosphorylation of G-6-P (Nozaki et al., 2020) is followed by phosphoglucomutase isomerization of G-6-P to glucose-1-phosphate. After a high energy uridine-diphosphate is added, glucose moieties conjugate to form a chain using glycogen synthase to become the glycogenin center that controls synthesis of the main glycogen chain by attaching UDP glucose onto itself to create a chain of 8–12 glucose moieties with  $\alpha$ -1,4 links (Zeqiraj and Sicheri, 2015). With glycogenin still at the core, the resulting oligosaccharide continues to add glucose, using glycogen synthase and glycogen branching enzyme, which add  $\alpha$ -1, 6 branch points every 12–13 glucose moieties. This results in compact, globular glycogen granules that accumulate in the liver. Skeletal muscle builds glycogen at highest rates after exercise, showing the importance of refueling after intense exercise (Adeva-Andany et al., 2016).

Not all the excess glucose can be stored as glycogen, so insulin also activates lipogenic enzymes to capture energy and metabolites generated from glycolysis, CAC, and electron transport to store it as fat. Specifically, pyruvate is transformed to acetyl CoA to become building blocks for synthesis of long-chain fatty acids. Glyceraldehyde formed during glycolysis becomes glycerol and serves as the triglyceride backbone. High energy metabolites available from CAC and electron transport, such as NADH or FADH<sub>2</sub>, drive lipogenesis.

## Glycogen utilization

Glycogen is utilized in the fasting (postabsorptive) state, which occurs after all ingested foods have been digested and absorbed or during fasts of 6–8 h or longer. During an overnight fast, glycogen drops to ~40 g (range 15 g–80 g) because the brain and erythron continue to utilize glucose, then blood glucose drops as no glucose is entering the bloodstream. This causes glucagon release, which upregulates enzymes of glycogenolysis—glycogen phosphorylase to split glucose 1-phosphate from the linear chains of glycogen and the glycogen-debranching enzyme too split glucose at the branch points (Kanugo et al., 2018).

Glucagon also activates enzymes involved in gluconeogenesis (see next section). New glucose release frequently equals the rate of glucose uptake into tissues, which stabilizes blood glucose concentration between 4.0 and 5.5 mmol L<sup>-1</sup> (70–100 mg dL<sup>-1</sup>). Hepatic glycogen stores may even be partially replenished. If heavy exercise causes liver glycogen to drop as much as 80%, glucose utilization and removal from blood outpace its production. During weeks of starvation or extremely low-carbohydrate (<50 g d<sup>-1</sup>) diet, blood glucose concentration rarely falls below 3 mmol/L, and usually only when gluconeogenesis is impaired.

Muscle glycogen supplies its own energy needs, even when glucose is needed elsewhere. However, the breakdown of muscle glycogen during exercise inhibits glucose uptake from the bloodstream, thereby aiding glucose supply to other tissues. Muscles lack glucose-6-phosphatase, which means that glucose released from glycogen cannot be phosphorylated to the form needed to travel in the bloodstream. Instead, anaerobic glycolysis in the muscle produces lactate. This enters the bloodstream and is delivered to the liver, where it is reconverted to glucose by gluconeogenesis.

## Glycogen and health

Low glycogen often occurs in early morning hours before breakfast, but timing depends on factors such as meal size and time since the last food ingestion, food characteristics and physical nature (food matrix and fluidity), macronutrient and fiber content. For those with impaired glucose tolerance, low blood glucose in the morning causes hypoglycemia and can have serious ramifications.

A variety of inborn errors of metabolism affecting enzymes involved in the synthesis or breakdown of glycogen can result in the inability to access glycogen or result in the accumulation of excess glycogen. There are at least 13 identified disorders that affect a wide range of organs and systems including neuronal loss (Duran and Guinovart, 2015), muscle weakness or obesity.

### Gluconeogenesis

When blood glucose is low, gluconeogenic enzymes for *de novo* glucose synthesis are activated. “New” glucose enters the bloodstream to meet energy needs of the brain and other tissues and partially replenishes liver glycogen stores. Most gluconeogenesis occurs in the liver, but some occurs in the renal cortex, especially in diabetes and prolonged fasting. Regardless of location, gluconeogenesis requires a ready supply of glucose precursors. During exercise, lactate produced in the muscle from the anaerobic glycolysis is transferred to the liver and converted to glucose, which is returned to the muscle as part of the Cori cycle. Physical training can optimize the use of lactate and fatty acids as fuel alternatives.

During prolonged fasting or starvation, the release of glucogenic amino acids from proteolysis of skeletal muscle is needed for glucose synthesis. Alanine has a special role in gluconeogenesis, not only for providing three-carbon carbohydrate backbones to the liver as glucose precursors, but also for shuttling all amino acids released by muscle catabolism to the liver. The following are glucose building blocks: alanine, pyruvate, glycerol, and other glucogenic amino acids including glutamine/glutamate. The latter function in kidney gluconeogenesis in response to acidosis. The glycerol portion of triglycerides and the short-chain fatty acid propionate are the only fat precursors used in gluconeogenesis; no other fatty acids serve glucose precursors.

Gluconeogenesis is inhibited by eating, so insulin released in the fed state inhibits gluconeogenic enzymes, such as the rate-limiting phosphoenolpyruvate carboxykinase. Alcohol ingestion inhibits gluconeogenesis, so individuals consuming substantial energy as alcohol may develop severe hypoglycemia.

### Hormones and glucose homeostasis

Glucose supply to the body tissues and in the bloodstream is regulated by numerous hormones, signal metabolites, sensors, and allosteric enzymes, often with counterbalancing effects. While the central nervous system aided by the pancreas and the gut form the command center, the liver has the important job of balancing glucose release, glycogen synthesis and degradation, and gluconeogenesis. If these hepatic processes are disrupted, they can contribute to hyperglycemia in the fasted and postprandial states. The body also has many neural and hormonal mechanisms at its disposal to correct or overcome any fall in blood glucose to below the critical level necessary for maintenance of normal body and brain functioning.

Insulin and glucagon have major roles in meeting energy needs, supplying a steady amount of glucose to the bloodstream, and promoting glucose movement from the bloodstream and body pool into peripheral tissues as needed. However, these hormones are intricately enmeshed to other key hormones, metabolites, and feedback control loops.

*Insulin* is a glucose-utilizing anabolic hormone that both works in tandem with, and is antagonistic to, glucagon. Insulin is among the smallest proteins and has two chains joined by disulfide bonds. This protein is released by pancreatic  $\beta$ -cells upon sensing a rise in blood glucose concentration, although food thoughts and smells can cause its release in the cephalic phase. Insulin's main function is to lower blood glucose and encourage glucose utilization. In that way it differs from other hormones, except somatostatin and IGH-1, in that others raise blood glucose.

Insulin removes glucose from the bloodstream or encourages glucose utilization in the following ways.

- It stimulates the expression of GLUT4, a principal glucose transporter protein in muscle and adipose. This enables glucose uptake from the bloodstream into these tissues (Exercise and hyperglycemia increase GLUT4 action).
- It promotes glucose breakdown by stimulating enzymes of glycolysis.
- It facilitates energy storage by stimulating glycogen synthase and fatty acid synthetase and lipogenesis.
- It inhibits gluconeogenesis by decreasing the expression of rate-limiting enzymes involved in glucose synthesis.

*Glucagon*, a 29- amino acid peptide hormone, is a glucose mobilizing catabolic hormone. It is released by  $\alpha$ -cells (that comprise 40% of the pancreatic islet cells) when they sense low blood glucose. Glucagon acts by:

- Activating liver glycogen phosphorylase to start glycogenolysis.
- Activating enzyme machinery associated with gluconeogenesis to raise blood-glucose. Thus, it promotes muscle breakdown to produce glucogenic amino acids that can be deaminated to serve as substrates for glucose synthesis. Further, it promotes utilization of pyruvate, lactate, and other carbohydrate intermediates.
- Blocking insulin action to increase or maintain plasma glucose and stimulate ketogenesis to provide alternate fuels if needed.
- Causing insulin release to enable utilization of glucose generated by its actions.

In abnormal glucose tolerance or diabetes, glucagon response to hypoglycemia is defective and results in chronic hyperglucagonemia.

*Somatostatin*, released by the anterior pituitary, controls growth. It decreases hormones associated with growth, and thereby inhibits somatotrophin release and suppresses glucagon's response to low blood glucose. Somatostatin also slows digestion and nutrient (glucose) absorption by inhibiting gastrin and the subsequent release of stomach acid.

*Cortisol* is a steroid hormone released by the adrenal cortex during physical and emotional stress. It provides glucose needed, in the short term, to address the stressful situation. Cortisol not only increases hepatic glucose output by stimulating gluconeogenic enzymes, but also acts to keep glucose in the bloodstream by reducing insulin secretion.

Constant stress causes continuous cortisol release and leads to both increased blood sugar levels, elevated inflammation, and insulin resistance. *ACTH* is released from adrenal glands and stimulates cortisol, which in turn, stimulates release of fatty acids from adipose tissue, so the glycerol portion can provide glycerol for gluconeogenesis.

*Norepinephrine* and *epinephrine* are released after stimulation by the sympathetic and parasympathetic nervous systems - adrenaline by the adrenal medulla and noradrenaline from nerve terminals in the liver. Strong emotions (e.g., fear or anger) trigger their release to increase heart rate, muscle strength, blood pressure, and glucose metabolism.

Both work in similar ways and increase blood glucose by:

- Inhibiting postprandial glucose uptake in insulin-dependent tissues.
- Stimulating liver glycogenolysis.
- Activating lipolysis in muscles to release glycerol, which can be used in gluconeogenesis, and free fatty acids to fuel muscle.

*Growth hormone* is released by the hypothalamus. It is antagonistic to insulin action by inhibiting liver glucose uptake and promoting lipolysis and gluconeogenesis. However, it works with insulin to promote use of amino acids to build tissue.

*Thyroxine* is released by the thyroid gland and stimulates carbohydrate metabolism by:

- Promoting intestinal glucose absorption.
- Enhancing insulin-dependent glucose entry into cells.
- Stimulating glucose generation through gluconeogenesis and glycogenolysis.

Many other hormones also control glucose by acting with insulin and glucagon. **Insulin-like growth factor-I (IGF-1)**, a polypeptide, structurally akin to insulin, is synthesized in liver and some peripheral tissues. Under the direction of growth hormone, it promotes normal growth and development of bone and tissue. Because nearly half the amino acid sequence is homologous with insulin, IGF-1 binds to insulin receptors stimulating glucose transport into fat and muscle. It acts in tandem with insulin to remove glucose from the bloodstream and promotes glucose homeostasis and glucose tolerance. In the brain IGF-1 works with insulin to modulate glucose metabolism, but faulty pathways are thought to contribute to neurological disorders ([Fernandez et al., 2017](#); [Zheng and Tong, 2017](#)).

Food ingestion activates specialized endocrine cells distributed along the length of the intestinal epithelium. These include the activation of L-cells that triggers release of **glucagon-like peptide-1 (GLP-1)** and K-cells that triggers release **gastric inhibitory polypeptide (GIP)**. These two incretin hormones affect glucose metabolism by binding to their respective glucose-coupled receptor proteins (G-proteins) in fat, bone, brain, and pancreas. They bind to  $\beta$ -cells to enhance insulin secretion, especially under hyperglycemic conditions. They simultaneously suppress glucagon release. Both hormones promote  $\beta$ -cell proliferation and inhibit their apoptosis. In addition, they may impact memory formation, gastric emptying, and appetite control. They can sense and signal information related to the rate of nutrient absorption, the intestinal lumen contents, or integrity of the epithelial barrier and play a role in signaling glycogen breakdown and gluconeogenesis in the liver. However, some actions of the two hormones are antagonistic:

- GIP enhances postprandial glucagon response (and bone formation), while GLP-1 suppresses them.
- GIP, but not GLP-1, facilitates fat deposition in adipose.

**Vasopressin (VP)** is secreted by the posterior pituitary gland and facilitates glucose homeostasis in several ways. Through receptors in the pancreas and other site, it regulates:

- Hepatic glucose production,
- Insulin signaling,
- Aldosterone secretion.

High VP is a risk factor for glucose metabolism disorders in humans ([Nakamura et al., 2017](#)).

**Adrenocorticotrophic hormone (ACTH)**, **growth hormone**, and **prolactin** are released by the anterior pituitary gland. All four can cause glucose release by enhancing glycogenolysis in the liver.

**Amylin**, formed primarily in pancreatic islet  $\beta$  cells, is co-secreted with insulin in response to caloric intake. Amylin helps maintain glucose homeostasis by suppressing glucagon release in response to energy intake, slowing gastric emptying, and activating satiety signals from the brain to limit energy intake.

**Table 1** gives a short synopsis about some hormones that affect blood glucose.

## Insulin and blood glucose

Insulin release from pancreatic *B*-cells depends on the glucose concentration in the blood perfusing the islets. In the fed state, insulin concentration in peripheral blood ranges from  $\sim 150\text{--}600\text{ pmol L}^{-1}$ , which markedly increases uptake of absorbed glucose from arterial blood into peripheral tissues, helping blood glucose return to basal concentration. As glucose is removed, plasma insulin falls. Fasting adults with normal glucose tolerance have insulin concentration in peripheral blood of  $\sim 30\text{ pmol L}^{-1}$ , making glucose uptake by striatal muscle nearly zero and fatty acid release from lipocytes a major energy source.

**Table 1** Hormones that affect blood glucose.

<i>Hormone</i>	<i>Stimuli</i>	<i>Inhibitors</i>	<i>Main effect on glucose homeostasis</i>
Insulin	Cephalic triggers Hyperglycemia Incretins- GIP & GLP-1 Glucagon Arginine and leucine Long chain fatty acids Vagus nerve/parasympathetic G-protein-coupled receptors (GPCRs)	Hypoglycemia Sympathetic Adrenaline Somatostatin GPCRs Short chain fatty acids	↓ Blood glucose by: ↓ Glycogenolysis ↓ Gluconeogenesis ↑ Peripheral glucose uptake and utilization
Glucagon	Hypoglycemia Adrenaline Most amino acids Fatty acids Cold	Insulin Hyperglycemia Ketones	↑ Liver glycogenolysis ↑ Gluconeogenesis
Adrenaline	Hypoglycemia, by sympathetic nerve stimulation Physical/mental stress		↑ Glycogenolysis in liver and peripheral tissues, ↓ Insulin secretion ↑ Glucagon secretion ↓ Adipose and muscle sensitivity to glucose ↓ Peripheral glucose utilization ↑ Lipolysis (i.e., ↑ plasma non-essential fatty acids levels)
Cortisol	Hypoglycemia through hypothalamic release of ACTH		↓ Peripheral glucose uptake ↑ Insulin resistance Permits hepatic glycogenesis
Growth hormone	Hypoglycemia through hypothalamus Ghrelin from stomach following food ingestion	Hyperglycemia Somatostatin Alcohol	↓ Peripheral glucose uptake ↑ Adipocytes ↓ Lipolysis by inhibiting lipoprotein lipase
Vasopressin	Hypoglycemic stress Dehydration	Hypo-osmolality alcohol	↑ Hepatic glycogenesis
<b>Gut incretin hormones</b>			
Glucose-dependent insulintropic peptide, also Gastric inhibitory polypeptide (GIP)	Actively absorbed sugars e.g., glucose and galactose, actively absorbed fats especially polyunsaturated	Glucagon Insulin	↑ Insulin secretion under hyperglycemia
Glucagon-like peptide- 1 (GLP-1)	Ingested food (absorbed and unabsorbed)	Glucagon Insulin	↑ Insulin secretion during hyperglycemia ↓ Glucagon secretion ↓ Gastric emptying ↓ Appetite

When blood glucose reaches  $\sim 3.5\text{--}4.0\text{ mmol L}^{-1}$ , insulin secretion continues, but at a reduced rate. In individuals without diabetes, insulin concentration is low enough to permit release of glucose by the liver and fatty acids by adipocytes. When *B*-cells fail and insulin secretion ceases, gross hyperglycemia and ketosis occur. Both are hallmarks of insulin-dependent diabetes.

During prolonged starvation (20 days or more without food), small amounts of insulin reach the liver. The amounts reaching adipocytes are, however, insufficient to prevent rapid lipolysis leading to hyperketonemia comparable with that seen in diabetic ketoacidosis ( $\sim 10\text{--}20\text{ mmol L}^{-1}$ ). However, small amounts of insulin secreted during starvation affect gluconeogenesis and glycogenolysis to help blood glucose remain within normal range during the prolonged fast. This is in sharp contrast to elevated blood glucose observed with *B*-cell malfunction and impaired glucose tolerance.

Insulin's ability to lower blood glucose depends not only on serum insulin concentration, but also whether the insulin is **exogenous** or **endogenous** (pancreatic). Proteases in pancreatic *B*-cells cleave the C-peptide from pro-insulin activating it prior to its release into the bloodstream, however C-peptide accompanies insulin to peripheral tissues. This creates a synergistic duo that causes a key difference between the functioning of endogenous and exogenous insulin. The endogenous insulin C-peptide complex reaches the liver at higher concentration than in peripheral tissues, but without the attendant C-peptide a higher concentration of exogenous insulin is found peripheral tissues. Both the lack of C-peptide and higher exogenous insulin in the periphery are thought to contribute to vascular complications of diabetes.

## Glucose in the urine

Each day, more than 100 g of glucose are filtered from the bloodstream through the glomeruli of the kidneys. Under normal conditions, more than 99% of the glucose is reabsorbed by the kidney tubules. As a result, healthy people lose less than 150 mg of glucose in their urine each day, an amount too small to be detected in most screening procedures. When the glucose pool increases above a threshold level ( $\sim 10$  mmol of glucose/L), the amount of glucose filtered by the glomeruli exceeds the reabsorption capacity of the tubules, causing glucose to appear in the urine. Glucosuria is defined as urinary glucose concentration  $>0.15$  g L<sup>-1</sup> (0.8 mmol L<sup>-1</sup>), but concentrations can be many times greater than in the blood. This causes increased excretion of water, sodium, chloride, and potassium resulting in osmotic diuresis associated with hallmarks of hyperglycemia and diabetes.

While temporary increases in glucose pool size (hyperglycemia) are not immediately harmful, decreases in glucose pool size (hypoglycemia) are. In pregnancy and other conditions that may impair glucose transport through the renal tubules, normal blood glucose concentration may result in glycosuria. However, under conditions with normal tubular glucose reabsorption when blood flow through the glomeruli is reduced or glomerular filtration is impaired, gross hyperglycemia may not produce glycosuria. Many mechanisms have evolved to prevent or overcome such potentially dangerous conditions.

## Conclusion

Supplying energy in the form of glucose is critical to the functioning of tissues in the body, and therefore is under the control of a complex array of hormones, incretins, sensors, and organs. Many have countervailing effects. Some, such as insulin, initiate glucose breakdown by glycolysis and utilization of its metabolites to create ATP and other high-energy compounds; others, such as glucagon, inhibit these reactions. Insulin also orchestrates the storage of energy not immediately needed for future use by up-regulating enzymes responsible for glycogenesis and lipogenesis. Countervailing hormones, such as glucagon, promote glycogenolysis and gluconeogenesis. While insulin and glucagon are key, the array of feedback loops and reactions and hormones that impact glucose concentration in the blood and body pool are many and complicated. The number of hormones, allosteric enzymes and their counteracting reactions, and alternate glucose pathways such as the Cori cycle, illustrate the complicated and interrelated mechanisms for meeting the body's energy needs while maintaining the glucose body pool and blood glucose. Homeostasis in these many reactions must occur despite wide ranges of carbohydrate intake and rates glucose of utilization, because it is key to good health.

### Key points

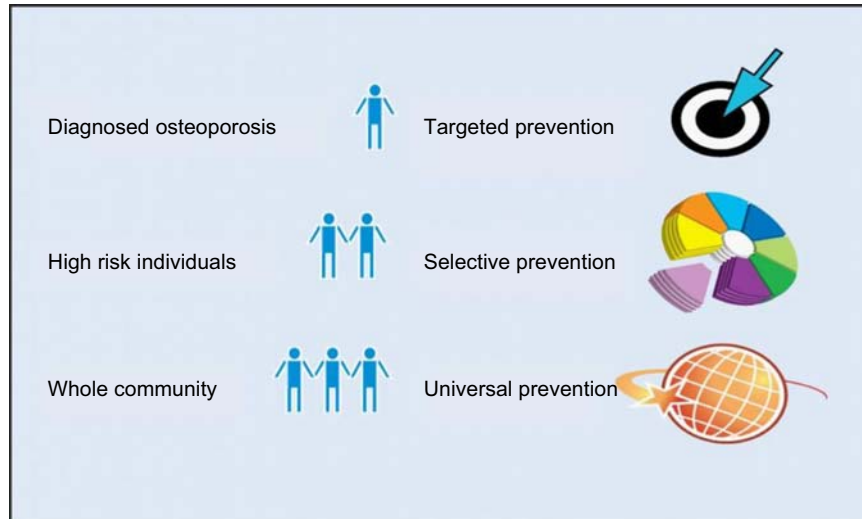

- The pathogenesis of poor bone health across the lifecycle is multifactorial.
- Musculo-skeletal health is determined by the development of peak bone mass in the younger population and the rate of bone loss in the older population.
- Musculo-skeletal health is affected by a combination of genetic, endocrine, mechanical, and nutritional factors, with evidence of extensive interactions within and between these groups.
- Low calcium intake (<400 mg per day) has been associated with inadequate calcium retention and poor peak bone mass attainment. It is also associated with increased bone loss in the ageing Caucasian population.
- Vitamin D deficiency (<25 nmol/l) across the lifecycle has been shown to be detrimental to musculo-skeletal health in the long-term.
- Acid-base homeostasis may play a key role in reducing bone loss in the ageing population. Studies demonstrate that a high intake of potassium salts may reduce bone resorption but more longer-term studies are required.
- More research is needed on the importance of other micronutrients (including the trace elements, vitamin K) to bone health in the long term.
- Physical activity (impact loading) across the life-course is key to bone health.

### Introduction

The pathogenesis of poor bone health is multifactorial. Both the development of peak bone mass in the younger population and the rate of bone loss in postmenopausal women and the elderly men and women are determined by a combination of genetic, endocrine, mechanical, and nutritional factors, with evidence of extensive interactions within and between these groups (Fig. 1).

**Fig. 1** Modifiable (endogenous) versus nonmodifiable (exogenous) factors affecting bone health.

**Fig. 2** Nutritional approaches to osteoporosis prevention.

Endogenous factors have a critical influence on the skeleton. Monozygotic and dizygotic twin research and mother/daughter pairs show a genetic influence on bone health in the region of 75%. In addition, the skeletal determinants of osteoporotic fracture risk, such as areal bone mineral density (BMD), bone geometry, and bone turnover, are all subject to strong genetic influences (Bou-din et al., 2016).

Nutritional advice, which is based on sound scientific evidence, is of paramount importance to ensure and enable the optimization of bone health throughout the life cycle. Even a small or modest effect on bone health is likely to have a significant impact on fracture prevention – for example, an increase in BMD by one standard deviation unit is likely to result in a 50% reduction in fracture rates. For effective strategies, emphasis needs to be given, in combination, at three different levels as shown in Fig. 2: (1) Universal primary prevention, (2) selective prevention for high-risk groups and, (3) targeted prevention for individuals.

## Calcium

It is well considered that calcium is critical to health. Calcium is the most abundant mineral element in the body and has two key roles. The first role is structural and the second is regulatory. For its structural role, bone consists of protein matrix encased in a crystalline mineral. Approximately 1 kg of calcium is contained within the skeleton (99% of Ca is contained in bones and teeth) and it is this mineral part that contributes to the strength of bone. Bone mineral provides a huge reserve of Ca, behaving as a large “ion exchanger” allowing interaction between ions in body fluids and bone. Ca is the most abundant mineral element in the body. For its regulatory role, plasma concentrations of calcium are maintained within very narrow limits (90–110 mg L<sup>-1</sup>) and although only 1% of calcium is found in soft tissues and body fluids, this calcium is required for a number of key functions including cellular structure; inter- and intracellular metabolic function and signal transmission; muscle contractions including heart muscle, nerve function, activities of enzymes, and normal clotting of blood. The regulation of serum calcium levels is carefully maintained by calcitrophic hormones (parathyroid hormone, calcitriol (hormonally active metabolite of vitamin D, 1,25 (OH)<sub>2</sub>D) and calcitonin).

### Peak bone mass attainment

Peak bone mass (PBM), the highest level of bone mass attained during normal growth, is one of the key factors determining bone mass and fracture risk later in life. The age at which peak mass is attained ranges from approximately 17–35 years and varies for different skeletal sites.

Calcium absorption and bone calcium deposition rates peak (approximately five times that of adulthood) in girls shortly before menarche. Thus, low calcium during growth and late menarcheal age may affect peak bone mass and consequently fracture risk later in life. There are data to show that adolescent girls are less likely than boys to meet the current recommended dietary levels for calcium and that calcium intake in girls may begin to decline around the time of puberty. The demand to provide calcium to the fetus and neonate during pregnancy and lactation is considerable, and the results of a few recent small studies on the effect of adolescent pregnancy on bone turnover and later risk for osteoporosis as well as fetal bone development highlight the need for adequate calcium intake in pregnant teens (Lanham-New et al., 2007).

To date, clinical trials investigating the effect of increased calcium intake (either through foods or supplements) on peak bone mass development have been of relatively short duration, and it has been difficult to determine whether the positive effects of calcium supplementation on bone are maintained. In a very important calcium and bone study, Matkovic et al. (2005) looked at the effects of calcium intake over an extended period. They reported the results of a 4-year randomized clinical trial that involved 354 girls at stage 2 of puberty. The study was optionally extended for a further 3 years. The mean intake of calcium over the 7-year period was 830 mg day<sup>-1</sup>, with calcium-supplemented participants receiving an additional 670 mg day<sup>-1</sup> of calcium. The results indicated that calcium supplementation significantly influenced bone accretion in girls during the pubertal growth spurt. The effect diminished in young adulthood, but in tall girls, the significant effects remained at the metacarpals and at the forearm. Thus, calcium requirements for maximum skeletal development may be associated with bone size. While calcium intake from supplements, fortified foods, and dairy can increase skeletal mass and density measures, the positive effects may differ depending on the form that it is consumed in. A 2-year randomized controlled trial in Finland including girls aged 10–12 years who had low dietary calcium intake at inclusion found that increasing dietary calcium intake by consuming cheese was more beneficial for cortical bone mineral mass accrual than consuming a similar amount of calcium in tablet form (1000 mg day<sup>-1</sup>) (Cheng et al., 2005). This may be due to differences in the absorption of calcium, the distribution of intake during the day, and the absorption of other nutrients from dairy products compared to tablets. Therefore, while calcium supplementation may be useful for those with inadequate intakes, further studies are needed to establish potential differences in calcium intake from dairy and supplements on PBM.

### Postmenopausal bone loss

There are good data to suggest that calcium supplements are effective in reducing bone loss in late menopausal women (45 years postmenopause), particularly in those with low habitual calcium intake (400 mg day<sup>-1</sup>) (Lanham-New, 2008). In addition, a meta-analysis that includes 15 trials indicates that calcium supplementation at levels between 500 and 2000 mg day<sup>-1</sup> reduces postmenopausal bone loss (Shea et al., 2002). However, a secondary analysis of a randomized controlled trial involving 1471 healthy postmenopausal women (mean age 74 years) reported that calcium supplementation of 1000 mg day<sup>-1</sup> was associated with an increased rate of cardiovascular events (Bolland et al., 2008). Therefore, further studies are needed to investigate the benefits of calcium supplements against their potentially deleterious effects in postmenopausal women. The findings of calcium supplementation studies in the early stages of the menopause are conflicting, and this is an area for further investigation (Lanham-New, 2008).

### Vitamin D

Vitamin D is derived from both endogenous (skin) and exogenous (diet) sources. The main source of vitamin D for most people is through exposure to sunlight on the skin containing sufficient ultraviolet B (UVB) radiation. However, the relative contributions of these two sources are thought to vary widely among individuals and between different geographical areas. In northern latitudes, there is no UVB radiation of the appropriate wavelength (290–315 nm) for vitamin D synthesis from the end of September to the end of March; and for the remaining months of the year, 60% of the effective UVB radiation occurs between 11:00 a.m. and 3:00 p.m. The extent of UVB exposure not only depends on the latitude and time, but also cloud cover, ozone, and atmospheric pollution. There are relatively few dietary sources of vitamin D—the major providers being fish, eggs, meat, liver, and some fortified foods, such as fat spreads and cereals (Charoenngam et al., 2019).

Although it is well documented that vitamin D synthesis from sunlight is affected by the aging process, there is a remarkable lack of awareness of this public health nutrition message. Several studies indicate low nutritional status of vitamin D in at-risk groups, manifesting in the re-emergence of rickets in children in some communities. Lack of sufficient sunlight exposure, especially but not only in Northern countries during winter months, poor nutrition, or low milk consumption or vegetarian diet, urban residence, and poverty are key factors that have been cited for the low vitamin D levels. Ethnic groups with darker skin may also be at a higher risk of vitamin D deficiency due to skin pigment melanin which reduces the penetration of UVB in the skin (Buttriss et al., 2022).

### Vitamin D and calcium studies on bone

Vitamin D is involved in calcium and phosphate homeostasis, playing an important role in bone metabolism. Prolonged and severe vitamin D deficiency can lead to rickets in children and osteomalacia in adults, although these diseases are rare in most developed countries. Vitamin D deficiency may also be associated with osteoporosis and higher incidence of falls or fractures (Hill and Aspray, 2017). However, meta-analyses of clinical trials investigating the effect of vitamin D supplementation on BMD, fractures, and falls have yielded conflicting results (Bouillon et al., 2022). A meta-analysis of 23 trials by Reid et al. (2014) found a small benefit in femoral neck BMD, but no effect at other sites. Several studies have also reported that fracture risk does not appear to be influenced by vitamin D alone. The 2022 systematic umbrella review of meta-analyses by Chakhtoura et al. (2022) investigating vitamin D supplementation (with or without calcium) found no effect on fracture risk reduction in studies exclusively evaluating community-dwelling adults and younger adults (aged 50–65 years), or in studies on vitamin D alone compared to control. However, combined vitamin D and calcium supplementation overall reduced the risk of hip and any fractures, potentially driven by findings from older and institutionalized adults. Additionally, a meta-analysis of 15 trials by Liu et al. (2020) found that combined calcium and vitamin D significantly reduced the risk of hip fracture, and significantly increased BMD at several sites in postmenopausal women (50–79 years). Interestingly, this study found femoral neck BMD was significantly increased only when vitamin D intake was no more than 400 IU d<sup>-1</sup>.

### Vitamin D and risk of falling

Although there have been mixed results, low vitamin D status has been implicated in an increased risk of falling. A meta-analysis by Bischoff-Ferrari et al. (2009) showed that vitamin D supplementation of 700–1000 IU per day resulted in a reduction of falls in the elderly by around 20%, particularly in those with low vitamin D levels. Mechanisms of action need further elucidation, but certainly muscle weakness, which can affect balance and mobility, has been implicated (Bouillon et al., 2022). Vitamin D (and calcium) supplementation may also be helpful in reducing falls by improving body sway and by normalizing blood pressure.

### Protein intake and bone

There is controversy concerning the relationship between dietary protein and bone metabolism. Although dietary protein has been shown to result in urinary calcium loss, negative calcium balance and increased bone loss, cross-sectional and longitudinal epidemiological studies examining the effect of protein intake on BMD, bone loss, and risk of fracture show mixed results: with some studies showing protein intake to be detrimental to bone health, whereas others demonstrating a beneficial effect. Conversely, protein-energy undernutrition is considered to be a risk factor for bone loss and osteoporosis. Low protein intake is related to low bone mass and increased risk of fracture, and protein supplementation has been shown to improve recovery from hip fracture (Darling et al., 2021).

Ecological studies have shown that worldwide *per capita* consumption of animal protein has been associated with a higher risk of hip fracture in women aged over 50 years. More recently, the correlation has been shown to be stronger with the ratio of animal protein to vegetable protein, a study which has adjusted for important cultural differences (Darling et al., 2009). It is important to note, however, that in these correlational studies, the unit of measurement is country and not individual and as such, these types of studies have a number of limitations, which must be considered in the interpretation of such data. In the most recent meta-analysis, total protein was found to have an overall beneficial effect on bone health throughout the lifecycle (Darling et al., 2019).

### Vitamin K

Vitamin K has an important function for the skeleton; it acts as a cofactor in the posttranslational carboxylation of several bone proteins, with osteocalcin being the most abundant. Deficiency of vitamin K results in the synthesis of under-carboxylated osteocalcin (ucOC). Vitamin K<sub>1</sub>, which is also known as phylloquinone, is a component of the Photosystem I of plants and is present in foods of plant origin. Alfalfa and green leafy vegetables are good sources of Vitamin K<sub>1</sub>. Vitamin K<sub>1</sub> is also a component of some dietary supplements. Vitamin K<sub>2</sub> is a bacterial form of the vitamin and is also known as menaquinone.

There are observational data to show that low serum concentrations of both vitamin K<sub>1</sub> and ucOC are associated with an increased risk for osteoporotic fractures (Lanham-New, 2008). Studies examining the association between vitamin K and BMD have been inconsistent, and the most recent meta-analysis of vitamin K on measures of musculo-skeletal health do not support a protective effect (Mott et al., 2019).

### Dietary alkali/potassium consumption

#### Importance of acid–base homeostasis to health

Acid–base homeostasis is absolutely critical to health. It is well documented that extracellular fluid pH remains between 7.35 and 7.45 and thus it is a major requirement of our metabolic systems to ensure that hydrogen ion concentrations are maintained

between 0.035 and 0.045 mEq. On a daily basis, humans eat substances that both generate and consume protons and as a net result, adult humans on a normal Western diet generate 81 mEq per kg body weight of acid per day. Of course, the more acid precursors a diet contains, the greater the degree of systemic acidity. As humans become older, their overall renal function declines, which includes their ability to excrete acid. Hence, with increasing age, humans become slightly but significantly more acidic.

### Skeletal link to acid–base maintenance

The theoretical considerations of the role of alkaline bone mineral may play in the defense against acidosis date back as far as the late 1880s/early nineteenth century. The fundamental concepts were established in the late 1960s/early 1970s—a number of studies published during this period provided evidence that in natural (e.g., starvation), pathological (e.g., diabetic acidosis), and experimental (e.g., ammonium chloride ingestion) states of acid loading and acidosis, an association exists with both hypercalciuria and negative calcium balance.

There are clear mechanisms for a deleterious effect of acid on bone. Novel work in the 1980s by Arnett and Dempster demonstrated a direct enhancement of osteoclastic activity following a reduction in extracellular pH. This effect was shown to be independent of the influence of parathyroid hormone. Furthermore, osteoclasts and osteoblasts appear to respond independently to small changes in pH in the culture media in which they are growing (New, 2002).

### Observational and intervention studies

A variety of population-based studies published in the latter part of the twentieth century and more recently between 2001 and 2011 have demonstrated a beneficial effect of fruit and vegetable/potassium intake on indices of bone health in young boys and girls, premenopausal women, perimenopausal women, postmenopausal women, and elderly men and women. Further support for a positive link between fruit and vegetable intake and bone health can be found in the results of the DASH (Dietary Approaches to Stopping Hypertension) and DASH-Sodium intervention trials. In DASH, diets rich in fruit and vegetables were associated with a significant fall in blood pressure compared with baseline measurements. However, of particular interest to the bone field were findings that increasing fruit and vegetable intake from 3.6 to 9.5 daily servings decreased the urinary calcium excretion from 157 mm day<sup>-1</sup> to 110 mg day<sup>-1</sup>. This study is the first population-based fruit and vegetable intervention trial showing a positive effect on calcium economy (albeit a secondary finding) (New, 2002). Research is now required to determine the long-term clinical impact of the DASH diet on bone health and fracture risk as well as clarification of the exact mechanisms involved with respect to this diet on skeletal protection. In the most recent meta-analysis, potassium supplementation was found to have a beneficial effect in reducing bone resorption but more longer-term studies are required (Lambert et al., 2015).

### Isoflavones and bone health

Soy protein consumption may also help to explain why it is so difficult to find a clear-cut answer to whether there are bone health differences between populations who follow a vegetarian-based diet and those following a nonvegetarian diet. Soy isoflavones have a chemical structure similar to that of estradiol and have been shown to possess a certain degree of weak estrogenic activity. In the animal model, comparable favorable bone effects have been shown between 17 $\beta$ -estradiol and soy protein isolate, genistein or daidzein. Although there are studies that support a beneficial effect of soy protein isolates on bone mass in both pre- and perimenopausal women, more data are urgently required. In the most recent trials, no effect of soy isoflavones on indices of bone health have been found. Furthermore, the available epidemiological studies looking at the association between soy product consumption and hip fracture rates are conflicting (Cashman, 2007).

### Folate, vitamin B<sub>12</sub>, and bone health link

The homocysteine–fracture risk link suggests the potential for a positive effect of vitamin B complex on the skeleton. There is increasing evidence at the experimental, clinical, and epidemiological level that raised homocysteine levels are associated with increased fracture risk. These levels can be reduced simply and cheaply through folic acid supplementation. In the absence of specific folic acid/fracture reduction trials, we cannot yet say whether this is an effective strategy for osteoporosis prevention but it is certainly an area for urgent research. There is also some evidence to show that vitamin B<sub>12</sub> deficiency *per se* adversely affects bone health through the criticality of vitamin B to the collagen crosslinks but further randomized controlled trials are urgently required (Swart et al., 2013).

## Nutrients adversely affecting bone health

### Vitamin A

Vitamin A refers to a family of essential, fat-soluble compounds called retinoids. Retinol is the principal dietary form of vitamin A. The main natural sources of vitamin A are provided by animal foods such as liver, meat, milk products, eggs, and fatty fish. In addition, some foods are fortified with vitamin A. Cod liver oil (which is commonly used in a number of population groups, particularly postmenopausal women/elderly) also contains high levels of vitamin A. There are approximately 600 or so carotenoids, with approximately 10% of these having provitamin A activity.

Vitamin A is necessary for normal bone growth. However, intakes of vitamin A  $>1500$   $\mu\text{g}$  of retinol equivalents (Res) have been associated with lower BMD and higher fracture risk in populations in the US and Sweden (Nieves, 2005). In both these countries dairy products and cereals are generally fortified with vitamin A. It should also be noted that high doses of pure cod liver oil can provide as much as 1200 mg RE of vitamin A in a 10 mL dose.

### Sodium

There are insufficient data to make the claim that salt is a significant risk factor for osteoporosis. However, high salt intakes have been associated with increases in urinary calcium loss. For example, it has been estimated that a 100 mmol increment in daily sodium intake is associated with an average loss of urinary calcium of approximately 1 mmol in free-living normocalciuric healthy populations. This loss has not been specifically correlated to bone loss, however. Some studies have shown an effect (i.e., higher sodium intake and higher bone turnover), but other studies have found no difference (Lanham-New et al., 2007).

## Impact of physical activity on bone health

### Introduction

More than a century ago, a German scientist called Julius Wolff stated the theory, which is now called “Wolff’s Law”: “Bone accommodates the forces applied to it by altering its amount and distribution of mass”. More recently, this concept has been refined to a general theory of bone mass regulation, known as the mechanostat model. It is well known that in the absence of weight-bearing exercise bone loss will occur at both axial and appendicular skeletal sites. Although the exact mechanism whereby mechanical loading affects bone remains to be clarified, the scientific literature supports a positive relationship between physical activity, physical fitness, muscle strength, and bone mass at the lumbar spine and femoral neck sites (Wilson-Barnes et al., 2022).

### Importance of exercise to bone

There is evidence that supports a positive relationship between weight-bearing exercise and bone mass in all age groups, including children, adults, and the elderly. Data also support a specific role for high-impact exercise to increase bone density in premenopausal women (Wilson-Barnes et al., 2022). Very little information is available on the relationship between exercise and fracture and is an area for further research. Although clearly exercise is of benefit to the skeleton, what remains undefined is exactly the type, intensity, and duration of weight-bearing physical activity required for optimum bone health. Furthermore, exercise may be of benefit in the prevention of osteoporosis, not necessarily via the mechanism of increasing bone mass but instead by increasing muscle strength, coordination, flexibility, and balance and thus reducing the tendency to fall.

Although bone mass has been shown to be higher in athletes involved in different sports, including tennis players, skaters, rowers, and volleyball players, there is increasing concern for the bone health of women engaged in high-intensity physical training, for whom amenorrhea is a common characteristic. Often, these types of sports also demand extremely low body weights and there is high reported incidence of anorexia nervosa among participants. The combination of amenorrhea (and/or anorexia) is detrimental to bone mass and there is now good evidence to show that they “under achieve” their peak bone mass (PBM) potential and thus are at a considerably increased risk of osteoporosis and indeed, by World Health Organization criteria, are often diagnosed as having the disorder. This picture of under-nutrition, amenorrhea, and osteoporosis is defined as the “female athletic triad” and in 1997, the American College of Sports Medicine published a position stand to “encourage the prevention, recognition and management of this syndrome” (American College of Sports Medicine, 1997) and this has now been updated and is referred to as Relative Energy Deficit Syndrome (REDS) (Fig. 3) (Mountjoy et al., 2018).

The exact mechanisms involved in PBM reduction remain unclarified. There are data to suggest that there is a suppression of the osteoblasts rather than an increase in osteoclastic activity, a finding that is further supported by the finding that hormone replacement therapy (HRT) is not as effective in reducing bone loss in elite sportswomen as it is in young women with primary ovarian failure. Of further interest is the finding that in gymnasts, despite a high prevalence of oligo- and amenorrhea, bone mass shows a higher than predicted value (American College of Sports Medicine, 1997). Clearly this is an important group to study because it might provide insight into the type of mechanical loads that are most osteogenic.

**Fig. 3** Potential performance effects of Relative Energy Deficiency in Sport (RED-S).

## Conclusions

The effects of nutrition on the skeleton are key. There is evidence to suggest that such effects begin *in utero* and remain in place throughout the entire life span, providing target audiences on whom nutrition and bone health messages can be focused. On the dietary front, calcium and vitamin D are important nutrients for optimum bone health. At all costs, we must try to prevent population groups from the potential of suboptimum intakes and vitamin D and look to dietary strategies of fortification for particularly vulnerable groups such as the elderly, postmenopausal women, adolescent females, and amenorrheic women. Given that the decline in bone mass is seen as a natural aging phenomenon, we must encourage sufficient protein:energy nutrition in our aging population. Newer nutritional ideas, with a sound evidence-base for a positive effect are appearing, including dietary alkali. Although there are plausible mechanisms for the effect of other micronutrients on bone health, such as magnesium, trace elements, vitamin C, more research is required on the specific supplementation effects of these nutrients on markers of bone health.

## Concluding remarks

It is common ground that there are genetic, environmental, lifestyle, and dietary determinants of risk of osteoporotic fracture as well as interactions between them. The key to secondary prevention is the understanding of how these components can be integrated into an effective assessment of the major risks after a previous fracture has occurred. The key to primary prevention is to understand both the pathological and physiological basis of bone fragility. It is not unreasonable to suppose that in a western lifestyle our limited and stereotypic patterns of locomotion from middle age onwards may offer considerably less protection than, for example, the more physically demanding activity of subsistence farming.

It is absolutely critical, given the fact that by 2030, 1:4 in the adult population will be elderly, that special attention is given to nutritional strategies for the optimization of bone health throughout the life cycle. Clearly, calcium and vitamin D nutrition are of great importance. Recent data suggest that calcium works synergistically with physical activity to enhance peak bone mass development and both should be on the agenda as recommended strategies for maximizing peak bone mass attainment during growth. At the other end of the age spectrum, calcium and vitamin D have been shown to be effective strategies for fracture prevention in the elderly, particularly for those populations where vitamin D insufficiency is rife.

Data continue to accumulate showing a positive impact of dietary potassium/fruit and vegetables on skeletal integrity. Although intervention trials are urgently required, it is sensible for the clinician to promote a high potassium intake in the patient's diet, because potassium has been shown to conserve calcium. A high intake of fruit and vegetables is likely to have numerous other health-related benefits.

Further data are urgently required to enable a fuller understanding of the complex interaction between dietary factors and bone health. However, there are promising data showing a positive impact of vitamin K on reducing post-menopausal bone loss. Furthermore, caution needs to be given to the overconsumption of carbonated soft drinks in our younger population, particularly if dairy products in the diet are displaced.

In this era of functional genomics, data are now urgently required to characterize the key nutrient:gene interactions that exist and that are likely to affect bone health in both our younger and older population groups. Targeting dietary advice at those genetically susceptible to osteoporosis is likely to become a useful toolset for the practising clinician.

## Glossary

**Kyphosis** Abnormal curvature of the spine, resulting in a reduced height.

**Occiput** The most prominent part of the back of the cranium. Used as a reference to place the measuring tape to obtain head circumference.

**Stadiometer** Calibrated board used to measure height.

**Stunting, stunted** Chronic undernutrition, resulting in a reduced height-for-age and weight-for-age.

## Uses of Anthropometric Measurements

In adults and children, anthropometric measurements can be used to estimate body fat and lean body mass, and assess their distribution and change over time. Body fat includes storage fat, found inter- and intramuscularly, around the organs and gastrointestinal tract and subcutaneously, as well as lipids in bone marrow, central nervous tissue, mammary glands, and other organs. Normal-weight men and women have approximately 10% and 20% body fat, respectively. Lean body or fat-free mass is approximately 73% water and protein with relatively small amounts of glycogen and minerals. Inadequate diets are associated with low body fat stores and reduced lean body mass in adults and growth failure of children. Consumption of food greater than requirements results in excessive body fat stores in adults and children. Body fat stores, which are too low or too high, are associated with increased risk of morbidity and mortality. The proportion and distribution of fat and fat-free mass vary with age, sex, genetics, disease, some hormones, and some drug treatments.

Different anthropometric measurements and combinations of measurements provide information on body composition and fat distribution and, therefore, nutritional status. The choice of measurements depends on the purpose of the assessment, the equipment available, the subjects being measured, and the skills of the observer making the measurements. Measurements can be made in laboratories, clinics, and hospitals using fixed, precision equipment with a high degree of accuracy, or in the field, including people's homes or rural centers, with portable equipment.

## Advantages and Limitations of Anthropometric Measurements

Anthropometric measurements are quick and relatively easy to obtain, and require inexpensive equipment. For most measurements, there are adequate measurement protocols and reference standards for comparison. Limitations include inability to detect small differences in body composition, dependency on subject's cooperation (problem with small children and handicapped adults), and require an operator with a certain amount of training and experience, particularly for skinfold measurements.

## Errors of Anthropometric Measurements

All anthropometric measurements should be made as accurately as possible. Measurement errors may result in the misclassification of subjects' nutritional status or may lead to changes in nutritional status over time being over- or underestimated. Very precise and accurate measurements are needed for nutrition research and in some clinical situations. The same degree of precision may not be possible in nutritional screening and surveillance programs in field studies. Errors in making measurements arise from the equipment, the physical state and age of the subjects, the time of day when the measurements are made, misreading of measurements by the observer, and as a result of rounding up or down to the nearest half or whole integer. These technical errors of measurement (TEM) vary with the age of the subjects, the measurements being made, and between (inter-) and within (intra-) observers. Values for a particular anthropometric measurement of a group of people by age and sex can be considered accurate if the inter- and intra-observer error is close to a reference value for TEM in a series of repeated measurements, and if there are no biases in the measurement. For measurements of subjects outside the age range, the coefficient of (*R*) can be calculated as  $R = 1 - [(TEM)^2 / (SD)^2]$ , where SD is the total inter-subject variance including measurement error. It has been recommended that an *R* of 0.90, i.e., a measurement 90% error-free, is an acceptable lower limit of accuracy, although an intraobserver *R* of 0.95 might be more realistic in some circumstances.

TEM can be minimized by careful training of all observers and by making measurements using appropriate equipment in triplicate and then calculating the mean. If measurements for a research study are to be made by more than one person, the interobserver measurements made must be comparable. *R* can be calculated for interobserver variability by making a series of measurements.

## Anthropometric Measurements

### Height

Height or stature is measured in adults and children over the age of 2 years using a stadiometer, a portable anthropometer, or a moveable headboard on a vertical measuring rod. The measuring device should be checked for accuracy using a standard 2-m steel tape. Subjects should be measured to the nearest 0.1 cm. Subjects, in minimal clothing with bare heads and feet, should stand straight, arms hanging loosely to the side, feet together and with heels, buttocks and shoulder blades in contact with the vertical surface of the stadiometer. Errors occur if subjects do not stand straight, do not keep heels on the ground, or overstretch. Diurnal variation results in people being 0.5–1 cm shorter in the evening than in the morning.

Height cannot be measured accurately in adults with severe kyphosis of the spine and in those who are bed- or chair-ridden. Because knee height is highly correlated with stature, height in such adults can be estimated from the measurement of knee height, using a sliding calliper. The regression equations, derived from a nonrandom sample of American people over the age of 60 years, are as follows: Height (cm) for men =  $(2.02 \times \text{knee height, cm}) - (0.04 \times \text{age, years}) + 64.19$ ; height (cm) for women =  $(1.83 \times \text{knee height, cm}) - (0.24 \times \text{age, years}) + 84.88$ . Variations in the proportion of limb length to trunk length can lead to a standard error in the estimate (SEE) of height from knee height of  $\pm 8$  cm. Demispan, which is the distance between the sternal notch of the right collar bone and the left finger root of the middle and ring finger when the subject's arm is horizontal and in line with the shoulders, can also be used to estimate height.

Length, rather than height, is measured in infants and children under the age of 3 years. Length is measured by laying a child face upwards on a measuring board with the head against the fixed headboard, and moving another board up to and resting against the child's heels with the legs straight (Figure 1). Small changes in length ( $\pm 0.5$  cm) may not be significant as it is a difficult measurement to make. Children wriggle and will not stretch out their legs. Length measurements are 1–2 cm longer than height.

Height (stature) or length indicates attained size or growth of adults and children. Long periods of inadequate food intake or increased morbidity result in a slowing of skeletal growth and individuals being short for their age, or stunted. Consecutive

**Figure 1** Measurement of recumbent length in children younger than 3 years of age. The head should be in contact with the fixed headboard, with child facing straight up. With legs fully extended, the mobile footboard should be placed firmly against the infant's heels. Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.

measurements of height every 3–6 months can be used to assess growth velocity in children and to indicate the timing of the adolescent growth spurt.

### Weight

Weight is measured with digital weighing scales, using a pan, basket, sling, standing platform, or chair, depending on the age and mobility of the people being measured. Weighing scales must be set on a hard, level, and even surface. Scales should be accurate, sensitive, and robust. They must be carefully maintained, calibrated, regularly checked for accuracy using known weights, and always set at zero before use. Weight is usually measured to the nearest 0.1 kg for adults and 0.01 kg for infants.

Weight measures total body mass but does not provide information on the proportions of fat, water, protein, and minerals. Adults can be heavy for height if very muscular, over-fat, and big framed. With accurate scales, small changes in weight are detectable but may not necessarily reflect change in body fat or lean body mass. In healthy persons, day-to-day variation in body weight is usually small ( $\pm 0.5$  kg). Consecutive measurements of weight can be used to monitor the effects of treatment such as weight loss on reduction diets or weight gain with nutritional interventions and supplementation. Weight changes are assumed to reflect changes in the amount of body fat. However, changes in body weight may also result from differences in hydration, edema, tumor growth, and trauma, as well as from factors such as the amount of food in the gastrointestinal tract and the fullness of the bladder. Weight may remain constant if the loss of muscle mass is masked by increased fat as seen in sarcopenia, the age-related loss of muscle, or by increased fluid retention.

Weight-for-height (or length) can be used to indicate body composition in adults and is an age-independent measure of body composition in children. Growth can be measured in children by consecutive measurements of weight over time (growth velocity) or by weight-for-age if the children's ages are known.

### Head Circumference

Head circumference is measured in infants and young children, to the nearest 0.1 cm, with a narrow flexible nonstretch tape laid over the supraorbital ridges and the part of the occiput, which gives the maximum circumference. The head circumference of infants increases rapidly in the first 2 years of life. Increase in head circumference in the first 2 years of life is affected by nutritional status and nonnutritional problems, including some diseases, genetic variation, and cultural practices.

### Midupper Arm Circumference (MUAC)

MUAC is measured in adults and children, to the nearest 0.1 cm, using a flexible nonstretch tape laid at the midpoint between the acromion and olecranon processes on the shoulder blade and the ulna, respectively, of the arm (**Figure 2**). MUAC is a measure of the sum of the muscle and subcutaneous fat in the upper arm. In severe malnutrition both fat and muscle are reduced in the upper arm. Edema may increase a limb's circumference but it is not usually a problem of the upper arm. MUAC can be used as an indicator of body composition in adults and children. Since MUAC increases little between the age of 6 months and 5 years, it can be used in preschool children as an age-independent screening tool for severe malnutrition. An MUAC less than 12.5 cm suggests malnutrition; an MUAC greater than 13.5 cm is normal.

### Skinfold Thickness

Precision skinfold thickness callipers are used to measure the double fold of skin and subcutaneous fat to the nearest millimeter. The usual sites of measurement are at the triceps (TSFT), the midpoint of the back of the upper arm (**Figure 3**); the biceps (BSFT) at the same level as the TSFT but to the front of the upper left arm; the subscapular (SSFT) just below and laterally to the left shoulder blade (**Figure 4**), and the suprailiac (SISFT) obliquely just above the left iliac crest. Skinfold thicknesses can also be measured at the mid-thigh, midcalf, and abdomen.

**Figure 2** Measurement of upper arm circumference at the midpoint of the upper arm. Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.

Skinfold thicknesses are difficult measurements to make with precision and accuracy without rigorous training. It is difficult to pick up a consistent fold of skin and subcutaneous fat; in the very obese, the skinfold may be bigger than the callipers can measure; the fold of skin and fat compresses with repeated measurements; and the careless use of the callipers causes pain, bruising, and skin damage to subjects. There is, therefore, likely to be considerable inter- and intraobserver error in the measurements.

Skinfold thicknesses measure subcutaneous body fat and, therefore, indicate body composition. TSFT and SSFT indicate subcutaneous fat on the limbs and body trunk, respectively. Skinfold thickness measurements mistakenly assume that subcutaneous fat, measured at one or more selected sites, measures total body fat stores. However, subcutaneous fat at one site may not reflect fat stores at another site, and may not be positively correlated with the amount of visceral fat deposited around the internal organs of the body. Subcutaneous fat, and therefore skinfold thicknesses at the different sites, changes at varying rates with age, weight change, with diseases such as diabetes, and in women during pregnancy, postpartum, and at the menopause. Skinfold thicknesses are not useful for monitoring short-term change in fat stores. If only one skinfold thickness measurement is made, TSFT is most commonly selected. TSFT correlates with estimates of total body fat in women and children. SSFT is better than TSFT as an indicator of total body fat in men. SSFT has been shown to be a predictor of blood pressure in adults independently of age and racial group.

### Waist and Hip Circumferences

Waist and hip circumferences are measured to the nearest 0.1 cm using a flexible narrow nonstretch tape in adults wearing minimal clothing, standing straight but not pulling in their stomach. Waist circumference is measured halfway between the lower ribs and the iliac crest, whereas hip circumference is measured at the largest circumference around the buttocks. Measurement error occurs if the tape is pulled too tight or loose, or if subjects wear clothes with belts or full pockets.

With increase in waist circumference there is a decrease in insulin sensitivity, and an increase risk for cardiovascular disease.

### Elbow Width

Elbow width is the width of the epicondyles of the humerus with the elbow flexed at 90°. Sliding callipers are used to measure elbow width in adults to the nearest 0.1 cm. Elbow width is a measure of bone size. Frame size can be determined by comparison with reference values either by age or by height and sex.

### Nutritional Indices

Most single anthropometric measurements do not in themselves assess nutritional status. Nutritional indices are derived either by combining two or more anthropometric measurements, shown in laboratory studies to be predictive of body composition, or by

**Figure 3** Measurement of triceps skinfold using a Lange caliper. With the subject's arm in a relaxed position, the skinfold is picked with thumb and index fingers at the midpoint of the arm. Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.

**Figure 4** Measurement of subscapular skinfold using a Lange caliper. With subject's arm and shoulder relaxed, a horizontal skinfold is picked approximately 1 cm below the tip of the scapula with thumb and index fingers. The caliper is applied 1 cm from fingers. Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.

comparison of the anthropometric measurements with reference values of healthy, well-fed populations. A combination of these methods can also be used.

### Body Mass Index (BMI)

BMI relates weight (kg) with height (m) by a simple calculation to indicate body composition ( $\text{BMI} = \text{weight}/\text{height}^2$ ). It is the most commonly used screening measurement for both obesity and underweight, and to track growth patterns. By consensus, a healthy range of BMI for adults has been defined as the interval between 18.5 and 24.9  $\text{kg m}^{-2}$ . Overweight or 'mild' obesity is defined from 25 to 29.9, obesity from 30 to 39.9, and morbid or severe obesity as  $>40$ . In children, because weight and height change proportions at different stages of growth, a normalized percentile distribution is used, defining the range of desired BMI for age and gender as

between the 5th and 95th percentiles. In most but not all age groups, there is a good correlation between BMI and body fat in the population, but predicting body fat from BMI at an individual level can be misleading.

### **Weight-for-Height**

A deficit of weight relative to height indicates recent (acute) weight loss or undernutrition. Coupled with other rapid assessment methods (such as midarm circumference), a reduced weight-for-height may alert on acute, severe undernutrition requiring prompt response.

### **Weight-for-Age**

Weight-for-age may indicate either acute or chronic weight deficit, and thus cannot be used to discriminate between these two conditions. The most common cause of a reduced weight for age is chronic undernutrition, also called stunting. It is usually accompanied by a reduced height-for-age, resulting in a child who is of small body size for his/her age, but otherwise healthy and with a BMI within the normal range.

### **Growth Velocity**

Growth velocity, or change in weight or height over time, can be used to assess growth in children when compared with reference values by age and sex. Growth rates decline in the first few years of life and then increase with the pubertal growth spurt. Premature and small-for-dates children and those recovering from malnutrition and severe infections tend to have higher growth velocities (catch-up growth). Growth velocities are useful to monitor growth and assess the response to therapy including nutritional supplementation.

### **Head Circumference-for-Age**

Head circumference-for-age by sex is used by pediatricians to identify children up to 2 years of age with severe chronic malnutrition pre- and postpartum and the need for further medical investigations. It is not a good indicator of children's nutritional status.

### **Midupper Arm Circumference-for-Age**

MUAC-for-age indicates body composition (upper arm fat and muscle) in adults and children when used with measurements of weight and height. MUAC measurements are compared with reference values by age and sex. Because the rate of change of arm circumference is slow, it cannot be used to assess growth or monitor the response to therapy.

### **Midupper Arm Circumference-for-Height**

Midupper arm circumference-for-height (the QUAC stick) is a cheap, quick, and age-independent screening tool for children with malnutrition. It is a vertical stick on which are inscribed the 80% and 85% median reference values for MUAC and height, respectively. A child is considered malnourished if the MUAC is less than 80% of the MUAC expected for height.

### **Skinfold Thickness-for-Age**

Measurement of BMI with skinfold thicknesses can identify people who are heavy owing to excess fat or muscle mass. A high BMI and low TSFT and SSFT indicate a large muscle mass; a high BMI and high TSFT and SSFT indicate a high subcutaneous body fat.

### **Midupper Arm Muscle Circumference (MUMAC) and Upper Arm Muscle Area (AMA)**

MUAMC and upper AMA are estimates of upper arm muscle and, therefore, body composition. They can be used as indicators of muscle mass and protein stores. Both MUAMC and AMA are calculated from measurements of MUAC and TSFT on the mistaken assumption that the arm is cylindrical, the subcutaneous fat is equally distributed, the bone atrophies in proportion to muscle wastage in malnutrition, and the cross-sections of neurovascular tissue and bone are small. The formula, with MUAC and TSFT in millimeter, is as follows:  $MUAMC = MUAC - (\pi \times TSFT)$  AMA can be calculated from revised formulae, which take account of errors resulting from the noncircular nature of muscle and the inclusion of nonskeletal muscle with MUAC and TSFT in centimeters. For men:  $AMA = [MUAC - (\pi \times TSFT) / 4\pi]^2 - 10.0$ . For women:  $AMA = [MUAC - (\pi \times TSFT) / 4\pi]^2 - 6.5$ . MUAMC and AMA can be compared with reference values by age and sex. AMA cannot be used to monitor change in muscle stores because of the problems in making this measurement. The ratio of AMA to total body muscle mass changes with age and certain diseases.

### Arm Fat Area (AFA)

AFA can be derived from measurements of MUAC and TSFT. AMA is a better indicator of total body fat but not percentage body fat, than TSFT alone. The formula used to calculate AFA (with MUAC and TSFT in millimeter) is  $AMA = [(TSFT \cdot MUAC / 2) - (\pi \cdot TSFT^2 / 4)]^2$ . AMA can be compared with reference values by age and sex. Theoretically, limb fat area can be calculated for other limbs and the body trunk, but there are no reference values available.

### Waist-to-Hip Ratio (WHR)

The WHR in adults discriminates between those with upper body or intraabdominal obesity (WHR greater than 1 in men and 0.8 in women) and those with lower body or peripheral obesity. Genetics, sex, and age partly determine body fat distribution. A high WHR is associated with an increased risk of premature mortality and morbidity.

## Reference Values

### Adults

Reference values for adults have been historically based on the relationship between body size and mortality risk. Since the early twentieth century, life insurance companies used actuarial tables to adjust premiums based on risk of premature death. This risk curve is J-shaped, and the BMI interval comprising the lowest portion of the curve was subsequently used to identify the desired or healthy BMI range. By consensus that interval was eventually defined as between BMI of 18.5 and 24.9, which is considered healthy or 'normal' BMI for adults. The segment from 25 to 29.9 is sometimes called overweight or mild obesity, from 30 to 39.9 obesity, and above, severe obesity.

There is ongoing debate on the limitations of using BMI to predict adverse health events. While the link of diseases such as type 2 diabetes and dislipidemias with obesity (i.e., high BMI) is well established, it is less clear if this indicator can be used to track risk for a number of other disorders. Furthermore, the risk level-BMI association varies with ethnicity, making difficult to adopt a universal cutoff point, as has been attempted.

### Children

Traditional reference growth charts are descriptive, meaning that they reflect the body size of the population selected as 'reference'. Given the secular trends of 'healthy' populations to increase their body size, reference values derived from recent measurements would yield undesirably high BMIs. Therefore, reference charts, such as the CDC 2000, have used older datasets, collected at a time when excess weight was less prevalent.

The World Health Organization (WHO) released in 2006 the first prescriptive reference charts for children 0–5 years. These charts reflect the growth patterns of children raised on a healthy environment and fed and stimulated according to recommended practices. The WHO subsequently released charts for 5–19 years, following the more traditional descriptive approach but introducing a number of adjustments to optimize use of the chart across countries.

### Key points

- Identify the adipose tissue as an extremely active endocrine organ involved in multiple biological functions
- Distinguish the different types and functions of adipose tissue as well as the diverse distribution characteristics
- Consider the physiological depot- and gender-specific differences of adipose tissue and their derangement in pathophysiological circumstances
- Recognize the implication of dysfunctional excess adiposity in the development of the comorbidities accompanying obesity

### Glossary

**Adipogenesis** Development or formation of fat

**Angiogenesis** Formation of new blood vessels by branching morphogenesis

**Autocrine** A secreted substance which acts on surface receptors of the same cell

**Catecholamines** Any of various amines (e.g., epinephrine, norepinephrine, and dopamine) that contain a dihydroxy benzene ring, are derived from tyrosine and operate as hormones and/or neurotransmitters

**Fatty-acid-binding proteins (FABPs)** Family of carrier proteins for fatty acids and other lipophilic substances such as eicosanoids and retinoids. These proteins are thought to facilitate the transfer of fatty acids between extra- and intra-cellular membranes. Some family members are also believed to transport lipophilic molecules from the plasma membrane to certain intracellular receptors such as PPAR

**Lipogenesis** Normal deposition of fat or the conversion of carbohydrate or protein to fat

**Lipolysis** Triacylglycerol breakdown to yield fatty acids and glycerol

**Paracrine** Mode of hormone action in which a hormone binds to receptors on and affects the function of cells near to the cell that produced it

**Peroxisome proliferator-activated receptors (PPARs)** Group of nuclear receptor proteins that function as transcription factors regulating the expression of genes. PPARs play essential roles in the regulation of cellular differentiation, development, and metabolism (carbohydrate, lipid and protein) of higher organisms

**Pleiotropic** Producing many effects; multiple effects from a single gene; the control by a single gene of several distinct and seemingly unrelated phenotypic effects

### List of Abbreviations

**ALBP/FABP4/aP2** Adipocyte fatty acid binding protein

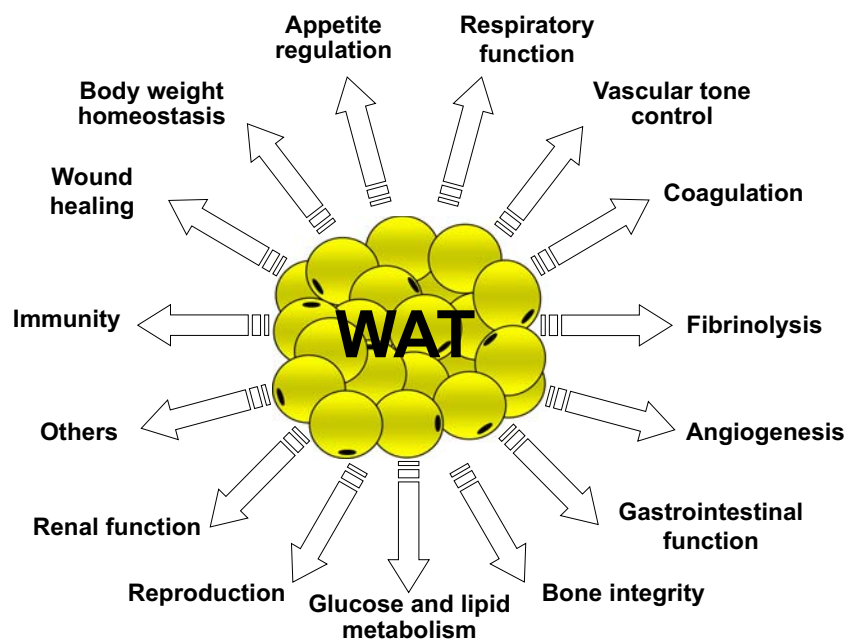

**BAT** Brown adipose tissue

**BMP** Bone morphogenetic protein

C/EBPs CCAAT/enhancer binding proteins

 PRDM16 Positive regulatory domain containing 16  
 Pref-1 Preadipocyte factor-1  
 RBP4 Retinol binding protein-4  
 UCP Uncoupling protein  
 WAT White adipose tissue

## Introduction

The role of white adipose tissue (WAT) in storing and releasing lipids for oxidation by skeletal muscle and other tissues became so firmly established decades ago that a persistent lack of interest hindered the study of the extraordinarily dynamic behavior of adipocytes (Frühbeck et al., 2001; Scherer, 2019). However, disentangling the neuroendocrine systems, which regulate energy homeostasis and adiposity has jumped to a first-priority challenge, with the recognition of obesity as one of the major public health problems. Strictly speaking, obesity is not defined as an excess of body weight but as an increased adipose tissue accretion, to the extent that health may be adversely affected. Therefore, in the last decades, adipose tissue has become the research focus of biomedical scientists for epidemiological, pathophysiological, and molecular reasons (van Baak and Mariman, 2019). Although the primary role of adipocytes is to store triglycerides during periods of caloric excess and to mobilize this reserve when expenditure exceeds intake, it is now widely recognized that adipose tissue lies at the heart of a complex network participating in the regulation of a variety of quite diverse biological functions (Fig. 1).

**Fig. 1** Dynamic view of white adipose tissue based on the pleiotropic effects on quite diverse physiological functions. WAT, white adipose tissue.

## Development

During fetal development WAT emerges at midgestation in humans or postnatally in rodents. Although the evolutionary and developmental features of WAT and brown adipose tissue (BAT) already suggested that they are quite distinct tissues, until recently, white and brown adipocytes were thought to be derived from the same precursor cell (Frühbeck et al., 2009b). Elegant *in vivo* fate mapping experiments in mice have recently provided a clear evidence that brown adipocytes arise from a separate and distinct population of progenitors (Fig. 2).

Brown fat cells are now known to exhibit a “myogenic” signature and share a common mesenchymal origin with skeletal muscle. In brief, mesenchymal stem cells can enter several cell lineages which culminate in the formation of bone, muscle, and adipose tissue, among others. The precursor cells destined to become white adipocytes first differentiate into adipoblasts and then preadipocytes through carefully-timed exposure to key regulators. Two members of the family of bone morphogenetic proteins (BMP), specifically BMP2 and BMP4, as well as PPAR $\gamma$  and C/EBPs are pivotal to drive these different phases. *Myf5*-expressing precursors give rise to skeletal muscle and brown adipose tissue, but not white adipose tissue (Fig. 2). BMP7 singularly drives the brown fat cell fate in both mesenchymal progenitor cells and committed brown preadipocytes suppressing early adipogenic inhibitors, such as *neclin*, *Pref-1*, and *WNTs*, at the same time inducing the key molecular determinant positive regulatory domain containing 16 (PRDM16) that triggers the activation of the complete brown adipogenesis program and blocks the induction of myotube-specific genes such as *Myf5*, *MyoD* and *myogenin*. PRDM16 binds and coactivates PPAR $\gamma$  with subsequent induction of key features to specify a brown fat fate, i.e., increased mitochondrial biogenesis and expression of UCP1, among others.

Pericytes, the cells that surround the endothelium tubes of the microvasculature, have been also identified as progenitor cells that become committed to the white adipocyte lineage either prenatally or in the early postnatal period. Adipose tissue has long been

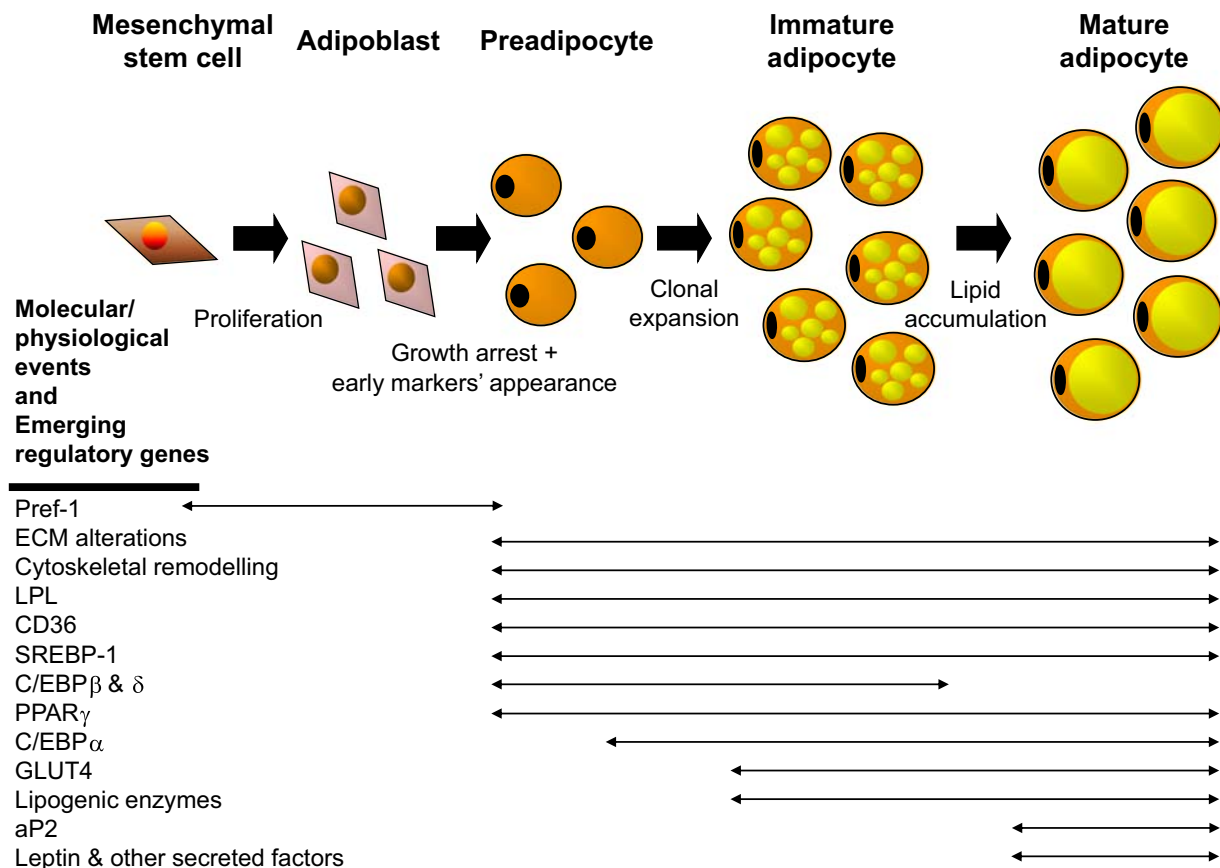

**Fig. 2** Schematic diagram of the histogenesis of white and brown adipocytes. BMP, bone morphogenetic protein; C/EBPs, CCAAT/enhancer binding proteins; PGC-1 $\alpha$ , peroxisome proliferator-activated receptor- $\gamma$  coactivator-1 $\alpha$ ; PPAR, peroxisome proliferator-activated receptor; PRDM16, positive regulatory domain containing 16; UCP1, uncoupling protein 1.

recognized to expand in conjunction with its vasculature, but these new findings suggest that the blood vessels may actively direct the process (Bouloumie et al., 2002; Tang et al., 2008; Yang et al., 2013; Crewe et al., 2017). Thus, as well as serving as a progenitor niche, blood vessels may also produce signals for adipocyte development.

The determination phase results in the conversion of the stem cell to a preadipocyte, which still shares some morphological features with its precursor cell but has lost the potential to differentiate into other cell types (Fig. 3). In the subsequent phases of terminal differentiation, the committed preadipocyte takes on the characteristics of the white mature adipocyte by acquiring all the machinery needed for lipid transport, synthesis, and mobilization, hormonal responsiveness and the secretion of adipocyte-specific proteins. The morphological and functional changes that take place in the course of adipogenesis represent a shift in transcription factor expression and activity leading from a primitive, multipotent state to a final phenotype characterized by alterations in cell shape and lipid accumulation (Ghaben and Scherer, 2019). Various redundant signaling pathways and transcription factors directly influence fat cell development by converging the upregulation of PPAR $\gamma$ , which embodies a common and essential regulator of adipogenesis as well as of adipocyte hypertrophy. Among the broad panoply of transcription factors C/EBPs and the basic helix–loop–helix family (ADD1/SREBP-1c, adipocyte determination and differentiation factor-1/sterol regulatory element binding protein-1c) also stand out together with their link with the existing nutritional status. The transcriptional repression of adipogenesis includes both active and passive mechanisms. The former directly interferes with the transcriptional machinery, whereas the latter is based on the binding of negative regulators to yield inactive forms of known activators.

Adipose tissue develops extensively in homeotherms with the proportion to body weight varying greatly between species. There are two processes of adipose tissue formation. In the primary fat formation, which takes place relatively early (in human fetuses the first traces of a fat organ are detectable between 14 and 16 weeks of prenatal life), gland-like aggregations of epitheloid precursor cells, called lipoblasts or preadipocytes are laid down in specific locations and accumulate multiple lipid droplets. The secondary fat formation takes place later in fetal life (after the 23rd week of gestation) as well as in the early postnatal period, whereby the differentiation of other fusiform precursor cells that accumulate lipid to ultimately coalesce into a single large drop per cell leads to the dissemination of fat depots formed by unilocular white adipocytes in many areas of connective tissue. Adipose tissue may be

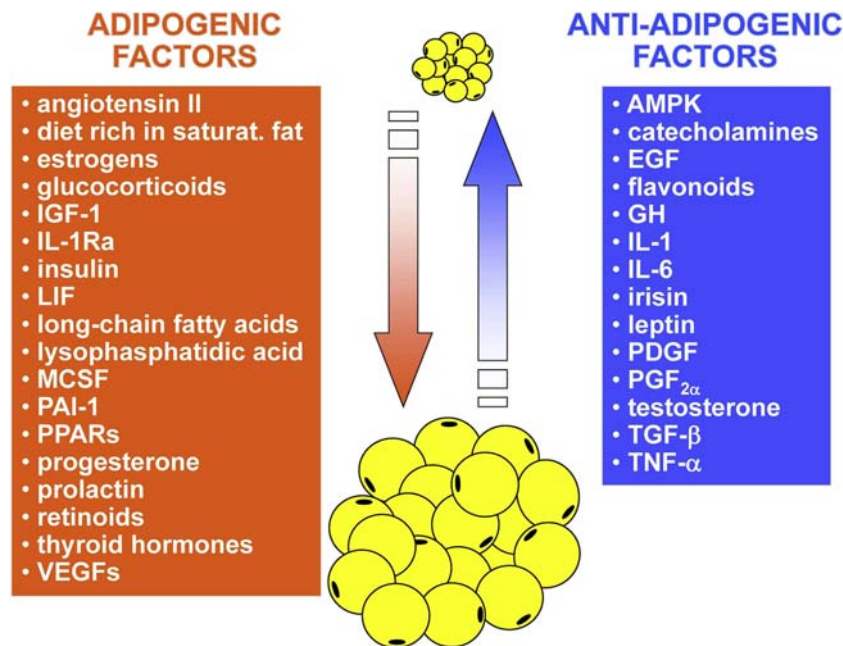

**Fig. 3** Multistep process of adipogenesis together with events and participating regulatory elements. aP2, adipocyte fatty acid binding protein; CD36, fatty acid translocase; C/EBPs, CCAAT/enhancer binding proteins; ECM, extracellular matrix; GLUT4, glucose transporter type 4; LPL, lipoprotein lipase; PPAR, peroxisome proliferator-activated receptor; SREBP-1, sterol regulatory element binding protein-1.

partitioned by connective tissue septa into lobules. The number of fat lobules remains constant, whereas in the subsequent developmental phases the lobules' size grows continuously. At the sites of early fat development, a multilobular morphology of adipocytes predominates, reflecting the early developmental stage. Microscopic studies have shown that the second trimester may be a critical period for the development of obesity in later life. At the beginning of the third trimester, adipocytes are present in the main fat depots but are still relatively small. During embryonic development it is important to emphasize the temporo-spatial tight coordination of angiogenesis with the formation of fat cell clusters. At birth, body fat has been reported to account approximately for 16% of total body weight (with brown fat constituting 2–5%) with an increase in body fat from approximately 0.7 to 2.8 kg during the 1st year of life.

Adipogenesis, i.e., the development of adipose tissue, varies according to sex and age (Wajchenberg, 2000; Karastergiou et al., 2013; Sanchez-Gurmaches and Guertin, 2014). Two sensitive periods for changes in adipose tissue cellularity with peaks of accelerated adipose mass enlargement have been established, namely after birth and from 9 to 13 years. The capacity for cell proliferation and differentiation is highest during the 1st year of life, whereas it is less pronounced in the years before puberty. Childhood-onset obesity is characterized by a combination of fat cell hyperplasia and hypertrophy, whereas in adult-onset obesity a hypertrophic growth predominates. Initially, excess energy storage starts as hypertrophic obesity, resulting from the accumulation of excess lipid in a normal number of unilocular adipose cells (Jo et al., 2009). In this case, adipocytes may be four times their normal size. If the positive energy balance is maintained, a hyperplastic or hypercellular obesity characterized by a greater than normal number of cells is developed. It has been recently shown that adult humans are capable of new adipocyte formation with samples containing a significant proportion of cells with the ability of undergoing differentiation. Multipotent stem cells and adipoblasts, which are found during embryonic development, are still present postnatally.

Hormones, cytokines, growth factors, and nutrients influence the dynamic changes related to adipose tissue mass as well as its pattern of distribution (Fig. 4). The responsiveness of fat cells to neurohumoral signals may vary according to peculiarities in the adipose lineage stage at the moment of exposure. Moreover, the simultaneous presence at specific threshold concentrations of some adipogenic factors may be a necessary requirement to trigger terminal differentiation.

By measuring the relative abundance of  $^{14}\text{C}$  in genomic DNA from adipocytes it has been recently clarified that in individuals approximately 10% of adipocytes experience apoptosis, whereas a comparable proportion are renewed, each year. Thus, WAT turns out to be a more dynamic tissue than was previously assumed. These findings are consistent across a wide range of body mass index (BMI), including subjects with early-onset obesity, and following weight loss. The adipocyte number has been shown to be a major determinant of fat mass in the adult; the number of adipocytes in both people with normal weight and obesity appears to be set during childhood. However, it remains possible that the common scenario of gradual but significant weight gain throughout adult life may be underpinned by an initial increase in triacylglycerol loading until an adipocyte size threshold is reached, when additional new adipocytes are recruited from committed precursor cells or mesenchymal stem cells.

## Structure

Adipose tissue is a special loose connective tissue dominated by adipocytes. The name of these cells is based on the cell's content of a large lipid droplet with "adipo" being a combining form derived from the Latin *adeps* meaning "pertaining to fat." In adipose tissue, fat cells are individually held in place by delicate reticular fibers clustering in lobular masses bounded by fibrous septa surrounded by a rich capillary network. In adults adipocytes may comprise approximately 90% of adipose mass accounting only for roughly 25% of the total cell population. Thus, adipose tissue itself is composed of not only adipocytes, but also by other cell types, termed as the stroma-vascular fraction, comprising blood cells, endothelial cells, pericytes as well as adipose precursor cells among others (Fig. 5), which account for the remaining 75% of the total cell population, representing a wide range of targets for an extensive autocrine–paracrine cross-talk.

Adipocytes, which are typically spherical and vary enormously in size (20–200  $\mu\text{m}$  in diameter, with variable volumes ranging from a few picoliters to approximately 3 nL), are embedded in a connective tissue matrix and are uniquely adapted to store and release energy (Smorlesi et al., 2012). Surplus energy is assimilated by adipocytes and stored as lipid droplets. The stored fat is composed of mainly triacylglycerols (approximately 95% of the total lipid content comprised principally by oleic and palmitic acids) and to a smaller degree diacylglycerols, phospholipids, unesterified fatty acids, and cholesterol (Frühbeck et al., 2014). To accommodate the lipids adipocytes are capable of changing their diameter 20-fold and their volumes by several thousand-fold. However, the increase in size of fat cells is not indefinite. Once a maximum capacity is attained, which in humans averages 1000 pL, the formation of new adipocytes from the precursor pool takes place. The interior of adipocytes appears unstained since the histological techniques of standard tissue preparation dissolve the lipids, leaving a thin rim of eosinophilic cytoplasm that typically loses its round shape during tissue processing, thus contributing to the sponge-like appearance of WAT in routine preparations for light microscopy (Figs. 6 and 7). Owing to the fact that approximately 90% of the cell volume is a lipid droplet, the small dark nucleus becomes a flattened semilunar structure pushed against the edge of the cell and the thin cytoplasmic rim is also pushed to the periphery of the adipocytes. Mature white adipose cells contain a single large lipid droplet and are described as unilocular. However, developing white adipocytes are transiently multilocular containing multiple lipid droplets before these finally coalesce into a single large drop (Fig. 8). The nucleus is round or oval in young fat cells, but is cup-shaped and peripherally displaced in mature adipocytes. The cytoplasm is stretched to form a thin sheath around the fat globule, although a relatively large volume is concentrated around the nucleus. A thin external lamina called basal lamina surrounds the cell. The smooth cell membrane shows no microvilli but has abundant smooth micropinocytotic invaginations that often fuse to form small vacuoles appearing as rosette-like configurations (Fig. 9). Mitochondria are few in number with loosely arranged membranous cristae. The Golgi zone is small and the cytoplasm is filled with free ribosomes, but contains only a limited number of short profiles of the granular endoplasmic reticulum. Occasional lysosomes can also be found. The coalescent lipid droplets contain a mixture of neutral fats, triglycerides, fatty acids, phospholipids, and cholesterol. A thin interface membrane separates the lipid droplet from the cytoplasmic matrix.

Peripheral to this membrane is a system of parallel meridional thin filaments. Because of the size of these cells, relative to the thickness of the section, the nucleus (accounting for only one-fortieth of the cell volume) may not always be present in the section. Unilocular adipocytes usually appear in clumps near blood vessels, which is reasonable because the source and dispersion of material stored in fat cells depends on transportation by the vascular system.

Brown fat is a specialized type of adipose tissue that plays an important role in body temperature regulation ([Frühbeck et al., 2009a](#)). It is present in significant amounts in rodents and hibernating animals. In the newborn brown fat is well developed in the neck and interscapular region. Until recently, it was generally accepted that BAT involutes steadily during the first few months, with clearly recognizable depots having essentially disappeared within the 1st years after birth. In normal adults, only occasional brown adipocytes were thought to be scattered through white fat masses. However, recent findings using positron emission tomography (PET) with fluorodeoxyglucose (a marker of metabolic activity) have shown in adults symmetrical areas of increased tracer

**Fig. 9** (A) Transmission electron micrographs with the characteristically displaced nucleus to one side and slightly flattened by the accumulated lipid. The cytoplasm of the fat cell is reduced to a thin rim around the lipid droplet (7725 $\times$ ). (B) The cytoplasm contains several small lipid droplets that have not yet coalesced. A few filamentous mitochondria, occasional cisternae of endoplasmic reticulum and a moderate number of free ribosomes are usually visible (15,000 $\times$ ). uptake in the upper parts of the body, broadly corresponding to the distribution of BAT in lower mammals and in human neonates. The main BAT depots in adults are found in the supraclavicular region and neck, with additional activity in the paravertebral, mediastinal, para-aortic, and suprarenal areas. The activity of this BAT can be acutely enhanced by cold exposure and stimulated by the sympathetic nervous system (Frühbeck et al., 2014).

The brown color of BAT is derived from a rich vascular network and abundant mitochondria and lysosomes. The individual multilocular adipocytes are frothy-appearing cells due to the fact that the lipid, which does not coalesce as readily as in white fat cells, is normally stored in multiple small droplets, has been leached out during tissue processing (Fig. 10). The spherical nuclei are centrally or eccentrically located within the cell. Compared to the unilocular white adipocytes, the cytoplasm of the multilocular brown fat cell is relatively abundant and strongly stained because of the numerous mitochondria present. The mitochondria are involved in the oxidation of the stored lipid, but because they exhibit a reduced potential to carry out oxidative phosphorylation, the energy produced is released in the form of heat due to the uncoupling activity of UCP and not captured in adenosine triphosphate (ATP). Therefore, brown adipose tissue is extremely well vascularized so that the blood is warmed when it passes through the active tissue.

## Distribution

WAT may represent the largest endocrine tissue of the whole organism especially in people with overweight and obesity (Ahima and Flier, 2000). The anatomical distribution of individual fat pads dispersed throughout the whole body and not connected to each other collides with a classic organ-specific localization. WAT exhibits clear, regional differences in its sites of predilection (Table 1). The hypodermal region invariably contains fat, except in a few places such as the eyelids and the scrotum. Adipocytes also accumulate around organs like kidneys and adrenals, in the coronary sulcus of the heart, in bone marrow, mesentery, and omentum. Unilocular fat is widely distributed in the subcutaneous tissue of humans but exhibits quantitative regional differences that are influenced by age and sex. In infants and young children there is a continuous subcutaneous fat layer—the panniculus adiposus, over the whole body. This layer thins out in some areas in adults but persists and grows thicker in certain other regions. The sites

differ in their distribution among sexes being responsible for the characteristic body form of males and females, termed android and gynecoid fat distribution. In males, the main regions include the nape of the neck, the subcutaneous area over the deltoid and triceps muscles, and the lumbosacral region. In females, subcutaneous fat is most abundant in the buttocks, epitrochanteric region, anterior and lateral aspects of the thighs as well as the breasts. Additionally, extensive fat depots are found in the omentum, mesenteries, and the retroperitoneal area of both sexes. In well-nourished, sedentary individuals, the fat distribution persists and becomes more obvious with advancing age with males tending to deposit more fat in the visceral compartment. Depot-specific differences may be related not only to the metabolism of fat cells but also to their capacity to form new adipocytes. Additionally, regional differences may result from variations in hormone receptor distribution as well as from specific local environmental characteristics as a consequence of differences in innervation and vascularization.

Regional distribution of body fat is known to be an important indicator for metabolic and cardiovascular alterations in some individuals (Hamdy et al., 2006; Goossens, 2017). The observation that the topographic distribution of adipose tissue is relevant to understanding the relation of obesity to disturbances in glucose and lipid metabolism was formulated before the 1950s. Since then numerous prospective studies have revealed that android or male-type obesity correlates more often with an elevated mortality and risk for the development of type 2 diabetes mellitus, dyslipidemia, hypertension, and atherosclerosis than gynoid or female-type obesity. Obesity has been reported to cause or exacerbate a large number of health problems with a known impact on both life expectancy and quality of life. In this respect, the association of increased adiposity is accompanied by important pathophysiological alterations, which lead to the development of a wide range of co-morbidities (Fig. 11).

## Function

Although many cell types contain small reserves of carbohydrate and lipid, the adipose tissue is the body's most capacious energy reservoir. Because of the high energy content per unit weight of fat as well as due to its hydrophobicity, the storage of energy in the form of triglycerides is a highly efficient biochemical phenomenon (1 g of adipose tissue contains approximately 800 mg triacylglycerol and only approximately 100 mg of water). It represents quantitatively the most variable component of the organism,

**Fig. 11** Main comorbidities associated with increased adiposity. NAFLD, non-alcoholic fatty liver disease; MAFLD, metabolic-associated fatty liver disease.

varying from a few percent of body weight in elite athletes to more than half of the total body weight in people with severe obesity. The normal range is approximately 10–20% body fat for males and approximately 20–30% for females, accounting approximately for an energy reserve of 25–50 days in men and 40–60 days in women. During pregnancy most species accrue additional reserves and functionality of adipose tissue to help support the development of the fetus and to further facilitate the lactation period, which is identified as “pink fat” (Table 1).

Energy balance regulation is an extremely complex process composed of multiple interacting homeostatic and behavioral pathways aimed at maintaining constant energy stores. It is now evident that body weight control is achieved through highly orchestrated interactions between nutrient selection, organoleptic influences, and neuro-endocrine responses to diet as well as being influenced by genetic and environmental factors. The concept that circulating signals generated in proportion to body fat stores influence appetite and energy expenditure in a coordinated manner to regulate body weight was proposed almost 70 years ago. According to this model, changes in energy balance sufficient to alter body fat stores were signaled via one or more circulating factors acting in the brain to elicit compensatory changes in order to match energy intake to energy expenditure. This was formulated as the “lipostatic theory” assuming that as adipose tissue mass enlarges, a factor that acts as a sensing hormone or “lipostat” in a negative feedback control from adipose tissue to hypothalamic receptors informs the brain about the abundance of body fat, thereby allowing feeding behavior, metabolism, and endocrine physiology to be coupled to the nutritional state of the organism. The existing body of evidence gathered in the last decades through targeted expression or knockout of specific genes involved in different steps of the pathways controlling food intake, body weight, adiposity, or fat distribution has clearly contributed to unraveling the underlying mechanisms of energy homeostasis. The findings have fostered the notion of a far more complex system than initially thought, involving the integration of a plethora of factors.

The identification of adipose tissue as a multifunctional organ as opposed to a passive organ for the storage of excess energy in the form of fat has been brought about by the emerging body of evidence gathered during the last decades. This pleiotropic nature is based on the ability of fat cells to secrete a large number of hormones, growth factors, enzymes, cytokines, complement factors, and matrix proteins, collectively termed as adipokines or adipocytokines (Table 2, Fig. 12), at the same time as expressing receptors for most of these factors (Table 3), which warrants an extensive cross-talk at a local and systemic level in response to specific external stimuli or metabolic changes (Rodríguez et al., 2015). The vast majority of adipocyte-derived factors have been shown to be dysregulated in alterations accompanied by changes in adipose tissue mass such as overfeeding and lipodystrophy, thus providing evidence for their involvement in the etiopathology and co-morbidities associated with obesity and cachexia.

WAT is actively involved in cell function regulation through a complex network of endocrine, paracrine, and autocrine signals, which influence the response of many tissues, including the hypothalamus, pancreas, liver, skeletal muscle, kidneys, endothelium, and immune system. Adipose tissue serves the functions of being a store for energy reserve, insulation against heat loss through the skin, and a protective padding of certain organs. A rapid turnover of stored fat can take place, and with only a few exceptions (orbit, major joints as well as palm, and foot sole), the adipose tissue can be used up almost completely during starvation. Adipocytes are uniquely equipped to participate in the regulation of other functions such as reproduction, immune response, blood pressure control, coagulation, fibrinolysis, and angiogenesis. The advent of microarray technology has dramatically changed the study of the pattern of gene expression by enabling the simultaneous analysis of thousands of genes in a single experiment. Interestingly, the high number and ample spectrum of genes found to be expressed in WAT together with the changes observed in samples from obese patients substantiates the view of an extraordinarily active and plastic tissue (Sun et al., 2011). The complex and

**Table 2** Relevant factors secreted by adipose tissue to the bloodstream.

<i>Molecule</i>	<i>Function/effect</i>
Adiponectin/ACRP30/AdipoQ	Plays a protective role in the pathogenesis of type 2 diabetes and cardiovascular diseases
Adipsin	Possible link between the complement pathway and adipose tissue metabolism
Angiotensinogen	Precursor of angiotensin II; regulator of blood pressure and electrolyte homeostasis
ASP	Influences the rate of triacylglycerol synthesis in adipose tissue
Chemerin	Regulates adipocyte differentiation and glucose uptake. It is potentially involved in the inflammatory response
FFA	Oxidized in tissues to produce local energy. Serve as a substrate for triglyceride and structural molecules synthesis. Involved in the development of insulin resistance
Glycerol	Structural component of the major classes of biological lipids and gluconeogenic precursor
IGF-I	Stimulates proliferation of a wide variety of cells and mediates many of the effects of growth hormone
IL-6	Implicated in host defense, glucose and lipid metabolism and regulation of body weight
Leptin	Signals to the brain about body fat stores. Regulation of appetite and energy expenditure. Wide variety of physiological functions
NO	Important regulator of vascular tone. Pleiotropic involvement in pathophysiological conditions
Omentin	Enhances insulin-stimulated glucose uptake
PAI-1	Potent inhibitor of the fibrinolytic system
PGI <sub>2</sub> & PGF <sub>2α</sub>	Implicated in regulatory functions such as inflammation and blood clotting, ovulation, menstruation and acid secretion
Resistin	Putative role in insulin resistance. Participates in inflammation
SAA	Acute phase protein involved in inflammation and HDL metabolism
TNF-α	Interferes with insulin receptor signaling and is a possible cause of insulin resistance in obesity
Vaspin	Exhibits insulin-sensitizing effects
VEGFs	Stimulation of angiogenesis
Visfatin/PBEF/NAMPT	Catalyzes the biosynthesis of nicotinamide adenine dinucleotide. Regulates vascular smooth muscle and immune cells function. Potentially involved in the regulation of insulin sensitivity

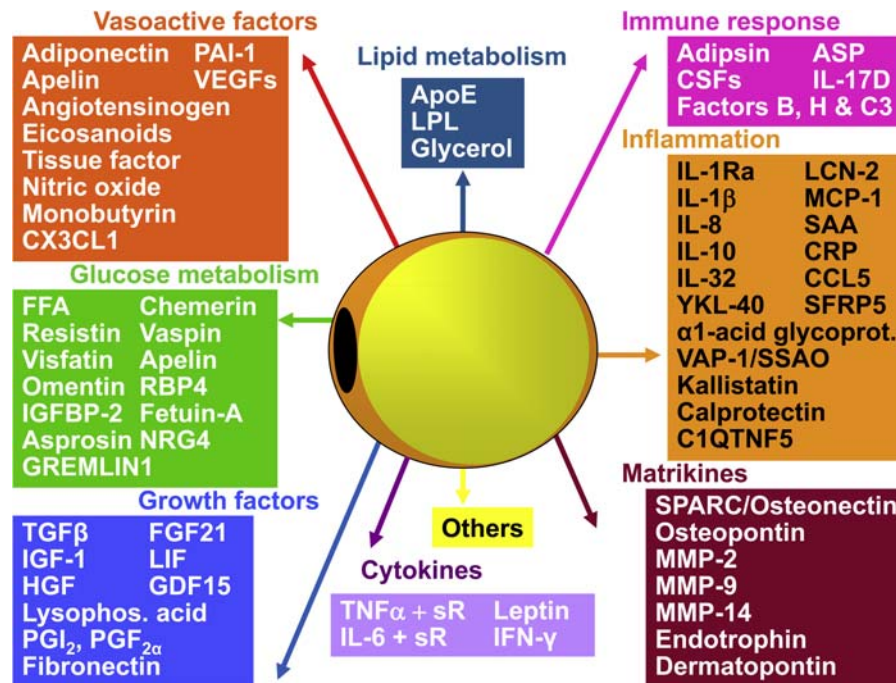

complementary nature of the expression profile observed in obese adipose tissue reflects a pleiad of adaptive changes affecting crucial physiological functions that may need to be further explored through genomic and proteomic approaches (Scherer, 2019).

The endocrine activity of WAT was postulated almost 40 years ago alluding to the tissue's ability for steroid hormone interconversion. In recent years, especially since the discovery of leptin, the list of adipocyte-derived factors has been increasing at a phenomenal pace (Galic et al., 2010). Another way of addressing the production of adipose-derived factors is by focusing on the functions in which they are implicated (Fig. 12). One of the best known aspects of WAT physiology relates to the synthesis of products involved in lipid metabolism such as perilipin, fatty acid-binding protein 4 (ALBP, FABP4 or aP2), CETP, and retinol binding protein (RBP). Adipose tissue has been also identified as a source of production of factors with immunological properties participating in immunity and stress responses as is the case of ASP and metallothionein. More recently, the pivotal role of adipocyte-derived factors implicated in cardiovascular function control such as angiotensinogen, adiponectin, peroxisome proliferator-activated receptor  $\gamma$  angiopoietin related protein/fasting-induced adipose factor (PGAR/FIAF), and C-reactive protein (CRP) has been established. A further subsection of proteins produced by adipose tissue concerns other factors with an autocrine–paracrine function like PPAR $\gamma$ , IGF-1, monobutyrin, and the UCPs.

BAT is specialized for heat production; its lipid stores turn over rapidly, and the liberated fatty acids are oxidized by the brown adipocyte's mitochondria in a process that generates heat directly. In neonatal mammals, hibernators, and rodents, a crucial function of BAT is the maintenance of body temperature through cold-induced thermogenesis. In addition, BAT thermogenesis is activated during overeating—an important aspect of diet-induced thermogenesis. In humans, as is the case in other larger mammals, the functional capacity of brown adipose tissue decreases because of the relatively higher ratio between heat production from basal metabolism and the smaller surface area encountered in adults. In addition, clothing and indoor life have reduced the need for adaptive nonshivering thermogenesis. However, it has been recently shown that human WAT can be infiltrated with brown adipocytes expressing UCP-1. The prevalence of active BAT in normal adults can be only estimated indirectly, but is thought to be present in approximately 10% of the general population. BAT, therefore, has the potential to play a role in normal energy balance and could become a pharmacological target for new drugs to treat obesity (Frühbeck et al., 2009a).

## Regulation of metabolism

The control of fat storage and mobilization has been marked by the identification of a number of regulatory mechanisms in the last decades. Isotopic tracer studies have clearly shown that lipids are continuously being mobilized and renewed even in individuals in energy balance. Fatty acid esterification and triglyceride hydrolysis take place continuously. The half-life of depot lipids in rodents is

**Fig. 12** Factors secreted by white adipose tissue, which underlie the multifunctional nature of this endocrine organ. Although owing to their pleiotropic effects some of the elements might play more than one physiological role, they have been included only under one function for clarity of the figure. ApoE, apolipoprotein E; ASP, acylation-stimulating protein; C1QTNF5, C1q and TNF related 5; CCL5, C-C motif chemokine ligand 5; CHI3L1 (YKL-40), chitinase-3-like protein 1; CSF, colony-stimulating factor; CX3CL, C-X3-C motif chemokine ligand 1; FGF21, fibroblast growth factor 21; GDF15, growth differentiation factor 15; GREMLIN1, GREM1, DAN family BMP antagonist, HGF, hepatocyte growth factor; IGF-1, insulin-like growth factor-1; IGFBP-2, insulin-like growth factor binding protein-2; IL-1, interleukin-1; IL-1 $\beta$ , interleukin-1  $\beta$ ; IL-6, interleukin-6; IL-8, interleukin-8; IL-10, interleukin-10; IL-17, interleukin-17; IL-1Ra, interleukin-1 receptor antagonist; IFN- $\gamma$ , interferon- $\gamma$ ; LCN-2, lipocalin-2; LIF, leukemia inhibitory factor; LPL, lipoprotein lipase; MCP-1, monocyte chemoattractant protein-1; MMP-2, matrix metalloproteinase-2; MMP-9, matrix metalloproteinase-9; NRG4, Neuregulin 4; PAI-1, plasminogen activator inhibitor-1; PGF<sub>2 $\alpha$</sub> , prostaglandin F<sub>2 $\alpha$</sub> ; PGI<sub>2</sub>, prostacyclin; RBP4, retinol binding protein-4; SAA, serum amyloid A; SFRP5, secreted frizzled related protein 5; SPARC, secreted protein acidic and cysteine rich; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; VAP-1/SSAO, vascular adhesion protein-1/semicarbazide-sensitive amine oxidase; VEGF, vascular endothelial growth factor.

approximately 8 days, meaning that almost 10% of the fatty acid stored in adipose tissue is replaced daily by new fatty acids. The balance between lipid loss and accretion determines the net outcome on energy homeostasis.

The synthesis of triglycerides, also termed lipogenesis, requires the supply of fatty acids and glycerol. The main sources of fatty acids are the liver and the small intestine. Fatty acids are esterified with glycerol phosphate in the liver to produce triglycerides. Since triglycerides are bulky polar molecules that do not cross cell membranes well, they must be hydrolyzed to fatty acids and glycerol before entering fat cells. Serum very low-density lipoproteins (VLDLs) are the major form in which triacylglycerols are carried from the liver to WAT. Short-chain fatty acids (16 carbons or less) can be absorbed from the gastrointestinal tract and carried in chylomicra directly to the adipocyte. Inside fat cells glycerol is mainly synthesized from glucose. In WAT fatty acids can be synthesized from several precursors, such as glucose, lactate, and certain amino acids, with glucose being quantitatively the most important in humans. In the case of glucose, GLUT4, the principal glucose transporter of adipocytes, controls the entry of the substrate into the adipocyte. Insulin is known to stimulate glucose transport by promoting GLUT4 recruitment as well as increasing its activity. Inside the adipocyte, glucose is initially phosphorylated and then metabolized both in the cytosol and in the mitochondria, to produce cytosolic acetyl-CoA with the flux being influenced by phosphofructokinase and pyruvate dehydrogenase. Glycerol does not readily enter the adipocyte, but the membrane-permeable fatty acids do. Once inside the fat cells, fatty acids are re-esterified with glycerol phosphate to yield triglycerides. Lipogenesis is favored by insulin, which activates pyruvate kinase, pyruvate dehydrogenase, acetyl-CoA carboxylase, and glycerol phosphate acyltransferase. When excess nutrients are available insulin decreases acetyl-CoA entry into the tricarboxylic acid cycle while directing it toward fat synthesis. This insulin effect is antagonized by growth hormone. The gut hormones glucagon-like peptide 1 and gastric inhibitory peptide also increase fatty acid synthesis, whereas glucagon and catecholamines inactivate acetyl-CoA carboxylase, thus decreasing the rate of fatty acid synthesis.

The release of glycerol and free fatty acids by lipolysis plays a critical role in the ability of the organism to provide energy from triglyceride stores (Frühbeck et al., 2014). In this sense, the processes of lipolysis and lipogenesis are crucial for the attainment of body weight control. For this purpose adipocytes are equipped with a well developed enzymatic machinery, together with a number of non-secreted proteins and binding factors directly involved in the regulation of lipid metabolism. The hydrolysis of triglycerides

**Table 3** Main receptors expressed by adipose tissue.

<i>Receptor</i>	<i>Main effect of receptor activation on adipocyte metabolism</i>
<b>Hormone-cytokine receptors</b>	
Adenosine	Inhibition of lipolysis
Adiponectin (AdipoR1 and AdipoR2)	Regulation of insulin sensitivity and fatty acid oxidation
Angiotensin II	Increase of lipogenesis. Stimulation of prostacyclin production by mature fat cells. Interaction with insulin in regulation of adipocyte metabolism
Chemerin	Regulation of adipocyte differentiation and glucose uptake. Potential role in inflammatory response
GH	Induction of leptin and IGF-I expression. Stimulation of lipolysis
Ghrelin	Stimulation of adipogenesis and lipogenesis. Induction of glucose uptake
IGF-I and -II	Inhibition of lipolysis. Stimulation of glucose transport and oxidation
IL-6	LPL activity inhibition. Induction of lipolysis
Insulin	Inhibition of lipolysis and stimulation of lipogenesis. Induction of glucose uptake and oxidation. Stimulation of leptin expression
Leptin (OB-R)	Stimulation of lipolysis. Autocrine regulation of leptin expression
NPY-Y1 and Y5	Inhibition of lipolysis. Induction of leptin expression
PDGF (PDGFR $\alpha$ and PDGFR $\beta$ )	Control the differentiation balance of adipocytes and stromal cells. Involved in the regulation of fibrosis
Prostaglandin	Strong antilipolytic effects (PGE <sub>2</sub> ). Modulation of preadipocyte differentiation (PGF <sub>2<math>\alpha</math></sub> and PGI <sub>2</sub> )

<b>Nuclear receptors</b>	
Androgen	Control of adipose tissue development (antiadipogenic signals). Modulation of leptin expression
Estrogen	Control of adipose tissue development (proadipogenic signals). Modulation of leptin expression
Glucocorticoids	Stimulation of adipocyte differentiation
PPAR $\delta$	Regulation of fat metabolism. Plays a central role in fatty acid-controlled differentiation of preadipose cells
PPAR $\gamma$	Induction of adipocyte differentiation and insulin sensitivity
RAR/RXR	Regulation of adipocyte differentiation
T <sub>3</sub>	Stimulation of lipolysis. Regulation of leptin secretion. Induction of adipocyte differentiation. Regulation of insulin effects
<b>Lipoprotein receptors</b>	
HDL	Clearance and metabolism of HDL
LDL	Stimulation of cholesterol uptake
VLDL	Binding and internalization of VLDL particles. Involvement in lipid accumulation

ACRP30, adipocyte complement-related protein of 30 kDa; ASP, acylation-stimulating protein; FFA, free fatty acids; GH, growth hormone; HDL, high density lipoprotein.; IGF, insulin-like growth factor; IL-6, interleukin 6; LDL, low density lipoprotein; LPL, lipoprotein lipase; NO, nitric oxide; NPY-Y1 and -Y5, neuropeptide receptors Y-1 and -5; OB-R, leptin receptor; PAI-1, plasminogen activator inhibitor -1; PDGFR, platelet-derived growth factor receptor; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; PGF<sub>2 $\alpha$</sub> , prostaglandin F<sub>2 $\alpha$</sub> ; PGI<sub>2</sub>, prostacyclin; PPAR, peroxisome proliferator-activated receptor; RAR, retinoic acid receptor; RXR, retinoid x receptor; T<sub>3</sub>, triiodothyronine; TGF- $\beta$ , transforming growth factor- $\beta$ ; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; VEGF, vascular endothelial growth factor; VLDL, very low density lipoprotein;  $\alpha_1$ - &  $\alpha_2$ -AR,  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors;  $\beta_1$ -,  $\beta_2$ - and  $\beta_3$ -AR,  $\beta_1$ -,  $\beta_2$ - and  $\beta_3$  adrenergic receptors.

from circulating VLDL and chylomicrons is catalyzed by lipoprotein lipase (LPL). This rate-limiting step plays an important role in directing fat partitioning. Although LPL controls fatty acid entry into adipocytes, fat mass has been shown to be preserved by endogenous synthesis. From observations made in patients with total LPL deficiency it can also be concluded that fat deposition can take place in the absence of LPL. A further key enzyme catalyzing a rate-limiting step of lipolysis is hormone-sensitive lipase (HSL), which cleaves triacylglycerol to yield glycerol and fatty acids within adipocytes. Some fatty acids are re-esterified, so that the fatty acid-glycerol ratio leaving the cell is usually less than the theoretical 3:1. Increased concentrations of cAMP activate HSL as well

as promote its movement from the cytosol to the lipid droplet surface. Catecholamines and glucagon are known inducers of the lipolytic activity, whereas the stimulation of lipolysis is attenuated by adenosine and prostaglandin E<sub>2</sub>. Interestingly, HSL deficiency leads to male sterility and adipocyte hypertrophy, but not to obesity, with an unaltered basal lipolytic activity suggesting that other lipases may also play a relevant role in fat mobilization.

The lipid droplets contained in adipocytes are coated by structural proteins, such as perilipin, that stabilize the single fat drops and prevent triglyceride hydrolysis in the basal state. The phosphorylation of perilipin following adrenergic stimulation or other hormonal inputs induces a structural change of the lipid droplet that allows the hydrolysis of triglycerides. After hormonal stimulation, HSL and perilipin are phosphorylated and HSL translocates to the lipid droplet. ALBP, also termed aP2, then binds to the N-terminal region of HSL, preventing fatty acid inhibition of the enzyme's hydrolytic activity.

Adipose tissue has been shown to contain 0.6–1.6 mg of cholesterol per gram wet weight. When expressed per unit of protein or organ mass, fat tissue contains more cholesterol than most other organs or membranes. The cholesterol content of adipose tissue increases with age and weight. The specific activity of adipose cholesterol exceeds that of plasma three- to five-fold. The half-life disappearance time of adipose tissue cholesterol is approximately 1 month, which is consistent with its function as a slowly turning over storage pool. The function of CETP is to promote the exchange of cholesterol esters and triglycerides between plasma lipoproteins. Fasting, high cholesterol diets as well as insulin stimulate CETP synthesis and secretion in WAT. In plasma CETP participates in the modulation of reverse cholesterol transport by facilitating the transfer of cholesterol esters from high-density lipoproteins (HDL) to triglyceride-rich apoB containing lipoproteins. VLDLs, in particular, are converted to low-density lipoproteins (LDLs), which are subjected to hepatic clearance by the apoB/E receptor system. Adipose tissue probably represents one of the major sources of CETP in humans. In obesity the activity and protein mass of circulating CETP is increased showing a negative correlation with HDL concentrations at the same time as a positive correlation with fasting glycemia and insulinemia suggesting a potential link with insulin resistance.

Synthesis and secretion of RBP by adipocytes is induced by retinoic acid and shows that WAT plays an important role in retinoid storage and metabolism. In fact, RBP mRNA is one of the most abundant transcripts present in both rodent and human adipose tissue. Hepatic and renal tissues have been regarded as the main sites of RBP production, whereas the quantitative and physiological significance of the WAT contribution remains to be fully established.

## Conclusion

The processes participating in controlling energy balance as well as the intermediary lipid and carbohydrate metabolism are intricately coupled by neurohumoral mediators. The coordination of the implicated molecular and biochemical pathways underlies, at least in part, the large number of intracellular and secreted proteins produced by WAT with autocrine, paracrine, and endocrine effects. The realization that WAT secretes a plethora of pleiotropic adipokines at the same time as expressing receptors for a huge range of compounds has led to the development of new insights into the functions of adipose tissue at both the basic and clinical level. At this early juncture in the course of adipose tissue research, much has been discovered. However, much more remains to be learned about its physiology and clinical relevance. Given the adipocyte's versatile and ever-expanding list of secretory proteins, additional, and unexpected consequences are sure to emerge. The growth, cellular composition and gene expression pattern of adipose tissue is under the regulation of a large selection of central mechanisms and local effectors. The exact nature and control of this complex cross-talk has not been fully elucidated representing an exciting research topic.

## Key points

- To describe the most frequent forms of arthritis and the physiopathology.
- To understand the subjacent proinflammatory status, fundamental to know the objectives of dietary strategies.
- To review the most important dietary modifications useful to slow or control the disease activity according to recent evidence.

## Introduction

The group of arthritis includes diverse forms of joint disease with or without some degree of inflammation. In this article these entities will be reviewed from a physiopathological and clinical perspective. Among the reviewed pathologies RA and OA are the most prevalent. It is obvious that dietary recommendations are not a substitute of treatments, but they are integrated into the multidisciplinary intervention. The review of the evidence is necessary to propose those diets or dietary modifications able to improve the prognosis of the patients, not only from a clinical point of view but also considering quality of life. Diet is particularly relevant by modulating the inflammatory response and even modifying the cardiovascular risk. There is plenty of information about diet, but the validated studies are scarce. The main approaches have been supplementation and elimination. Elimination diets suppress dietary components that may be related to immune response. The supplementation approach is also interesting, and omega 3 fatty acids are one the most investigated elements. This article also includes some ideas about the positive effect of exercise combination.

## Definitions and etiology

Over a hundred types of arthritis are currently recognized. Among the degenerative arthritides, OA is the most common form, and the prototype of this group. In OA there is inflammation within the joint, but there is no evidence of whole-body inflammation, a key feature in distinguishing OA from the inflammatory arthritides. Clinically the patient presents pain, stiffness and functional disability with a reduced quality of life.

In general, OA is monoarticular or oligoarticular and affects a few joints, usually the large weight-bearing joints of the lower extremities, such as the knees and hips, but can be polyarticular. OA can also affect the hands, especially in women, but without the systemic illness that characterizes inflammatory diseases such as RA. The etiology of OA is unknown. The process starts with the micro rupture of the cartilage with a progressive inflammatory cascade that affects synovium, cartilage, and the surrounding structures. This evolution origin a loss of joint space and bony overgrowth, causing pain first with weight-bearing, then with passive

motion, and finally at rest. Obesity is considered a factor leading to a greater load over articular cartilage. Some publications have described the possible causal effect of vitamin D and antioxidant deficiency.

In contrast, in an inflammatory arthritis, such as RA, there is a systemic autoimmune disease with inflammatory polyarthritis, usually affecting the small joints of the hands, wrists, and feet, often spreading to include the knees and hips. Untreated inflammation may lead to bone and cartilage erosions with joint destruction and functional impairment. There is evidence of a systemic immune response, with initial activation of clones of autoreactive T cells into the joint space with development of a thickened synovial membrane that releases proinflammatory cytokines, including interleukin (IL)-1 $\beta$ , tumor necrosis factor alpha (TNF)- $\alpha$ , IL-6, and proteases that induce bone erosions. There is also activation of the acute-phase response, with reduced albumin synthesis and increased production of fibrinogen, C reactive protein (CRP), and other acute-phase reactants. The systemic inflammation leads to altered energy and protein metabolisms and wasting of body cell mass and muscle mass, process described as “rheumatoid cachexia,” that comprises the effects of undernutrition on motor and sensory functions with a combination of weakness, muscle atrophy and functional impairment.

## Prevalence

OA is the most common joint affliction, and its prevalence increases dramatically with age. Radiographic evidence of OA is seen in 70% of people aged over 65 years, but symptoms do not necessarily correspond with X-ray changes. OA of the hip has been reported in 7–25% of adults aged 55 years and older, whereas knee OA is approximately twice as common, and OA of the hands three times as common. After 50 years of age there is an increased incidence in females. RA, however, affects 1–2% of the population, but generally attacks many more joints than OA and is associated with a twofold or higher increased risk of death. Other inflammatory arthritides, such as the seronegative spondyloarthropathies, are much less common.

## Clinical features

The term “arthritis” means the presence of pain and inflammation (heat, swelling, redness) in a joint. Joint pain without inflammation is “arthralgia” and may be due to disease within the joint or in the surrounding soft tissues, ligaments, and tendons. Degenerative arthritis, such as OA, is generally a disease of the large weight-bearing joints of the lower extremities. In addition, OA commonly strikes the distal interphalangeal (DIP) and first carpometacarpal joints of the hands, especially in women. The affected joints have pain on motion, stiffness, mild swelling, and sometimes intra-articular effusions or swelling. As the disease progresses, bony overgrowth becomes clinically apparent, coinciding with the development of osteophytes on radiographic examination. These osteophytes, together with loss of joint space, are the radiographic hallmarks of OA, and reflect new bone formation at the joint margins. Over time, the range of motion in the joint is restricted, with loss of function, first by pain, later by loss of joint space, and finally by the osteophytes. Treatment of OA is essentially symptomatic. Nonpharmacologic therapies include exercise as a useful intervention for OA of the hands, hips and knees. The evidence is limited for topical creams, cognitive-behavioral therapy and acupuncture. Diverse pharmacologic interventions have been used: analgesics (topical and systemic), duloxetine and nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce pain and limit the intra-articular inflammation. However, this treatment is seldom completely satisfactory, and occasionally the utility is limited by secondary effects. Finally, progression of the disease is usually seen, although prognosis is variable depending on the extent of the disease. Joint replacement surgery has revolutionized the care of end-stage OA, allowing return of function of joints that are otherwise immobile.

In inflammatory arthritis the situation is quite different. RA is a symmetric, additive polyarthritis involving up to several dozen small joints of the hands, wrists, and feet, often with involvement of the knees, hips, and ankles, and sometimes the elbows, shoulders, and cervical spine, distal interphalangeal joints are spared. There is pain, swelling, and warmth in the affected joints and morning stiffness or after prolonged immobility that can last for several hours. Unlike OA, in RA there is evidence of whole-body inflammation with constitutional symptoms such as fatigue, low grade fever or weight loss and often extraarticular manifestations. This leads to suppression of albumin gene expression and upregulation of the production of acute-phase proteins such as CRP, transferrin, and fibrinogen. In addition, there is suppression of serum iron, reduced zinc, and increased whole-body protein breakdown and resting metabolic rate. Treatment begins with rest, physical therapy, and use of NSAIDs to reduce pain and mild inflammation. Low-dose oral corticosteroids, equivalent to 5–10 mg day<sup>-1</sup> of prednisone, are often necessary to control inflammation. However, these therapies do not alter the natural history of the disease and frequently is necessary to use nonbiologic disease-modifying antirheumatic drugs (DMARD) such as methotrexate, and biologic DMARD such as TNF- $\alpha$  inhibitors (infliximab, etanercept, adalimumab), and others (tocilizumab, rituximab) that have been shown to prevent erosions. It should be noted that some of these medications may also affect the nutritional status of individuals with RA via either altered appetite, blood sugar, plasma lipids, absorption, or protein metabolism.

## Role of diet in the management of inflammatory arthritis

### Nutritional assessment in RA

It is important to recognize that patients with RA do not have a normal nutritional status. It is useful to define the concomitant nutritional alterations based on the physiopathological mechanisms involved in the clinical practice: cachexia, when predominate chronic disease-related inflammatory conditions, protein-caloric malnutrition in case of malnutrition associated to acute inflammatory conditions and starvation-related malnutrition, where inflammation is not present. Cachexia is generally seen in the presence of hypermetabolism (elevated resting energy expenditure) and hypercatabolism (elevated protein breakdown), along with reduced physical activity. Clinical expression of malnutrition associated to rheumatic diseases can be different in the patient with low weight or overweight but is common the existence of lean body mass depletion with functional impact and impaired quality of life. On the other hand, the increase in body fat mass, or even the existence of sarcopenic obesity, is related with greater cardiovascular risk.

These metabolic abnormalities are linked to increased production of the catabolic cytokines IL-1 $\beta$ , IL-6 and TNF- $\alpha$ . The problems are further exacerbated by reduced physical activity, which minimizes the anabolic stimulus to muscle. In general, is described an increased baseline energy expenditure, muscle proteolysis, insulin resistance, anemia of chronic disease, osteoporosis, endothelial dysfunction, atherogenesis and even metabolic syndrome.

The combined effect of these metabolic alterations in a proinflammatory state leads to anorexia, unintentional weight loss, decreased muscle mass with reduced muscle strength and functional limitations, poor quality of life and shorter life expectancy. It is important do not forget the effect of potential side effects of the drugs used for treatment of rheumatologic diseases.

### Diet and RA activity

Although many foods or food components have been considered as possible treatments for RA, most studies have focused on either supplementation (particularly the use of fish oil) or the use of an elimination diet, especially fasting or a vegetarian regimen (Tedeschi and Costenbader, 2016). Certain nutrients (omega-3 fatty acids, beta-hydroxymethylbutyrate and leucine) have regulatory properties over the immune and inflammatory response, typically present in these diseases. The investigation about the role of diet and microbiota in the development of RA is growing (Alpizar-Rodríguez et al., 2020). Microbiota and the intestinal barrier can be the link between various nutritional factors and the development of RA, although more clinical trials are necessary. The most recent systematic review published in 2020 was based on the Disease Activity Score in 28 joints (DAS28). The positive effects on RA disease activity were demonstrated for Mediterranean diet (MD), spices, antioxidants (quercetin and ubiquinone) and probiotics (*Lactobacillus casei*) (Nelson et al., 2020).

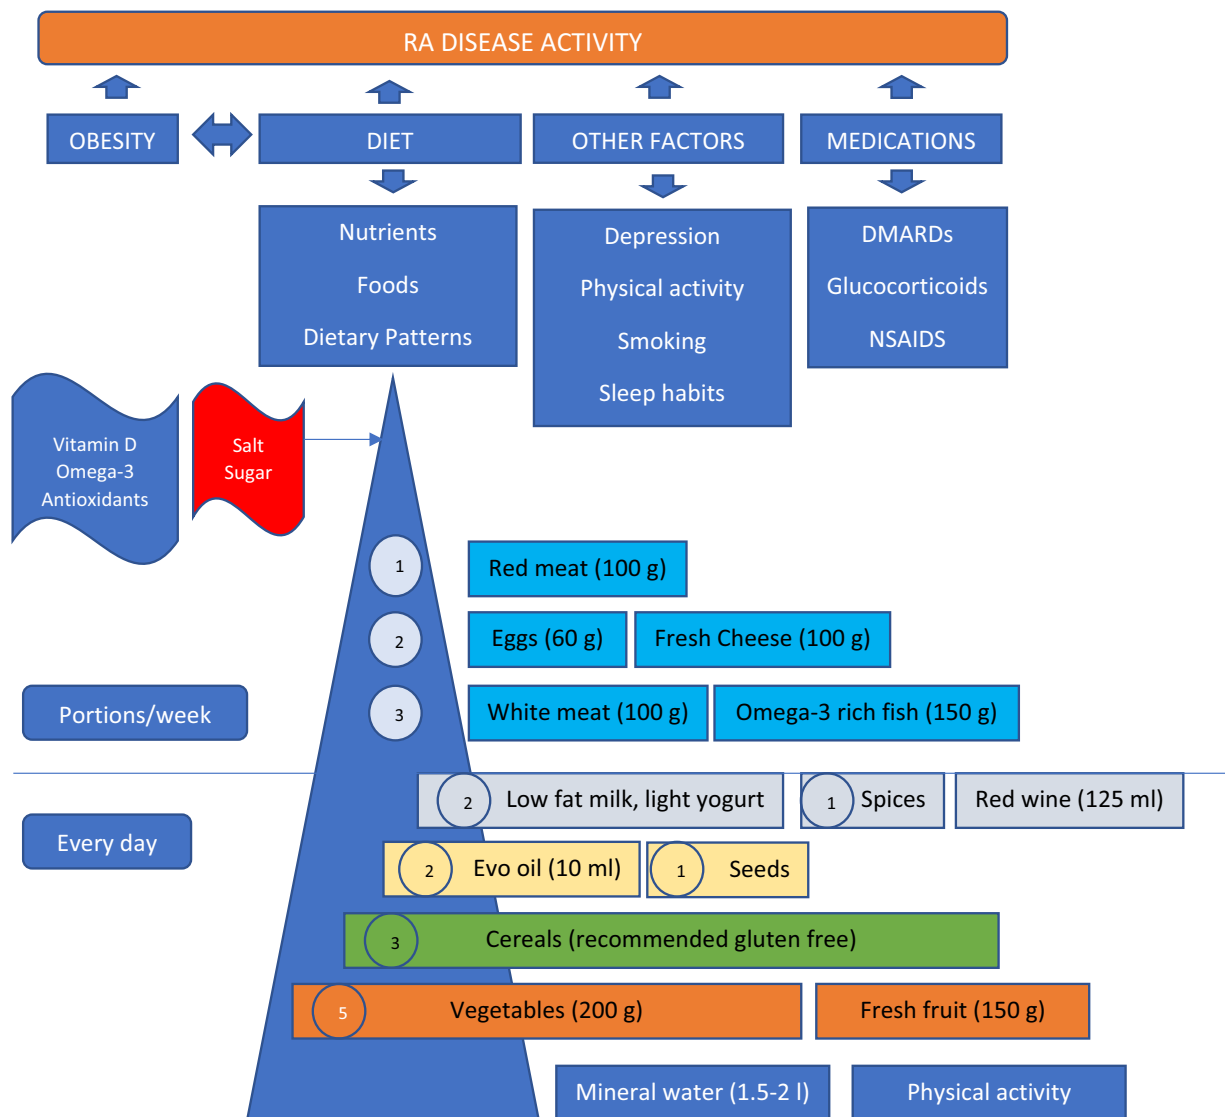

The recommended diet includes a low-fat low-sodium MD rich in vegetables, whole grains, fruits and poor in sugar-sweetened beverages, red and processed meat and trans fats (Genel et al., 2020). Another important aspect would be the supplementation with omega-3 fatty acids, essential amino acids and probiotics. A recent review evaluated a food pyramid for patients with RA (Rondanelli et al., 2021). This pyramid is similar to the recommended for the general population with some differences: 5 portions of fruit and vegetables are at the base, instead of carbohydrates (preferable gluten free). The seeds have been considered as daily consumption. At the apex two warnings, to avoid the excessive intake of salt and simple sugars and the recommendation to take a supplement of vitamin D, omega 3 and antioxidants in most cases (Fig. 1).

### Supplementation with dietary fatty acids

Various dietary fatty acids have shown numerous immunomodulatory effects. Some fatty acids are considered essential because human body cannot synthesize them. Is the case of linoleic acid (LA) and alfa-linolenic acid (ALA). LA is a n-6 polyunsaturated fatty acid (PUFA) precursor of Arachidonic acid (AA), synthesized in mammalian tissues. ALA is a n-3 PUFA precursor. Both are essential components of phospholipid membranes and precursors of inflammatory mediators, such as prostaglandins (PG) and leukotrienes (LT). LA has a pro-inflammatory profile and ALA offers an anti-inflammatory response. In clinical practice is more interesting to explain the role of a dietary pattern than to focus on a specific nutrient. MD typically contains a balanced n-6/n-3 PUFA ratio and is a reasonable diet intervention (Chehade et al., 2019). A higher adherence to the MD is associated with a more diverse microbiota and elevated levels of fecal short chain fatty acids (SCFA), characterized by their anti-inflammatory properties. In patients under treatment with glucocorticoids, sugar and salt intake should be restricted.

More specifically, Eicosapentaenoic acid (EPA) derived eicosanoids result in decreased platelet aggregation, reduced neutrophil chemotaxis, and anti-inflammatory effects. Some meta-analysis have demonstrated a significant reduction in leukotriene B<sub>4</sub> (LTB<sub>4</sub>) levels after n-3 PUFA supplementation in RA patients. This lipid mediator has a relevant participation in the recruitment of leukocytes in cases of inflammation.

EPA and docosahexaenoic acid (DHA) supplementation causes modest improvement in the number of tender joints and fatigue among patients with RA, although clinical benefits have generally been small, subjective, and transient (Petersson et al., 2018). Possible mechanisms for this improvement in clinical symptoms of inflammation include altered neutrophil membrane lipid composition, reduced IL-1 production, or a change in the  $\alpha$ -tocopherol content of the diet. Overall, findings suggest that clinical benefits of dietary supplementation with PUFAs are more commonly observed among patients consuming higher dosages of fish oil (minimum required dose 2.6 g/day of EPA + DHA), for longer periods than those previously studied. Indeed, beneficial

**Fig. 1** Ideal food pyramid for RA. Number of portions (in circle). Not recommended (red flag). NSAIDS (nonsteroidal anti-inflammatory drugs). DMARDs (disease-modifying antirheumatic drugs). Modified from Rondanelli, M., et al., 2021. Ideal food pyramid for patients with rheumatoid arthritis: a narrative review. Clin. Nutr. 40(3), pp. 661–689. <https://doi.org/10.1016/j.clnu.2020.08.020>.

clinical effects have been observed for as long as 1 year among patients with RA ingesting 2.6 g daily of n-3 PUFA supplements. In terms of optimal dosage of supplementation, however, a level of  $130 \text{ mg kg}^{-1} \text{ day}^{-1}$  (9 g of n-3 PUFAs in a person weighing 70 kg) has been shown to result in no additional improvement compared with patients receiving doses ranging from 3 to 6 g daily. Therefore, although the optimal level of fish oil supplementation is yet to be determined, there does appear to be an upper limit beyond which no additional benefit exists for patients.

Although some studies seem to suggest modest clinical improvements as a result of dietary fish oil supplementation in patients with RA, the effectiveness of n-3 PUFA supplementation combined with biologic DMARDs is not clear. On the other hand, the role in the RA comorbidities is under investigation (Navarini et al., 2017).

NSAIDs are known to inhibit the cyclooxygenase enzyme system, which is the same pathway that seems to be inhibited by EPA and DHA. It is therefore possible that in studies of fish oil supplementation, where patients are simultaneously maintained on NSAIDs, the effect of EPA is diminished, because the cyclooxygenase pathway is already inhibited by concurrent treatment with NSAIDs. Several studies have attempted to address this issue and have demonstrated a modest effect of n-3 fatty acid supplementation in both, patients who are treated with NSAIDs and those who are not, suggesting that concurrent treatment with NSAIDs does not seem to diminish the effect of n-3 fatty acids. A meta-analysis published in 2007 indicated that n-3 PUFA supplementation was associated with a decrease in NSAID consumption.

Although most studies regarding manipulation of dietary fatty acids have focused on fish oil supplementation, other fatty acids have also been studied. The use of ALA, the precursor of EPA and DHA, has not been shown to be of any benefit in RA. However,

$\gamma$ -linolenic acid, found in blackcurrant seed, evening primrose, and borage seed oils, has resulted in clinically important reductions in the signs and symptoms of disease activity in patients with RA, perhaps via a reduction in PGE<sub>2</sub>, IL-1, and IL-6. Because these oils do not cause an unpleasant fishy taste and odor in recipients, they may be preferred to fish oils for chronic treatment.

In summary, most studies of dietary supplementation with n-3 fatty acids suggest a modest improvement in clinical symptoms associated with RA, which are to some extent dose- and time-dependent. The most consistent clinical benefits have been reductions in tender joint counts and morning stiffness. Studies do not suggest that benefits are great enough to warrant discontinuing patients' other medications. However, the use of fish oil supplements, or diets rich in marine fish, may further improve clinical symptoms among patients with RA. Beyond the possible benefits in terms of controlling inflammatory symptoms of RA, increases in n-3 PUFAs are also associated with reduced risk of cardiovascular disease, increase of muscle mass in patients with primary and secondary sarcopenia and other health benefits.

### Vitamin, mineral supplementation and probiotics

Most studies involving vitamin or mineral supplementation in RA have focused on either the antioxidant nutrients (vitamin C, vitamin E, beta carotene, selenium) or B vitamins. In general, results from randomized controlled trials of vitamin E supplementation have been of relatively short duration and have led to conflicting results so that there continues to be a lack of concrete evidence to support vitamin E supplementation at a particular dosage. Nonetheless, patients with RA could certainly be encouraged to increase their intake of vitamin E-rich foods, including edible vegetable oils (sunflower, safflower, canola, olive), unprocessed cereal grains, and nuts. Similarly, the effect of dietary sources of other antioxidant nutrients, such as selenium and vitamin C, on inflammatory symptoms in RA has also been ambiguous. Selenium is a nuclear component of antioxidant enzymes that intervenes in the oxidative and inflammatory state affecting disease activity. It should be emphasized that providing individual nutrient supplements does not necessarily offer the same overall benefit as when nutrients are obtained from whole foods. It is possible that the combinations of nutrients that are present in whole foods, or even some unidentified components of a food, are responsible for any observed beneficial effects, and that supplementing a typical diet with individual nutrients will not provide the same benefit.

In previous studies plasma levels of pyridoxal-5-phosphate (PLP), the metabolically active form of vitamin B<sub>6</sub>, were lower in patients with RA compared to control subjects. Furthermore, plasma levels of PLP were inversely associated with TNF- $\alpha$  production by peripheral blood mononuclear cells, suggesting that abnormal vitamin B<sub>6</sub> status may be contributing to inflammation in RA. However, there is no evidence to support the efficacy of oral vitamin B<sub>6</sub> supplements for treating the symptoms of RA at this time. Furthermore, large doses of vitamin B<sub>6</sub> can be toxic; therefore, as with the antioxidant nutrients, patients with RA would obtain the greatest benefit by increasing dietary sources of vitamin B<sub>6</sub>, consistent with the dietary reference intake (DRI) for this nutrient. If supplementation is considered, it should not exceed twice the DRI level. The active metabolite of vitamin D shows immunomodulatory effects mediated by vitamin D receptor expressed in multiple immune cells. Some authors describe the possible role of vitamin D deficiency in the progression from preclinical to clinical RA. In the Women's Health Initiative clinical trial higher levels of vitamin D intake were associated to an increased risk of RA.

Various authors have investigated the application of probiotics on disease activity and metabolic status of RA patients. There was a reduction in the levels of pro-inflammatory cytokines (TNF, IL-5, IL 12) with increased levels of anti-inflammatory IL-10. In the most recent meta-analysis (2018), the effect over disease related outcomes was considered weak in RA patients. Some observational and interventional studies suggest that diverse fermented foods (foods and beverages produced under controlled microbial growth) can have a protective role against immune mediated disorders such as RA. The benefit is based on microbiota modulation secondary to bioactive metabolites such as SCFA. Polyphenols are plant derived molecules with anti-inflammatory properties. Their use can be useful for OA treatment, but more clinical trials are needed.

### Fasting and vegetarian diets

An alternative approach to alleviating the symptoms associated with chronic inflammation is elimination of various foods or food components, most often by fasting or assuming a lactovegetarian diet. Some studies have demonstrated a significant improvement in various objective and subjective measures of disease activity, including number of tender and swollen joints, Ritchie's articular index, morning stiffness duration, erythrocyte sedimentation rate (ESR), CRP, grip strength, and score on health assessment questionnaires, among patients with RA, 6 weeks-2 years after initiating a vegetarian diet. Furthermore, these clinical improvements were accompanied by changes in biochemical and immunological parameters consistent with a substantial reduction in inflammatory activity. Other studies included in the last Cochrane review (2009), have demonstrated no clinical improvement among patients with RA following different dietary interventions. Some meta-analysis described long-term benefits in subjects with RA that include fasting programs followed by lactovegetarian diets.

Several possible mechanisms have been proposed to explain the impact of elimination diets on clinical symptoms in RA. One possibility is that RA might be the result of hypersensitivity to environmental toxins or specifically to foods or food-related products, resulting in a food allergy of sorts that exacerbates symptoms of RA. Gluten free diets followed for 1 year were associated with a decrease of disease activity. However, true food intolerance, involving a systemic humoral immune response against food items, appears to be relatively uncommon among patients with RA. Another possible mechanism that has been proposed includes an alteration in the fatty acid content of the diet. Vegetarian diets contain more LA, but less AA, EPA, and DHA than omnivorous diets.

Therefore, the eicosanoid precursors (AA, EPA, and DHA) must be produced endogenously from LA and ALA. It has been hypothesized that if this endogenous production cannot compensate for the absence of AA in the diet, then the precursor of the proinflammatory eicosanoids would be reduced, perhaps explaining the beneficial effect of vegetarian diets in patients with RA. Furthermore, it has also been demonstrated that fasting for 7 days resulted in decreased release of LTB<sub>4</sub> from neutrophils, in addition to reductions in morning stiffness, articular index, and ESR, but that this reduction in LTB<sub>4</sub> occurred despite an increased AA content of the serum, platelets, and neutrophils. These findings suggest that perhaps fasting may impair a metabolic step of AA conversion. Caloric restriction could have beneficial effects on RA disease activity by inhibiting NLRP3 inflammasome (component of the innate immune system that mediates secretion of proinflammatory cytokines).

Other potential mechanisms include the possible effect of a vegetarian diet on antioxidant status acting as scavengers of free radicals, or on other dietary practices frequently associated with vegetarianism. Plant-based foods are naturally high in antioxidant nutrients (vitamin C, vitamin E, and beta-carotene) and low serum antioxidant levels have been associated with an increased risk of developing RA, although the specific mechanism involved remains unknown. Different investigations have described oxidative stress, lipid peroxidation, DNA damage, increased formation of reactive oxygen species and reduced antioxidant protective systems. Certainly, RA is associated with increased production of reactive oxygen species; these compounds seem to contribute to the inflammatory process, so a diet high in antioxidants could limit damage via their anti-inflammatory properties. Although changes in fatty acid composition or antioxidant status seem to be the most plausible explanations for the potential benefit of adhering to a vegetarian diet, there are other possible mechanisms as well. Fasting, for example, suppresses inflammation and frequently a period of fasting is recommended before initiating an elimination or vegetarian diet; it is possible that this fasting period contributes to the reduction in inflammation among patients with RA following a vegetarian diet.

## Conclusion

In summary, the notion that food sensitivity reactions contribute significantly to clinical symptoms associated with RA remains controversial. However, it seems that at least a small subgroup of patients with RA may benefit from individualized dietary manipulation involving elimination of specific foods or food components, in combination with other medical therapies. However, fasting and other elimination diets should be used with caution in light of the prevalence of rheumatoid cachexia in this population. Such patients are prone to further loss of cell mass during restrictive diets, and the net effect may be to do more harm than good.

Nutritional alterations are prevalent in patients with rheumatologic disease. The initial diagnosis is essential, with application of instruments that provide an objective evaluation of body composition, particularly lean body mass. Comparison studies on hand-grip strength and other related measures could explain the difference between hand inflammation and muscle function. Of the two primary approaches to the dietary management of inflammatory arthritis—supplementation and elimination diets—it appears that dietary supplementation with fish oil may result in the most consistent clinical benefits, although improvements still remain modest. Elimination diets, including fasting and vegetarian regimens, may provide some benefit for a limited number of patients with RA, but consistent alleviation of disease activity by objective clinical measures has not been demonstrated.

In neither case does the use of dietary management warrant discontinuing a patient's medical regimen; rather, diet may be useful as an adjunct to other more substantiated therapies. Perhaps the most prudent approach for patients with RA interested in attempting to control their disease activity is to adopt a lifestyle modification program based on diet and physical activity. More definitive research demonstrating consistent, objective clinical benefits is needed before specific dietary manipulations for patients with RA can be recommended. The physical activity program requires an active lifestyle with aerobic and resistance exercise. Low levels of physical activity and glucocorticoids use are associated with nutritional complications. The French Society for Rheumatology published in 2021 specific dietary recommendations for patients with Chronic Inflammatory Rheumatic Diseases (Daïen et al., 2021). **Table 1** resume the main aspects (here).

## Role of diet in the management and prevention of degenerative arthritis

Much less is known about the role of diet in the treatment of OA and other degenerative arthritides (Thomas et al., 2018). The above discussion regarding n-3 PUFAs in RA may also pertain to OA, although the strength of the effect has not been studied as thoroughly. However, the same eicosanoid metabolism occurs in OA as in RA, with the exception that the disorder is limited to the joint rather than involving the whole body. Thus, fish oils may well be of benefit in OA. The evidence for dietary lipid modification is low but can improve metabolic health. Antioxidant intervention with vitamin E may also be effective in OA, with several studies showing an effect comparable with those of NSAIDs. Although not strictly nutrients, glucosamine and chondroitin sulfate, which are two of the constituents of normal cartilage that decline with arthritis, have been shown to be useful when given as an oral supplement, especially in patients with early OA. Glucosamine sulfate decreased the risk of developing radiographic knee OA over 2.5 years in overweight middle-aged women.

In contrast to RA, where diet's main role is in the treatment and little is known about prevention, there is more known about dietary components that lead to OA than about nutritional management of OA (Berenbaum et al., 2018).

It is clear that OA of the lower extremities is largely a problem brought on by obesity, especially OA of the knee (and hip, to a much lesser extent), suggesting that obesity seems to be a mechanical rather than systemic risk factor. Thus, maintaining body

**Table 1** Dietary recommendations for patients with chronic inflammatory rheumatic diseases.

<i>Recommendations</i>	<i>Level of evidence</i>
In patients who are overweight or obese, weight loss support should be proposed to control chronic inflammatory rheumatic disease activity; weight loss also has beneficial cardiometabolic and psychological effects	C
A gluten-free diet should not be proposed to control chronic inflammatory rheumatic disease activity, in the absence of confirmed celiac disease	C
Fasting or vegan diets should not be proposed to control the activity of chronic inflammatory rheumatic diseases	D
Eliminating dairy products should not be proposed for managing chronic inflammatory rheumatic disease	C
Supplementation with polyunsaturated fatty acids, mainly omega-3, of more than 2 g per day, could be proposed for symptomatic relief in patients who have rheumatoid arthritis and likely for those suffering from other chronic inflammatory rheumatic diseases.	A
A Mediterranean-type diet could be proposed to patients who have rheumatoid arthritis and likely to those affected by other chronic inflammatory rheumatic diseases given its effects on joint symptoms and the cardiometabolic diseases	C
To control the activity of chronic inflammatory rheumatic disease, there is no indication for proposing vitamin (B9, D, E, K) or trace element (selenium and/or zinc) supplementation	B
Given that the data on the effectiveness of probiotics is insufficient and disparate, they are not recommended for controlling chronic inflammatory rheumatic disease activity.	B
<i>General principles</i>	
<ul style="list-style-type: none"> <li>✓ Nutritional advice is not a substitute for pharmacological treatment of chronic inflammatory rheumatic diseases.</li> <li>✓ The nutritional advice given to patients affected by chronic inflammatory rheumatic diseases should be based on data from the scientific literature.</li> <li>✓ Nutritional support is integrated into the overall care of patients affected by chronic inflammatory rheumatic diseases</li> <li>✓ Broaching dietary habits can help patients get actively involved in the overall care of their chronic inflammatory rheumatic disease</li> <li>✓ The nutritional advice given to patients affected by chronic inflammatory rheumatic diseases must take into account the intra- and extra-articular effects, particularly cardiometabolic and bone</li> <li>✓ The nutritional advice must take the cultural and socioeconomic context into account</li> <li>✓ Nutritional advice is indissociable from the promotion of exercise.</li> <li>✓ If other nutritional recommendations exist that are specific to a disease, clinical condition or associated treatment, these continue to apply (e.g., undernutrition, obesity, sarcopenia, osteoporosis, etc.)</li> </ul>	

Modified from Daien, C., et al., 2021. "Dietary recommendations of the French society for rheumatology for patients with chronic inflammatory rheumatic diseases". *Joint Bone Spine* p. 105319. <https://doi.org/10.1016/j.jbspin.2021.105319>.

weight within the recommended ranges is probably the most important nutritional intervention to prevent OA. Weight loss leads to reduction in joint stress, and often reduces symptoms. In fact, recent studies have suggested that if all overweight and obese individuals reduced their body weight by 5 kg, or until their body mass index (BMI) was within the desirable range, 24% of surgeries for knee OA could be avoided. A recent meta-analysis described that a substantial loss of weight is necessary to reduce knee pain and joint stiffness improving physical function. Furthermore, studies have demonstrated that exercise can improve OA symptoms even independently of weight loss, presumably by increasing muscle strength and thus improving the shock-absorbing power of the muscles, hence sparing the cartilage and joint (Alrushud et al., 2017). However, patients with OA have a great deal of difficulty with exercise, and their sedentary life style is reinforced by their joint pain, generally leading to weight gain after the onset of OA, which in turn exacerbates the disease, creating a vicious cycle. Adults with knee OA are at high risk of sarcopenia. Some studies have demonstrated the combined effect of protein-rich supplementation and resistance exercise training over physical activity level and muscle gain (Liao et al., 2021). Exercise programs that increase physical activity and strengthen the muscles surrounding afflicted joints clearly improve symptoms in OA. Thus, OA can be thought of as a disease of overnutrition, whereas RA is generally

a disease of undernutrition. Interestingly, recent twin studies have examined the role of genetic versus environmental factors as mediators of the obesity–OA relationship, and have suggested that shared genetic factors are not as important as environmental factors in mediating the obesity–OA relationship. Dietary modification leading to weight loss is a critical component of the management of OA. MD influences inflammatory and cartilage degradation biomarkers, although longer effects require more investigation. A lower prevalence of OA is observed in subjects with a high adherence to MD. Obesity and metabolic syndrome have a role in the development of OA, including hand OA. The link between the two conditions can be a chronic low-grade inflammation related to obesity and gut dysbiosis. Another risk factor is vitamin D deficiency. In this point the adherence to a Mediterranean dietary pattern may counteract this proinflammatory state. Its consumption has been related to decreased pain, disability, reduce depressive symptoms and a clear improvement in knee cartilage (Dyer et al., 2017). A greater adherence to the DASH (Dietary Approaches to Stop Hypertension) dietary pattern is also associated with lower prevalence of OA.

## Conclusion

The treatment of OA, with no existent disease-modifying drugs, is essential in Rheumatology so dietary modifications, and an additional exercise program, are basic to modify risk factors and preventing or limiting the consequences. Many epidemiological studies focus on the link between metabolic syndrome and OA, and include the presence of some potentially modifiable factors, such as obesity and dietary habits. The actual evidence is suggesting an important role for MD.

## Glossary

**Blood–brain barrier** Now not known really to be a ‘barrier’, but a set of transporter mechanisms located in the cell membranes of the endothelial cells that make up the brain capillaries, which promote or retard the exchange of certain small and large water-soluble molecules between the blood and the brain.

**Central nervous system (CNS)** The portion of the nervous system consisting of the brain, retina, and the spinal cord.

**Glia** Non-neuronal cells of the nervous system that provide physical and metabolic support for neurons, and insulate axons and nerve terminals, to ensure privacy in signaling.

**Ketone bodies** Small breakdown products of fatty acids, such as acetoacetate and beta-hydroxybutyrate, made in the liver when circulating fatty acids increase, such as during starvation, which are then taken up by brain (and other tissues) and used to generate ATP. Ketone bodies are a key source of energy for the brain during starvation.

**Neuron** The principal functional cells of the nervous system, which are organized into very complex circuits (analogous to the components of electronic circuits) that manage all of the housekeeping functions of the body and elaborate behavior and cognitive functions.

**Neurotransmitter** A molecule that is released by neurons that couples with specific receptors on other cells and induces a functional response, such as depolarization (a neuron), contraction (a muscle cell), or secretion (an endocrine or exocrine cell).

**Parkinson's disease** A disease of unknown etiology in which neuronal circuits in the brain that control certain features of muscle function and coordination degenerate. Patients, who are usually older, gradually develop muscle tremor, a bent posture, and difficulty in initiating voluntary movements, such as walking.

**Peripheral nervous system** The portion of the nervous system consisting of neurons and glial cells lying outside the CNS, which either supply sensory information to the CNS or send commands from the CNS to effector cells in the rest of the body, such as muscle and gland cells.

**Rhodopsin** The light-responsive pigment of the eye, which elicits phototransduction when struck by photons of light. It is synthesized in retina photoreceptor cell membranes through the covalent linkage of a protein, opsin, and a metabolite of vitamin A, 11-*cis*-retinaldehyde. Rhodopsin breaks down to opsin and a metabolite of 11-*cis*-retinaldehyde after phototransduction but is quickly regenerated.

**Spina bifida** A malformation of the spinal cord that occurs early during fetal development, when the spinal cord is forming, which when serious can compromise body functions controlled by nerves entering and exiting the spinal cord below the lesion. The incidence of spina bifida is markedly reduced when women take a folic acid supplement before and during pregnancy.

## Design of the Nervous System

The nervous system has two principal cell types, neurons and glia. Neurons (like wires) conduct electrical signals and are organized into circuits to perform specific functions. They have a unique cellular architecture: small cellular extensions (dendrites), which receive chemical and electrical signals from other neurons; a longer extension (the axon, which can be up to a meter in length), which sends electrical signals down its length to one or more nerve terminals. Nerve terminals contain neurotransmitters, molecules released by arriving electrical signals that modify the electrical activity of the adjacent neurons. Neurons have considerable energy needs; indeed the brain, which is approximately 2% of body weight, consumes 15–20% of the body's daily energy intake. Glial cells, which make up approximately 60% of the brain's cell mass, provide physical and metabolic support for neurons and insulate axons and nerve terminals to insure privacy in electrical signaling. The glial cells found in peripheral nerves serve the same functions.

The nervous system is broadly divided into two parts, the central nervous system (CNS) and peripheral nervous system. The CNS consists of the brain, retina, and the spinal cord. It also contains complex neuronal circuits that control body functions (e.g., blood pressure, breathing, hunger, and movement). The peripheral nervous system consists of groups of neurons that mostly lie outside of the CNS and either supply sensory information to the CNS or send CNS commands to effector cells, such as muscle and gland cells.

## The Blood–Brain Barrier (BBB)

Each portion of the nervous system is separated from the blood (and thus the rest of the body) by a metabolic 'barrier,' which modulates the access of nutrients to and the removal of metabolites from the neurons and glia within it. For the brain and spinal cord, this barrier is termed the 'blood–brain barrier' (BBB; there is also a blood–cerebrospinal fluid (CSF) barrier; CSF is made from blood); for the retina, it is the 'blood–retinal barrier,' and for peripheral neurons, the 'blood–nerve barrier.' The functions of these barriers are very similar; the focus of the discussion will be the BBB, because it has been the most studied.

The BBB is located in the endothelial cells that make up the brain's capillaries. Unlike the capillaries elsewhere in the body, the endothelial cells of the brain capillaries are tightly joined, such that nothing passes into (or out of) the brain without passing through these cells. The BBB thus presents a continuous lipid barrier to molecules. One implication is that the ease with which molecules in the blood gain access to brain should depend on their lipid solubility: The more lipid soluble, the greater the accessibility to brain by diffusion. However, most molecules of biologic importance to brain are not lipid soluble and thus do not easily diffuse across lipid membranes into brain. Examples include glucose, amino acids, and water-soluble vitamins. Consequently, endothelial cell membranes must be more than just lipid barriers; in fact, embedded in them are specific transport carriers that mediate the brain uptake of most nutrients.

## Energy Substrates

The brain uses glucose as its primary energy substrate. Glucose is not lipid soluble and thus requires a BBB transporter. The glucose transporter has a maximal transport capacity for glucose of  $1.4 \text{ mol min}^{-1} \text{ g}^{-1}$  of brain or approximately  $1200 \text{ g d}^{-1}$  for the entire brain (a human brain weighs 1400 g). The human brain consumes 15–20% of the body's oxygen consumption; brain glucose utilization is therefore about  $100 \text{ g d}^{-1}$ . The BBB transporter thus has a maximal capacity for transporting glucose well in excess of the daily requirements of the brain.

Inside the brain, glucose is rapidly taken up into the neurons by a cellular glucose transporter. Within the neuron, glucose enters the glycolytic pathway. The initial enzyme, hexokinase, has a very high affinity for glucose and is fully saturated at normal brain glucose concentrations. Hence, overall, each step in the glucose pipeline from the blood to brain neurons is designed to maximize glucose supply for neuronal energy production. It only fails when the blood glucose supply is abruptly curtailed, such as when a diabetic patient injects too much insulin and blood glucose levels rapidly fall (the transporter cannot compensate for such abrupt drops in blood glucose). The effect is dramatic: confusion, delirium, seizures, coma, and finally death occur as blood glucose drops to very low levels. Such effects are most rapidly reversed by the infusion of glucose, suggesting that no other compound in blood readily substitutes for glucose as the brain's primary energy substrate.

Normally, the body carefully maintains blood glucose concentrations. During starvation, however, blood glucose falls enough to cause the brain to recruit an additional energy source, ketone bodies. Ketone bodies are liver-produced by-products of the breakdown of stored fat and provide an extended supply of energy when the input of food-derived energy is low. The brain uses ketone bodies whenever their blood levels rise; blood ketone body concentrations rise during starvation. The BBB ketone body transporter (ketone bodies are not lipid soluble) is induced during starvation, enhancing the flow of ketone bodies into the brain. During prolonged starvation, more than half of the energy used by the brain is derived from ketone bodies. However, continued use of some glucose appears obligatory and is supplied via liver gluconeogenesis.

The chronic ingestion of high-fat diets also elevates blood ketone body concentrations, promoting their use by brain for energy production. However, extremely high levels of fat must be consumed and such diets are unpalatable. Hence, diet is not thought normally to influence cerebral energy production via dietary fat manipulation of ketone body supply to brain. Very high fat diets are occasionally used clinically to treat intractable seizures. Although the beneficial effect is linked to circulating ketone bodies levels, the mechanism is presently unknown.

## Amino Acids and Protein

Neurons and glial cells in brain use amino acids to produce proteins. In addition, certain amino acids are used to produce small functional molecules such as neurotransmitters. Does diet influence amino acid flow into brain and their use in generating proteins and transmitters? The path from diet to brain begins with amino acid absorption from the gastrointestinal tract, insertion into the circulation, and extraction by the brain. This extraction process involves the BBB, which contains a number of transporters of amino acids. The properties of these transporters dictate how much of each amino acid enters (and exits) the brain. Currently, six carriers have been identified. Of special interest are two carriers: (1) The large neutral amino acid (LNAA) carrier – this carrier is shared by several amino acids (some are precursors for neurotransmitters, namely phenylalanine, tyrosine, tryptophan (TRP), and histidine). This carrier is competitive, allowing changes in the plasma concentration of any one LNAA to affect not only that amino acid's BBB transport but also that of each of its transport competitors. Glutamine, an LNAA present in the brain in high concentrations, drives the brain uptake of the other LNAA, by serving as the principal amino acid counter transported from the brain to blood each time an LNAA is taken up into brain. (2) The acidic amino acid carrier, which transports glutamic and aspartic acids. This carrier primarily transports glutamate (GLU) and aspartate from the brain to the circulation. The other transporters include one selective for basic amino acids; two selective for subgroups of the small, neutral amino acids; and one selective for taurine.

The carriers that move amino acids into brain are those that primarily transport essential amino acids (the large, neutral and basic amino acids), whereas those that move amino acids out of brain are those transporting nonessential amino acids (the acidic and small neutral amino acids). A small, net influx of the essential amino acids into brain no doubt reflects their consumption in brain by biosynthetic and metabolic pathways. The net efflux of the nonessential amino acids, notably aspartate, GLU, glycine, and cysteine may serve to remove from brain the amino acids that act directly as excitatory transmitters or cotransmitters. The brain carefully compartmentalizes these amino acids metabolically, because they excite neurons, and a mechanism to remove them from brain may be a component of this compartmentalization design.

Changes in dietary protein intake have no effect on brain protein synthesis in adults. Indeed, the chronic ingestion of very low levels of dietary protein does not depress brain protein synthesis; brain cells may thus be efficient in retaining and reusing amino acids released during intracellular protein breakdown. In neonatal and infant animals, however, low levels of protein intake are associated with below normal rates of protein synthesis in the brain. But, the presumed mechanism of this association, reduced uptake of essential amino acids into brain, and abnormally low brain concentrations of these amino acids has not been proven. Hence, at present, there is no convincing evidence linking dietary protein intake and brain protein synthesis via a limitation of amino acid availability to brain. For neurotransmitters, the evidence of this diet–brain link is more certain and provides interesting examples of the fundamentally different manner in which the brain uses transport carriers to handle amino acids that are neurotransmitter precursors and those that are neurotransmitters themselves. Good examples are TRP (an LNAA) and GLU (an acidic amino acid), which have been most extensively studied.

TRP is the precursor for the neurotransmitter serotonin (5-HT). The TRP concentration in brain rapidly influences the rate of 5-HT synthesis: Raising brain TRP concentrations increases 5-HT synthesis, whereas lowering brain TRP decreases 5-HT synthesis. Brain TRP uptake and concentrations are directly influenced by the plasma concentrations of TRP and its BBB LNAA transport competitors. The plasma concentrations of TRP and the other LNAA are readily modified by food intake, thereby linking diet to brain 5-HT synthesis. Dietary proteins and carbohydrates are the food components that change brain TRP and 5-HT: Carbohydrate ingestion increases plasma TRP, while lowering the plasma concentrations of its LNAA competitors (an effect dependent on the release of insulin), causing BBB TRP uptake, brain TRP concentrations, and 5-HT synthesis all to increase. The effect of ingesting a meal containing protein depends on the protein: A meal containing  $\alpha$ -lactalbumin, a milk protein rich in TRP, causes the plasma concentrations of TRP to rise much more than those of its LNAA competitors. As a consequence, TRP gains a sizeable advantage in the competition for BBB transport, and brain TRP concentrations and 5-HT production increase (considerably more than that seen after carbohydrates are ingested). In contrast, consuming a meal containing zein, a corn protein very low in TRP, causes a marked decline in plasma TRP concentrations, while the plasma concentrations of its LNAA competitors rise. The result is considerable reduction in brain TRP uptake and 5-HT synthesis. The ingestion of meals containing proteins, such as casein, which contain moderate levels of TRP and other LNAA, modifies plasma concentrations of TRP and the other LNAA in a manner that results in no change in the competitive transport of TRP into brain. Consequently, brain TRP levels and 5-HT production are unchanged. Hence, a key feature of the LNAA transporter, its competitive nature, explains the impact of meals containing carbohydrates with or without protein on the production of a molecule important to normal brain function (5-HT).

Although there are many implications of the previously mentioned findings, one earlier hypothesis, based on the now erroneous idea that the ingestion of carbohydrate – but not protein – would raise brain TRP and stimulate 5-HT production, is no longer tenable. This hypothesis argued that a phenomenon termed 'carbohydrate craving' occurred in individuals who experienced no rise in brain TRP levels or 5-HT synthesis when ingesting carbohydrates (due to insulin resistance, which occurs in type-2 diabetics and in insulin-resistant obese subjects). Because increases in brain 5-HT release are known to suppress appetite, the argument was, such individuals would not experience the normal 5-HT-mediated suppression of hunger on eating carbohydrates and continue consuming them (thus 'carbohydrate craving'). Clearly, because the ingestion of even modest amounts of common dietary proteins is now known also to raise brain TRP and 5-HT (the  $\alpha$ -lactalbumin in milk and also egg protein), a person seeking to raise brain 5-HT by ingesting carbohydrates could just as easily accomplish this by consuming these proteins. Thus carbohydrate craving, at least as envisioned in this earlier hypothesis, should not exist.

Chronic dietary effects are also observed. For example, chronic ingestion of diets containing proteins by rats with high proportions of one or more LNAA relative to TRP cause brain TRP and 5-HT concentrations to decline. The chronic ingestion of diets low in protein also causes the plasma concentrations of all LNAA to decline (including TRP), and brain TRP and 5-HT. In this case, brain TRP falls not because of a change in BBB competition but simply because the BBB uptake of all LNAA declines with falling plasma concentrations (the transporter becomes unsaturated, eliminating competition).

Other LNAA are neurotransmitter precursors in substrate-driven pathways in brain. Phenylalanine and tyrosine are substrates for catecholamine synthesis and histidine is the precursor of histamine. Like TRP, the brain concentrations of these amino acids are influenced by their competitive BBB uptakes from the circulation, and thus the diet. However, dietary effects for these amino acids are generally less noteworthy than for TRP.

The nonessential amino acid GLU is an excitatory neurotransmitter, causing neurons that express GLU receptors to depolarize. Because GLU is excitatory, responsive neurons can become overexcited, when subjected to prolonged GLU exposure, and die. The term 'excitotoxicity' was coined to describe this effect and led to the concern that GLU ingested in food (as a constituent of dietary proteins or as a flavoring agent) might cause the brain to become flooded with GLU, causing widespread neurotoxicity. The BBB acidic amino acid transporter prevents this from occurring: It primarily transports GLU out of the brain and not into it. Consequently, the BBB functions as a 'barrier' to GLU penetration from the blood.

Another mechanism also protects brain neurons from excessive exposure to GLU. Glial cells rapidly remove GLU from brain extracellular fluid and convert it to an electrically inert amino acid, glutamine. Although glial cells efficiently absorb neuronal GLU, they also readily clear any GLU that might stray into the brain from the circulation.

## Fatty Acids and Choline

### Fatty Acids

The brain uses fatty acids to synthesize the complex fat molecules that form neuronal and glial cell membranes. This process is more active in growing animals than in adults. The brain synthesizes some fatty acids from smaller molecules, but their uptake from the circulation is also an important source and is the only source for certain fatty acids (the essential fatty acids, which cannot be manufactured in the body). The details of the uptake process are not well understood.

From the nutritional perspective, diet influences essential fatty acid availability to the brain, with potentially important functional consequences. In almost all mammals, there are two essential fatty acids, linoleic acid and  $\alpha$ -linolenic acid (termed polyunsaturated fatty acids (PUFAs)). In the nervous system (as elsewhere), linoleic and  $\alpha$ -linolenic acid are incorporated into phospholipid molecules and inserted into cellular membranes, where they influence membrane fluidity and membrane-associated functions (e.g., the functionality of receptors and transporters). In addition, the linoleic acid in membrane lipids can be released and converted into arachidonic acid, a key precursor in the synthesis of prostaglandins and leukotrienes, which are families of important signaling molecules.  $\alpha$ -Linolenic acid can be converted into docosahexanoic acid, a molecule found in very large amounts in the rods and cones of the retina and in the nerve terminal membranes of brain. Docosahexanoic acid is thought to be a key component of phototransduction and has been demonstrated to have important effects on vision. Dietary modifications in essential fatty acid intake might therefore be expected to influence membrane functions in brain, leading to alterations in brain function (as has been demonstrated for vision).

### Choline

Choline occurs in the body as a constituent of lipid molecules in cell membranes, as a source of methyl groups, and as a precursor for the neurotransmitter acetylcholine (ACh). Choline is not an essential nutrient in humans, and deficiencies are rarely seen, because it is ubiquitous in the diet. However, in recent decades, dietary choline has been a focus of interest because of the possibility that changes in choline intake could influence neuronal ACh synthesis. ACh is a neurotransmitter; its synthesis and release by brain neurons is influenced by choline availability, which in turn can be altered by dietary choline intake, either in the form of free or fat-bound choline (phosphatidylcholine). In this context, oral choline and phosphatidylcholine have found some application in human diseases thought to involve ACh. For example, they have been used successfully to treat movement disorders such as tardive dyskinesia, a drug-induced muscular disorder in schizophrenic patients linked to low ACh function. However, they proved to be of little value in controlling abnormal muscle movements associated with Huntington's disease (also linked to low ACh function). Dietary choline and phosphatidylcholine supplements have also been studied as potential memory enhancers because CNS ACh neurons play an important role in memory. Patients with Alzheimer's disease have been most studied, but in general, the disappointing outcome has been that neither choline nor phosphatidylcholine has afforded much improvement in memory.

### Vitamins

Neurons and glia have the same functional demands for vitamins as do other cells in the body. Their access to brain is thus an important consideration, particularly given the existence of the BBB. Water-soluble vitamins are transported across the BBB, and in some cases, the blood-CSF barrier, most often by non-energy-requiring carriers. After they are taken up into the neurons and

glial cells, most are rapidly converted into their biologically active derivatives, namely cofactors in enzyme-mediated reactions. Because cofactors are recycled, dietary deficiencies in one or another vitamin do not immediately lead to brain dysfunction, inasmuch as cofactor pools may take extended periods of time to become depleted. Although fat-soluble vitamins are lipid soluble, their passage through the BBB most likely involves more than simply diffusion.

### Water-Soluble Vitamins

Folic acid is transported into brain as methylenetetrahydrofolic acid, the major form of folic acid in the circulation. It is then transported rapidly into the neurons and glia from the CSF or extracellular fluid. Once inside the cells, folates are polyglutamated. Methylenetetrahydrofolate is used by neurons and glia in reactions involving single-carbon groups, such as in the conversion of serine to glycine or homocysteine to methionine. Once methylenetetrahydrofolate is consumed in these reactions, folic acid is transported out of the brain into the circulation. Folate has become an issue of neurologic concern because of a link between folate deficiency and abnormal CNS development. The incidence of spina bifida, a serious spinal cord abnormality, rises above the population mean in the children of women who are folate deficient during pregnancy. Moreover, the incidence of spina bifida can be reduced by folic acid supplementation during pregnancy, beginning before conception. Initiating supplementation before conception is essential because the basic design of the CNS is laid down during the first trimester. At present, the mechanism(s) by which folic acid deficiency leads to the improper formation of the spinal cord is unknown. Folate deficiency may also be linked to depression in adults, and occasional studies suggest that folate supplementation can be a mood elevator in depressed patients. The mechanism(s) by which folate modifies mood is presently unknown.

Ascorbic acid (vitamin C) is actively transported into the brain extracellular fluid through the blood–CSF barrier, from which it is actively transported into the cells. Brain ascorbate pools show minimal fluctuations over a wide range of plasma ascorbate concentrations, which presumably explains the absence of CNS signs in ascorbate deficiency. To date, the only defined biochemical function of ascorbic acid in brain is as a cofactor for the enzyme that converts dopamine to norepinephrine (although ascorbate is thought by some to function as an antioxidant).

Thiamine (vitamin B<sub>1</sub>) is taken up into brain by a BBB transporter; small amounts also gain entry via transport from blood into CSF. It is then transported into neurons and glia; conversion to thiamine pyrophosphate effectively traps the molecule within the cell. In nervous tissue, thiamine functions as a cofactor in important enzymes of energy metabolism. Severe thiamine deficiency in animals reduces thiamine pyrophosphate levels and the activities of thiamine-dependent reactions. It causes loss of the coordinated control of muscle movement; the exact biochemical mechanism is unsettled. The functional deficits are rapidly corrected with thiamine treatment, suggesting that neurons have not been damaged or destroyed. Thiamine deficiency in humans (beri-beri and Wernicke's disease) produces similar deficits in the control of muscle movements and also mental confusion. Korsakoff's syndrome, which occurs in almost all patients with Wernicke's disease, involves short-term memory loss and mental confusion. Severe thiamine deficiency in humans appears to produce neuronal degeneration in certain brain regions. The motor abnormalities can be corrected with thiamine treatment, but the memory dysfunction is not improved.

Riboflavin enters brain via a saturable BBB transport carrier. It is then transported into neurons and glia and trapped intracellularly by phosphorylation and converted to flavin adenine dinucleotide. Flavin adenine dinucleotide functions as a cofactor in carboxylation reactions. The brain contents of riboflavin and its derivatives are not notably altered in states of dietary riboflavin deficiency or excess.

Pantothenic acid is transported into brain by a BBB transport carrier. Neurons and glial cells take up pantothenic acid slowly by a mechanism of facilitated diffusion. Inside the cell, the vitamin becomes a component of coenzyme A, the coenzyme of acyl group transfer reactions. Relative to other tissues, the brain contains a high concentration of pantothenate, mostly in the form of coenzyme A. Brain coenzyme A concentrations are not depleted in pantothenate-deficiency states.

Niacin (vitamin B<sub>3</sub>) is transported into brain as niacinamide, primarily via the BBB. Most niacin in brain is derived from the circulation, although brain may be able to synthesize small amounts. Niacin is taken up into neurons and glia and rapidly converted to nicotinamide adenine dinucleotide. The half-life of nicotinamide adenine dinucleotide in brain is considerably longer than in the other tissues. Nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate are involved in numerous oxidation–reduction reactions. Dietary niacin deficiency in the presence of a low intake of TRP causes pellagra in humans, a deficiency disease that includes mental depression and dementia, loss of motor coordination, and tremor. The mechanism(s) for these effects have not been identified.

Pyridoxine (vitamin B<sub>6</sub>) is taken up into brain via a transport carrier that has not been well described. The vitamin can be transported in any of its nonphosphorylated forms (pyridoxine, pyridoxal, and pyridoxamine). Once within the brain extracellular fluid, the vitamin is readily transported into the neurons and glia and phosphorylated (primarily to pyridoxal phosphate or pyridoxine phosphate). Pyridoxal phosphate is a cofactor in a variety of neurotransmitter reactions, such as aromatic-L-amino acid decarboxylase (an enzyme of monoamine biosynthesis), glutamic acid decarboxylase (the enzyme of  $\gamma$ -amino butyric acid (GABA) synthesis), and GABA transaminase (the enzyme which catabolizes GABA). In humans, pyridoxine deficiency is rare because of its widespread occurrence in food. However, when identified, it has been associated with increased seizure activity, an effect dissipated by pyridoxine treatment. This effect may be linked to the production of GABA, an inhibitory neurotransmitter.

Biotin is transported into brain by a BBB carrier. It is a coenzyme for a variety of key carboxylation reactions in gluconeogenesis, fatty acid synthesis, and amino acid metabolism. Normally, biotin is recycled in cells during protein (enzyme) turnover, but not in brain; brain cells are thus more immediately dependent than the other cells on circulating biotin availability. Biotin deficiency is

rare; when it occurs, it can involve CNS symptoms (depression or sleepiness); the underlying basis for these effects is presently unknown.

Cobalamin (vitamin B<sub>12</sub>) is thought to be transported into brain by a carrier-mediated mechanism. Little is known about this process or about the function of vitamin B<sub>12</sub> in the nervous system. Vitamin B<sub>12</sub> deficiency is associated with neurologic abnormalities, which are presumed to be derived from the demyelination of CNS axons seen in advanced deficiency cases. These effects are reversed if vitamin B<sub>12</sub> treatment is provided early enough; when it is left untreated, axonal degeneration occurs. Vitamin B<sub>12</sub> may be important in neuronal repair mechanisms, which may become compromised in deficiency states. Nervous system damage associated with vitamin B<sub>12</sub> deficiency can occur at any age.

### Fat-Soluble Vitamins

Of the fat soluble vitamins, vitamin A (retinol) has been the most studied in relation to the CNS. The others have been considerably less examined, although vitamin E is currently of some interest because of its function as an antioxidant. The CNS is not thought to be a major focus of action for vitamins D and K, and thus little information is available regarding their roles in brain function.

The principal role of vitamin A in the CNS is as a component of the photoreceptive pigment of the eye, rhodopsin. In the blood, vitamin A circulates bound to the retinol-binding protein and transthyretin (prealbumin). Its transport into retinal cells occurs at the blood–retinal barrier (the retinal pigmented epithelial (RPE) cells), after the retinol–protein complex binds to retinol-binding protein receptors. Once bound, retinol is released into the RPE cell. The retinol-binding protein and transthyretin molecules are released back into the circulation. Inside the RPE cell, retinol binds to a specific protein and ultimately is esterified to a fatty acid. This molecule serves as the substrate for the conversion of retinol into the visually active form of the molecule, 11-*cis*-retinaldehyde, which then finds its way into the photoreceptor cell to be bound to opsin to form rhodopsin, the light-responsive pigment of the eye. When light strikes rhodopsin, phototransduction occurs and 11-*cis*-retinaldehyde is isomerized to all-*trans*-retinaldehyde, hydrolyzed from opsin, and released by the photoreceptor into the extracellular space (the opsin is retained and reused). The all-*trans*-retinaldehyde is shuttled into the RPE cell, where it is reconverted into 11-*cis*-retinaldehyde, and then recycled to the photoreceptor cells again to form rhodopsin.

From the nutritional perspective, retinal cells have an efficient system for managing and maintaining vitamin A pools. Hence, depletion of retinal vitamin A pools secondary to dietary deficiency only occurs over an extended time period. Deficiency appears functionally as ‘night blindness,’ as rhodopsin levels decline. Extended vitamin A deficiency leads to a loss of photoreceptor elements and eventually of the photoreceptor cells themselves. The cause of this cellular degeneration is not well understood.

Vitamin E is an antioxidant and a free radical scavenger that protects fatty acids in cellular membranes. It is transported in blood associated with lipoproteins. The mechanism of its transfer into nervous tissue is unknown. Dietary vitamin E deficiency is extremely rare in humans. It occurs in association with certain abnormalities of vitamin E transport and fat absorption and sometimes in individuals with protein-calorie malnutrition. The neurological manifestations are peripheral nerve degeneration, spinocerebellar ataxia, and retinopathy. Vitamin E has been proposed to play a role in a number of CNS diseases linked to oxidative damage. One example is Parkinson's disease, a movement disorder caused by the degeneration of certain groups of brain neurons. Evidence of oxidative damage is present in the brains of Parkinsonian patients, although controlled clinical trials of vitamin E supplementation have proved to be ineffective. Such negative findings question the likelihood of a vitamin E link to the etiology of the degenerative changes. A second example is Alzheimer's dementia, which is associated with a progressive, ultimately catastrophic degeneration of the brain. Several types of oxidative damage have been found in the brains of Alzheimer's patients, although it is presently unclear if this damage is the cause or effect. Vitamin E supplementation can slow the progression of Alzheimer's disease. However, such findings do not indicate if vagaries in vitamin E intake over an extended period of time are a cause of the disease.

### Minerals

All of the essential minerals are important for cellular functions in brain, as they are elsewhere in the body. These are sodium, potassium, calcium, magnesium, iron, copper, zinc, manganese, cobalt, and molybdenum. Although most function as cofactors in enzymatic reactions, sodium and potassium are key ions in electrical conduction in neuronal membranes, calcium functions as a secondary messenger within neurons, and magnesium is an important component of certain neurotransmitter receptors. The diet normally provides more than adequate amounts of almost all minerals, except possibly for calcium, iron, magnesium, and zinc. The BBB permeability to most metals is quite low. For example, although the brain extracts 20–30% of the glucose in blood in a single capillary transit, it extracts <0.3% of any metal. The mechanisms of transport into brain for most metals are unknown. However, some details regarding the transport and/or functions of iron, calcium, and copper are available.

Iron circulates bound to a protein, transferrin. Iron uptake into brain occurs primarily at the BBB and involves a transferrin receptor-mediated endocytosis of the iron–transferrin complex by capillary endothelial cells. Iron dissociates from transferrin inside the cell and is delivered into the brain interstitial fluid; the transferrin is returned to the circulation. Brain iron associates with ferretin, a protein, and is stored intracellularly. The bulk of the iron–ferretin stored in brain resides in glial cells and is laid down early in postnatal life. Marked regional differences in iron and ferretin concentrations occur in brain; levels in some areas are as high as those in the liver. However, this distribution does not correlate with the density of transferrin receptors in brain capillaries; it is

presently unknown how or why the unequal distribution of iron develops. Numerous enzymes in brain are iron-requiring, including several hydroxylases involved in neurotransmitter production, and a key metabolic enzyme, monoamine oxidase.

Iron deficiency can cause impairments in attention and cognition in children. Similar effects are seen in animals. In iron-deficient rats, brain iron concentrations decline, with newborn and infant animals showing more rapid declines than older animals. Iron repletion in brain occurs in infant and adult rats with iron supplementation but not in animals depleted at birth. While outside of the brain, the activities of many iron-dependent enzymes are depressed by iron deficiency, whereas their activities are unaffected inside the brain. However, a reduction in certain dopamine receptors occurs, along with aberrations in dopamine-dependent behaviors (dopamine is a CNS neurotransmitter). The inability of brain iron stores to recover in rats made them iron deficient as newborns coincides with a persistence of dopamine-linked behavioral deficits, despite normal repletion of iron stores elsewhere in the body. Restoration of normal behavior with iron supplementation, along with brain iron stores, is seen in animals made iron deficient at other ages.

Iron deficiency also interferes with myelination. Since marked glial proliferation and myelin formation occur early in infancy, iron deficiency during this period could prevent the optimal development of neuronal communications (glial cells provide insulation for axons and synapses). This effect could account for some of the behavioral deficits associated with neonatal iron deficiency.

Calcium is actively transported into the CNS, primarily via the blood–CSF barrier and is not sensitive to vitamin D. Because calcium concentrations in the circulation are regulated, under most circumstances, this process should also help to maintain brain calcium uptake and levels in the face of vagaries in calcium intake. Deficiencies in brain calcium should thus be a relatively rare occurrence.

Copper functions as a cofactor for numerous enzymes, including dopamine  $\beta$ -hydroxylase (DBH), which converts dopamine to norepinephrine. Dietary copper deficiency in humans is fairly rare. When produced in animals, it leads to reduced DBH activity in neurons and cells anywhere in the nervous system that synthesize norepinephrine. The mechanism of copper transport into the brain is presently unknown. Copper deficiency occurs as an X-linked genetic disease of copper transport in Menkes disease, in which tissue and brain copper levels become extremely low and produce neurodegeneration. Children with Menkes disease die at a very young age.

### Key points

- To present the main carcinogenic substances in food in relation to their origin: natural, contaminants, derived from food processing
- To highlight the importance of the mechanisms of carcinogenicity, including genotoxic and non-genotoxic substances.
- To describe the main *in vivo* assays for carcinogenicity evaluation
- To highlight the *in vitro* and *in vivo* short-term tests to predict carcinogenicity
- To emphasize that monitoring and control of cancer should be based on the risk analysis methodology

### Glossary

**Benchmark Dose (BMD)** The minimum dose of a substance that produces a clear, low level health risk, usually in the range of 1–10% change in a specific toxic effect such as cancer induction

**Bioassay** Test of biological activity using living organisms

**Carcinogen** Agent capable of initiating the development of malignant changes leading to tumors

**Carcinogenicity** Cancer-causing property of a substance when an animal or human is exposed to it

**Epigenetic** Heritable change in the activity of a gene without affecting structure

**Genotoxicity** Processes that alter the structure, information content, or segregation of DNA including those that can cause DNA damage at the replication level

**Hazard** Potential of an agent to cause an adverse effect

**Margin of Exposure (MOE)** The ratio of two factors which assesses for a given population: the dose at which a small but measurable adverse effect is first observed and the level of exposure to the substance considered. It indicates if exposure should be considered of concern for public health

**Mutation** Heritable genetic changes that may be manifested at the phenotypic level or underlying DNA modifications (including specific base pair changes and chromosomal translocations)

**Risk** Probability that an (adverse) event will occur

## Introduction

Carcinogenic substances in food may have different origins. They occur naturally in the physical environment and are found in a very large number of higher plants, fungi, and microorganisms, many of which are part of the human diet. The presence of carcinogenic environmental pollutants such as pesticides, industrial waste, drugs, etc. in food is significantly increasing due to human activity and industrialization worldwide. In addition, some carcinogens can be formed as a result of the traditional cooking, processing and preserving practices of food.

Since 1971, The International Agency for Research on Cancer (IARC) works in identifying the environmental chemicals that are carcinogenic hazards to humans classifying them into four groups: Group 1 (Carcinogenic to humans); Group 2A (Probably carcinogenic to humans); Group 2B (Possibly carcinogenic to humans) and Group 3 (Not classifiable as to its carcinogenicity to humans) (<https://www.iarc.who.int/>) (International Agency for Research on Cancer, 2021); Organization for Economic Cooperation and Development (OECD). In this article we focused on the compounds classified in Groups 1, 2A and 2B which may be present in foods, and they have been selected according to their nature: natural occurring, environmental contaminants, and produced by food preservation, processing and cooking.

Although carcinogens act through a wide variety of mechanisms, a substantial number have a common mechanism of action since they react with the genetic material of the body, DNA. These so-called genotoxic carcinogens generally require metabolic activation by the “host” animal to express their carcinogenicity. Although substantial efforts are being made to develop short-term, non-animal tests to predict the carcinogenicity of chemicals, animal bioassays remain the only reliable method for establishing the potential of a chemical to be a carcinogen (Anderson and Phillips, 2013).

## Naturally occurring carcinogens

Naturally occurring substances identified as carcinogens in animals and humans present in foods may include natural components that are part of the food itself (plants) and natural compounds or toxins produced by fungi and microorganisms (Table 1). In addition, different chemical products (inorganic chemicals, organic chemicals and radioactive compounds) can be present in foods due to contamination (Table 2). They are present in the environment either as naturally occurring minerals or as a result of natural processes acting in the environment such as combustion, radioactive decay, or biodegradation of plant materials to oils.

## Carcinogenic substances present in edible plants

Although the acute toxicity of many plant species has been known since written records first appeared, only comparatively recently has the carcinogenicity of plant-derived products been recognized. They are usually secondary metabolites, often present as part of the plant's natural defense mechanism against predation (i.e., natural pesticides), and are widespread in fruits, vegetables, herbs, and spices (Anderson and Phillips, 2013). However, the list of confirmed animal carcinogens present in plants is still relatively short, and only few of them are currently confirmed or suspected human carcinogens classified by IARC (Table 1).

Areca nut or betel nut is the seed of the tropical palm tree *Areca catechu* which is consumed in chewed form. Due to its stimulating and addictive properties, this natural product is used across the globe (over 600 million of people, WHO). Moreover, it is the primary ingredient in all betel quid preparations and is classified, together with areca nut, in the group 1 by IARC. Among their chemical constituents the alkaloids cause the addictive and carcinogenic effects (oral and pharynx cancer), therefore the consumption of areca nut in any form should be treated as a “neglected global public health emergency”. Aristolochic acids are abundant in wild ginger and *Aristolochia* genus plants are widely used in traditional medicines for their therapeutic effects, although their intake has been directly linked to cancers of the urinary tract and hepatocellular carcinomas. On the other hand, the presence of aristolochic acids in edible parts of crops, originated from aristolochic acids-contaminated soil, has been demonstrated being considered as one of the major pathways by which humans become exposed to these compounds. Methoxsalen (8-methoxypsoralen) is a furanocoumarin found in a variety of natural products (celery, parsley, carrot, orange, lemon etc.). It has been used to treat epidermal proliferative diseases (psoriasis, vitiligo, eczema). The joint action of Methoxsalen plus ultraviolet A is required for the induction of carcinogenic effects.

Other natural compounds present in plants are classified in group 2B by the IARC. Among them, cycasin (methylazoxymethanol-3-glucoside), a colon carcinogen, is a naturally occurring compound that has been isolated from genus cycad plants, being its metabolite (methylazoxymethanol) formed by action of enzymes present in the intestinal microflora the active carcinogenic compound. Safrole, component of different species of plants such as *Ocimum basilicum*, *Piper nigrum* or *Myristica fragrans*, is mainly considered as liver carcinogen. Methyleugenol is widely distributed in plants, its intake is mainly through spicy foods and herbal beverages. Thus, methyleugenol-containing herbal beverages show an increasing consumption trend in countries like Indonesia; nonetheless it should be limited to about two weeks a year during a lifetime to be considered safe.

One of the first classes of naturally present toxic compounds identified in plants were the pyrrolizidine alkaloids from the genus *Senecio*. Subsequently, more than 650 related compounds have been isolated from numerous families and plant species, many of which are potent liver toxins and liver carcinogens affecting livestock, wildlife, and humans (Anderson and Phillips, 2013). In

**Table 1** Naturally occurring carcinogenic substances classified according to IARC in plants, fungi and microorganisms.

Carcinogenic agent	Classification group according to IARC	Food where it can be found	Producer organisms
<b>Plants</b>			
Areca nut	1	Betel palm fruit by chewed	<i>Areca catechu</i>
Aristolochic acid	1	Traditional Chinese herbal therapy	<i>Aristolochia</i> and <i>Asarum</i> genus (wild ginger)
Betel quid with or without tobacco	1	Betel leaves and areca nut mixed with other aromatic substances	<i>Piper betle</i>
Cycasin	2B	Seeds	<i>Cycad circinalis</i> and <i>Cyca revoluta</i>
Dihydrosafrole	2B	Sassafras oil and root bark tea	<i>Sassafras albidum</i>
<i>Ginkgo biloba</i> extract	2B	Infusion of the leaves	<i>Ginkgo biloba</i>
8-Methoxypsoralen (plus ultraviolet A)	1	Celery, parsley, carrot, orange, lemon etc.	Apiaceae family
Methyleugenol	2B	Clove oil, basil, nutmeg, cinnamon, ginger etc.	<i>Syzygium aromaticum</i> , <i>Ocimum basilicum</i> , <i>Cinnamomum verum</i> , <i>Myristica fragrans</i> , <i>Zingiber officinale</i> etc.
Pyrrolizidine alkaloids: Lasiocarpine, monocrotaline and riddelliine	2B	Honey, tea, herbal infusions and food supplements	Asteraceae, Boraginaceae, Fabaceae, Orchidaceae and Apocynaceae families
Saffrole	2B	Sassafras oil and root bark tea	<i>Sassafras albidum</i> , <i>Sassafras officinalis</i> and <i>Cinnamomum camphora</i>
<b>Fungi and microorganisms</b>			
Aflatoxins (B1, B2, B2A, G1, G2 and G2A)	1	Cereals, oilseeds, fruits, vegetables, nuts, dried fruits, coffee beans, cocoa beans and spices	<i>Aspergillus</i> spp. and others
Aflatoxin M1	2B	Antineoplastic agents	<i>Streptomyces peucetius</i>
Daunomycin	2B	Cereals, oilseeds, fruits, vegetables, nuts, dried fruits, coffee beans, cocoa beans and spices	<i>Fusarium graminearum</i> and <i>Fusarium verticillioides</i>
Fumonisin (B1, B2 and C)	2B	Fish, molluscs and vegetables	Microcystis, Plankthotrix, Anabaena, Nostoc, Aphanizomenon, Anabaenopsis, Rivularia and Fisherella, among other genera
Microcystin-LR	2B	Antitumor, antibiotic drugs	<i>Streptomyces</i> spp.
Mitomycin C	2B	Cereals, oilseeds, fruits, vegetables, nuts, dried fruits, coffee beans, cocoa beans and spices	<i>Aspergillus ochraceus</i> and <i>Penicillium verrucosum</i>
Ochratoxin A	2B	Cereals, animal feed, hard cheese, pecan nuts and green coffee beans	<i>Aspergillus</i> spp.
Sterigmatocystin	2B	Antibiotic drugs	<i>Streptomyces</i> spp.
Streptozotocin	2B		

particular, 1,2-unsaturated compounds are considered as genotoxic and carcinogenic substances due to their potential to undergo metabolic activation into reactive pyrroles. Among them, the IARC classified lasiocarpine, monocrotaline and riddelliine in the group 2B, while other pyrrolizidine alkaloids assessed were not classifiable (category 3) due to the limited information available. Humans can be exposed to pyrrolizidine alkaloids through herbal teas and milk honey, eggs or spices and food supplements; their presence in these foods, even at low levels, may be of concern for human health due to their hepatotoxic and genotoxic properties. Globally, most of these natural compounds are ingested through plant infusions. People perceive herbal beverages as safe although they contain carcinogenic compounds that may put consumers at risk due to over consumption of them. Further law enforcement to restrict the sale and use of products containing natural occurring chemicals is required to protect human health.

### Carcinogenic substances produced by fungi and microorganisms

A number of naturally occurring organic chemicals or toxins produced by lower plants, such as fungi, and by microorganisms may contaminate and bioaccumulate in food (Table 1).

Mycotoxins are small-molecular natural products, toxic secondary metabolites mainly produced by filamentous fungi of *Aspergillus*, *Fusarium*, *Penicillium* and *Alternaria* genus. These toxins include aflatoxin B<sub>1</sub>, B<sub>2</sub>, B<sub>2A</sub>, G<sub>1</sub>, G<sub>2</sub> and G<sub>2A</sub> classified into the group 1 by IARC and are of the most potent carcinogens known. Moreover, with variable molecular structures, fumonisins, ochratoxin A and sterigmatocystin (a precursor of aflatoxin B<sub>1</sub>) (group 2B), are also of interest. Human exposure to such mycotoxins occurs

Radium	1	
Radon-222	1	

mainly as a result of cereal crops and nuts stored in humid conditions (Anderson and Phillips, 2013). Food and feed contamination by mycotoxins is extremely common worldwide (about 25% of cereals according to the Food and Agriculture Organization of the United Nations, FAO) and it is very much related to the regional and climatic conditions. Recently, different studies have been focused on the occurrence of mycotoxins in different foods and feed showing that in Europe the content of fumonisins (mainly B1) is in general high, ochratoxin A is relatively low and aflatoxins are lowering. A continuous adjustment of the maximum legal maximum limits of these toxins together with the establishment of monitoring teams and improved agricultural production methods seems necessary to protect human health and food trade.

Microcystin-LR (MC-LR) is the most toxic and widespread microcystins (MCs), cyanotoxins produced by several genera of cyanobacteria. Among the structural multifarious variants of MCs (more than 246 MCs) (Hinojosa et al., 2019), only MC-LR is classified into the group 2B. The potential effects of this toxin on carcinogenesis include primary liver, colorectal and prostate carcinomas. MC-LR intake from contaminated water and food is a growing and an important source of human exposure is related to its bioaccumulation in various edible aquatic organisms, plants, and algae-based food supplements.

### Contaminants present in food: inorganic chemicals, organic chemicals and radioactive compounds

Exposure to carcinogenic compounds through ingestion of contaminated food can be frequent. Many metallic contaminant elements are present in food, derived from a range of sources including the water used in food processing, soil residues, packaging, and cooking equipment. Several metals and some of their salts have been shown to be carcinogenic in animals and humans, particularly to the lungs (Anderson and Phillips, 2013). These include arsenic, beryllium, cadmium, chromium, cobalt, lead, and nickel which are classified into group 1 or 2B by IARC (see Table 2).

Methylmercury ( $\text{CH}_3\text{Hg}^+$ ) is the most common organic component of Hg in the food chain. It is produced by direct chemical reaction or by the action of bacteria. To protect consumers against toxicity of  $\text{CH}_3\text{Hg}^+$  and achieve the benefits of fish consumption, different international organizations and health authorities recommend that the consumption of fish/seafood species with a high content of mercury should be limited.

The formation of dimethyl arsenic acid (DMAA), commonly named cacodylic acid, occurs as a result of methylation of inorganic As by soil microorganisms, mainly from the genera *Aeromonas*, *Aspergillus*, *Escherichia* and *Saccharomyces*. The extensive use of As-derived herbicides during the 20th century led to a significant increase of anthropogenic DMAA acid into the environment, and severe accumulation of organic arsenic in soil and crops.

In relation to pesticides, dichlorvos (organochlorine insecticide) and dieldrin (organophosphorus pesticide) have been classified into group 2B by IARC. Dichlorvos is one of the most used pesticides due to its ample application in a high variety of crops (paddy, soybean, wheat, mustard, castor, groundnut, cucurbits). Moreover, the contamination of water bodies by dichlorvos has now become a global phenomenon. Along the food chain, pesticide residues are transferred from lower to higher trophic levels, and residues are also biomagnified in the process.

Polychlorinated biphenyls (PCBs) (Group 1, IARC) are a group of compounds of industrial origin present in plants, animals, and humans, and although huge efforts have been made to stop or limit their formation in developed countries, they are still widely spread and found due to their bioaccumulative nature and long-lasting existence mainly in industrialized regions. Much attention has been paid to research on human exposure risks posed by these compounds.

Regarding radioactive elements, some of them are also carcinogenic for humans, particularly to the lungs. These include iodine-131, radium, and radon gas and may act by damaging DNA directly or by increasing oxidative damage as a result of an increase in reactive radical species.

### Carcinogens produced by food processing

A number of procedures used in food preparation/processing can introduce significant amounts of carcinogens into the food chain or the local environment. The most widely studied of these processes are the preservation of meats and fish by salting or smoking, grilling or broiling of meats, and cooking in vegetable oils (Anderson and Phillips, 2013). Moreover, frying, roasting, and baking foods rich in sugars, or even food fermentation may origin derived carcinogens as well.

Traditional methods for preserving meat and fish involve either salting or smoking. Epidemiological evidence has found an association between an increased incidence of cancer of the mouth and pharynx and the intake of salted meat and fish. It seems likely that a reaction between sodium nitrate or nitrite used for preserving the meat and alkylamides present in the meat results in the formation of N-nitrosamines, nitrosamides, and nitrosoguanidines. These compounds have been shown to be potent carcinogens in animal experiments to the mouth, pharynx, and other sites. Plenty of nitrosamines are found in different foods (Table 3), including N-nitrosodimethylamine (NDMA), N-nitrosodiethylamine (NDEA), etc. although not all of them show carcinogenic effects. Humans may be exposed to two different forms of Nitrosocompounds (NOCs): (i) exogenous, derived from different sources (e.g., tobacco products, diet, etc); (ii) endogenous nitrosamines and nitrosamides, generated by the reaction of nitrite with the products of amino acids' degradation in the stomach, accounting for up to 75% of the total NOC exposure (Cameán et al., 2006). Although dose levels required to induce tumor formation in animal studies are substantially higher than those likely to be ingested by humans, there is a concern that the presence of nitrosamines in food implies a significant risk. Several epidemiological and pre-clinical studies conducted on animal models reported a strong link between endogenous NOCs and colorectal cancer.

Preservation of meats and fish by smoking, and also their grilling can generate polycyclic aromatic hydrocarbons (PAHs). They are formed by incomplete combustion or pyrolysis and generally occur in complex mixtures. Both carcinogenic and noncarcinogenic compounds have been identified, being the PAHs of greatest concern those that are genotoxic and carcinogenic. For non-smokers the major route of exposure to PAHs is food. The main PAH (over 100 identified) classified by the IARC is the benzo[a]pyrene (BaP) (Group 1). EFSA Panel on Contaminants in the Food Chain (CONTAM Panel) concluded that among PAHs, eight of them (Table 2) either individually or in a combination were the possible indicators of the carcinogenic potency of PAHs in food. The combination of two (BaP + chrysene = PAH2), four (PAH4) and eight PAH8 of these compounds represented around 34%, 60% and 80%, respectively of the amount of 15 PAHs found in food. BaP is not a suitable indicator of the occurrence of PAHs in food, being PAH4 and PAH8 the most adequate ones, with PAH8 not providing much added value compared to PAH4. Occurrence and toxicological data for individual PAHs, as well as oral carcinogenicity data with mixtures relevant for dietary exposure are needed for a more realistic risk assessment approach.

Heating oil during food cooking may generate a range of carcinogenic chemicals, including PAHs. However, many of the compounds produced are volatile and may therefore represent more of a risk to the cook than to the food consumer. The IARC considers that emissions from high temperature frying are classified in the 2A group (Anderson and Phillips, 2013).

In addition, practices such as frying or grilling of meats and fish have been found to generate significant quantities of heterocyclic nitrogenous compounds (HCAs), which contain methyl and/or amine groups in several positions. These heterocyclic amines, include more than 21 compounds, some of them are mentioned in Table 2. Their concentration in cooked food could oscillate considerably. They are some of the most potent bacterial mutagens known and have been shown to induce a wide range of tumors in animals and are classified in the group 2. They are particularly implicated in the induction of liver and gastrointestinal tract (GI) cancer (Cameán et al., 2006).

Moreover, acrylamide is formed in some carbohydrate rich foods, such as potatoes, grains, during high-temperature cooking, such as frying, roasting, and baking. Acrylamide is generated from natural reducing sugars and the amino acid asparagine in foods, and is not typically associated with meat, dairy, or seafood products. It is classified in the 2A group of IARC. Neurotoxicity, adverse effects on male reproduction, developmental toxicity and carcinogenicity were identified as possible critical endpoints for acrylamide from experimental animal studies, although the data from human studies were inadequate for dose-response assessment. Furan and methylfurans are formed in foods during thermal processing from several precursors such as ascorbic acid, amino acids, carbohydrates, unsaturated fatty acids and carotenoids, and are found in a variety of foods including coffee and canned and jarred foods. They induced neoplastic effects in animals, but only few data are available on the effect of furans in humans.

Sometimes, the toxic is formed during fermentation processes or during storage, such is the case of ethyl carbamate, that can occur naturally in fermented foods and beverages. It can be formed from various substances, including hydrogen cyanide, urea, citrulline, and other N-carbamyl compounds. The compound is a genotoxic classified in the group 2A and it could represent a health concern, particularly with respect to consumers of particular brands of stone fruit brandies.

**Table 3** Carcinogens produced by food processing, following the IARC classification (<https://monographs.iarc.who.int/agents-classified-by-the-iarc/>).

<i>Carcinogenic agent</i>	<i>Classification group according to IARC</i>	<i>Food where it can be found</i>
<b>Heterocyclic amines</b>		
IQ (2-amino-3-methylimidazo[4,5-f]quinoline)	2A	Grilled fish and meat, meat extracts, bacon, fried or panfried meat, casein pyrolysates and products pyrolysis of proteins

<b>Polycyclic aromatic hydrocarbons (PAHS)</b>		
Benzo[a]pyrene (BaP)	2A	Meats (barbequed, grilled, smoked), fish (preserved, processed, smoked), coffee, cereals, etc.
Chrysene	2B	
Benz[a]anthracene	2A	
Benzo[b]fluoranthene	2B	
Benzo[k]fluoranthene	2B	
Benzo[ghi]perylene	3	
Dibenz[a,h]anthracene	2A	
Indeno[1,2,3-cd]pyrene	2B	
<b>Others</b>		
Acrylamide	2A	Potatoes (especially French fries and potato chips), grain products (such as breakfast cereal, cookies, and toast), coffee
Ethyl carbamate (urethane)	2A	Spirits, wine, beer, bread, soy sauce and yoghurt
Furan and methylfurans (2-methylfuran, 3-methylfuran and 2,5-dimethylfuran)	2B	Ready-to-eat meals, toasted coffee, toasted bread

Globally, the scientific interest for derived toxicants in food is increasing in the last years in comparison to natural compounds and several international organizations have recommended different mitigation measures in order to prevent or reduce their formation.

### Mechanisms of carcinogenicity

There are a wide range of mechanisms by which carcinogens can cause cancer in human and it is well established that cancer is a multi-step process. The genotoxic carcinogens, interact directly with DNA, resulting in a permanent heritable change to a cell following replication (i.e., an altered genotype). In contrast, nongenotoxic (so-called epigenetic) carcinogens do not interact directly with DNA but cause cancer by other mechanisms (Anderson and Phillips, 2013). Specifically, ten key characteristics of carcinogens have been described so far (Smith et al., 2016): they are electrophilic in nature or can be metabolically activated to an electrophile specie; they are genotoxic; they alter DNA repair or causes genomic instability; induce epigenetic alterations; induce oxidative stress; induce chronic inflammation; they could have immunosuppressive action; they modulate receptor-mediated effects; cause

immortalization and alter cell proliferation, cell death, or nutrient supply. These criteria have been introduced by IARC to facilitate systematic consideration of mechanistic evidence in carcinogens' evaluations.

Chemicals that react with DNA are invariably electrophiles, that target the nucleophilic (electron-rich) sites in the DNA. The electrophilic center may be present in the molecule itself (activation independent) as in  $\beta$ -propiolactone, dimethyl sulfate, and  $\alpha,\beta$ -unsaturated aldehydes or be generated following metabolism (activation dependent) in the target species. Examples of classes of compounds that are converted to reactive electrophiles by oxidative metabolism include nitrosamines, chlorinated alkanes, hydrazines, and polycyclic aromatic hydrocarbons (PAHs) (Anderson and Phillips, 2013).

The mixed function oxidase system, cytochrome P-450, is the main enzymatic system involved in the activation of chemicals to carcinogenic species. This enzyme has a widespread distribution in the animal kingdom and it is known that different isoenzymes may activate the same compound in different species.

Most chemical carcinogens appear to be substrates of one particular isoenzyme called CYP1A1 thus including PAHs, aflatoxin, and 9-hydroxyellipticine, whereas the related isoenzyme CYP1A2 activates arylamines and amides such as 2-acetylaminofluorene and the cooked food mutagens. Other subfamilies include CYP2E1, which act on a wide range of small molecules, such as dialkyl-nitrosamines, urethane, vinyl monomers and haloalkanes, acrylamide, and CYP3A, which also activates PAHs, aflatoxins, and cooked food mutagens (Anderson and Phillips, 2013).

The chemistry of the activation process varies with the type of carcinogen. The oxidation of aflatoxin B<sub>1</sub>, for example, results in the formation of the 8,9-epoxide in a single step whereas the activation of PAHs, such as benzo(a)pyrene, is a multi-step process involving an epoxide that is converted to a diol by epoxide hydrolase, which is then converted to the proximate carcinogenic species, a diol-epoxide. Activation of arylamines and amides to DNA reactive species, in contrast, frequently involves an initial oxidation step to an *N*-hydroxy derivative, which is then further metabolized to a highly reactive N–O-ester. This latter reaction is catalyzed by a transferase enzyme, usually sulfotransferase or acetyltransferase for arylamines and glucuronotransferase for arylamides. Other oxidative reactions result in the formation of unstable compounds that decompose spontaneously to the ultimate carcinogenic species. Thus, simple nitrosamines are oxidized by CYP2E1 to an  $\alpha$ -hydroxy intermediate, which breaks down to the electrophilic alkyl-diazonium ion (Anderson and Phillips, 2013). This isoenzyme CYP2E1 is involved in the formation of glycidamide (GA) from acrylamide by epoxidation, which is considered the route underlying the genotoxicity and carcinogenicity of acrylamide.

Enzyme systems other than the mixed function oxidase system may also be involved in the metabolic activation of carcinogens: prostaglandin H synthetase in the case of aflatoxins; for arylamines, oxidation may be carried out by prostaglandin peroxidase, myeloperoxidase, or by flavin-containing monooxygenases.

Regarding nongenotoxic or epigenetic carcinogens, there is not a common mechanism describing their action mode. One group of epigenetic carcinogens naturally present in many fruits produce renal tumors in the rat by binding to and preventing the degradation of a specific kidney protein, alpha-2-microglobulin, which requires a prior metabolic activation for carcinogenic activity. Similarly, a wide range of food contaminants induce liver tumors in rodents due to their ability to induce the proliferation of hepatic peroxisomes (phthalate diesters, hypolipidemic drugs, chlorinated herbicides). Other mechanisms of some non-genotoxic compounds are promotion (phorbol esters, barbiturates, chlorinated hydrocarbons), endocrine modulation (androgens and estrogens, antithyroid agents), immunosuppression (cyclosporine), tissue specific toxicity (metals such as arsenic and beryllium) and cytotoxicity (metal chelators and branched chain hydrocarbons) (Anderson and Phillips, 2013). Sometimes, several indirect mechanisms are involved in the carcinogenic mode of action of some toxicants, such is the case of furans, including epigenetic changes, oxidative damage to DNA and regenerative hyperplasia. The contributing factors in carcinogenesis are likely to vary according to dose, duration of exposure and degree of severity of liver cellular damage induced, inflammation and compensatory proliferation.

## Carcinogenicity tests

### Animal bioassays

As the mechanism of carcinogenesis in both humans and animals is not well understood, the only acceptable procedure for determining whether a chemical is likely to be a carcinogen is the examination of experimental animals exposed to the suspect material under carefully controlled conditions (Anderson and Phillips, 2013).

The procedures of these bioassays are conducted under rigorous conditions defined by the Code of Good Laboratory Practice (GLP). Although many regulatory authorities have guidelines for carcinogenicity evaluation, globally, the most commonly used *in vivo* carcinogenic studies follow the guidelines supported by the Organization for Economic Co-operation and Development (OECD), especially, the guideline OCDE 451 (2018). Alternatively, some international authorities (i.e., EFSA in the case of testing food additives) use a combined protocol to study chronic toxicity and carcinogenicity in the same experiment (OECD 453). The combined test provides greater efficiency in terms of time and cost compared to conducting two separate studies, without compromising the quality of the data in either the chronic phase or the carcinogenicity phase, and in this case the principles of dose should be carefully chosen.

The objectives of carcinogenicity studies (OECD 451) are: the identification of the carcinogenic properties of a chemical, resulting in an increased incidence of neoplasms, increased proportion of malignant neoplasms or a reduction in the time of appearance of neoplasms, compared with concurrent control groups; the identification of target organ(s) of carcinogenicity; the identification of

the time of appearance of neoplasms; characterization of the tumor dose-response relationship; identification of a no-observed-adverse-effect level (NOAEL) or point of departure for establishment of a Benchmark Dose (BMD); extrapolation of carcinogenic effects to low dose human exposure levels; provision of data to test hypotheses regarding mode of action.

The basic approach for carcinogenicity testing involves administering the test material to two suitable animal species for a considerable proportion of their natural lifespan. Rats and mice have been the experimental models of choice because of their relatively short life span, their widespread use in pharmacological and toxicological studies, their susceptibility to tumor induction, and the availability of sufficiently characterized strains. The study should preferably be carried out in animals from the same strain and source as those used in preliminary toxicity study(ies) of shorter duration.

To examine the carcinogenic potential of food components, the test substance is usually added in the diet, although in some circumstances administration may be in the drinking water or by gavage. As a minimum, 50 animals of each sex are allocated at random to each of the experimental groups. The duration of the study will be normally 24 months in the rat and 18 or 24 months in the mouse. During the study, the animals' clinical state is regularly monitored and at the end of the study a complete necropsy is performed on all surviving animals. Any tumors found are classified as either neoplastic or non-neoplastic and attempts are made to determine whether any of the observed tumors were the cause of (early) death of the animal (fatal tumors) or were unrelated to the death (incidental tumors).

The carcinogenicity bioassay aims to determine whether the administration of the test chemical has resulted in an increase in the incidence of tumors at one or more sites as compared with the normal background level. In order to accomplish this analysis, two major confounding factors need consideration. The first is the effect of differences in mortality rates between the control and treated groups and the second is the effect of differences in food intake and its consequence on body weight. Both factors can substantially alter the tumor pattern observed in different groups. Early deaths may prevent the animals reaching tumor-bearing age, and reduced food intake and the associated reduction in body weight may result in a considerable reduction in tumor incidence ([Anderson and Phillips, 2013](#)).

The interpretation of the results from a bioassay is complex but most authorities work to the "weight of evidence" principle. This evidence is taken in the light of the "adequacy" of the bioassay, which is dependent on some of the factors previously discussed. Rare or unusual tumors at a site would be given added weight. When data from bioassays are considered in human risk assessment, other factors must clearly also be taken into consideration such as evidence of genotoxicity in short-term tests and data on metabolism and potential human exposure. Furthermore, a measure of risk at doses substantially below the bioassay dose may be needed, and this may require an extrapolation using mathematical models ([Anderson and Phillips, 2013](#)).

In the event of a carcinogenic response being demonstrated in the study, additional mechanistic information together with good data on toxicokinetics are usually essential for risk assessment, both with respect to extrapolation to humans and possible determination of a threshold for non-genotoxic carcinogens ([EFSA, 2012a](#)).

### Short-term predictive tests

A large number of test systems have been developed to detect damage to the genetic material of cells in an attempt to predict carcinogenic potential and thereby reduce the reliance on animal tests ([Table 4](#)).

*In vitro* assays for detecting genotoxicity include tests to detect gene mutation using bacterial or mammalian cells, and the so-called indicator tests that detect mechanistic changes associated with the formation of mutations, such as the binding of foreign molecules to the DNA bases ([Anderson and Phillips, 2013](#)). The most commonly used *in vitro* and *in vivo* tests supported by the OCDE are shown in [Table 4](#). Chromosome damage is considered in several tests and includes chromosome and chromatid aberrations. The *in vitro* micronucleus (MN) assay is a test for the detection of MN in the cytoplasm of interphase cells, and both aneuploids and clastogens can be detected. Micronuclei represent a damage that has been transmitted to daughter cells, whereas chromosome aberrations scored in metaphase cells may not be transmitted (OECD 487). While the Mouse lymphoma assay (MLA) has been widely used for regulatory purposes, the TK6 has been used much less frequently. The alkaline comet assay detects DNA damage, mainly DNA breaks, in eukaryotic cells.

Since many of the cell systems used are unable to metabolically activate the majority of test chemicals, an exogenous mammalian metabolizing system, the so-called S-9 mix, is incorporated into the assay ([Anderson and Phillips, 2013](#)).

*In vitro* tests are backed up by short-term *in vivo* tests to confirm that the effects seen *in vitro* appear in the whole animal. These tests are mainly undertaken in rats, mice (ordinary and transgenic). A short-term *in vivo* assay measuring unscheduled DNA synthesis (UDS) in rat liver or gut is recommended by most regulatory authorities if there is a positive response in any *in vitro* assay and a negative response in an *in vivo* cytogenetics assay. Other test methods and end points are under consideration by regulatory authorities as indicators of genotoxic potential including the Comet assay ([Anderson and Phillips, 2013](#)). To fulfill animal welfare requirements, in particular the reduction in animal usage (3Rs—Reduction, Refinement, Replacement—principles), the *in vivo* Comet assay can also be integrated with other toxicological studies, e.g., repeated dose toxicity studies, or the endpoint can be combined with other genotoxicity endpoints such as the *in vivo* mammalian erythrocyte micronucleus assay (OECD 489).

During the last two decades extensive efforts have been directed to determine whether short-term tests are suitable for predicting carcinogenic potential, and comparative analysis and reports on their applicability are published.

Although many regulatory authorities have released guidelines for carcinogenicity evaluation, including short-term tests, they all still require animal studies as the ultimate test for carcinogenicity. However, the use made of short-term tests varies. In the US, the FDA recommends a battery of short-term tests for all 'additives' for which cumulative dietary intake is expected to exceed 1.5 µg per

**Table 4** Short-term test systems for predicting carcinogenic potential.

Test system	Cells used/experimental model	End point	OECD
<b>In vitro</b>			
Bacterial mutation	<i>Salmonella typhimurium</i> TA strains <i>Escherichia coli</i> WP2	Reversion to histidine Independence	TG 471 (2020)
Mammalian cell gene mutation	Chinese hamster ovary (CHO), Chinese hamster lung (CHL) and Chinese Hamster lung (V79) lines cells, L5178Y mouse lymphoma cells, and TK6 human lymphoblastoid cells Mouse lymphoma with L5178Y cells (MLA assay) <sup>c</sup> , TK <sup>b</sup> gene mutations human transformed lymphoblastoid cell line (TK6)	Loss of Hprt <sup>a</sup> , Xprt <sup>a</sup> mutations	TG 476 (2016)
Chromosomal damage	Chromosome aberrations (CA) <i>in vitro</i> : CHL, CHO, Chinese Hamster lung V79 cells, human peripheral blood lymphocytes (PBL) Micronucleus assay (MN) <i>in vitro</i> in a variety of cultures of cell lines or primary cell cultures, such as: Human peripheral blood lymphocytes (PBL) or human lymphoblastoid (TK6) cells	Structural chromosome/chromatid aberrations (gaps, breaks, deletions) Micronuclei induction in the cytoplasm of interphase cells	TG 473 (2016)
Primary DNA damage	Comet assay (standard and enzyme-modified comet assay)	Single and double strand breaks, oxidation bases of DNA	TG 487 (2016)
<b>In vivo</b>			
Chromosomal damage	Chromosome aberrations (CA) Micronucleus assay (MN) in bone marrow erythrocytes	Micronucleus formation in erythrocytes sampled either in the bone marrow or peripheral blood cells of animals	TG 474 (2016)
DNA damage	Unscheduled DNA synthesis (UDS) in rat livers - Alkaline Comet assay The assay is most often performed in rodents (many tissues, such as liver, stomach, etc), although it has been applied to other mammalian and non-mammalian species. - Enzyme-modified comet assay	Uptake of labeled nucleosides in cells that are not undergoing scheduled (S-phase) DNA synthesis Single and double strand breaks. The enzyme-modified comet assay could detect oxidation bases of DNA	TG 486 (1997)
Transgenic mutations in rodents (TGR)	Transgenic rodent somatic and germ cell gene mutation assay: LacZ bacteriophage mouse (MutaMouse); lacZ plasmid mouse; gpt delta (gpt and Spi-) mouse and rat; lacI mouse and rat (Big Blue <sup>®</sup> ), etc	Point mutations, insertions, small deletions, large genome rearrangements	TG 488 (2020)

<sup>a</sup>Hypoxanthine-guanine phosphoribosyl transferase gene (Hprt in rodent cells, HPRT in human cells; collectively referred to HPRT test), and the xanthine-guanine phosphoribosyl transferase transgene (gpt) (referred to as the XPRT test).

<sup>b</sup>Thymidine kinase gene.

<sup>c</sup>MLA: Mouse lymphoma assay.

person per day to assist in the interpretation of animal feeding studies. The EFSA (2012a) recommended in the evaluations of food additives a battery of *in vitro* tests: a bacterial reverse mutation assay (OECD 471), and an *in vitro* mammalian cell micronucleus test (OECD 487). In the case of inconclusive, contradictory or equivocal results from *in vitro* testing, further testing *in vitro* will be conducted. In the case of positive results, it is appropriate to perform suitable *in vivo* testing (Micronucleus test, Comet assay, Transgenic rodent assay). Transgenic mouse models are a refinement, although not a complete replacement, to the rodent 2-year cancer bioassay, and may result in a significant reduction in the use of experimental animals (EFSA, 2012a). Some expert bodies, such as IARC, use short-term tests as an adjunct to animal carcinogenicity studies, thus giving added weight in the assessment process of likely human hazard to an animal carcinogen that is also positive in short-term tests (Anderson and Phillips, 2013).

## Monitoring and control of hazards

Foods are complex mixtures of chemical compounds that contain not only nutrients but also many other substances among them toxic agents and specifically animal carcinogens, which are widely distributed in the environment. Therefore, the presence of carcinogenic compounds in foods while not desirable is likely to happen.

Monitoring and control of carcinogenic substances in foods is based on the risk analysis methodology, in which the first step is independent scientific risk assessment. As a result of risk assessment, it is necessary to put into place the resulting measures as well as appropriate risk communication.

The identification and characterization of a carcinogenic hazard is mainly based on the reported animal carcinogenicity data and effects on human health from case reports and epidemiological studies. Other information, such as *in vitro* or *in silico* data, is increasingly being used to establish carcinogenic potential. These data should be assessed together with data on genotoxicity and any other relevant information to understanding the mode of action (MOA) by which the chemical compound causes cancer in humans or in experimental animals (COC, 2020). Dose-response assessment methodology is classically based on the determination of the relationship between the magnitude of exposure (dose) to an agent and the severity and/or frequency of the adverse health effects (response). Toxicological tests and experimental data are considered to derive health-based guidance values. But for the specific case of carcinogens (mainly those that are genotoxic in nature) any level can potentially cause adverse effects and thus no threshold for toxic effect or health-based guidance can be set. In these assumptions an alternative approach for risk assessment is the so called Margin of Exposure (MOE) approach, which supposes a qualitative description for a possible prioritization of risks based on the benchmark dose derived from dose response modeling (EFSA, 2012b), comparing animal dose-response data with human exposure. The MOE is in general more difficult to interpret in terms of health risk. The Benchmark Dose (BMD) is the dose corresponding to a specific change in effect over background (e.g., tumor formation). To perform mathematical modeling, sufficient experimental data are required together with the characteristics of the response. BMDL (Benchmark dose lower confidence limit) is then defined as the lower confidence limit of a point on the dose-response curve that presents an adverse effect, to consider uncertainty in the data. Hence a BMDL<sub>10</sub> give rise to a 10% of effect level and the BMDL cannot be considered as a safety reference value when dietary exposure is below it. MOE is then calculated by dividing BMDL<sub>10</sub> by the estimated dietary exposure. In summary, risk assessment based on MOE offers a relative indication of the level of health concern without quantifying the risk. In general, small MOEs indicate high concern, and large MOEs low concern. A MOE of 10,000 (based on a BMDL<sub>10</sub> from animal studies) supposes a low public health concern. At the same time, MOE should always be accompanied by an explanation on the background and the uncertainties in the reference point and exposure estimates.

On the other hand, it is well known that incorrect and unhealthy diet is one of the main causes of cancer. According to WHO, between 30 and 50% of the most common cancers could be prevented through healthy diet and an adequate level of physical activity. But it is a difficult task to identify specific dietary carcinogens due to the very complex nature of diets and the different epidemiological methods used. As a result, it is not very likely that epidemiological data link specific carcinogens present in food with carcinogenic outcomes. These compounds are usually present at very low concentrations in food and may only produce small increases in tumor incidence. But taking into account dietary habits, certain associations at the epidemiological level have been made as follow, between poor dietary fiber intake and colon cancer or excess of dietary fat and colon and breast cancer, even though specific agents involved have not been consistently identified (World Cancer Research Fund, 2018). Moreover, the exposure to both carcinogens and non-carcinogens is now being considered since some substances may only show carcinogenicity when present with other triggers (including life-style factors such as obesity) (COC, 2020).

Safe food is a topic of global concern that arouses interest among citizens and administrations due to the increasing international trade. The huge progress in analytical chemistry methods allows for the detection and quantification of contaminants present in foods at very low levels, among them carcinogens, helping to minimize risks and increasing consumers' protection through consistent risk management programs.

Although the current scientific approaches for assessing carcinogenic risk of food substances may seem adequate, there are still serious limitations. Hence, there is a need for proposal of methods to implement next generation assays together with new carcinogenic frameworks into food safety assessments.

## Conclusion/summary/outlook

In summary, cancer prevention is needed because the global burden of cancer is high and continues to increase as a result of population growth and aging and upward trends in some exposures. In this context, the identification of carcinogens presents in food from different origins (natural, contaminants or produced during processing) is relevant as well as to conduct a risk assessment in order to protect public health.

### Key points

- Nutrition has an important role to play throughout a person's cancer pathway
- Malnutrition and loss of muscle mass are common in those going through cancer treatment and negatively impact on clinical outcomes
- It is important to understand the role of diet, possible treatment side effects which may impact nutritional status and the role of nutrition interventions throughout a cancer pathway

### Glossary

**Anorexia** Loss of appetite. In cancer patients it is frequently secondary to chemotherapy, pain medication, or tumor factors

**Cachexia** Severe weight loss (characterized by loss of lean body mass as well as fat mass) associated with disease states (catabolic state), more commonly seen in advanced cancer patients

**Dysphagia** Difficulty to swallow. May be related to tumor location or as a consequence of surgery in the esophagus, and as a temporary symptom secondary to Oro/pharyngeal/esophageal treatment related mucositis or infection

**Enteral feeding** Refers to specialized form of feeding in which nutrition (usually a special formula) is delivered directly into the stomach or intestine via a tube

**Nutrition Support** Dietary or nutrition interventions that focus on optimizing food/nutrient intake when a patient is suffering from reduced intake or weight/muscle loss. Interventions can include food fortification, using commercially available nutritional supplement sip feeds and other similar products as well as enteral or parenteral nutrition

**Parenteral Nutrition (PN) (also referred to as Total parenteral nutrition -TPN)** Intravenous nutrition support (in the form of glucose, lipid, amino acids, some minerals, trace elements and vitamins) provided bypassing the GI tract. Generally delivered by central venous access although can be provided via peripheral IV route but not usually via a cannula

## Nutrition cancer (introduction)

Diet and nutrition are important considerations for most cancer patients. Weight loss, reduced food intake and poor appetite are common at presentation for some tumor types e.g., lung carcinoma or iatrogenic (as a consequence of treatment side effects) (Pinho et al., 2018). The impact of poor nutrition on clinical outcome is difficult to measure however it is widely observed that poorly nourished patients can struggle to tolerate treatment, require breaks in treatment, have prolonged hospital admissions and ultimately may not be able to receive their full course of treatment and therefore compromise efficacy of planned treatment (Mantzorou et al., 2017). Patients need excellent management of “nutrition impact symptoms” to optimize their nutritional status and hopefully improve or maintain a good quality of life (Kubrak et al., 2010; Omlin et al., 2013). Patients with advanced disease may need modified dietary advice and several patients will explore alternative or complimentary diets as a means of exerting some control over their diet and treatment in the hope of improving their prognosis.

As cancer treatment develops and improves, we are now seeing a significant proportion of patients surviving and needing to explore the optimal diet following treatment with the aim to promote long term survival and optimum quality of life (Aubrey et al., 2019).

## Guidelines

Throughout this article we refer to ESPEN guidelines (Muscaritoli et al., 2021; Arends et al., 2016, 2017) which are practical guidelines based on current science on nutrition in cancer. ESPEN makes recommendations for various health care professionals and grades the level of evidence for the various recommendations. The recent guidelines contain easy to follow evidence-based flow diagrams (Muscaritoli et al., 2021) to aid clinical decision making for various cancer related nutritional consequences.

## Malnutrition

Malnutrition can be defined as a state of poor nutrition; that can result from insufficient or excessive or unbalanced diet or from inability to absorb foods.

Within malnutrition there are separate terminologies to help differentiate between the various types of malnutrition which are defined in **Table 1** (Arends et al., 2017).

Sarcopenia & sarcopenic obesity have been shown to be associated with higher incidence of chemotherapy toxicity, shorter time to tumor progression, poorer outcomes of surgery, physical impairment, and shorter survival (Daly et al., 2018).

It is important that we screen for malnutrition regularly when someone is going through cancer treatment using a validated malnutrition screening tool to help identify those that would benefit from nutritional interventions (Shaw et al., 2014).

Once a patient is screened, they may be flagged as at risk of malnutrition or malnourished and hence referred for nutritional assessment. This assessment should include food intake, muscle mass, physical performance, and systemic inflammation. Muscle mass can be evaluated though dual X-ray absorptiometry (DEXA), computed tomography (CT) scans or bioimpedance analysis (BIA) but in practice is unlikely to be assessed due to time and financial constraints (De Las Peñas et al., 2019). Physical performance can be measured using dynamometry, gait speed and questionnaires, such as the Karnofsky performance status. Systemic inflammation can be estimated by serum C-reactive protein (CRP) and albumin (De Las Peñas et al., 2019).

As part of the nutritional assessment and intervention it is important that adequate nutritional requirements are calculated, and a plan put in place to meet these individual requirements. Total energy expenditure (TEE) may be predicted by assuming TEE to be 25–30 kcal/kg depending on the patient’s performance status (Arends et al., 2016). However, these rough estimates are likely to be overestimating in obese and underestimating in severely malnourished patients. Protein intake should be above 1 g/kg/day and if possible, up to 1.5 g/kg/day (Arends et al., 2016). It is important that not only macronutrients, but micronutrients (vitamins and minerals needed by the body in small amounts) are considered to ensure nutritional adequacy.

**Table 1** Terminology in cancer related malnutrition.

Anorexia	Associated with poor food intake which may be due to altered central nervous system appetite signals with the addition of symptoms from cancer treatment such as nausea or fatigue. It may also be due to physical limitations such as swallowing difficulties
Cachexia	Complex metabolic syndrome associated with underlying illness and is characterized by loss of muscle with or without loss of fat mass
Sarcopenia	Condition characterized by loss of skeletal muscle mass and function.

## Nutritional needs of specific patient groups

### Children, teenagers, and young adults with cancer

Cancer remains relatively rare in this patient group, however those patients with a cancer diagnosis often have complex nutritional needs. Nutritional requirements will need to encompass the additional energy, protein and micronutrient requirements required to support growth and development. A child's developing relationship with food can be disrupted by treatment side effects leading to increased levels of food aversions, restrictive eating, and behavioral eating difficulties which in turn lead to imbalanced diets. Many treatment regimens require intensive nutrition support and the wide use of enteral feeding tubes to support nutrition, hydration and the administration of medication while facilitating patients being at home. However, in contrast in the more common diagnosis in the patient group, Acute Lymphoblastic Leukemia, Lymphoma, and central nervous system tumors (brain tumors) the high level of steroid use in such treatment protocols leads to weight gain. This has now increasingly been identified as a risk factor for the long-term survival of patients as well as possible implications for health and wellbeing on treatment (Todatri et al., 2019).

Nutrients that need specific considerations in this group: energy, protein, calcium and Vitamin D.

## Nutritional interventions

Many cancer patients will require some form of nutritional interventions during their illness. Nutrition Support will be required by patients who experience an eating difficulty or weight loss. The first course of action is to assess their oral intake: if patients can eat, then they should be given appropriate advice to maximize their food and fluid intake (Table 2).

The measures in Table 2 should be considered to help prevent weight loss or encourage weight gain. It must be remembered that energy and protein requirements may be elevated due to the physiological effects of malignancy.

If patients are unable to achieve adequate nourishment by mouth to maintain their weight and nutritional status an enteral tube feed should be considered. The type of tube placed will depend on the factors outlined in Box 1.

### Box 1 Factors for considerations when choosing enteral feeding route

- (1) The anticipated length of time the feed will be required -e.g., NG tubes are generally designed for short term feeding -if likely to be needed for more than 6 weeks, consider whether longer term feeding tube solution is feasible and beneficial to the patient
- (2) The physical state of the patient; for example, a nasogastric tube or percutaneous endoscopically placed gastrostomy tube may not be suitable for patients with complete esophageal obstruction. A jejunostomy tube may be preferred following upper gastrointestinal tract surgery. Timing of chemotherapy may preclude the patient from having an invasive procedure due to limited time for wound healing
- (3) The wishes of the patient concerning the physical appearance of different tubes and the invasiveness of the procedure required to place them.
- (4) Practicalities around placement of the tube in a timely manner

Numerous types of commercially produced enteral feeds are available. Most cancer patients will require complete, whole protein feeds providing 4–6 kJ ml<sup>-1</sup> (1–1.5 kcal ml<sup>-1</sup>) or if experiencing mucositis/radiation enteritis may benefit from a peptide-based formulation. Only in cases of severe malabsorption, gastrointestinal fistula, or pancreatic insufficiency should an elemental or low-fat feeds be necessary. The choice of feeding regimen will depend on the patient's oral intake, their mobility and care needs and on the volume of feed tolerated. It may be administered via a feeding pump (for feeding during the day and/or overnight), gravity feeding, and bolus feeding.

PN is required where the gastrointestinal tract cannot be used, such as in patients with complete bowel obstruction or severe malabsorption. It should not be used as a first line of nutrition support when the enteral route is functioning and available. The relative risks and benefits of PN should be weighed up when planning nutrition care.

**Table 2** Dietary advice to help prevent weight loss.

Fortify food with cream, butter, milk powder, cheese, vegetable oils, ground nuts or seeds, honey, etc.
Have small, frequent snacks.
Use full-fat and full-sugar products.
Avoid large amounts of lower energy foods (e.g., fruit and vegetables).
Try proprietary supplements, such as milky or juice drinks.
Altering the portion sizes, consistency or timing of food or drink

**Table 3** Methods of nutritional support when oral intake is inadequate.

<i>Method</i>	<i>Route</i>
Enteral tube feeding	Nasogastric (NG) or nasojejunal tube (NJ)
	Percutaneous endoscopically guided
	Gastrostomy (PEG) surgically placed gastrostomy
	Low profile “button” style gastrostomy (long term)
	Radiologically inserted gastrostomy (RIG)
	Percutaneous gastrostomy with a jejunal extension
Parenteral nutrition (PN)	Jejunostomy
	Central line
	Peripheral line

**Table 4** Dietary management of anorexia.

- Small frequent meals and snacks, served on a small plate
- Provide familiar and preferred foods
- Fortify foods to maximize energy and protein content and avoid “filling up” with low nutrient dense foods e.g., plain salad, vegetables, tea, and coffee
- Separate drinks from meals if patient reports early satiety
- Try to eat in a pleasant environment e.g., out of bed
- Explore options for psychological support

### Practical management of eating difficulties

#### Anorexia (loss of appetite)

Anorexia (loss of appetite) is often associated with other eating difficulties, such as nausea and taste changes. Addressing these problems may improve the patient’s appetite. Anorexia may occur as a side effect of medication such as chemotherapy, antimicrobial agents as well as pain. Optimizing symptom management e.g., pain management through effective analgesia, is essential in providing an appropriate diet (Table 4). For patients who have severe anorexia, an appetite stimulant such as corticosteroids, progestins, androgens, cannabinoids or alcohol may be considered, however evidence of efficacy is limited and most come with significant side-effects (Turcott et al., 2021).

#### Taste changes (dysgeusia/ageusia)

Cancer patients may suffer from lack of taste or abnormal taste. This can severely reduce the desire for food and is usually associated with chemotherapy agents, some antimicrobials, oral candida and other infections, radiotherapy to the oropharyngeal area and a dry mouth (xerostomia). For most cancer patients, the taste changes are temporary. They may find that foods taste metallic, bitter or excessively salty or sweet or they develop a strong preference for a certain type of flavor. Depending on the taste change experienced, it is often worth excluding certain foods from the diet or using certain flavorings to try to ameliorate abnormal taste (Table 5). If food groups are excluded, the nutritional quality of the diet should be assessed by an appropriately trained nutrition health care professional. Patients should be encouraged to perform regular mouth care.

#### Nausea and vomiting

Often related to medication e.g., chemotherapy agents, oral potassium supplements, opiates but can also be associated with thickened secretions, bowel obstruction, severe constipation. Etiology of the symptom should be determined and for the majority of patients first line treatment should be administration of antiemetic drugs. Some dietary suggestions may help patients with food choice when they are feeling nauseous (Table 6).

#### Dysphagia (difficulty swallowing)

Dysphagia may occur because of obstruction from tumors, mucositis, or neurological changes. It may occur with solid food, semi-solid foods, such as porridge, or liquids. For the person who cannot manage solid food but is able to eat semisolids, altering the consistency of the food may be the only dietary change needed for example encouraging food with extra sauce, soft puddings, and

**Table 5** Suggestions for overcoming taste changes.

<i>Taste change</i>	<i>Suggestions</i>
Excessively sweet	Reduce sugar content of food and drink Add salt to drinks and puddings
Excessively salty	Avoid packet soups, gravy, and sauces Avoid salted snacks (e.g., crisps and nuts) or try unsalted varieties Avoid bacon and other cured or tinned meat
Metallic taste	Add a pinch of sugar to sauces or soups Marinate meats (e.g., vinegar and wine) or consider other protein sources such as white meat, fish, eggs, and cheese, nuts, beans, and pulses Avoid tea, coffee, and chocolate Trial use nonmetallic cutlery
Taste blindness	Use extra flavorings: Salt, pepper, pickles, mustard, herbs, and spices. Eat highly flavored food (e.g., curry) Encourage experimentation with the odor of food General: try sucking boiled sweets and hard candies or chewing gum

**Table 6** Suggestions for food and fluids when person has nausea.

Have cold food and drink in preference to hot because these have less odor
Sip fizzy drinks or flat fizzy drinks
Try drinking through a straw (to minimize exposure to odor)
Try ginger flavors (e.g., ginger ale and ginger biscuits).
Eat small, frequent snacks to avoid the stomach from becoming completely empty-carbohydrate foods are often preferred
Reduce greasy or very fatty foods as they may delay gastric emptying

nourishing drinks. For the patient who is only able to swallow fluids, close attention must be paid to their intake and dietary supplements are likely to be necessary. Some patients who can only manage liquids choose to liquidize their food; this dilutes the nutrients, so meals should be fortified to add energy and protein by adding butter, cream, honey, cheese, nut butters or beans. If there is complete dysphagia to both solids and liquids, feeding by an enteral tube should be considered (see [Table 3](#)). In some instances, people can swallow solid food but aspirate liquids. Patients should undergo a complete assessment from speech and language therapist/pathologist (SLT) to ascertain which textures are safe to swallow if any. A SLT may assess a patient's swallow as unsafe and place them nil by mouth, therefore to maintain hydration and nutrition alternative feeding routes need to be explored through provision of an enteral tube.

### Mucositis and stomatitis

Mucositis and stomatitis arise as a consequence of treatment such as high dose chemotherapy, radiotherapy (including total body irradiation) or infection.

If the mouth or throat is sore it can limit the physical ability to eat by affecting ability to chew and swallow. It can also affect taste. Analgesia taken before eating and drinking can help ease the pain and enable the person to eat a little more.

Modifying the diet is also helpful ([Table 7](#)).

### Xerostomia (dry mouth)

Xerostomia (dry mouth) may be a long-term side effect of cancer treatment such as oropharyngeal radiotherapy or surgery affecting the salivary glands. Opiates can also cause a dry mouth.

**Table 7** Suggestions to relieve mucositis and stomatitis.

---

<p>Avoid citrus fruits and drinks.</p> <p>Avoid salty, spicy food, vinegar, pickles, and other irritants and rough textured foods.</p> <p>Carbonated fizzy drinks can be irritating</p> <p>Experiment with the temperature of foods and drink. Tepid food and drinks can be soothing while others find iced drinks soothing</p> <p>Avoid dry foods that need extra chewing (e.g., toast).</p> <p>Eat soft food and use extra sauce.</p> <p>Use proprietary nutritional supplements or milkshakes</p> <p>Consider artificial nutrition support if adult patients are likely to have severe mucositis for &gt;5 days.</p>
---

---

**Table 8** Dietary advice for Xerostomia.

- 
- Add extra sauces to foods
  - Have sips of drinks between mouthfuls of food
  - Suck on ice cubes or popsicles
  - Try chewing sugar free gum (although this may be unhelpful if there is no saliva production)
  - Avoid dry foods such as bread as these form a dry bolus when chewed and can cause gagging or retching.
  - Avoid alcohol and any products containing alcohol such as some mouthwashes as this can have a “drying” effect
  - Try sucking tinned fruit, fresh pineapple, acidic sweets, and candy
- 

Good dental hygiene is particularly important because saliva protects the mouth against infection and tooth decay. Patients should be talked through various saliva sprays and mouth gels until they find one suitable for them. Xerostomia can affect appetite by causing taste changes (**Table 8**).

## Gastrointestinal fistulas

The etiology of a fistula must be considered as this determines the management options. A fistula can develop as a side effect of some cancer treatments including radiotherapy and surgery or be surgically formed (stoma) anywhere in the gastrointestinal tract. The site and whether it is an internal or enterocutaneous fistula will determine the dietary management (**Table 9**). Internal fistulas usually require the approach of nil by mouth, placing an enteral feeding tube lower than the fistula or commencing PN to help the healing of the fistula.

## Constipation

The etiology of constipation must be considered when formulating a nutrition care plan. If it is due to a tumor pressing on the bowel (e.g., cancer of the ovary or colon), a low-fiber diet may be helpful. Low-fiber food is less bulky and may pass through the bowel more easily, particularly if accompanied by appropriate laxatives (i.e., stool softener).

If constipation is due to dietary imbalance and lack of fiber in the diet, then an increase in fiber and fluid intake will be helpful. Where constipation is due to analgesia, then appropriate laxatives need to be used in conjunction with any changes in the diet. In addition to fiber, a good fluid intake must be maintained, approximately 2 L per day is recommended.

## Diarrhea

Before formulating a nutrition plan for diarrhea, it is essential to consider the etiology of the symptom. Diarrhea can be “overflow” secondary to severe constipation and needs to be managed with an intensive laxative regimen.

**Table 9** Sites of fistulas and their management.

<i>Fistula</i>	<i>Site</i>	<i>Management</i>
Enterocutaneous	Neck, salivary fistula	"Nil by mouth" and enteral tube feed until healed
Internal	Chyle leak (e.g., in neck)	Low-fat diet initially; if unsuccessful, a low-fat, medium-chain triglyceride enteral tube feed
Enterocutaneous	Large bowel	If unsuccessful, consider parenteral nutrition
Enterocutaneous	Small bowel	Low-residue diet or elemental enteral tube feed
		See <a href="#">Table 10</a>

There are several causes of diarrhea which include bowel disease, medications, or infection. Once the cause is investigated anti-biotics, antivirals and anti-diarrheal agents may be prescribed. Patients may be advised to avoid excessive intakes of high-fiber foods, which can increase bowel transit time. If the cause for diarrhea is considered to be malabsorption, the patient should also be investigated for signs of pancreatic insufficiency, bile salt malabsorption or small intestine bacterial overgrowth ([Andreyev et al., 2021](#)).

When diarrhea is severe, it is important to replace the fluid lost to prevent dehydration, oral rehydration sachets are useful to replace fluid losses. Diarrhea caused by pelvic area radiotherapy needs to be controlled with drugs, and a low-fiber diet is not thought to be helpful in this instance ([Wedlake et al., 2017](#)).

## Intestinal failure

A long-term side effect of pelvic radiotherapy may be enteritis resulting in intestinal failure. Extensive gastrointestinal surgery leaving less than 100 cm of small bowel, or an enterocutaneous fistula in the small bowel causing high stoma losses, may also cause intestinal failure. Previous chemotherapy that may affect the function of the bowel can contribute to this condition. Intestinal failure is more likely to occur when the patient does not have a functioning colon (e.g., in the case of ileostomists or when the ileo-cecal valve is absent). Dietary manipulation can greatly alleviate the symptoms of intestinal failure, such as thirst, dehydration, and high stoma losses (>1.5 L/24 h) or large volumes of diarrhea ([Table 10](#)).

An oral rehydration solution consisting of 20 g glucose, 3.5 g sodium chloride, 2.5 g sodium bicarbonate, and 1000 mL water provides 90 mmol of sodium per liter. It may be used chilled and to dilute weak fruit squashes/cordials. If the patient remains dehydrated despite following the advice detailed in [Table 10](#), intravenous fluid replacement is necessary. Medication may be given to decrease gut transit time or reduce fluid losses. If medication is in the form of capsules, these should be opened, and the drugs given 60 min before meals. Suitable drugs include those that slow transit such as codeine phosphate, loperamide and those medications that reduce secretions for example omeprazole, and octreotide. In the longer term, due to the impact on micronutrient absorption the following should be monitored: plasma electrolytes, ferritin, vitamin D, serum albumin, magnesium, zinc, calcium, phosphate, alkaline phosphate, folate and vitamin B<sub>12</sub> concentrations, prothrombin time, body weight, and urinary sodium concentration.

## Bowel obstruction

Bowel obstruction may be partial or complete. In cases of complete bowel obstruction, the clinical condition of the patient must be considered. If it is anticipated that the obstruction will resolve, or if aggressive treatment such as surgery is planned, PN support

**Table 10** Dietary management to reduce gut losses in intestinal failure.

Restrict fluids to 500–1000 mL daily, increasing to 1500 mL.
Avoid drinks for 30 min before and 45 min after meals.
Avoid foods that are particularly high in fiber.
Sprinkle salt liberally on food.
Consider fat restriction if patient has a colon and there is evidence of steatorrhea.
Take salt and carbohydrate foods together to help sodium absorption.
If gut losses are 1000 mL or more, part or all of fluid intake should consist of an oral rehydration solution.

should be considered. PN may not always be appropriate and needs a multidisciplinary approach to discuss the aims before commencing (Muscaritoli et al., 2021).

Depending on the degree of obstruction, in cases of subacute/partial obstruction, the following action may be taken under medical supervision:

- First day: sips of clear fluid, approximately 10 mL h<sup>-1</sup>
- Second day: 30 mL h<sup>-1</sup> clear fluid
- Third day: 60 mL h<sup>-1</sup> clear fluid
- Fourth day: free clear fluids
- Fifth day: free fluids, including milk, low-fiber soup, custard, and jelly
- Sixth day: low-fiber diet, avoiding all fruit and vegetables, nuts, pulses, and whole grain cereals, whole meal bread, etc.

A patient who starts to vomit should return to the diet prescribed for the preceding day. If symptoms of bowel obstruction, such as abdominal pain and indigestion, remain controlled, fruit and vegetables may be introduced as tolerated, starting with small amounts.

## Palliative care

In some patients, cancer will not be cured which in turn can mean they may have a short prognosis where there are no longer any treatment options, or they may go through palliative treatment and live many years with cancer. Palliative care focuses on the relief of symptoms rather than aggressive curative treatment. Most people receiving palliative care will suffer from at least one eating difficulty. Much of the advice detailed previously for overcoming dietary problems is relevant but depending on the individual's prognosis they may have varying nutrition priorities (Muscaritoli et al., 2021). If patients are unconcerned about their poor dietary intake, it may be appropriate not to offer any advice; conversely, for those who are very concerned, the problem should be addressed seriously, and it might be that enteral tube feeding and PN are appropriate in individual cases.

## Living with and beyond cancer

Living with and beyond cancer covers a wide variety of circumstances, including people at diagnosis, during and post-treatment, and those with recurrence, therefore including people with potentially differing nutritional needs. People can be struggling with a poor nutritional intake because of treatment side effects or may need to optimize their nutritional status preoperatively or require advice post-treatment for optimum recovery and rehabilitation. People often want to change their dietary intake after cancer, and actively seek information, therefore it is important to provide evidence-based information appropriate for the various time points in an individual's cancer journey.

Prehabilitation can help people with cancer prepare for treatment through promoting healthy behaviors by addressing exercise, nutrition, and psychological needs. The aim of prehabilitation is often to empower individuals to maximize resilience to treatment and improve long term health. Providing advice on increasing physical activity and tailored nutritional advice can help manage individuals' symptoms, prevent, or reduce treatment side effects, improve quality of life and clinical outcomes, and reduce risk of recurrence (Veen et al., 2019).

**Table 11** Lifestyle recommendations for those living with and beyond cancer.

- |   |
|---|
| <ul style="list-style-type: none"> <li>• Be a healthy weight, aiming to keep weight within a healthy body mass index (BMI 18.5–25 kg/m<sup>2</sup>)</li> <li>• Be physically active, aiming for 150 min of moderate exercise or 75 min of vigorous activity a week</li> <li>• Eat a diet rich in wholegrains, vegetables, fruit, and beans, aiming to provide 30 g of fiber per day</li> <li>• Limit consumption of “fast food’s” and other processed foods high in fat, starches, or sugars</li> <li>• Limit consumption of red meat to three portions a week (350–500 g cooked red meat) and consume very little processed meat</li> <li>• Limit consumption of sugar sweetened drinks</li> <li>• Limit alcohol consumption, ideally to no alcohol but if consumed within the recommendations of 14 units a week</li> </ul> |
|---|

For those living with and beyond cancer, nutrition advice should be tailored to individual needs depending on symptoms as discussed throughout this article. Gastrointestinal symptoms have been reported as the most common of the chronic physical side effects of cancer treatment and may require input from a gastroenterology team (Andreyev et al., 2014). General advice can be provided where appropriate, Table 11 has a list of recommendations that can be suggested to people living with and beyond cancer.

## Alternative and complementary diets

With increasing use of the internet for nutrition information, there has been an increase in patients wanting to explore specific diets for their purported anti-tumor effect. Such diets may be followed alongside (complementary) or in place of (alternative) conventional treatment. Often the diets have not been tested or demonstrated to be effective in scientifically rigorous clinical trials with many relying on pre-clinical or in vitro studies alone.

Dietary regimens may share common features: they are mainly vegetarian or vegan or macrobiotic, promote organic food, raw foods and juices and limit unprocessed foods, sugar, and fat. Such diets often promote the use of high doses of vitamins and minerals.

Much interest has been expressed in the therapeutic role of micronutrients, but they can potentially lead to drug-nutrient interactions and affect treatment e.g., antioxidant could reduce efficacy of free-radical forming chemotherapy agents or even promote tumor growth as was seen in a study using  $\beta$ -carotene supplementation in patients with lung cancer (Alpha-tocopherol Beta Carotene Cancer Prevention Study Group, 1994).

Proponents of such diets tend to advocate these diets based on research into the causes of cancer but showing that a particular food group may be beneficial in preventing cancer formation e.g., high fruit and vegetable intake may help in reducing the risk of colon cancer, but this is not to say that such a diet can conversely assist in curing colon cancer. The popularity of these different diets varies over time with current trends toward ketogenic and alkaline diets.

Nutritional inadequacies may arise particularly if the patient has a poor appetite. The diets may cause weight loss and are restrictive, and time-consuming to prepare. Some ingredients may be difficult to obtain and are often costly.

Studies appear to show no difference in survival rates between patients following complementary therapies and patients receiving conventional treatment alone. Patients who use complementary therapies, however, do report psychological benefits, such as feelings of hope and optimism. However, patients should have enough information about the possible advantages and disadvantages before embarking on strict complementary or alternative diets.

## Conclusion

Diet and Nutrition are an important part of the treatment of the cancer patient. Providing patients with timely, effective nutrition advice and interventions may help overcome the effect of nutrition related impact symptoms and support patients in tolerating treatment and living with and beyond their diagnosis.

## Key points

- Dietary factors account for a large proportion of human cancers, particularly overnutrition that results in weight gain and obesity.
- Evidence linking diet and human cancer began to grow in the middle part of the 20th century, and has become stronger and more refined with modern epidemiological methods, including case–control studies, cohort studies, Mendelian randomization studies, randomized controlled trials, and meta-analyses.
- Overall, an eating pattern to lower cancer risk is one that is largely plant-based, rich in vegetables, fruits, whole grains, and legumes, and low in red and processed meat, salt, sugar, and alcohol.

## Glossary

**Case–control study** A study that compares two groups of people: those with the disease or condition under study (cases) and a very similar group of people who do not have the disease or condition (controls). Researchers study the medical and lifestyle histories of the people in each group to learn what factors may be associated with the disease or condition. For example, one group may have been exposed to a particular substance that the other was not. Also called retrospective study

**Cohort study** A research study that compares a particular outcome (such as lung cancer) in groups of individuals who are alike in many ways but differ by a certain characteristic (e.g., female nurses who smoke compared with those who do not smoke)

**Ecologic study** A study that compares large groups of people instead of individuals for differences in things such as cancer rates. The groups can differ by location (e.g., city, county, or country). They can also differ by time (a few days, years, or decades). Groups can be immigrants (compared with people who are native to the country) or people with different types of jobs

**Mendelian randomization study** A type of observational study in which a gene variant, or collection of variants, serves as a proxy for a modifiable factor (e.g., alcohol intake)

**Meta-analysis** A type of systematic review that combines published results from individual studies into summary findings, or reanalyzes individual participant data, which can have greater statistical power and precision than those of the individual studies alone

**Randomized clinical trial** A study in which the participants are assigned by chance to separate groups that compare different treatments; neither the researchers nor the participants can choose which group. Using chance to assign people to groups means that the groups will be similar and that the treatments they receive can be compared objectively. At the time of the trial, it is not known which treatment is best. It is the patient's choice to be in a randomized trial

**Relative risk** A measure of the risk of a certain event happening in one group compared to the risk of the same event happening in another group. In cancer research, relative risk is used in prospective (forward looking) studies, such as cohort studies and clinical trials. A relative risk of one means there is no difference between two groups in terms of their risk of cancer, based on whether or not they were exposed to a certain substance or factor, or how they responded to two treatments being compared. A relative risk of greater than one or of less than one usually means that being exposed to a certain substance or factor either increases (relative risk greater than one) or decreases (relative risk less than one) the risk of cancer, or that the treatments being compared do not have the same effects. Also called risk ratio

## Introduction

Dietary factors account for a large proportion of human cancers, particularly overnutrition that results in weight gain and obesity. The evidence linking diet and cancer has been developing since the early 1900s, beginning with early laboratory studies and ecologic studies of cancer rates in different parts of the world. Modern epidemiologic methods, including case-control studies, cohort studies, Mendelian randomization studies, randomized controlled trials, and meta-analyses have helped define in detail the associations between specific dietary factors and cancer. Factors with strong links to an increased risk of various cancers include: over-nutrition/obesity, alcohol, red and processed meat, and salt. Factors with strong links to a decreased risk include: fruits, vegetables, whole grains, fiber, dairy, calcium, and coffee.

Laboratory scientists have known since the early 20th century that various nutritional manipulations can influence the occurrence of tumors in animals. Despite this discovery of the relationship between diet and cancer in animals, widespread interest in the study of diet and cancer in humans did not develop until decades later, when large international differences in cancer rates were correlated with variations in dietary factors. For example, investigators found strong correlations between estimated per capita fat consumption and breast cancer rates internationally, raising the possibility that dietary fat could have an important role in the etiology of breast cancer. Other observations such as those demonstrating that migrating populations adopted, sooner or later, the cancer rates of their new host population strengthened the evidence that international differences were the result not of genes, but of noninherited factors, including diet.

This chapter will provide an introduction to the study designs used to investigate diet and cancer, including their history, their strengths and weaknesses, and finally their combined evidence on specific associations between dietary and related factors and individual cancers.

## Sources of evidence linking diet and cancer

### Descriptive studies

Rates of cancer show large differences between countries for many malignancies not merely due to different age structures of the populations. International correlations compare disease rates with lifestyle factors such as per capita consumption of specific dietary factors.

Age-adjusted rates of colon and breast cancer are many times higher in some global regions than others. For example, south Asia (8.1), western sub-Saharan Africa (9.0) and central sub-Saharan Africa (9.1) have the lowest incidence rates of colorectal cancer per 100 000; in contrast, Australasia (which includes Australia and New Zealand) (46.4), high-income Asia Pacific (41.9), and North America (39.1) have the highest ([Collaborators, 2019](#)).

Strong nutritional correlates exist for specific cancers. These studies, also known as ecological studies, use the country or other geographic area as the unit of measure rather than the individual. Diet is estimated from national food supply or disappearance and not by individual level measures of consumption. For example, Armstrong and Doll in 1975 compared per capita total fat intake and national breast cancer mortality rates among women and found a correlation of 0.89: Countries with higher fat intake had higher breast cancer mortality. They also compared per capita fat intake and mortality from colon cancer and observed a correlation of 0.85 for men and 0.81 for women.

One important strength of these correlation studies was that the contrasts in dietary intake were very large. For example, the range of fat intake within a population tends to be small compared with the range of fat intake between different populations.

Although correlation studies opened the door to new leads in the study of diet and cancer, certain limitations prevented them from advancing past the level of hypothesis generation. First and foremost, there are many factors other than dietary differences that distinguish countries with a high incidence from those with a low incidence. This makes it difficult to identify dietary factors as the primary explanation for the differences in the etiology of cancers. For example, besides consuming a diet with a higher proportion of

energy from fat, populations of countries that are more industrialized will also have shifted from an agrarian to an urbanized, sedentary society with lower total energy expenditure. Therefore, with increasing industrialization, exposure to many aspects of life will decrease exercise and increase fat intake. Consider the example of colon cancer. The international correlation between fat and colon cancer mortality in men is 0.85, and for meat it is 0.85 (Armstrong and Doll, 1975). There is also a correlation between gross national product and colon cancer mortality (0.77 for men); more industrialized countries have higher economic production and higher rates of cancer. Owing to the many factors that are associated with industrialization it is not possible to separate out which factor is important in the etiology of colon cancer, lack of physical activity or increased consumption of fat or meat. Studies with data on lifestyle factors at the individual level are needed to clarify which of these variables is important (see **Analytical studies** below).

### Special-exposure groups

Within populations there are groups that have unique dietary patterns which may provide valuable information in the probe for further information on the relationship of diet and cancer. These groups are called special-exposure groups and are often defined by ethnic or religious characteristics. In addition to offering many of the advantages of correlation studies, the number of alternative explanations for any observations may be reduced if the special-exposure group lives in the same area as the comparison group.

As a largely vegetarian group, the Seventh-day Adventists have been used in studies of meat eating and cancer. Studies of these groups, however, are limited in the same ways that other ecological studies are limited. For example, although lower rates of colon cancer have been observed among Seventh-day Adventists—supporting the hypothesis that meat is related to colon cancer—there are other lifestyle choices that characterize the group, such as low rates of tobacco use and alcohol intake, which could also modify their rates of colon cancer.

### Evidence from descriptive studies

In 1981, Doll and Peto made an estimate based largely on descriptive studies that 35% of cancers in the USA may be attributable to dietary factors; but reflecting uncertainty in the sources of data used for this estimate, they noted that the range of possible dietary contribution was from as low as 10% to as high as 70% (Doll and Peto, 1981). The marked variation in the rates of most cancers among countries is evidence that dietary factors may influence the development of cancer. Though their analysis focused largely on potential mechanisms through which diet could impact cancer risk, Doll and Peto highlighted a range of potential dietary factors that could influence risk, including overnutrition, dietary fat, carotenoids, cooking method, and aflatoxins. Despite the fact that descriptive studies provide an excellent source of hypotheses, it is necessary to conduct analytical studies to collect data that will provide more definitive evidence.

### Time trends within countries

The analysis of cancer trends over time can lead to useful findings in the study of diet and cancer. By looking at the change in cancer rates in a specific population over time and comparing these rates with changes in specific factors over the same period (e.g., changes in dietary habits), investigators can uncover possible associations supporting the dietary factors hypotheses. For example, in 1991 researchers examined vital statistics for Japanese natives and US whites that revealed changes in cancer mortality and related antecedent patterns of lifestyle in the two populations (Wynder et al., 1991). These investigations uncovered that animal fat consumption in Japan steadily increased from a daily level of 6.5 g per person in 1955 to 27.6 g in 1987; at the same time the Japanese rate of colon cancer in men rose at a rapid pace; in fact, the mortality rates owing to colon cancer in men almost tripled over this time. This evidence lent more support to the hypothesis that mortality from colon cancer in men is influenced by high dietary fat consumption.

Similar data were collected in Singapore to determine trends in the incidence of breast cancer: in 1996, an average annual increase in breast cancer incidence of 3.6% over a 25-year period for all women was reported (Seow et al., 1996). The most convincing evidence that the observed trend was real was that it was clearly cohort-related rather than period-related. The risk was observed to increase in successive birth cohorts from the 1890s to the 1960s. Changes in dietary consumption patterns (e.g., the adoption of a more Western diet) among other factors, such as decreasing parity, are cited as having a possible effect on the continuing increase in rates of breast cancer among women in Asia. Like descriptive studies, time-trend studies are a valuable source for hypotheses generation, but more definitive evidence is required from analytical epidemiology to uncover any real associations between dietary factors and cancer rates.

### Migrant studies

Migrant studies examine the rates of specific diseases in migrating populations. These studies have been important in addressing the possibility that observed correlations in ecological studies are owing to genetic factors. Generally, results from migrant studies have found that the migrating group takes on the rate of cancer of the new country. Hence genetic factors are excluded as the dominant cause for varying rates of cancer between countries. A landmark example of this is seen in breast cancer incidence rates of Asian migrant populations to the USA. Though rates are increasing, Asia has historically had low rates of breast cancer relative to the

USA. Two studies in the 1990s documented that these rates among certain Asian migrants to the USA moved toward the higher US rates (Stanford et al., 1995; Ziegler et al., 1993). The increased risk of breast cancer among migrants occurs primarily in later generations, leading investigators to believe that the causal factors operate early in life. Investigators also consider major changes in the rate of disease that occur within a population over time as evidence that nongenetic factors play an integral role in the etiology of cancer. The limitations of migrant studies are similar to those of ecological studies.

## Analytical studies

### Cohort studies

Cohort studies involve the collection of information from healthy participants who are followed over time and observed for the occurrence of new cases of disease (incident cases). During or at the end of follow-up, the disease frequency within a cohort may be measured as either a cumulative incidence rate (the number of cases divided by the entire base population) or an incidence density rate (the number of cases divided by the total follow-up time accumulated by all members of the population, or “person-time” follow-up). The relative risk is the rate of disease (cumulative incidence rate or incidence density rate) in the exposed (e.g., those with a high intake of dietary fat) divided by the rate of disease in the unexposed (e.g., those on a low-fat diet). A relative risk of 2 implies that the exposed group has twice the rate of disease compared with the unexposed group.

For illustration, in a study of 121 700 women, a group of participants who completed dietary questionnaires and had no previous diagnosis of cancer in 1980, were followed through 1988 to address the hypothesis that dietary fat increases and fiber intake decreases the risk of breast cancer (Willett et al., 1992). This outcome was defined by histologically confirmed cases of breast cancer. In one analysis, the primary exposure of interest was energy-adjusted intake of total dietary fiber. Among the women in the highest quintile of energy-adjusted dietary fiber intake there were 299 cases of breast cancer compared with 305 cases among the women in the lowest quintile. This gave a relative risk (with adjustment for established breast cancer risk factors) of 1.02 (95% CI 0.85–1.23) for those in the highest quintile of energy-adjusted dietary fiber intake compared with those in the lowest quintile. In this cohort study, dietary fiber was not associated with breast cancer.

During the same period, there was also a growing body of evidence from cohort studies for the assessment of dietary fat intake and breast cancer in developed countries. In one pooled analysis based on individual level data from seven prospective studies with at least 150 incident breast cancer cases each ( $n = 4980$ ) and a large comparison series (i.e., noncases), the average relative risk was 1.05 (95% CI 0.94–1.16) comparing highest quintile of total fat intake with the lowest, which was not statistically significant (Hunter et al., 1996).

The use of cohort studies can be advantageous in many ways when studying the relationship between diet and cancer. A cohort study allows the assessment of multiple effects of a given dietary exposure. Dietary data can be updated during follow-up and the temporal relation between diet and cancer can be addressed. For example, the potentially beneficial effects of moderate alcohol intake in reducing the risk of outcomes like gallstones, ischemic stroke, and coronary heart disease, and the potentially deleterious effects of alcohol on outcomes like cancer, bone fractures, and hemorrhagic stroke can be weighed against each other in a cohort study (Colditz et al., 2016; Mostofsky et al., 2016). It is also possible to measure the absolute rates of disease according to the level of food or nutrient intake.

Among the limitations of cohort studies is the concern that current practice, usage, or exposure may change over the duration of the follow-up, limiting the ability to come to any relevant conclusions in studies of diet and cancer that have measured exposure just once at the beginning of the study. Controlling for extraneous variables such as smoking, which are related both to risk of cancer and to dietary intake, and separating the effects of specific dietary factors from those that exist together, also limit the range of knowledge that can be extracted from cohort studies.

Some investigators believe that the large number of subjects required to study rare disease and the high expense of management and maintenance also limit the usefulness of cohort studies. Others believe that the larger overall monetary investment most cohort studies require can be advantageous: more variables can be studied and in the long run further hypotheses can be generated and more conclusions produced than in a single case-control study that relies on recall of past habits.

### Case-control studies

In case-control studies information is obtained from diseased participants and compared with information provided by disease-free controls with respect to a possible risk factor (e.g., level of a dietary factor). Data collected from these studies can be used to evaluate the hypothesis that the risk factor is a cause of the disease. The cases are selected from a defined population, such as a country population. The population represents those at risk of developing the disease under study. Each time someone in the defined population is diagnosed with the disease during the duration of the study, this individual joins the case series. As each case arises from the population, one or more controls should be sampled to estimate the prevalence of the exposures among those remaining free from disease. The controls may be chosen from any population of individuals that provides valid information about those at risk for the disease. It is important to choose controls so that their probability of selection is unrelated to the exposure being studied.

In the study of the relationship of diet and cancer, case-control studies may be used to evaluate the hypotheses that individual or multiple dietary factors are the cause of the cancer under investigation. For example, a study in 1977 identified all cases of lung cancer diagnosed during an 18-month period from 1972 in three Singapore hospitals (MacLennan et al., 1977). Controls were chosen from other hospital patients free of any smoking-related diseases. There were a total of 233 cases and 300 controls

interviewed regarding their frequency of consumption of dark-green leafy vegetables and food preparation habits. The investigation found a substantially increased risk of lung cancer among those reporting a low consumption of dark-green leafy vegetables.

Case-control studies are better suited to the study of rare diseases because in cohort studies tens of thousands of individuals must be followed in order to study the most common cancers. It is also thought that case-control studies may be quicker and less expensive to conduct because they require fewer subjects, and they are therefore often employed as an alternate mode of investigation to cohort studies.

Among the limitations of case-control studies is the comparability of information between the cases and the controls. Although in a cohort study the exposure of interest is measured before the onset of disease, in case-control studies the exposure is assessed in individuals who (in most cases) already know their own disease status. Often the person collecting the data will also know the disease status of the patient. This may influence the accuracy of the data collected, either through differential recall by cases and controls, or by an interviewer being more persistent in questioning cases than controls. For rapidly fatal cancers, a biased subset of cases may be well enough to participate. In cohort studies neither the participant nor the investigator knows whether or not the subject will be a case or noncase by the end of the follow-up period, and typically all cases are ascertained for analysis.

### **Mendelian randomization studies**

Mendelian randomization studies are a relatively new method of assessing the relationship between select dietary factors and chronic disease, including cancer (Qi, 2009). In Mendelian randomization, a gene variant, or collection of variants, serves as a proxy for a modifiable dietary factor. Because such gene variants should be distributed randomly in populations, the method may help limit the potential confounding and related issues that can exist with other observational studies, and therefore may help provide evidence of causation. However, three key assumptions need to be met in Mendelian randomization studies (Yarmolinsky et al., 2018b). Briefly: the gene variant should be associated with the dietary factor of interest; the gene variant should not be associated with confounders; and, finally, the gene variant should not be associated with the cancer of interest. Because of this, Mendelian randomization analyses can currently only be applied to a select number of modifiable dietary factors. But with the continued growth of genome-wide association studies, the list of applicable factors is likely to grow as well.

The study of links between selenium and prostate cancer risk provides a good illustration of Mendelian randomization analysis. As a follow-up to the SELECT selenium and vitamin E supplementation trial, Yarmolinsky et al. studied the association between circulating selenium levels and prostate cancer by using a proxy of eleven single nucleotide polymorphisms (SNPs) strongly linked to serum selenium levels (Yarmolinsky et al., 2018a). In line with previous results, the Mendelian randomization analysis found no statistically significant link between blood selenium and overall risk of prostate cancer (RR 1.01, 95% CI 0.89–1.13).

As with all study methods, Mendelian randomization analyses have both strengths and weaknesses. While they can limit biases and help provide evidence of causation using observational data, for their results to be reliable, they must also satisfy a number of assumptions, which can be difficult to meet, and which also limit the number of factors that are able to be studied.

### **Intervention studies**

In principle, the most powerful means of determining the effects of dietary factors on cancer risk is an intervention study (i.e., a randomized trial). In randomized trials bias is removed because of the equal distribution of risk factors in each group. For example, it had been proposed that a randomized trial of fat reduction could help uncover the mystery of the relationship between dietary fat intake and breast cancer. The Women's Health Initiative was started in 1992 by the US National Institutes of Health with the goal of enrolling and randomizing over 48,000 postmenopausal women, half of whom would be trained to follow a diet deriving less than 20% of energy from fat. Given its focus, the trial was limited in the hypotheses it could test. For example, it would not be able to assess the potential impact that dietary fat reduction at an early age could have on breast cancer risk several decades later. Other problems with such a randomized trial included the difficulty of maintaining compliance with a diet incompatible with prevailing food consumption habits, and the gradual secular population decline in total fat consumption which reduced the size of the comparison of fat intake between the intervention group and the control groups. The Women's Health Initiative Trial counseled the women in the intervention group to adopt a diet that was high in fruits, vegetables, and grain products as well as low in total and saturated fat, therefore making it more difficult to distinguish between the effect of the fat reduction and that of increasing intake of fruits, vegetables, and grain products. The trial failed to show any significant benefit of reducing fat intake on breast cancer risk, both within the initial intervention period of 8.3 years and a post-intervention follow-up of 5.2 years (Prentice et al., 2006; Thomson et al., 2014).

All in all, while intervention studies may, in principle, have a great chance of determining effects of dietary factors on cancer risk, trials of sufficient duration and size may not be feasible because of issues such as long-term compliance and cost.

### **Meta-analysis**

A meta-analysis is a type of systematic review that combines published results from individual studies into summary findings, which can have greater statistical power and precision than results in the individual studies (Deeks et al., 2021). It can be a particularly useful method when single studies on a particular topic are underpowered and/or have inconclusive results.

As an illustration, in a 2014 meta-analysis assessing the association of calcium intake and risk of colorectal cancer, 5 of 15 included cohort studies found modest, statistically significant protective effects with calcium intake (Keum et al., 2014). Results from the ten other studies were non-significant, two of which had positive associations. When combined, the meta-analysis included over 12,000 cases of colorectal cancer and approximately 1.4 million total participants. The summary does-response result

showed that for each 300 mg per day increase in calcium intake, the risk of colorectal cancer decreased by 8% (RR 0.92 95% CI 0.89–0.95).

A number of factors determine the quality of a meta-analysis, including the quality of the individual studies included, the heterogeneity of the results included, and consideration of publication bias, among others. To overcome some of these limitations, investigators often collaborate to reanalyze the original individual participant data in a common analysis generating a pooled summary result. This is considered highest quality meta-analysis (Tierney et al., 2021).

## Epidemiological issues in the study of diet and cancer

### Resolved and unresolved issues

Some of the issues that researchers have encountered in their attempt to uncover the mystery of the dietary factors linked to cancer include the difficulty of distinguishing the importance of parts of dietary factors from the overall effect of each dietary factor. Looking back, in a meta-analysis in 1990 of 12 case–control studies of dietary fat intake and cancer, four studies observed a significant positive association, six uncovered nonsignificant positive associations, and two saw inverse associations. When the data were analyzed together there was a positive association observed for both total fat intake and saturated fat intake. Investigators must ask themselves which factor has larger implications in the study of diet and cancer, as not all studies have included analyses of the individual types of fats along with their data on overall fat consumption. In the study of the influence of dietary fiber intake (which includes crude fiber and many soluble fiber fractions) on cancer rates, there is still ongoing debate about specific definitions of fiber and the most appropriate method of biochemical analysis for determining fiber content of individual foods (Fuller et al., 2016; Jones, 2014). This same issue arises with the study of most dietary factors and could affect important advances in the study of diet and cancer.

Biochemical indicators of food and nutrient intake have two fundamental uses in epidemiological studies. Most often they serve as a “surrogate” for actual dietary intake in studies of disease occurrence. For nutrients that vary widely in concentration within foods and for which food composition tables are inaccurate, biochemical indicators may be the most feasible way of measuring intake. Within-food variation may occur owing to differences in food storage, processing, or preparation, or may be owing to geographical differences in soil nutrient content. For example, it has been found that selenium content in US soil can vary by as much as 100-fold, which in turn causes the selenium content of swine muscle to vary more than 15-fold.

Like most exposures driving risk of chronic disease, nutrient exposures relevant to disease are usually long-term. As the promotion period for cancers may be years or decades, it is usually desirable that a biomarker indicates the cumulative effect of diet over an extended period of time. There are a few possible methods to surpass the barrier of an indicator that is only sensitive to short-term intake, and to overcome the day-to-day intake fluctuations that occur with most nutrients: (1) experimental studies, in which nutrient levels are manipulated; (2) Mendelian randomization studies, which can assess by proxy lifetime nutrient exposure and (3) sampling levels in individuals longitudinally. Biomarkers of nutrient levels in blood or other tissues can provide a useful assessment of intake of certain nutrients, although the above considerations must be acknowledged, and careful attention must be given to specimen collection, storage, and analysis in order to avoid misclassification or bias. With an expanding array of biochemical indicators that have been validated as measures of dietary intake, their use in nutritional epidemiology will continue to grow.

The limited range of diet within most populations adds its own set of complexities to the epidemiological study of nutrition and cancer. For example, in the majority of populations where foods high in fat are readily available, very few individuals consume less than 30% of their energy from fat. This makes it difficult to study the impact of reducing fat intake to less than 30% of total energy intake. At the same time, some individuals of a relatively homogeneous population may have very different dietary patterns: For example, a range of dietary fat intake from 25% to 40% of total energy was seen within a cohort of 52,000 male health professionals in the USA.

Given that most neoplasms have a long induction period (the time from an exposure to a carcinogen to the development of cancer), often spanning several decades, accurate measure of long-term dietary intake is of utmost importance in the study of the implications of diet on cancer. Therefore, short-term methods of dietary assessment such as 24 h recalls are usually insufficient. In the context of case–control studies these short-term methods are inappropriate because they measure current diet, and it has been found that individuals alter their diet after the diagnosis of cancer. Mendelian randomization studies can measure lifetime exposures, but reliable links between gene variants and dietary exposures are currently limited. The most feasible method of measuring long-term intakes in large numbers of individuals is the food frequency questionnaire: These questionnaires measure the usual frequency of a selected list of foods.

Food frequency questionnaires to assess dietary intake need to be carefully designed. First of all, the food items on the questionnaire must represent the major source of nutrients of interest within the study population. Depending on the consistency of the concentration of a nutrient in a given food, the precision of dietary questionnaires varies. Food frequency questionnaires may provide rankings by level of intake, but they do not quantify actual intake. A dietary questionnaire may efficiently distinguish between participants with low-fiber and high-fiber intakes in a given population, but it will not necessarily provide a precise assessment of the absolute fiber intake. In the case of larger studies, it is possible for a random sample of participants to provide a more comprehensive assessment of intake by keeping several weeks of dietary records. This additional information will provide a more

precise quantification of dietary intake by helping estimate true dose–response relationships between a nutrient and diet expressed in absolute intake.

### Summary of known relations between diet and cancer

With the wealth of studies since the 1970s and important advances in analytical methods, there are clearly documented and strong associations between diet and cancer (**Table 1**) (World Cancer Research Fund/American Institute for Cancer Research, 2018b; Bouvard et al., 2015; Lauby-Secretan et al., 2016; World Cancer Research Fund/American Institute for Cancer Research, 2018a). Convincing evidence based on consistent findings from epidemiological studies conducted in diverse populations now shows that diet is an established cause of multiple cancers, including two of the most common cancers worldwide, breast and colorectum (Sung et al., 2021). With these rich epidemiological data we can more confidently conclude that close to 30% of cancer is attributable to diet (Colditz et al., 2012).

Public health officials have taken the accumulated evidence and developed strategies for minimizing cancer risk. Among these recommendations is a largely plant-based diet high in vegetables, fruits, whole grains, and legumes and low in red and processed meat, salt, sugar, and alcohol. Fats that are consumed should be polyunsaturated or monounsaturated, examples being canola oil and olive oil. Regular physical activity, in addition to independently lowering the risk of multiple cancers, can help with weight control, particularly when combined with a healthy eating pattern.

**Table 1** Strong and convincing evidence for increased and decreased risk of major forms of cancer and excess body weight by foods and drinks, micronutrients, dietary nonnutrients, and nutrition-related indicators.

	<i>Strong evidence</i>	<i>Convincing evidence</i>
<b>Increased risk</b>		
<i>Foods and drinks</i>		
Red meat	Colorectum, pancreas, prostate (mainly advanced)	
Processed meat	Stomach	Colorectum
Western diet and fast food	Excess weight	
Sugar-sweetened beverages		Excess weight
Alcohol	Breast (premenopausal), stomach	Oral cavity, pharynx, larynx, colorectum, breast (postmenopausal), liver, esophagus
<i>Micronutrients</i>		
Salt (NaCl)	Stomach	
<i>Nutritional covariates</i>		
Overweight/obesity	Oral cavity, pharynx, larynx, stomach (gastric cardia), gallbladder, ovary, prostate (advanced), meningioma, thyroid, multiple myeloma	Colorectum, breast (postmenopausal), endometrium, kidney, esophagus, liver, pancreas
Height	Endometrium, kidney, pancreas, prostate, melanoma	Breast (premenopausal), breast (postmenopausal), colorectum, ovary
<b>Decreased risk</b>		
<i>Foods and drinks</i>		
Fruits and vegetables	Aerodigestive	
Whole grains	Colorectum	
Dairy	Colorectal	
Mediterranean diet	Excess weight	
Coffee	Endometrium, liver	
Alcohol	Kidney	
<i>Micronutrients</i>		
Calcium	Colorectum	
<i>Nonnutrients</i>		
Fiber	Colorectum, excess weight	
<i>Nutritional covariates</i>		
Overweight/obesity	Breast (premenopausal)	
Physical activity	Breast (premenopausal), breast (postmenopausal), endometrium, excess weight	Colorectum

## Conclusion

Over the past decades our understanding of the links between what we eat and our risk of cancer has become increasingly refined. Overall, an eating pattern to lower cancer risk is one that is largely plant-based, rich in vegetables, fruits, whole grains, and legumes, and low in red and processed meat, salt, sugar, and alcohol. Identifying such links between diet and cancer, though, is in many ways only an initial step toward improving the health of individuals and the broader public. Many different factors determine eating patterns, and successfully promoting healthy changes to eating patterns can be difficult and take sustained efforts on multiple levels using multiple methods. So, while it is important to continue to uncover and clarify connections between diet and cancer, it is also important that we continue to apply that knowledge by exploring, implementing, and promoting effective, evidence-based efforts in prevention.

## Key points

- Briefly review the epidemiology of lung cancer and non-dietary causes of lung cancer.
- Provide an overview of methodologic challenges in studying the potential influence of dietary factors on lung cancer risk, with emphasis on the ubiquitous challenge of confounding by cigarette smoking. Further, epidemiology relies mostly on evidence from observational studies, and even when randomized trials are possible there are important differences in research methodology.
- Provide an overview of the evidence of dietary factors that have been widely studied in relation to lung cancer.

## Glossary

**Biomarker** A compound measured in human tissue as a marker of the body's exposure; for example, measurement of concentrations of beta-carotene in blood to measure dietary intake of beta-carotene

**Case-control study** An observational (nonexperimental) study that starts with patients of disease (lung cancer) and controls without disease and attempts to measure exposures that occurred in the past

**Confounding** When an extraneous variable (e.g., cigarette smoking) affects the association between the independent variable (e.g., dietary factor) and dependent variable (e.g., lung cancer)

**Epidemiology** The study of health and disease in human populations

**Phytochemical** Low molecular weight molecules produced by plants

**Prospective study** An observational (nonexperimental) study that starts with measurement of exposure and follows participants up over time for occurrence of the disease (lung cancer)

## Introduction

Lung cancer was a rare condition in the early 1900s but since then its occurrence increased markedly so that it is now accounts for 18% of all deaths globally, making it the leading worldwide cause of cancer death. Lung cancer is the third most common cancer

globally. Overall, an estimated 2.2 million new cases of lung cancer, constituting 11.4% of all cancer cases, were reported in 2020. Lung cancer is the most common cancer in males (14% of all male cancer cases) and the third most common cancer in females (8% of all female cancer cases) (Sung et al., 2021). One predominant cause is the major contributor to the global lung cancer epidemic: cigarette smoking. The link between cigarette smoking and lung cancer is so strong that population patterns of cigarette smoking are the primary determinant of the occurrence of lung cancer at the population level (Malhotra et al., 2016; Pesch et al., 2012).

Distinct patterns are present in the occurrence of lung cancer globally. The age-adjusted incidence rates and mortality rates for lung cancer rates are presently declining in high-income countries primarily due to decreases in the prevalence of cigarette smoking. The majority (62%) of lung cancer cases now occur in low- and middle-income countries. Western and central Africa have the lowest lung cancer rates in both men and women, primarily due to the low prevalence of cigarette smoking. Eastern Asia, Central and Eastern Europe currently experience the highest lung cancer rates in men, whereas northern Europe and North America have the highest lung cancer rates in women. The trends are mostly driven by historic cigarette smoking patterns (McIntyre and Ganti, 2017; Sung et al., 2021). In other countries such as China, and several parts of Africa where cigarette smoking prevalence increased more recently, lung cancer rates are increasing and will continue to do so unless reductions in the prevalence of cigarette smoking are achieved (Bray and Weiderpass, 2010; McIntyre and Ganti, 2017; Sung et al., 2021).

In addition to the high lung cancer incidence rate, an important contributor to the high lung cancer mortality rate is a poor survival rate. Due to poor survival from lung cancer, the population patterns in lung cancer mortality rates tend to closely mirror the incidence rates. For example, the 5-year survival rate is 21% and 13% in the United States and United Kingdom, respectively (Allemani et al., 2018; American Cancer Society, 2021). Lung cancer survival rates are especially low for late-stage disease (Bade and Cruz, 2020).

In addition to cigarette smoking and other forms of combustible tobacco, many other environmental risk factors and clinical risk indicators for lung cancer have been identified. A substantial body of evidence has been generated on the potential influence of dietary factors on lung cancer risk.

## Lung cancer histopathology

The four most common histological types of lung cancer are adenocarcinoma, squamous cell carcinoma, large cell carcinoma, and small cell carcinoma. All four histologic types are caused by cigarette smoking (Alberg and Nonemaker, 2008; Warren et al., 2020). For clinical purposes these diagnoses are dichotomized as non-small cell lung cancer, which comprise approximately 85% of the total, with the remaining 15% comprised of small cell lung cancer. This classification is used because surgery is not a primary curative treatment option for small cell lung cancer due to its high metastatic potential to the central nervous system.

Characterizing lung tumors based on molecular characteristics plays an increasingly important role in classifying and treating lung cancer using precision medicine approaches. For example, mutations and genetic events in *EGFR*, *ALK*, and *ROS1* are routinely tested for in the US to guide treatment plans for adenocarcinoma of the lung.

## Risk factors

Cigarette smoking is the major cause of lung cancer, and the most important factor responsible for the worldwide lung cancer epidemic. Cigarette smoking causes approximately 85% of all lung cancer cases in regions where the cigarette smoking epidemic is fully mature. In smokers, the risk of lung cancer increases with both the duration of smoking and the number of cigarettes smoked. There is no known safe level of smoking, as even the secondhand tobacco smoke involuntarily inhaled by nonsmokers is causally associated with lung cancer. Lung cancer risk decreases in those who quit smoking compared to persistent smokers, but not to the level of those who never smoked (Alberg and Nonemaker, 2008; U.S. Department of Health and Human Services, 2020).

In addition to cigarette smoking, many other causes of lung cancer have been established. Numerous occupational lung carcinogens have been identified; the substances involved include radon (found in underground mines), arsenic, asbestos, chromium, chloromethyl ethers, nickel, and polycyclic aromatic hydrocarbons (Shankar et al., 2019; Steenland et al., 1996). Synergism with smoking has been shown for several of these agents, such as asbestos and radon. Many other agents are suspected occupational carcinogens (Alberg et al., 2013; Errenet al., 1999; Shankar et al., 2019).

Air pollution is associated with increased lung cancer risk. Outdoor air pollution increases lung cancer risk through inhalation of air contaminants from combustion sources that generate polycyclic aromatic hydrocarbons and radionuclides. Carcinogens in indoor air vary with the setting but may include radon, tobacco smoke, smoke from wood or coal burning, and cooking fumes (Alberg et al., 2013; Eckel et al., 2016).

The observed familial aggregation of lung cancer suggests that genetic factors may influence susceptibility. Data from genome-wide association studies (GWAS) have provided promising leads. The results of four GWAS have been remarkably consistent in identifying genetic variants within a region on the long arm of chromosome 15 that are associated with lung cancer risk. For example, those with at least one variant allele of a specific SNP in this region (rs8034191) had a 1.3-fold greater risk of lung cancer than those homozygous for the wild type allele (Wei et al., 2011).

## Diet

### Dietary hypotheses and mechanisms

Epidemiological research on diet and lung cancer has been both hypothesis-driven and descriptive, exploring associations between foods, nutrient indexes, or biomarkers and lung cancer risk. Interest in macronutrients has emphasized indices of dietary fat, which has long been known to have the capacity to act as a tumor promoter. Micronutrients have been extensively studied, spurred initially by the pioneering studies of Bjelke and the original vitamin A and  $\beta$ -carotene hypotheses. Bjelke and subsequent researchers originally focused on vitamin A because of its role in cellular differentiation, but this line of inquiry was subsequently expanded to include antioxidant micronutrients, with an emphasis on  $\beta$ -carotene. The more general hypothesis has been advanced that antioxidant micronutrients may protect against oxidative damage to DNA and thereby protect against cancer. Hypotheses concerning specific beverages have also been proposed; for example, animal studies have shown a link between alcohol and changes in lung lipids, including surfactant, and in levels of enzymes that can activate procarcinogens and mutagens.

Another epidemiologic approach, empirical rather than hypothesis-driven, has been to explore the intakes of several specific foods or food groups for associations with lung cancer risk. The evidence documenting inverse associations between fruit and vegetable consumption and lung cancer stem from this inductive approach.

Certain methodological issues are relevant to the topic of diet and lung cancer. Foremost among these is the major challenge posed by the potential confounding effects of cigarette smoking due to the potent causal role of cigarette smoking, combined with the fact that smokers tend to eat less healthful diets than nonsmokers. This makes it very difficult to disentangle the potential impact of cigarette smoking on any observed diet–lung cancer association. Thus, even when efforts are made to attempt to control for smoking, residual confounding of diet–lung cancer associations may persist. Complicating matters further is that cigarette smoke can directly affect nutritional biomarkers (Fig. 1); for example, smokers tend to have lower levels of circulating antioxidant micronutrients even after accounting for differences in dietary intake. Similar associations have even been noted for secondhand smoke exposure.

Characteristics of epidemiological studies in general further introduce challenges to clear-cut inferences concerning observed associations between dietary factors and lung cancer. Approaches to dietary assessment are not fully standardized, so there may be differences between studies in the number of foods queried, the measurement of serving sizes, and the data collection approach employed. There is also uncertainty as to the biologically relevant exposure window for lung cancer, and dietary agents may plausibly act in early or later stages of carcinogenesis. Clinically diagnosed lung cancer reflects a series of complex molecular genetic events that occur over many years, and the relevant windows for dietary exposures are uncertain. Case–control studies usually measure past diet during some reference period, whereas cohort studies tend to focus on current diet. Case–control studies have commonly been employed to study diet and lung cancer; many of these studies focus on diet during the 5 years preceding diagnosis. These studies provide direct information concerning dietary factors in the later stages of carcinogenesis. To the extent that such measures reflect usual adult (or lifetime) diet, these studies may also be relevant to the earlier stages of carcinogenesis. However, as lung cancer tends to be rapidly fatal, many case–control studies include data collected from deceased subjects' next-of-kin. Data from surrogate respondents are likely to be less accurate than self-reported data, and therefore introduce substantial misclassification.

Evidence concerning relationships between lung cancer and fruits, vegetables, micronutrients, phytochemicals, fat, body mass index, beverages, and meat intake is described in the section on dietary associations with lung cancer. To provide a guide for assessing the evidence for each dietary factor, evidence ratings from an objective assessment of the world's evidence on these topics, summarized in the continuous update report of the World Cancer Research Fund (WCRF), are used for factors that were assigned

**Fig. 1** Cigarette smoking complicates the study of diet and lung cancer.

evidence ratings. The rating scale used included evidence ratings of “convincing,” “probable,” “limited–suggestive”, and “limited–no conclusion” for whether a dietary factor was associated with increased or decreased risk of lung cancer (World Cancer Research Fund, 2021).

## Dietary associations with lung cancer

### Fruit

In total, the evidence points toward greater levels of fruit consumption being inversely associated with lung cancer risk. The WCRF meta-analysis of 23 studies showed a statistically significant 8% decrease in the risk of lung cancer for every 100 g of fruit intake per day. Evidence of a dose response relationship was found for fruit intakes up to 200–300 g per day. The WCRF report rated the overall evidence as “limited–suggestive” that fruit consumption is inversely associated with lung cancer risk (World Cancer Research Fund, 2021). No clear pattern emerges when studies have examined specific fruits or classes of fruits. For example, apples and citrus fruits are associated with reduced risk of lung cancer in some studies but not in others (Wang et al., 2021).

### Vegetables

Evidence for an inverse association between vegetable consumption and lung cancer risk parallels the evidence for fruit consumption. The WCRF meta-analysis of 20 studies showed a statistically significant 6% decrease in the risk of lung cancer for every 100 g of vegetable intake per day. Evidence of a dose-response relationship was found for vegetables intakes up to 300–400 g per day (World Cancer Research Fund, 2021). Consequently, the WCRF report rated the overall evidence as “limited–suggestive” that higher levels of vegetable intake are associated with decreased lung cancer risk.

In addition to vegetable intake as a whole, the results for a number of specific vegetables, such as carrots and cruciferous vegetables, have been consistently observed to be inversely associated with lung cancer risk. The association with cruciferous vegetable intake has tended to remain strong and robust even in studies that have carefully controlled for cigarette smoking (Lam et al., 2009). As discussed below, the growing evidence of an inverse association between cruciferous vegetable intake and lung cancer risk has bolstered interest in isothiocyanates as a promising chemopreventive agent.

### Micronutrients

Two different strategies have been used to evaluate the relationship of micronutrients to lung cancer. One approach has been to use food-frequency questionnaires to measure micronutrient intake. A second approach is to use biomarkers, assaying the circulating concentrations of micronutrients. The former approach provides a better average measure of micronutrient “exposure,” whereas the latter approach has the advantage of measuring micronutrient concentrations closer to cellular level, where the biologic effect is postulated to occur. However, a single assay of circulating micronutrient concentrations may fail to capture the biologically appropriate window of exposure.

The strongest evidence for the biomarker approach is generated from prospective cohort studies, where blood is collected from a population that is initially cancer-free and the population is then followed for the occurrence of lung cancer. The results of such prospective studies bolster the evidence supporting the premise that in general, higher circulating concentrations of carotenoids ( $\alpha$ -carotene,  $\beta$ -carotene,  $\beta$ -cryptoxanthin, lutein, lycopene, and total carotenoids), are associated with reduced lung cancer risk. Circulating concentrations of retinol, tocopherol, and selenium have not been associated with a reduced risk of lung cancer in most studies. In contrast to prospective studies, biomarker studies of micronutrients based on measurements made after a patient is diagnosed with lung cancer are limited because a clinical diagnosis of lung cancer and its treatment and concomitant changes in diet can lead to decreases in circulating micronutrient levels, introducing the potential for reverse causality.

For dietary intake, the evidence is most abundant for vitamins A, C, and E, and carotenoids. The evidence relating measures of retinol intake to lung cancer risk provide “limited–suggestive” evidence that retinol is actually associated with increased risk of lung cancer (World Cancer Research Fund, 2021), contrary to Bjelke’s initial hypothesis. However, studies of dietary intake of carotenoids and vitamin C point more consistently toward an inverse association. For example, in a systematic review of the evidence from prospective studies, both dietary intake and circulating concentrations of total carotenoids were associated with 20–30% lower risk of lung cancer in the highest-versus-lowest exposure categories. Associations of similar magnitude were observed for the provitamin A carotenoids  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin and for the nonprovitamin A carotenoids lycopene and lutein. Based on these data, the WCRF concluded that foods containing carotenoids were “probable” protective factors for lung cancer (World Cancer Research Fund, 2021).

Thus, prospective studies of both biomarkers and of dietary intake favor a protective association between carotenoids and lung cancer. However, uncertainty remains about whether a generally protective association is specific to these carotenoids or whether carotenoid intake merely serves as a marker of the intake of other protective substances or healthier dietary habits in general. The evidence for vitamin C and vitamin E is suggestive of a protective association (Huang et al., 2020; Luo et al., 2014), whereas the data on vitamin A, and selenium have yielded null findings (Fritz et al., 2011). Conversely, the use of vitamin B6 and B12 supplements were observed to increase lung cancer risk by 30%–40% among men in a prospective cohort study (Brasky et al., 2017).

### Phytochemicals

Phytochemicals are low molecular weight molecules produced by plants. Of the many classes of phytochemicals, those studied in relation to lung cancer include phytoestrogens, flavonoids, and glucosinolates. The tumor promoting effects of steroid hormones can be blocked by phytoestrogens. Soya beans are a primary source of a specific class of phytoestrogens known as isoflavonoids. The relatively few studies to date of isoflavonoids in relation to lung cancer have not provided evidence of a link ([World Cancer Research Fund, 2021](#)).

Flavonoids are polyphenolic compounds found in many foods derived from plants; flavonoids often exhibit potent antioxidant activity. Some fruits contain high levels of flavonoids, such as apples (quercetin) and white grapefruit (naringin). Flavonoid intake has been at least weakly associated with reduced risk of lung cancer in many, but not all, of the studies to date.

Isothiocyanates are metabolites of the class of phytochemicals known as glucosinolates. Isothiocyanates could exert anticancer effects by blocking carcinogens *via* induction of phase II detoxification enzymes, such as glutathione S-transferase. Cruciferous vegetables contain high concentrations of glucosinolates, and hence consumption leads to higher endogenous isothiocyanate levels. As with cruciferous vegetables, lung cancer risk is also consistently lower with higher intakes or urinary levels of isothiocyanates.

A postulated biologic relationship between isothiocyanates and a common polymorphism in the *GSTM1* gene provides an example of a potential gene–diet interaction relevant to lung carcinogenesis. A focus in cancer epidemiology is to characterize inter-individual susceptibility to cancer by studying polymorphisms in genes involved in carcinogenic pathways, including how these genetic markers interact with environmental exposures to contribute to cancer risk. The role of glutathione S-transferase as a phase II detoxification enzyme has made a common polymorphism in the glutathione S-transferase M1 (*GSTM1*) gene of interest in relation to lung cancer. Compared to persons with the *GSTM1* present genotype, those with the *GSTM1* null genotype have a small but statistically significantly higher risk of lung cancer.

When isothiocyanates have been studied in combination with *GSTM1*, the decreased risk of lung cancer associated with isothiocyanates has been especially pronounced in persons with the *GSTM1* null genotype. This association could represent the cancer blocking activity of isothiocyanates being allowed to play an enhanced role in *GSTM1* null individuals because they are not being metabolized as quickly as in those with the *GSTM1* present genotype. This example illustrates the potential interactions between genetic and dietary factors. Integrating genetic and epigenetic markers into the study of nutritional factors provides a mechanistically-based approach that holds promise for advancing understanding of the complex role of diet in the etiology of lung cancer.

### Fat

Evidence that dietary fat may facilitate tumor growth was reported as early as 1940. Correlation exists between international or regional dietary fat consumption and lung cancer mortality. In case–control studies, total fat intake is consistently associated with lung cancer risk, with less consistent results for saturated fat, unsaturated fat, and cholesterol intake. In a pooled analysis of data from ten prospective cohort studies, lung cancer risk was weakly positively associated with total fat and saturated fat intake, whereas a weak inverse association was observed for polyunsaturated fat intake ([Yang et al., 2017](#)). In the WCRF report the evidence was rated as “limited–no conclusion” that total dietary fat is associated with increased lung cancer risk ([World Cancer Research Fund, 2021](#)). With respect to specific foods, the same level of evidence was applied to butter.

### Body mass index

In contrast to the situation for most types of cancer, prospective cohort studies consistently show a strong inverse relationship between body mass index (BMI) and lung cancer risk ([Wang et al., 2018](#)). These remarkably strong, consistent findings clearly demonstrate that leanness is statistically associated with lung cancer risk. The key remaining question is whether this association is genuine or whether it is indirect. Confounding by cigarette smoking is a viable explanation for these findings because cigarette smoking is strongly associated both with the risk of lung cancer and with leanness. However, the inverse association between BMI and lung cancer has been observed among never smokers ([Zhu and Zhang, 2018](#)). Therefore, research is needed to further test the hypothesis that leanness is a susceptibility factor for lung cancer, and if so to advance understanding of the underlying biological mechanisms.

### Beverages

Many beverages, including alcohol, coffee, tea, and milk have been studied for a possible link to lung cancer, although the issue of potential confounding by cigarette smoking recurs. The majority of studies of alcohol drinking in relation to lung cancer risk that have adjusted for age and cigarette smoking have observed either null or weak associations. After adjusting for cigarette smoking, the WCRF meta-analysis found a significant dose-response relationship between ethanol drinking and increased lung cancer risk. The association was not significant for specific alcoholic beverages, but a significant inverse association was observed for wine. The mechanistic basis for an association between alcohol drinking and lung cancer is plausible based on factors such as the presence of carcinogens such as acetaldehyde in alcoholic beverages and the ability of alcohol to lead to increased cellular penetration of other carcinogens. The WCRF report concluded the evidence is “limited–suggestive” that alcoholic drinking is associated with increased lung cancer risk ([World Cancer Research Fund, 2021](#)).

Some studies have observed heavy coffee consumption to be associated with an elevated risk of lung cancer after adjustment for cigarette smoking, but a host of case-control studies have generated findings that fluctuate around the null (Galarraga and Boffetta, 2016). The issue of confounding between coffee drinking and other health behaviors, particularly cigarette smoking, has not been addressed adequately, indicating that much stronger evidence is needed for coffee drinking to be considered a risk factor for lung cancer. Despite numerous *in vitro* and *in vivo* studies that have observed potential tumor-inhibitory effects of tea, the epidemiologic evidence provides inconsistent link between tea drinking and lung cancer risk. A meta-analysis of prospective cohort studies showed a greater risk of lung cancer among tea drinkers ( $\geq 2$  cups/day) who were non-smokers. The biological link modulating this risk needs to be explored (Zhu et al., 2021). Based on evidence such as this, the WCRF report concluded the evidence is “limited–no conclusion” that tea is associated with lung cancer risk (World Cancer Research Fund, 2021).

The associations observed between milk drinking and lung cancer depend on milk fat content. Milk drinking is not strongly associated with lung cancer risk when milk fat content is ignored. The associations between whole milk and lung cancer tend to be either null or in the direction of increased risk, whereas the associations for reduced fat or nonfat milk tend to be either null or in the protective direction (Yang et al., 2016). Perhaps milk consumption, including type of milk, is merely serving as a marker of fat intake, which as noted above tends to be associated with increased lung cancer risk. Consistent with the equivocal nature of the evidence and concerns about confounding by cigarette smoking, the WCRF report did not provide evidence ratings for any of these beverages in relation to lung cancer risk (World Cancer Research Fund, 2021).

Drinking water can be a route of exposure to environmental contaminants. This is exemplified by the clear increase in lung cancer risk associated with drinking water that is contaminated with high levels of arsenic (World Cancer Research Fund, 2021). Based on studies conducted in geographic regions where drinking water is contaminated with high concentrations of arsenic, the WCRF report rated the evidence as “convincing” that high concentrations of arsenic in drinking water is a risk factor for lung cancer (World Cancer Research Fund, 2021).

### Meat and fish

A pooled meta-analysis found an increased risk of lung cancer associated with higher intakes of red meat and processed meat (Xue et al., 2014). The cooking method may play a role, as heterocyclic amines from cooked meat may contribute to an increased lung cancer risk. Based on the slight trending of the results toward increased risk, the WCRF report rated the evidence for both red meat intake and processed meat intake to be “limited–suggestive” of increased risk (World Cancer Research Fund, 2021). A meta-analysis provided evidence that fish consumption may be inversely associated with lung cancer risk (Song et al., 2014), but further research is needed to determine if this association is genuine. The WCRF report rated this evidence as “limited–no conclusion” (World Cancer Research Fund, 2021).

## Diet and prevention

### Chemoprevention trials

Three large-scale, randomized, double-blind, placebo-controlled trials were undertaken to test the hypothesis that  $\beta$ -carotene supplementation protects against lung cancer (World Cancer Research Fund, 2021). All three studies indicated that  $\beta$ -carotene supplementation in later adulthood does not protect against lung cancer. In fact,  $\beta$ -carotene supplementation was unexpectedly associated with an increased risk of lung cancer among the high-risk populations of heavy smokers in the Alpha-Tocopherol, Beta-Carotene (ATBC) Cancer Prevention Study (Omenn et al., 1996) and among the smokers and asbestos-exposed workers in the Carotene and Retinol Efficacy Trial (CARET) Study (Virtamo et al., 2003). The WCRF thus rated this strong, consistent evidence from two randomized controlled trials as “convincing” that  $\beta$ -carotene supplement increase lung cancer risk in current smokers (World Cancer Research Fund, 2021). These experimental results thus not only failed to corroborate the evidence from observational studies, but clearly demonstrated that  $\beta$ -carotene supplementation increased risk in groups at the highest risk of lung cancer. The combined results of multiple randomized controlled trials of vitamin E supplements are clearly consistent with no effect on lung cancer risk.

### Observation versus experiment

The ATBC and CARET studies enrolled older, high-risk individuals who had high cumulative exposure to tobacco smoke or asbestos (Virtamo et al., 2003; Omenn et al., 1996). The results therefore presumably apply mainly to the latter stages of carcinogenesis. The doses administered were far higher than the normal dietary range, and the dose–response relationship for preventive effects, anticipated from the observational evidence, may not be applicable. Because antioxidant nutrients may exert their protective effect in the earlier stages of carcinogenesis,  $\beta$ -carotene may have been administered too late to halt the evolution of cellular changes that lead to lung cancer. Alternatively, compounds present in fruits and vegetables other than the micronutrients studied in the trials may protect against lung cancer. The protective associations for fruit and vegetable consumption were allied to the micronutrient hypothesis, but the results of the chemoprevention trials of both  $\beta$ -carotene and vitamin E raise questions about the potential pay-off from large trials designed to test single micronutrients, unless there is a strong mechanistic basis combined with substantial observational evidence pointing to an individual micronutrient as the primary protective agent. Indeed, fruits and vegetables contain an

abundance of antioxidants and phytochemicals with diverse anticarcinogenic activities. Then again, fruit and vegetable intake may be acting as a marker of a healthier lifestyle that is associated with lower cancer risk.

## Conclusions

Knowledge of the relationship between diet and lung cancer has increased tremendously during past 50 years. Promising leads suggest that nutritional factors could have a substantial impact on lung cancer risk in humans. In general, persons who eat more fruits and vegetables have a lower risk of lung cancer than persons who consume less of these foods. The specific constituents of fruits and vegetables that may confer protection are unknown. An important unanswered question is whether fruits and vegetables directly confer protection against lung cancer or whether estimates of fruit and vegetable consumption are indicators of differences between individuals who eat healthy and unhealthy diets that are leading to uncontrolled confounding. Nevertheless, the protective association noted for fruit and vegetable consumption has the potential to contribute to prevention. A diet adequate in fruit and vegetables is already known to be prudent for preventing chronic diseases in general.

Even for factors such as fruit and vegetable consumption, the highest category of intake is usually associated with at most a halving in the risk of lung cancer. An association of this magnitude could result from residual confounding by cigarette smoking. Future research that provides the strictest possible control for cigarette smoking, such as studies that match cases and controls in the study design or studies limited to never smokers, will help to resolve longstanding questions about dietary factors and lung cancer by addressing head-on the persistent concern about residual confounding by cigarette smoking.

Advances in understanding of the role of diet in lung cancer etiology should not obscure the fact that cigarette smoking is the predominant cause of lung cancer. Many important questions about the complex relationship between diet and lung cancer remain, but the primary way that the lung cancer epidemic will be controlled is to prevent the uptake of cigarette smoking among children and effectively assist addicted smokers to stop smoking cigarettes.

## Key points

- Celiac disease is a disease caused by sensitivity to gluten protein in dietary wheat, barley or rye in genetically susceptible individuals
- The HLA-DQ genes have a strong genetic influence on development of celiac disease
- The disease primarily affects the small intestine, although it may manifest in a number of different ways
- The diagnosis is made through use of serological tests followed, in most cases, by duodenal biopsy
- Treatment is lifelong and complete withdrawal of wheat from the diet

## Introduction

Celiac disease is a disorder primarily affecting the small intestine, which manifests in genetically predisposed individuals who consume wheat, barley or rye. The disease is due to an aberrant immune response to storage proteins found in these cereals, and provides an example of the interaction between host genetics and the environment. The disease is rare or uncommon in areas of the world where wheat is not consumed, for instance in South East Asian countries where rice is the staple cereal or in sub-Saharan Africa where maize is the staple cereal. On the other hand, it is very prevalent in areas such as Europe and North America where wheat is regularly consumed in the diet. From the evolutionary point of view, celiac disease can be considered as a consequence of the change to a pastoral life and cultivation of cereals. The name celiac disease is attributed to Aretaeus, a Greek physician in the first century CE, who described a similar disease and called it “koeliakos” (Paveley, 1988). No major recorded descriptions of the disease exist thereafter until the detailed description of the disease in children in 1888 published by Dr. Samuel Gee, a British pediatrician (Paveley, 1988). The recognition that wheat ingestion is responsible for celiac disease is credited to the Dutch pediatrician Willem-Karel Dicke (Paveley, 1988). Celiac disease was recognized to be quite prevalent in Europe, and subsequently there has been recognition that the disease is equally prevalent in North America. The availability of serological tests to screen for the disease has resulted in recognition of the magnitude of disease burden in many other parts of the world. The diagnosis of celiac disease is initially made serologically by testing for the presence of antibody to tissue transglutaminase, the finding of characteristic changes on small intestinal biopsy, and ultimately by a response (clinical, biochemical and histological) to complete withdrawal of gluten from the diet.

## Pathogenesis

The pathogenesis of celiac disease involves interactions between host genetics and environmental factors, the most significant of the latter being ingestion of wheat, barley or rye (Kagnoff, 2007). Celiac disease occurs due to an immune reaction to the storage proteins of wheat, rye and barley, which are closely related members belonging to the Triticeae tribe of the grass family. Their storage

proteins are rich in proline and glutamine. The disease-inducing proteins in wheat are called gluten (consisting of two major protein types gliadins and glutenins) while the related proteins in rye and barley are called hordeins and seccalins. Oats do not belong to the Triticeae tribe and have proteins called avenins which have a much lower proline content, and are only rarely associated with celiac disease. Rice, maize, sorghum and millets belong to very distantly related subfamilies of grass and their storage proteins are not associated with celiac disease.

Celiac disease develops only in genetically susceptible individuals. The strongest genetic association of celiac disease is with the HLA system (Kagnoff, 2007). The HLA complex, located on chromosome 6p21, contains more than 200 genes and over 3000 known alleles. The HLA class II molecules—DP, DQ and DR—are involved in exogenous peptide antigen presentation to T cells. The expression of either HLA-DQ2 or of HLA-DQ8 antigen is a pre-requisite for the development of celiac disease. The HLA DQ molecules are proteins that are found on the cell surface of antigen-presenting cells mainly macrophages, dendritic cells and B cells. They are composed of two chains, the  $\alpha$  and the  $\beta$  chains. These are encoded by the genes HLA-DQA1 and HLA-DQB1 respectively. Many persons have two  $\alpha$  and two  $\beta$  chain variants resulting in the presence of four different DQ proteins in the same individual. The  $\beta$  chain of HLA-DQ2 protein is encoded by one of two alleles either HLA-DQB1\*0201 or HLA-DQB1\*0202. The  $\alpha$  chain of HLA-DQ2 is encoded by either HLA-DQA1\*0201 or HLA-DQA1\*0501. The HLA-DQ8 protein is encoded by the gene HLA-DQB1\*0302.

HLA-DQ2 and HLA-DQ8 can bind proline-rich peptides containing deamidated glutamine residues. An enzyme called tissue transglutaminase, probably produced by fibroblasts, binds to gliadin-derived peptides and deamidates glutamine to glutamic acid, resulting in negatively charged residues and improved binding of the gliadin peptides to pockets in the DQ2 or DQ8 molecules on antigen presenting cells. There may be up to 50 peptides in wheat, 60 in rye and 35 in barley that can bind to HLA-DQ2 or -DQ8. CD4<sup>+</sup> T lymphocytes in the lamina propria of the small intestine are activated when these peptides bind to HLA molecules. The release of tissue transglutaminase into the inflamed gut also results in a strong autoimmune response to tissue transglutaminase with high levels of circulating IgA specific for tissue transglutaminase (tTG-IgA) present in untreated celiac patients. Thus, the main characteristics of celiac disease are the DQ2/DQ8 restricted responses to gliadin peptides, the strong intestinal T cell response to deamidated gliadin peptides, and the production of tTG-IgA (Kagnoff, 2007).

Gluten peptides reach the lamina propria of the intestine through paracellular and transcellular pathways (Kagnoff, 2007). After binding to and presentation by the HLA-DQ2 or DQ8 proteins, they activate gluten-specific CD4<sup>+</sup> T helper 1 cells in the lamina propria which secrete the cytokines and chemokines necessary to induce inflammation with crypt hyperplasia and villus atrophy that are characteristic of the disease. Apart from the adaptive immune response involving T helper 1 cells, it is likely that there is also an innate immune response to certain proteins from wheat that results in epithelial cell activation and increased intraepithelial lymphocytes (IEL). The innate immune activation of IEL results in the expression of MICA (MHC Class I Chain-related A protein), which binds to and activates a receptor found on NK cells,  $\gamma\delta$  T cells and on some CD4<sup>+</sup> and CD8<sup>+</sup> T cells. This results in antigen-dependent cell-mediated cytotoxicity with release of cytokines as well as cytotoxic granules containing perforin and granzymes that enter target epithelial cells and trigger apoptosis leading to cell death. Interleukin-15 (IL-15) is the cytokine that is implicated in linking innate to adaptive immunity in celiac disease. This cytokine is produced by dendritic cells and macrophages in response to exposure to gluten peptides, and activates intraepithelial lymphocytes. The exact nature by which epithelial cell destruction occurs and the roles of cytotoxic and regulatory T cells is not yet fully defined. The cytokines secreted by T cells may be important in driving matrix remodeling, that leads to villus atrophy and crypt hyperplasia. Interferon- $\gamma$  from activated T cells appears to be involved as an agent of damage, and this may activate macrophages that secrete tumor necrosis factor- $\alpha$  and matrix metalloproteinases MMP-12 and MMP-13 which lead to proteolysis of the matrix followed by villus-crypt remodeling.

## Genetics

The combination of HLA-DQA1\*0501 and DQB1\*0201 that encodes the HLA-DQ2 heterodimer can be encoded by alleles on the same haplotype, or by one subunit each from paternal and maternal haplotypes (Trinka et al., 2001). Homozygosity for the above combination or possession of a second DQB1\*02 allele increases the susceptibility to celiac disease in European populations. This “gene dose” effect is supported by evidence that T lymphocyte proliferation and cytokine responses to gluten depend on the DQ type and gene dose. An extended haplotype comprising A1-B8-DR3-DQ2 is found in about 10% of European subjects and is associated with other autoimmune diseases including type 1 diabetes and autoimmune thyroid disease. In India, celiac disease may be detected in up to 11% of patients with type 1 diabetes mellitus.

HLA-DQ2 and DQ8 proteins are expressed in 30% of the population, yet only 2–5% of the appropriate HLA gene carriers develop celiac disease, suggesting that there are either other genes or other environmental factors or both that contribute to the development of celiac disease in the susceptible host. The evidence suggests that the HLA background leads to a usually suppressed T cell response to gluten in DQ2/DQ8 carriers, and that this suppression is removed in some individuals due to either other genes or environmental conditioning leading to overt celiac disease.

Several lines of evidence suggest that genetic influences outside the HLA system are also at work in determining susceptibility to celiac disease. When monozygotic twins are compared to HLA allele-identical dizygotic twins (i.e., same gene dose in both), the concordance for celiac disease in dizygotic twins is less than among monozygotic twins. Similarly, while HLA-DQ2 prevalence is equally high among Sardinians and the Saharawi tribes, the prevalence of celiac disease in Sardinia is only one-fifth of that in the Saharawi. The identification of genes outside the HLA complex that contribute to development of CD has been facilitated by

genome-wide association studies (GWAS) in multiple populations. Several non-HLA risk loci have been identified for celiac disease through GWAS (Kumar et al., 2021), the strongest association being with a locus close to the IL-2/IL-21 locus on Chromosome 4q27. Modifier genes may influence expression of celiac disease through mechanisms such as the release of specific cytokines or other molecules that up-regulate HLA-DQ2 and HLA-DQ8 proteins on antigen presenting cells. Together, these non-HLA genes account for only 3–4% of the genetic susceptibility to celiac disease compared to 30–40% for the HLA genes.

## Epidemiology

Celiac disease was originally identified to affect around 1% of individuals in Northern Europe, but has now been recognized to occur around the world (Lebwohl and Rubio-Tapia, 2021). Meta-analysis of studies around the world indicate that the global prevalence of biopsy-confirmed celiac disease is around 0.7% being highest in Europe and Oceania. There are major geographical differences in prevalence that appear to be driven by differences in diet and by the population prevalence of HLA-DQ2 and -DQ8. The disease is rare in Southeast Asia and South India where rice is the predominant dietary cereal, and in sub-Saharan Africa where maize constitutes the main dietary cereal. On the other hand, prevalence is high in Europe, North America and North India where wheat is regularly consumed in the diet. The prevalence of celiac disease among the Saharawi, an inbred North African tribe with high prevalence of DQ2 and high wheat intake, is close to 5%.

The prevalence of celiac disease in different populations around the world mirrors also the genetic susceptibility to celiac disease. The most prominent factor hitherto associated with genetic susceptibility to CD is the HLA system. The HLA complex is a highly polymorphic region located on chromosome 6p21, and containing more than 200 genes and over 3000 known alleles. The HLA class II molecules—DP, DQ and DR—are involved in exogenous peptide antigen presentation to T cells. The expression of either HLA-DQ2 or of HLA-DQ8 is considered to be a necessary pre-requisite for the development of celiac disease. The population prevalence of CD in Europe, North America, North Africa, the Middle East, and North India averages 1%. In these populations, either HLA-DQ2 or HLA-DQ8 is present in approximately 40% of the population. Among the Saharawi tribes of Africa, who are of mixed Arab-Berber ancestry with a high degree of inbreeding, there is a 5% prevalence of CD probably the highest in the world. In this population, carriage of HLA-DQ2 or HLA-DQ8 is around 60% of the population. On the other hand, celiac disease is virtually unknown in Japan and in Burkina Faso where most of the population does not express either HLA-DQ2 or HLA-DQ8.

Another evidence for a strong genetic effect comes from twin studies, with concordance for celiac disease being observed in 75% of monozygotic twins but only in 10% of dizygotic twins. There is a familial clustering of celiac disease with a 10% prevalence of celiac disease in first degree relatives compared to the general population. The relative risk for developing celiac disease in a sibling of an index patient varies from 20 to 60.

The prevalence of celiac disease in many regions has steadily increased in the past six decades, even after adjusting for increased physician and patient awareness and increased sensitivity of the diagnostic tests. This suggests the presence of an altered environment contributing to disease expression, as the genetic makeup of the population is unlikely to have changed. Putative environmental factors could include increased consumption of wheat, alteration in type or content of gluten in wheat, or factors affecting the immune response. Evidence indicates that the modern hexaploid wheat, *Triticum aestivum*, is more immunogenic to T cells than diploid or tetraploid wheats cultivated a couple of centuries ago. Thus, human agricultural practices may have contributed to the increasing incidence of celiac disease. Changes in human dietary practices are probably also responsible. The Saharawi traditionally had prolonged breastfeeding, and later consumed camel's milk, dates, and meat and very little cereal. Over time, breastfeeding duration reduced and wheat flour products especially bread became the staple, leading to a high incidence of celiac disease. The time of exposure to gluten-containing foods appears to be also important. Celiac disease incidence is lower in Denmark and Estonia compared to Sweden, and this has been attributed to higher infant consumption of gluten in the latter country. In an apparent natural experiment in Sweden, a significant increase of celiac disease was noted in children who were weaned between the years 1984–1996, the incidence during this period being nearly three times as much as in the periods before or after (Myléus et al., 2009). This coincided with changes in the wheat protein content of infant foods and early weaning during the period under consideration, and led to the recommendation that complementary feeds should not be introduced before four months of age and not much later than 6 months. Breast feeding at the time of introduction of wheat is now considered to have a protective effect against development of the disease, suggesting that it may induce tolerance to dietary gluten. The "hygiene hypothesis" has also been advanced as an explanation for an increasing incidence of celiac disease in the modern world. In this hypothesis, reduced childhood exposure to intestinal infections or alterations in the gut microbiome may alter T cell conditioning away from the normal balance that is maintained between T helper 1, T helper 2 and T regulatory mechanisms, leading to a dysregulated immune system and increased gluten sensitivity. On the other hand, case-control studies suggest a mild increase in risk for celiac disease in children who had multiple enteric infections in infancy, the speculation being that these increase intestinal permeation of the antigens that induce celiac disease.

## Pathology

The pathology of celiac disease was first appreciated after the introduction of small intestinal capsule biopsy by Margot Shiner in 1956. The disease affects mainly the proximal small intestine, but the changes may be patchy. The pathology of jejunal capsule

**Table 1** Histological classification of small bowel changes in celiac disease.

Marsh type	IEL/100 enterocytes		Crypt length	Villus height	Comments
	Jejunum	Duodenum			
0	<40	<30	Normal	Normal	Normal
1	>40	>30	Normal	Normal	Celiac in remission, other enteropathies
2	>40	>30	Increased	Normal	Treated celiac, dermatitis herpetiformis
3a	>40	>30	Increased	Mild atrophy	Symptomatic celiac disease
3b	>40	>30	Increased	Marked atrophy	
3c	>40	>30	Increased	Complete atrophy	

IEL = intraepithelial lymphocytes.

Original Marsh classification modified by Oberhuber et al. (1999).

biopsies was described in detail by Michael Marsh, who originated a classification of histological severity (Oberhuber et al., 1999). Currently the histology is evaluated on mucosal biopsies taken from the duodenum or jejunum during fiberoptic endoscopy of the upper gastrointestinal tract. The Marsh classification, as modified by Oberhuber, remains widely used in the reporting of duodenal mucosal biopsies from patients with celiac disease (Table 1). In brief, the presence villous atrophy as well as crypt elongation or hypertrophy, along with increased intraepithelial cells, remains the cornerstone of diagnosis. Type 1 and type 2 in the Marsh classification are not considered compatible with the diagnosis of untreated celiac disease, but may occur in patients on gluten free diet. The Type 2 Marsh change may be seen in dermatitis herpetiformis. Complete villous atrophy (Fig. 1), seen in some patients with celiac disease, is seldom if never not found in other small bowel mucosal diseases.

## Clinical features

Celiac disease may present in a wide variety of ways. In children, the disease is diagnosed usually between the first to seventh year of life, with the child remaining quite healthy until the introduction of cereals into the diet. Young children may develop chronic diarrhea, failure to thrive, muscle wasting, abdominal distension, vomiting, and abdominal pain. Older children may present with anemia, short stature, rickets, behavioral disturbances, or poor performance in school. In some children constipation, pseudo-obstruction, and intussusception may be seen. Dental enamel defects involving secondary dentition as well as neurological syndromes and epilepsy with intracranial calcification have been reported in children. In adults, celiac disease may be overt in presentation with classic gastrointestinal symptoms of diarrhea, weight loss, and abdominal pain. These patients are categorized as having typical or classical celiac disease. Recurrent oral ulcers may be a feature of the disease. The presence of diarrhea or steatorrhea, which occurs in approximately 50% of patients, indicates severe disease and malabsorption.

**Fig. 1** Endoscopic duodenal biopsy from a patient with celiac disease showing complete loss of villi and marked elongation of crypts along with inflammatory infiltration of the lamina propria.

Celiac disease may also be diagnosed in individual with non-gastrointestinal symptoms, particularly in adults. Here the presentation may include anemia, abnormal liver tests, osteopenic bone disease, neurological symptoms, or menstrual abnormalities. These individuals are categorized as atypical celiac disease. Anemia may be secondary to iron and/or folate deficiency. Six to ten percent of patients with unexplained iron deficiency anemia may have celiac disease in the absence of any other features suggestive of the disease. They have predominant extra-gastrointestinal symptoms, but test positive to antibody to tissue transglutaminase, and show changes consistent with celiac disease on biopsy. Other symptoms present in this group include musculoskeletal signs and symptoms, such as bone pains, proximal muscle weakness, osteopenia, osteoporosis, and fractures; neurological manifestations including intractable epilepsy, cerebellar ataxia, peripheral neuropathy, dementia, myoclonus and myelopathy; gynecological disorders including late menarche, unexplained infertility, or unexplained abortions; and dental enamel defects.

A third group of individuals remains asymptomatic, but are identified by screening serology, and their duodenal biopsies show changes characteristic of celiac disease. Yet another group of asymptomatic individuals may be identified by positive serology during population surveys, but will have normal duodenal mucosal biopsies. These individuals are considered to have potential celiac disease. Thus, celiac disease has been characterized as an iceberg disease (Fig. 2). Typical celiac disease tends to be more common in children, while atypical disease is more common in adults. Although the term “celiac iceberg” has been used, the proportion of the disease burden that remains below the surface varies with the age of the cohort under study and with the population studied. Thus, most children with the disease are probably symptomatic, while many or most adults may remain asymptomatic. The clinical significance of potential celiac disease (positive serology, no histologic change or symptoms) remains unclear with some studies suggesting long term risks including malignancies, while others found no obvious long term risks for these individuals.

## Associations

Celiac disease may be considered a multi-system disorder, originating in and primarily affecting the gastrointestinal tract but also affecting a number of other systems (Therrien et al., 2020). Underlying many of these associations is a thread of autoimmunity, hence the term celiac autoimmunity is also used to denote the spectrum. Recent studies indicate that the mechanism may involve molecular mimicry of gliadin antigens by microbially derived peptides. Conditions that have been associated with celiac disease are listed in Table 2. In these groups of patients, screening is sometimes indicated to diagnose celiac disease. Screening is done by serological testing, and patients who test positive are advised small bowel biopsy. The high-risk groups include first-degree relatives of confirmed cases of celiac disease, those with type 1 diabetes mellitus, Down's syndrome, Turner's syndrome, and unexplained dental enamel deficits, and children with unexplained short stature.

**Fig. 2** Schematic representation of the celiac iceberg showing the different phenotypes. The proportions of typical, atypical, asymptomatic and potential celiac disease likely vary from population to population.

**Table 2** Associations of celiac disease.

Hematological	Iron deficiency anemia Folate deficiency anemia Pure red cell aplasia
Endocrine	Type 1 diabetes mellitus Graves disease Hypothyroidism
Reproductive	Autoimmune polyglandular syndrome type II Unexplained infertility Recurrent miscarriage Male infertility
Liver	Cryptogenic cirrhosis Autoimmune hepatitis Primary biliary cirrhosis Autoimmune cholangitis Non-cirrhotic portal hypertension
Dermatological	Dermatitis herpetiformis Lichen sclerosus Psoriasis Oral aphthous ulcers
Rheumatological	Pediatric rheumatological disease Metabolic bone disease
Dental	Enamel hypoplasia
Neuropsychiatric	Drug resistant epilepsy Myoclonus ataxia Autism spectrum disorders

## Diagnosis

Anemia due to iron deficiency or folate deficiency, hypoalbuminemia, abnormal transaminases, and evidence of metabolic bone disease may be present. The specific diagnosis of celiac disease has been facilitated by the development of serological tests, in particular the identification of IgA antibodies to human tissue transglutaminase (IgA anti-tTG). These enzyme linked immunosorbent assays use capture antigens isolated from human erythrocytes or antigens produced by recombinant technology. These tests are very sensitive and, in patients with a high pre-test probability of celiac disease, they are quite specific (Berry et al., 2021). When used to screen the general population, where the pre-test probability of celiac disease is low, they lose specificity. When the prevalence of selective IgA deficiency in a population is significant, it is necessary to measure serum IgA levels as the IgA anti-tTG test may be negative. Approximately 2% of patients with celiac disease may have selective IgA deficiency while 5–11% of IgA-deficient individuals have celiac disease. Measuring antibodies to gliadin, previously used to diagnose celiac disease, is not specific to the diagnosis and is now rather used to follow the response to a gluten free diet. In children under the age of two years, it has been suggested that measuring IgA antibody to deamidated gluten peptides is more useful than IgA anti-tTG to diagnose celiac disease. IgA or IgG antibody to endomysial antigen is considered to be very specific for the diagnosis of celiac disease. It is usually detected by immunofluorescence using monkey esophagus or human umbilical cord as a substrate. Unlike the anti-tTG and anti-gliadin assays it is confounded by subjective interpretation and lack of wide availability.

The next step in diagnosis usually involves getting a biopsy of the small intestine, usually now accomplished by upper gastrointestinal endoscopy. The classic endoscopic feature is scalloping of the duodenal mucosa and evidence of mucosal and villous atrophy which is visible using white light endoscopy but clearly highlighted during narrow band imaging. These findings also occur in other diseases that cause villous atrophy.

Small bowel biopsy remains the gold standard for diagnosis of celiac disease. Biopsies are taken from the duodenum (including the duodenal bulb in children) and jejunum. The diagnostic biopsy changes have been discussed in an earlier section. There has been debate about the need for small bowel biopsy in the diagnosis, particularly in children where invasive tests are preferably avoided. Several investigators have shown that high titers of anti-tTG correlate well with histological damage to the small intestinal mucosa, and have suggested that biopsy may be avoided in such patients.

Imaging is primarily useful in excluding infiltrative, inflammatory and neoplastic diseases. Contrast enhanced computed tomography (CT) and CT enterography may show nonspecific features of malabsorption including fluid filled loops, dilatation, dilution of positive contrast, and conformation. Celiac disease is characterized by excessive gas in the colon and a reversal of the mucosal fold pattern between jejunum and ileum referred to as jejunitization of the ileum.

HLA-DQ typing is sometimes useful in diagnosis. Almost or nearly all patients with celiac disease have the genes that code for HLA-DQ antigens 2 or 8. HLA-DQ testing is usually carried out by molecular typing using polymerase chain reaction and hybridization with sequence specific oligonucleotide probes. When used in patients with a high suspicion of celiac disease, the absence of HLA-DQ 2 or -DQ 8 generally negates the diagnosis of celiac disease.

Finally, the diagnosis of celiac disease is confirmed by the response to a gluten free diet. Response may be documented clinically (e.g., resolution of diarrhea, resumption of growth), in laboratory parameters (e.g., normalization of hemoglobin or iron status), and histologically (restoration of normal histology in duodenal biopsies). The extent to which such resolution needs to be documented remains contextual. Prior to advent of serological tests, it was mandatory to document histological improvement in small bowel biopsies on gluten withdrawal, and recurrence of changes upon gluten rechallenge. These measures are now considered unnecessary in the majority of patients.

## Treatment

Treatment, with rare exceptions, should ideally be commenced only after completing the investigative process including the duodenal biopsy. Detailed counseling is necessary before starting treatment. The lifelong nature of the disease and the need for strict gluten exclusion need to be emphasized to the patient and, in the case of children, to the parents. Some patients are unable to come to terms with such strict dietary restrictions, but most comply with these once they understand the central nature of gluten to their symptoms. Patients should be referred for professional dietary advice on how to achieve a gluten-free life style, and should be encouraged to join a local or national support group.

It is important to identify and to correct nutritional deficiencies, prominent among these being those of iron, folate, calcium, and the fat-soluble vitamins (A, D, E, K). In occasional cases additional measures, such as red cell transfusion or iron carboxymaltose infusion to correct anemia, and aggressive treatment of metabolic bone disease may be necessary. Osteomalacia presents with bone pain and pseudofractures, is associated with elevated alkaline phosphatase, and responds to a gluten-free diet and calcium and vitamin D supplementation. Osteoporosis is common in adults with celiac disease, and is diagnosed by testing for bone mineral density testing with a T-score less than 2.5 standard deviation below mean peak value in young adults. The primary treatment for osteoporosis in a celiac is a strict gluten-free diet with adequate calcium and vitamin D3, and all patients with celiac disease are recommended to take calcium and vitamin D3 supplements.

Intensive nutritional support and fluid replacement may be needed in very ill patients. Coexisting malignancy or autoimmune disease should be considered especially in elderly or ill patients. Follow up of patients to ensure response to gluten-free diet and compliance is crucial to ensure long-term compliance as well as in detecting potential complications of the disease. Screening of at-risk family members should be considered.

Complete avoidance of gluten, maintaining a gluten-free diet (GFD) is the single most important therapeutic intervention in celiac disease. Grains that should be totally avoided in the GFD include wheat, barley, rye, spelt, and kamut. The role of oats in genesis or perpetuation of celiac disease remains controversial. Recent studies have clearly demonstrated that oats are nontoxic for most patients with celiac disease; however, there is the concern that contamination of oat products by gluten takes place during the growing, milling, or processing of oat products. Thus, the inclusion or restriction of oats needs to be considered on an individual basis. Gluten intake in populations that consume wheat may range from 10 to 30 g per day. It is important to inquire if a food has any ingredients that are in any way derived from, or processed with, wheat, barley, or rye. This part needs expert counseling from a dietitian who is interested in celiac disease therapy and by interacting with celiac disease support groups which may be local, national or international. Many foods such as bread, cookies, biscuits, and pasta are obvious sources of gluten. Overlooked sources of gluten may include non-food items such as medications and religious offerings, foods containing malt or malt flavoring, hydrolyzed vegetable protein, modified food starch, natural flavorings, vegetable gum and fat substitutes. Food labeling is extremely important, and the treating dietitian must have access to up-to-date listings of commercially available processed foods that are gluten free, tailored to geographic location. Patients should not rely on the self-test of reaction to gluten as a means of detecting gluten in foods as symptoms may be delayed.

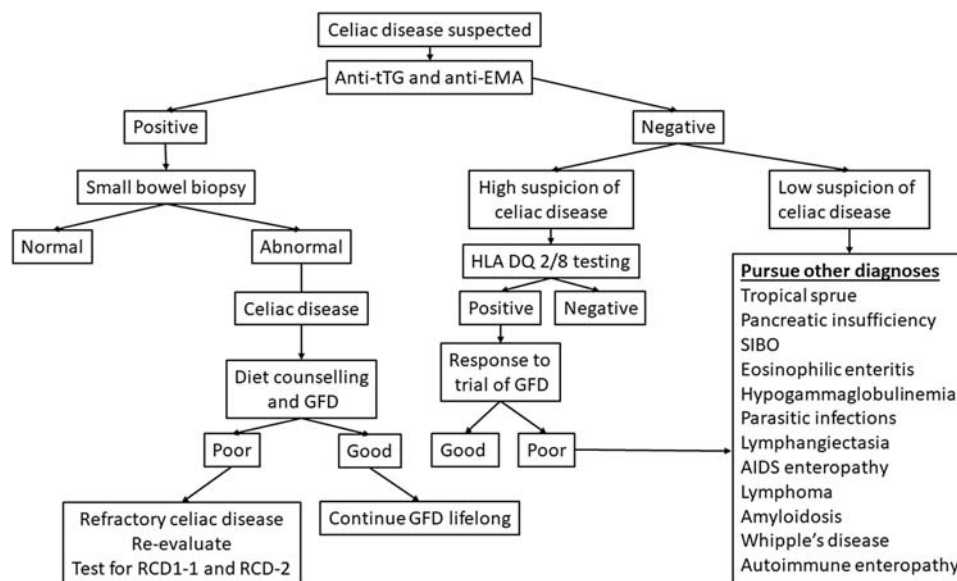

The response to GFD occurs within weeks, and improvement in overall well-being occurs early. Antibody titers may be used to follow recovery; they decline substantially within a year and may return to normal values after 2 years. Histological changes may persist despite this and may sometimes need to be assessed. Non-response to GFD, noted in about 10% of patients, is most often due to inadvertent ingestion of gluten. As little as 30 mg gluten per day for three months may trigger histological changes and symptoms in patients with celiac disease, highlighting the need for strict avoidance of gluten. Of concern are those foods that may contain hidden gluten, and the role of the dietitian becomes crucial here.

Maintaining a life-long gluten-free diet is challenging and this is an area where celiac disease support groups are especially helpful. There is ongoing research to look for alternative treatment strategies including enzymatic degradation of the immunogenic gluten peptides after a gluten meal in celiac patients, blocking the binding of gluten peptides to HLA-DQ2, and restoration of immunologic tolerance to gluten.

The approach to diagnosing and treating a patient suspected to have celiac disease is outlined in [Fig. 3](#).

## Complications

Microscopic colitis, either lymphocytic or collagenous, is sometimes associated with celiac disease and may cause continuing watery diarrhea. In addition to a strict GFD, symptomatic treatment with anti-diarrheal agents such as loperamide, or with topical steroids (budesonide) may be considered. Disaccharidase deficiency with lactose intolerance is usually secondary to mucosal injury and may

**Fig. 3** Flow chart for diagnosing and treating celiac patients. The proper procedure for diagnosing and managing a patient who potentially has celiac disease. tTG = tissue transglutaminase; EMA = endomysial antibody; GFD = gluten free diet; RCD = refractory celiac disease.

resolve with GFD, unless there is a primary hypolactasia. Small intestinal bacterial overgrowth may occur secondary to steatorrhea and reduced small bowel motility and may require use of non-absorbed antibiotics such as rifaximin. A small number of patients will fail to respond to all measures, and develop a condition called refractory celiac disease, which is classified into two types (Penny et al., 2020). In type 1 refractory celiac disease, intraepithelial lymphocytes have a normal phenotype (expressing CD3, CD4 and CD8 on their surface), while in type 2 disease the intraepithelial lymphocytes show a clonal proliferation and lose these surface markers but still express CD3 in the cytoplasm. Type 1 refractory celiac disease without a clonal proliferation of T cells responds much better to immunosuppression, and may represent a self-perpetuating autoimmune process within the intestine. Type 2 disease responds poorly to immunosuppressive treatment and progresses over a period of 5 years to a T cell lymphoma (enteropathy associated T cell lymphoma). Collagenous sprue has features similar to those of celiac disease but is characterized by a thick layer of collagen just below the intestinal epithelium and responds poorly to all therapies. These patients require long-term nutritional support. Adenocarcinoma of the small intestine may occur in patients with celiac disease. The prime reasons are the chronic inflammation of celiac disease, and the presence of defects of the DNA mismatch repair genes. Survival with aggressive surgical therapy may be better than that for sporadic small bowel adenocarcinoma.

## Conclusion

Celiac disease, caused by sensitivity to dietary gluten in genetically susceptible individuals, is a disease on the rise in many parts of the world. While the HLA-DQ genes have the strongest genetic influence on development of the disease a number of other causes—including non-HLA genes, infections, hygiene, and time of introduction of wheat into the diet in relation to breast feeding—may all influence expression of the disease. The disease primarily affects the small intestine, but affects many other systems due to immune and non-immune effects. The diagnosis is made through use of serological tests followed, in most cases, by duodenal biopsy. The disease is best treated by lifelong and complete withdrawal of wheat from the diet.

## Key points

- The reader will understand what cerebral palsy is and how it affects children with regard to their growth, diet and nutritional needs.

## Introduction

Nutritional issues such as diet, body composition and growth are integral aspects of medical care for children with cerebral palsy (CP). The first section defines CP and describes its causes, prevalence, and classification types. Associated deficits related to CP are also explored. The topic of nutritional assessment of children with CP includes discussions on growth, body composition, and energy, protein, fluid, and nutrient needs. Feeding and swallowing problems and the influence of muscle tone on the ability to eat safely are discussed in-depth, as are alternative feeding routes. The interdisciplinary approach is emphasized throughout as the ideal model to provide services to children with CP in order to ensure quality of life in the community.

## Definition and etiology

Cerebral palsy is a term that refers to a number of non-progressive disorders of movement and posture that result from an injury to the central nervous system (CNS) during early brain development (Stavsky et al., 2017). CP is the most common motor disability in childhood and prevalence estimates range from 1.5 to more than 4 per 1000 live births (CDC, 2018). Risk factors for CP during intrauterine, intrapartum or postnatal periods include premature birth, low birthweight, disruption of blood and oxygen supply to the developing brain, maternal infection, congenital malformations, multiple gestations, and genetic disorders (Graham et al., 2019). Acquired CP can also occur after the first month of life due to brain injury or infection. CP results in issues of muscle control such as uncoordinated movements or muscle stiffness, which can lead to poor balance, difficulty in mobility and problems completing basic daily living skills such as getting dressed, walking or feeding oneself. CP is a lifelong condition with no cure, but interdisciplinary treatment and therapeutic interventions can lessen the effects and assist the individual with CP in successfully functioning in their environment.

## Classification

Cerebral Palsy is classified in several different ways related to topographical distribution, level of severity, physiological classification and now most commonly by gross motor skill function. There are 4 types of CP classified by motor type including spastic, dyskinetic, ataxic and mixed, with spastic being the most common (CDC, 2018). These types are further characterized by the part of the body or number of limbs affected. The Gross Motor Functional Classification System (GMFCS) is a standardized functional classification system based on an ordinal grading system (Palisano et al., 2008). Classification systems have also been developed for upper extremity function (Manual Ability Classification System – MACS), communication (Communication Function Classification System – CFCS) and eating/drinking (Eating and Drinking Ability Classification System – EDACS) (Paulson and Vargus-Adams, 2017). Fig. 1 depicts the classification of CP by motor types, topography and function (McGrath, 2016). The type of CP and the degree of involvement play an important part in nutritional assessment and treatment.

## Associated disabilities/deficits

Associated deficits of CP are important to note since they affect nutritional status. Injury to the developing brain can affect multiple areas placing children with CP at increased risk for intellectual or learning disabilities. Sensory deficits, neurobehavioral and emotional issues are common (CDC, 2018). Seizures occur frequently and in addition to medical management, the ketogenic diet is often prescribed to treat seizures. It is a diet high in fat with limited nutrients and fluid and requires implementation and monitoring by both a neurologist and a nutritionist trained in the diet. Feeding problems including oral motor dysfunction, dysphagia, digestive problems and respiratory issues have a direct effect on nutritional status.

## The interdisciplinary team

Treatment of children with CP is best achieved with an interdisciplinary team whose members participate, share expertise and make decisions together to allow for successful functioning of the child in their environment (Patel et al., 2008). The team members working with children with CP may include but is not limited to Neurology, Developmental Pediatrics, Orthopedics, Gastroenterology, Physical Therapy, Occupational Therapy, Speech Language Pathology, Nutrition, Nursing, Social Work, Child Life and Psychology. The six F's framework – function, family, fitness, fun, friends and future – should be included as participation goals in the treatment of CP by all disciplines involved (Graham et al., 2019).

## Nutritional assessment

The goal for nutritional assessment and intervention is to have healthy, alert, interactive individuals who are able to take advantage of all that the environment has to offer. Each child must be able to participate to his or her capacity in the learning and therapeutic rehabilitative processes and in social, community, and leisure activities. Table 1 lists the common factors, which can affect the nutritional status of children with CP. Those children who present with poor weight gain at an early age, have significant motor impairments and have feeding and swallowing difficulties are at greatest risk of having significant nutritional problems (Rempel, 2015).

The Subjective Global Nutrition Assessment (SGNA) evaluates nutrition status based on a practitioner's judgment of nutritional indices, rather than based only on the quantitative measurements (Secker and Jeejeebhoy, 2012). It includes questions related to nutrition history and physical exam, signs of fat or muscle wasting and edema in conjunction with measures of weight, height and triceps skin fold (TSF). Minocha et al. (2018) found the SGNA questionnaire to be a simple, comprehensive, non-invasive and cost effective tool for screening for malnutrition in children with CP. The recent consensus statement from the Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition, which standardized the definition and identification criteria for diagnosing pediatric malnutrition, has not been validated in children with CP and should be used with caution in this population (Becker et al., 2014).

## MOTOR TYPES

**SPASTIC:** 80-90%. Most common form. Muscles appear stiff and tight. Arises from Motor Cortex damage.

**ATAXIC:** 5%. Characterised by shaky movements. Affects balance and sense of positioning in space. Arises from Cerebellum damage.

**DYSKINETIC:** 6%. Characterised by involuntary movements such as dystonia, athetosis and/or chorea. Arises from damage to the Basal Ganglia.

**MIXED TYPES:** A number of children with CP will have two motor types present e.g. spasticity and dystonia.

## PARTS OF THE BODY

Cerebral palsy can affect different parts of the body e.g.

## GROSS MOTOR SKILLS

The gross motor skills (e.g. sitting and walking) of children and young people with cerebral palsy can be categorised into 5 different levels using a tool called the Gross Motor Function Classification System (GMFCS) developed by CanChild in Canada.

**Fig. 1** Classifications of cerebral palsy. Reproduced from CP world day McGrath (2016).

---	---

## Growth

Adequacy of growth may be the single most valuable indicator of nutritional status in children. Healthy, typically developing children grow at predictable rates, with patterns reflective of certain age categories. Children with CP have altered growth patterns and tend to be shorter and lighter than the reference standard (Day et al., 2007). Growth patterns can be affected by gender, age, pubertal

**Table 2** Equation for estimation of stature using segmental measures.

<i>Age 0–12 years – children with CP</i>		
<i>Segmental measure</i>	<i>Equation to estimate stature (S) (cm)</i>	<i>SE of estimate (cm)</i>
Tibial length (TL)	$S = (3.26 \times TL) + 30.8$	1.7
Knee height (KH)	$S = (2.69 \times KH) + 24.2$	1.4
<i>Age 12–18 years – typically developing children, validated in a small group of children with CP</i>		
<i>Race and gender</i>	<i>Equation to estimate stature (S) (cm)</i>	<i>SE of estimate (cm)</i>
White males	$S = (2.22 \times KH) + 40.54$	4.21
Black males	$S = (2.18 \times KH) + 39.6$	4.58
White females	$S = (2.15 \times KH) + 43.21$	3.90
Black females	$S = (2.02 \times KH) + 46.59$	4.39

SE, standard error.

Adapted from [Samson-Fang and Bell \(2013\)](#).

stage, race, genetic potential, hormonal variations and dietary intake. Early identification and treatment of growth problems is paramount to ensuring overall health and development especially in children with CP.

Both nutritional and non-nutritional factors influence growth in children with CP. Non-nutritional factors influencing growth in children with CP include central nervous system abnormalities, muscle tone/contractures, immobilization/limited physical activity, lack of weight bearing, repeated orthopedic surgeries, and growth hormone deficiency/dysregulation. Children with asymmetric involvement of CP have decreased growth and fat mass on the affected side, with the difference increasing with age and functional severity, thereby supporting the impact of non-nutritional and non-endocrine factors ([Rempel, 2015](#)).

Obtaining accurate anthropometric measurements in children with CP can be very challenging secondary to joint contractures, scoliosis, ambulatory status and poor cooperation. Recumbent length should be measured for those under 2 years of age, and for those unable to stand where segmental measurements can be used as an estimation of height. Alternative measures for estimating height in those with CP who are not able to stand include tibial length (TL) and knee height (KH). These measurements require special calipers and techniques to be completed properly. Clinicians should be trained in obtaining these measurements to ensure accuracy and reproducibility. Equations to estimate height using these measurements based on age, gender and measurement site can be found in [Table 2 \(Sampson-Fang and Bell, 2013\)](#). Discrepancies in leg length should be noted, with the same side (longer side) measured each time. The estimate of stature from these equations have a degree of error and so caution should be exercised with the use of these estimations when calculating body mass index (BMI), for instance, as the standard of error will be magnified. Weight should be measured on a digital scale with the child wearing only light clothing, with a dry diaper if applicable. If the child is unable to independently stand on the scale, a sling scale or wheelchair scale can be used. All braces, splints and/or items on the wheelchair should be removed before measuring to eliminate confounding error.

The use of z scores for length-for-age, weight-for-age, and weight-for-length promotes an accurate evaluation of discrete changes from one measurement date to another. Percentile tables describe ranges, and consequently detection of minor movement within the range is difficult to describe. The z score denotes standard deviation units from the median and allows the practicing clinician and investigator to pinpoint precisely any given measurement.

## Growth charts

Early growth charts for children with CP were limited to those with quadriplegia who were between the ages of 1–10 years ([Krick et al., 1996](#)). Following the development of the GMFCS, new charts developed by [Day et al. \(2007\)](#), were stratified by gross motor levels. These charts also differentiated between those who were orally fed versus tube fed in the groups with more severe limitations (GMFCS levels 4 and 5). Both charts show that the rate of growth in children with CP is slower, the difference from the norm becomes greater as age increases, and there is further deviation as gross motor function declines. Enhanced charts produced by [Brooks et al. \(2011\)](#) demonstrate the risk of comorbidities based on weight-for-age for those at each GMFCS level. Individuals whose weight-for-age falls in the shaded area on the lower end of the chart have a higher risk of mortality than those outside of this area. The growth charts from [Day et al. \(2007\)](#) and [Brooks et al. \(2011\)](#) can be found at [www.lifeexpectancy.org](http://www.lifeexpectancy.org) (2011). It is important to note that all growth charts for children with CP describe growth patterns irrespective of nutritional status and therefore are not considered ideal standards. The growth charts for children with CP should be used with clinical judgment in conjunction with the CDC growth charts as well as with other anthropometric measurements.

## Ideal body weight

The estimation of an ideal body weight (IBW) allows the clinician to assess progress and effectiveness of intervention, while providing the child and family a goal to attain. The IBW should be aimed at maintaining adequate fat and muscle stores to endure repeated surgeries or a common virus while facilitating daily physical care and management. Weight-for-length and BMI are indicators of nutritional status, which obscure the issue of chronological age and address whether the individual is proportionate. IBW can be expressed as this ratio. Those with cerebral palsy should attain and maintain an IBW that takes into account their age, level of physical ability, and their independence. Measurement of arm anthropometry will provide a description of body composition and support clinical judgments related to IBW. In the absence of population specific guidelines, the 10th %ile weight for height or BMI on the CDC growth charts or the 50%ile BMI on the CP charts have been used historically. The growth charts developed by [Brooks et al. \(2011\)](#) can also be used in determining an appropriate weight above the shaded area on the graph, which is associated with improved health outcomes.

## Body composition

Children with CP have altered body composition with decreased muscle mass when compared to their age matched peers ([Caselli et al., 2017](#)). Analysis of body composition in the clinical setting can be challenging, and not all methods have been validated for use in children with CP.

Measurement of arm anthropometry can include but is not limited to TSF, subscapular skin fold (SSSF) and Mid arm-upper arm circumference (MUAC). Patient cooperation with the measuring techniques required for accuracy and safety, may be difficult to obtain or maintain. Assessment of these measurements can assist with classification of nutritional status, particularly related to adequacy of muscle and fat mass. [Gurka et al. \(2009\)](#) found that a simple correction factor to the commonly used Slaughter equations substantially improves the ability to estimate percentage of body fat from TSF and SSSF in children with CP. The corrected equations can be found in [Table 3](#). Dual-energy x-ray absorptiometry (DXA) scans are frequently performed to assess bone mineral density and this can provide measures of fat and fat free mass to assist with evaluation. Children with CP tend to have increased truncal fat with depleted extremity stores, which can make assessment challenging, requiring the clinician's clinical interpretation to assess nutritional status.

## Bone mineral density

Low bone mineral density, osteopenia and osteoporosis are found in most children with CP, particularly in those who are immobile. Fractures are common and many of those who sustain one fracture will sustain a repeated fracture, with the femur being the most common site ([Kuperminc and Stevenson, 2008](#)). Severity of the neurological impairment, Calcium and Vitamin D intake, limited weight bearing during growth, temporary immobilization associated with orthopedic surgery, use of anticonvulsants and lower TSF (fat stores) all independently contribute to the lower bone mineral density. It is important to provide physical therapy for weight bearing activities in addition to nutritional therapy including adequate Calcium and Vitamin D intake with supplementation if needed based on serum Vitamin D levels. There is promising work with the use of bisphosphonate medications and whole-body vibration in children with CP to improve bone density ([Jesus and Stevenson, 2020](#)).

## Energy needs

Children with moderate to severe CP have energy needs, which differ significantly from typically developing children. Equations that are frequently used to predict energy requirements were developed using healthy children and adults in usual environmental and physical activity conditions and do not provide an accurate assessment of the needs of those with CP. Factors affecting energy expenditure in children with CP include age, muscle tone, physical activity (with or without assistive devices), repeated surgical interventions, illness and the additional need for catch-up growth or wound healing. Most equations typically overestimate needs leading to overfeeding, particularly in those who are non-ambulatory and tube fed. [Culley and Middleton \(1969\)](#) historically described calorie needs based on height in centimeters, with those who are ambulatory requiring 13.9 kcal/cm and those who are non-ambulatory requiring 11.1 kcal/cm. More recently, energy needs for non-ambulatory children with CP have been estimated to be 60–70% of calculations using typical methods ([Bell and Samson-Fang, 2013](#)). Those with profound gross motor impairment could need even as little as 10–15 kcal/kg. Energy intake should be adjusted as needed to achieve weight goals, while care should be exercised to provide adequate protein, nutrients and fluid despite these very low calorie needs. The use of any approach should be a guidepost to start and with careful monitoring and modifications based on observed clinical changes in growth. For those who are tube fed, establishing tolerance at a lower level of calories and then gradually increasing intake can help achieve better tolerance, avoid overfeeding and limit gastroesophageal reflux (GER) and emesis. Increases or decreases in energy intake can be made in 10–20% increments, with frequent monitoring to achieve the desired goal.

**Table 3** Original Slaughter equations and corrections for children with cerebral palsy.

Population	Original Slaughter equation for predicting percentage body fat
<b>Sum (triceps, subscapular) ≤ 35 mm</b>	
Males	
Prepubescent <sup>a</sup> white	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} + \text{sub})^2 - 1.7$
Prepubescent black	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} - \text{sub})^2 - 3.2$
Pubescent white	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} - \text{sub})^2 - 3.4$
Pubescent black	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} - \text{sub})^2 - 5.2$
Postpubescent white	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} - \text{sub})^2 - 5.5$
Postpubescent black	% Body fat = $1.21(\text{tri} + \text{sub}) - 0.008(\text{tri} - \text{sub})^2 - 6.8$
Females (all)	% Body fat = $1.33(\text{tri} + \text{sub}) - 0.013(\text{tri} + \text{sub})^2 - 2.5$
<b>Sum (triceps, subscapular) &gt; 35 mm</b>	
Males (all)	% Body fat = $0.783(\text{tri} + \text{sub}) + 1.6$
Females (all)	% Body fat = $0.546(\text{tri} + \text{sub}) + 9.7$
	Cerebral-palsy-specific corrections to Slaughter-estimated percentage body fat <sup>b</sup>
Overall correction	+12.2
Additional correction for	
Males	
More severe GMFCS	−5.0
Black race	+5.1
Pubescent	−3.1
Postpubescent	+2.0
Sum (triceps, subscapular) > 35 mm	−4.6
	−3.2

<sup>a</sup>Prepubescent, Tanner stage 1,2; pubescent, Tanner stage 3; postpubescent, Tanner stage 4,5.

<sup>b</sup>Instructions for using these corrections on a given child with CP: always add 12.2 to the Slaughter-estimated percentage body fat. Then, if the individual falls within each of the additional categories, add that respective correction as well. For example, for a black pubescent male at GMFCS level 1 whose sum (triceps, subscapular) < 35 mm, the predicted percentage body fat = Slaughter percentage body fat + 12.2 − 5.0 − 3.1 + 2.0. Tri + sub, triceps skinfold + subscapular skinfold. GMFCS, Gross Motor Function Classification System.

From Gurka et al. (2009).

## Protein, nutrient and fluid needs

Protein and nutrient needs are based on the Dietary Reference Intakes (DRIs) of the general population. There is no evidence to support altered requirements of vitamins, minerals or trace elements in children with CP. As noted earlier, care must be taken to ensure that those with very low energy needs receive supplementation of protein and nutrients when needed. The undernourished child may require as much as 2 g protein/kg/day to promote catch-up growth (Bell and Samson-Fang, 2013). Children undergoing orthopedic surgeries or those with wounds also require additional protein and nutrients for stress and healing. It is important to monitor for and evaluate possible protein and nutrient deficiencies through a nutrition focused physical exam assessing subcutaneous tissue for edema, skin integrity, hair texture/color and muscle or adipose wasting. Children with CP are frequently deficient in calcium, iron, zinc, selenium and Vitamins C, D and E and may require supplementation (Romano et al., 2017).

Fluid needs are calculated based on body weight using the Holliday-Segar nomogram rather than based on calorie intake. For weights ranging from 0 to 10 kg, the fluid need is 100 mL/kg/day; from 10 to 20 kg the fluid need is 1000 mL plus 50 mL/kg for each kilogram of body weight more than 10; over 20 kg the fluid need is 1500 mL plus 20–25 mL/kg for each kilogram more than 20 (Holliday and Segar, 1957). Monitoring of hydration in a clinical setting is done by checking a urine specific gravity, while caregivers at home can monitor urine for quantity, color and odor. Additional fluid should be provided during periods of stress, illness, or significant environmental changes. For children receiving enteral tube feedings, total formula provided is counted entirely toward fluid intake, assuming there are no other health or renal concerns.

## Diet/feeding history

Obtaining accurate estimates of oral intake particularly in children with CP can be challenging. Overestimating intake in children with CP by caregivers is common, and care should be taken when assessing intake from food recalls or records, as these have not been found to be reliable or valid methods in this population (Walker et al., 2011). A 3-day weighted food record provides the most

**Table 4** Factors to consider in feeding history.

- 
- Frequency of meals and snacks
  - Meal length
  - Positioning at mealtimes
  - Modifications to food or liquid texture
  - Food loss/spillage
  - Use of adaptive feeding utensils
  - Assistance required at mealtimes
  - Use of supplements or calorie boosters
  - Food preferences and dislikes
  - Number of caregivers able to feed child
- 

accurate measure of energy intake in children with CP, but it requires training and considerable effort of the caregiver to complete (Scarpato et al., 2017). It is likely that length of mealtime, effort by the child and caregiver and oral motor losses contribute to overestimating intake. Food records and recalls can be used qualitatively to assess variety of food intake, versus quantitatively (Sampson-Fang and Bell, 2013). Meal observation to note actual intake including loss of solids and liquids in addition to mealtime interactions can be very useful. Factors to consider in the feeding history are listed in Table 4.

### Oral motor dysfunction and dysphagia

Oral motor dysfunction and dysphagia are common in children with CP, and the severity increases with increasing levels on the GMFCS having a direct effect on nutritional status (Benfer et al., 2017). Alterations in muscle tone result in abnormal movements of the lips, tongue and jaw which manifest as lip/tongue retraction, tongue tip elevation, tongue/jaw thrust, tonic bite, and instability of the lips, cheek and jaw (Arvedson, 2013). Problems may present as poor intake, inefficient and lengthy mealtimes, abnormal oral-motor patterns, inappropriate progression of feeding skills, and physiological compromise with feeding. A strong gag reflex, tactile hypersensitivity in the oral area and drooling, can also complicate feeding. Eating skills are acquired in a sequential pattern so that a developmental history is important to understand in planning any intervention. Sensory, cognitive and language deficits may also complicate the feeding process.

Aspiration, when swallowed food or liquids enter the airway or lungs and can result in coughing, choking, pneumonia or chronic lung changes over time. Aspiration can also occur from below when regurgitated gastric material enters into the esophagus, and depending upon how adequately the airway is protected, can lead to direct aspiration into the lungs. Aspiration can result in discomfort, arching, irritability, food refusal, esophagitis, apnea, frequent respiratory compromise and drooling. Aspiration can also be silent, with no overt signs of distress to the child such as coughing or choking. Children with spastic CP are most at risk for dysphagia and aspiration. Indicators of feeding and swallowing dysfunction or aspiration are listed in Table 5. Children who exhibit any of these symptoms may require radiological evaluation via Modified Barium Swallow Study or Fiber-optic Endoscopic Evaluation of Swallowing to assess for aspiration. These modalities can not only detect aspiration, but can provide more detailed information about the oral structures and the competency of the oral, pharyngeal, and esophageal phases of swallowing. They also provide information helpful in determining appropriate solid and liquid textures as well as proper head and neck positioning. Fatigue may occur in the child who is not able to sustain the work involved with feeding and may be expressed by an increase in respiratory rate, diaphoresis, or increased work of breathing. The causes may be muscular, respiratory, or cardiac, and they

**Table 5** Indicators of feeding and swallowing dysfunction/aspiration.

- 
- Facial weakness
  - Decreased sensation
  - Congestion, noisy “wet” sounds
  - Multiple swallows to clear a bolus
  - Unexplained fevers
  - Unexplained irritability
  - Coughing/choking/gagging before, during or after a swallow
  - Food refusal
  - Pain with swallowing
  - Difficulty managing secretions, drooling
  - History of upper respiratory infections, pneumonia
  - Apnea during feeding
  - Failure to thrive or maintain weight
-

may increase the risk of aspiration or hypoxia. The work required to eat a meal is accomplished at a higher physiological cost to the child, thereby increasing caloric needs. Setting time limits for meals and snacks is often suggested.

There are numerous scales developed which assess feedings skills, oral intake, safe intake and nutritional status in children with neurodevelopmental disabilities. Some are used for certain age groups, and others require special training to be able to administer. [Benfer et al. \(2012\)](#) determined that the Schedule for Oral Motor Assessment (SOMA) and the Dysphagia Disorders Survey (DDS) had the strongest clinical utility in pre-school children with neurodevelopmental disabilities. The EDACS mentioned earlier, is based on functional abilities including key features of safety and efficiency related to eating and drinking ([Sellers et al., 2014](#)). A recent screening tool developed by [Bell et al. \(2019\)](#) consists of a 4-item tool for feeding/swallowing difficulties and undernutrition in children with CP that can be used independently with parents or caregivers.

The importance of a feeding evaluation in conjunction with a Speech Language Pathologist or Occupational Therapist who is skilled in assessing feeding problems cannot be underscored in assessing function, safety and providing guidance in feeding techniques. An interdisciplinary team evaluation is essential for the assessment, development of appropriate goals and facilitation of a treatment plan that respects the developmental progression.

## **Other related problems**

### **Gastrointestinal issues (GI)**

Constipation is a chronic problem for most children with CP due to alterations in the enteric nervous system, which requires input from the CNS to coordinate intestinal motility. This can be exacerbated by changes in muscle tone, skeletal muscle incoordination, skeletal deformities and prolonged immobility ([Elawad and Sullivan, 2001](#)). Constipation is frequently underdiagnosed and therefore under treated. Factors such as loss of sensation, limited physical activity, medication side effects and inadequate dietary fiber and or fluid can also play a role. Oral motor dysfunction also plays a role in diminished intake as well as fluid and food losses. Modified fluid and food textures may also yield less free water and fiber. Discomfort associated with constipation may decrease appetite and increase GER and/or emesis. Dietary intervention may be limited and medical management may be necessary. Children with CP typically benefit from use of both a stool softener and stimulant with the goal of treatment promoting a soft, daily bowel movement.

GER is common in children with CP related to muscle tone, positioning, transient relaxation of the lower esophageal sphincter and increased intra-abdominal pressure ([Andrew et al., 2012](#)). This can result in irritability or arching during or after feeding. Treatment for GER includes medical therapy with antacids, acid blockers/proton pump inhibitors, medications to increase gut motility, reduction in feeding rate, positioning, thickening food or liquids, smaller, more frequent feedings or surgical intervention. Children who are fed enterally via a feeding tube and fail medical treatment may require a Nissen Fundoplication procedure to prevent reflux or post pyloric/jejunal feedings to by-pass the stomach completely. Jejunal feedings are also of assistance for those with delayed motility. Refusal of food by a child with CP likely arises from dysphagia and chronic GER, and should not be confused with behavioral avoidance ([Asgarshirazi et al., 2017](#)).

Superior Mesenteric Artery Syndrome (SMA) is a condition in which the third portion of the duodenum is intermittently compressed by the overlying superior mesenteric artery, resulting in gastrointestinal obstruction ([Neuman et al., 2014](#)). Symptoms include recurrent vomiting, abdominal distention, weight loss and postprandial distress. Children with CP are at high risk for SMA particularly if there has been severe weight loss eliminating the mesenteric fat pad, prolonged supine positioning and/or scoliosis surgery. An upper gastrointestinal evaluation (UGI) is used to define the problem and non-surgical treatments include gastric aspiration, naso-jejunal (NJ) or gastro-jejunal (GJ) feedings distal to the obstruction, slow continuous feedings, weight gain and positioning.

### **Muscle tone and positioning**

It is important to understand the influences of muscle tone and proper positioning on the ability to eat safely and efficiently in this population. Increased or decreased muscle tone contributes to difficulty preserving a patent airway, compromised self-feeding skills, poor rib cage expansion and esophageal motility, and difficulty in maintaining a stable supported base for seating ([Andrew et al., 2012](#)). Fluctuating muscle tone leads to involuntary movements and limited postural stability. Despite the type of muscle tone, optimal positioning is crucial for feeding and swallowing. The proper feeding position includes neutral alignment of head and neck, midline orientation, symmetrical trunk position, 90 degrees pelvic/femoral alignment, and symmetrical arm position with neutral shoulders ([Physiopedia, 2010](#)). Consultations with orthopedists and/or rehabilitation physicians to address current and potential musculoskeletal problems, physical and occupational therapists for functional assessment, orthotists for deformity management, and durable medical equipment specialists to customize standard wheelchair components are valuable.

### **Orthopedic surgeries**

Orthopedic procedures are common in children with CP and each surgery should be preceded by an evaluation of nutritional status and assessment of the child's ability to physically heal and recover quickly from the trauma ([Leonard et al., 2020](#)). Many children,

who are marginal oral feeders, decompensate, lose weight and have a difficult time healing because of a cascade of events including pain, poor positioning for safe feeding, worsening constipation, minimal intake, lethargy, and increased medications for pain, which may have a sedative effect. Some children require supplemental tube feedings prior to surgery or during the postoperative period to promote weight gain and circumvent poor oral intake.

## Medications

Drug-nutrient interactions should be considered for children receiving long-term medications for seizure disorders, alterations of muscle tone, attentional deficits, GI disorders and/or other chronic conditions. One drug or the combination of multiple drugs may affect nutrition in many ways including decreased appetite, interference with absorption of specific nutrients, nausea/vomiting and constipation (Ptomey and Wittenbrook, 2015). Medications used frequently for the treatment of seizures or reflux can result in decreased nutrient absorption or losses of Vitamins D, K, B6, B12, Folate, Iron and Calcium.

Medications used to treat spasticity and dystonia such as Valium or Baclofen can have significant effects on oral motor function, GI motility and constipation. Baclofen can be administered through oral routes or via an intrathecal pump. The surgically implanted pump delivers a continuous dose of medication directly into the spinal fluid in the lower back. As tone is significantly reduced in the children for whom intrathecal baclofen pumps are used, so is the energy requirement (Liu et al., 2008). With the use of the baclofen pump, weight gain can be seen in children who have been on tube feedings with a constant intake over time, and adjustments in the calorie level may be necessary. This decrease in tone is also associated with decreased GI motility and increased constipation.

## Dental

Increased incidence of cavities and erosion frequently occur due to poor oral hygiene and teeth grinding in children with CP (Ahmad et al., 2019). Hypersensitivity in the oral area and hyperplasia of the gums from long-term use of phenytoin may also be seen. Malocclusion is a common musculoskeletal problem and contributes to drooling, which can negatively affect daily oral care.

## Pain and discomfort

Inquiry into pain and discomfort as it relates to eating such as face grimacing, crying, arching, sweating, or stopping a preferred activity is an important aspect of a total assessment. Contributors to pain are multifactorial and can include hip subluxation, muscle spasms, dystonia, GER and constipation (Graham et al., 2019).

## Mealtime behaviors

Parent-child interactions can also influence feedings. Ineffective communication, lack of bonding, the absence of social interaction or poor interactive skills, family dysfunction, and decreased environmental stimuli can exacerbate feeding difficulties or lead to frustration and anxiety with subsequent food refusal or parental withdrawal. Aversion to oral feeds may result as an outcome of medical complications, such as esophagitis and GER, or lack of feeding experience at critical milestones secondary to prolonged tube feedings. Behavioral treatment should only be undertaken after thorough medical, nutritional, and neurodevelopmental assessments are completed.

## Intervention strategies

### Maximizing oral nutritional intake

The benefits of nutrition intervention include improved alertness and attention span/learning, enhanced health and immune function, decreased episodes of illness and hospitalizations, better respiratory muscle strength, reduced risk of decubitus ulcers, improved wound healing, reduced stress on the family and enhanced quality of life for the family and child. The feeding plan should be safe, promote growth or weight maintenance without excessive energy expenditure, and meet the needs of the family. It should reflect their resources in time and skill, and it should address their concerns and expectations. The goals for treatment once feeding and swallowing problems are identified include preventing aspiration and thereby respiratory compromise; providing adequate calories, protein, vitamins, minerals, and fluid; and educating caregivers regarding nutritional requirements.

For those children who are safe to eat by mouth, energy intake should be maximized. This can be done either by increasing the caloric density of the diet or by increasing total intake through smaller, more frequent meals. In children who are not able to take in more by mouth, intake can be boosted by increasing the concentration of formula if appropriate, addition of calorie boosters to meals, use of high-calorie foods or the addition of oral supplements. Table 6 provides ideas to maximize energy intake.

**Table 6** Foods to use for increasing energy intake.

<ul style="list-style-type: none"> <li>• Powdered skim milk</li> <li>• Cooked eggs</li> <li>• Cheeses</li> <li>• Ice cream</li> <li>• Mayonnaise or salad dressing</li> <li>• Cream cheese</li> <li>• Gravy</li> <li>• Baby cereals or potato flakes</li> <li>• Fruit in heavy syrup</li> <li>• Meats cooked in oil with breading/added gravy</li> </ul>	<ul style="list-style-type: none"> <li>• Carnation breakfast essentials</li> <li>• Butter, margarine, oils</li> <li>• Peanut butter</li> <li>• Wheat germ</li> <li>• Sour cream</li> <li>• Heavy cream/sweetened condensed milk</li> <li>• Concentrated juice</li> <li>• Pudding, yogurt, custard and milkshakes</li> <li>• Vegetables in cheese or cream sauces</li> <li>• Commercial oral formulas/supplements</li> </ul>
--	---

## Oral motor considerations

Management strategies for daily mealtime feeding include positioning, modification of the sensory properties of the food, oral motor facilitation techniques, and equipment adaptations (Bell and Samson-Fang, 2013). It is important to acknowledge the inability to change the underlying feeding problem while providing a method of circumventing the problem to allow adequate nutrition and growth. For example, facilitative techniques to minimize excessive jaw movement may entail the feeder providing physical jaw control/support; a change in the food consistency, texture, temperature, or taste to improve the ability to propel a bolus through the oropharynx; the careful selection of adaptive feeding equipment to assist with self-feeding and/or increased intake; and an appropriate seating system (Rempel, 2015).

## Diet/texture modifications

Changes in the texture of solids and liquids may be necessary to ensure safety, but may also improve efficiency, decrease effort and therefore result in increased nutritional intake. Once again, guidance from our interdisciplinary colleagues in Speech Language Pathology and Occupational Therapy who specialize in oral motor therapy is necessary to determine the appropriate texture of solids and liquids. Table 7 lists some common thickening agents for foods and liquids. The International Dysphagia Diet Standardization Initiative (IDDSI) Framework provides a common terminology to describe food textures and liquid thickness (IDDSI, 2019). There are resources for pediatrics, providing guidelines for how to assess foods at each level, as well as what to include and avoid. See Fig. 2 for a diagram of the IDDSI levels from thin liquids to regular texture solids. Table 7 lists some common thickening agents for foods and liquids.

## Alternative feeding routes

Supplemental or complete tube feeding may be necessary for the child who is not safe to eat or drink by mouth secondary to aspiration, for those who continue to fail to grow despite dietary interventions, or for those with prolonged, stressful mealtimes. In addition, those with evidence of low body fat stores or low weight in respect to height/length should be considered for supplemental feedings (Romano et al., 2017). A recent study noted that epilepsy, poor motor function, trunk muscle tone disorder

**Table 7** Thickening agents for foods and liquids.

**Fig. 2** The complete IDDSI framework. Reproduced from IDDSI (2019).

and male gender were accurate, sensitive and specific factors associated with the need for tube feedings (Bertoncelli et al., 2020). Enteral nutrition support can help improve growth, nutritional status, hydration, bowel function and allow for easier administration of medications.

Naso-gastric, naso-jejunal, gastrostomy, gastrostomy-jejunal, and jejunostomy tubes are options available for providing supplemental or total nutrition. The degree of GER and risk of aspiration determine where the tube is placed, whereas the length of time needed for tube feedings determines whether a naso-enteral or surgically placed tube is required. The decision regarding continuous, intermittent, or combination tube feeds is dependent on the individual needs and tolerance of the patient.

Tube feedings should be considered a tool to improve nutritional status rather than failure of the child's ability to eat. Based on the medical diagnosis and developmental stage of the child, the prognosis for return to oral feeding varies, and the length of time to achieve this goal is extremely variable. For some children, the goal of returning to full or partial oral feeding is not realistic. In a study evaluating the health of children with CP, Liptak et al. (2001) describes those who were tube fed as having the lowest mental age, requiring the most health care resources, using the most medications, and having respiratory problems. These children were characterized as especially frail and required numerous health-related resources and treatments. Oral motor therapy should focus on maintaining existing oral motor skills, encouraging pleasurable oral experiences, and tolerance of oral hygiene practices. Children who do not eat by mouth due to safety issues should receive non-nutritive oral motor stimulation to maintain their swallowing function. Benefits of non-nutritive stimulation include maintaining oral sensation and tolerance, saliva production and swallowing, and the facilitation of parent-child interactions. Parents of children who do not eat by mouth may require psychosocial support to process their feelings of guilt, fear and loss of normalcy with regard to eating (Craig, 2013).

Parenteral nutrition should only be used when the gastrointestinal tract is dysfunctional. When initiating feedings in patients with significant recent weight loss or failure to thrive, whether enteral or parenteral nutrition is used, it is important to be aware of the refeeding syndrome. This syndrome refers to phosphorus depletion and alterations in potassium, magnesium, and glucose metabolism, resulting in severe metabolic and physiological complications. It is imperative to increase calorie delivery slowly with close laboratory monitoring.

### Coordinated services

The provision of nutrition services and prevention of further disabling conditions can be done in a variety of health care, school, vocational, home, and community settings. Participation in physical fitness activities targeting muscle strength and cardiorespiratory fitness should be encouraged to prevent secondary conditions such as chronic pain, fatigue, and osteoporosis. It is the responsibility of the family in concert with the health care team to promote nutrition care planning in these settings. More than 90% of children with CP live to adulthood; however, their life expectancy is less than that of the general population. Similar to the general population, individuals with CP are susceptible to developing obesity, hypertension, diabetes and heart disease and therefore require awareness and adherence to prudent dietary guidelines. The chronicity of nutrition problems for individuals with CP is recognized and has in part created a need for care coordination and integrated service planning to provide meaningful and cost-effective services.

## Summary

Nutritional challenges are common in children with CP. The benefits of nutrition intervention can enhance overall health and development and improve the quality of life for the child and family. All interdisciplinary plans including nutrition should be safe, promote growth or weight gain without excessive energy expenditure and reflect the family's resources in time and skill, addressing their concerns and expectations. Early detection, assessment and treatment of nutritional deficiencies is imperative to avoid complications and improve outcomes in children with CP.

### Key points

To provide the reader with an understanding of:

- The anatomy and structure of the colon
- The enteric nervous system
- The intestinal microbiota, probiotics and prebiotics
- Intestinal disorders, including diarrhea, polyps, protein-losing enteropathy, infections, inflammation, and inflammatory bowel disease

### Glossary

**Diarrhea** Defined as either a decrease in stool consistency or an increase in stool frequency and volume

**Enteric nervous system** The ENS operates both in conjunction with and independent of the peripheral nervous system

**Inflammatory bowel disease** A chronic inflammatory condition of unclear etiology, categorized by location, extent, severity of disease, in addition to being a strictly mucosal process vs. a transmural process

**Polyps** Intestinal polyps are intraluminal protuberant tumors characterized by their gross morphological appearance, location(s), numbers, size, and presence (pedunculated) or absence (sessile) of the stalk

**Prebiotics** Naturally occurring nutrients that support the intestinal microbiome

**Probiotics** Bacteria present in nature and in naturally fermented foods that have benefits for the host following ingestion

**Protein losing enteropathy** Protein losses occurring from the colon, usually of an exudative process, and not only related to inflammatory conditions, but also to perturbations in oncotic and hydrostatic pressure equilibrium

**The intestinal microflora and the microbiome** The complement of bacteria that normally resides in the colon

## Introduction

The colon is not a static structure but only serves as a reservoir and conduit for stool and expulsion, but rather, is a dynamic organ involved in the absorption of salts, fluids and nutrients, protein and energy balance. The colon hosts immune tissue involved in the dynamic interplay with intestinal micro flora, important in both health and disease. This article reviews up-to-date understanding of the structure and function of the colon, both in health and disease states.

## Structure and function

### Gross morphology

The colon is a continuous structure originating at the ileocecal valve and extending to the anus. The cecum is the first part of the colon, which lies in a posterior position at the right iliac fossa, and has an ovoid-like shape. This cavity is more generous in proportion than other compartments of the colon. The appendix (a blind-ending outpouching) originates in the cecum and its opening is usually visible during colonoscopy.

The ascending colon runs cephalad and anteriorly from the cecum to just inferior to the liver, to the hepatic flexure, emerging into the peritoneum. The transverse colon continues from the hepatic flexure to the splenic flexure, from where it travels distally, and once again posteriorly to the sigmoid colon, an S-shaped, tortuous, narrow peritoneal structure. At the peritoneal reflection the rectum arises and, closely following the sacral curve leads to the anal canal. The rectum is a vault-like structure, which can distend in order to accommodate fecal load. The anal canal bears two sphincters, an internal and an external anal sphincter. The internal sphincter is comprised of inner circular smooth muscle fibers, and a distal external fiber on the other side of a muscular pelvic diaphragm. The fibers of the external sphincter are intertwined with those of the levator ani, tethered anteriorly and posteriorly to the perineal body and the coccyx, respectively (Fig. 1).

With respect to colonic mobility within the abdominal, peritoneal, and pelvic cavities, the cecum and flexures are less mobile, with the sigmoid colon being the most mobile. The transverse colon supports the greater omentum and has a variable degree of mobility.

Cross-sectionally, the colon has an external longitudinal muscle and an inner layer of circular musculature, the former has a coalescence of fibers forming band-like structures known as teniae. These teniae are particular to the large intestine, and are located at one-third of the circumference from each other, and run continuously from one end of the colon to the other. Haustra are hemilunar-like outpouchings, which are present between teniae. The more proximal rectal tenial fibers surround the rectum; the inner fibers form the internal anal sphincter. The external fibers are intertwined with those of the levator ani, and sandwiched between fibers running anterior to posterior, from the peroneal body to the coccyx, forming the external sphincter.

### Vasculature

The ascending colon and portions of the transverse colon are perfused by branches of the superior mesenteric artery, with the remainder of the colon receiving arterial blood from tributaries of the inferior mesenteric artery. Distal iliac arterial branches perfuse the anal canal. Venous drainage is achieved via the superior and inferior mesenteric veins lying in close approximation to their arterial counterparts, and subsequently dumping into the portal vein.

Additional gross morphologic structures include "lymphatic vessels," in close approximation to the vasculature, leading to lymph nodes in the celiac, superior, and inferior preaortic regions. Perianal drainage is via the inguinal lymph nodes.

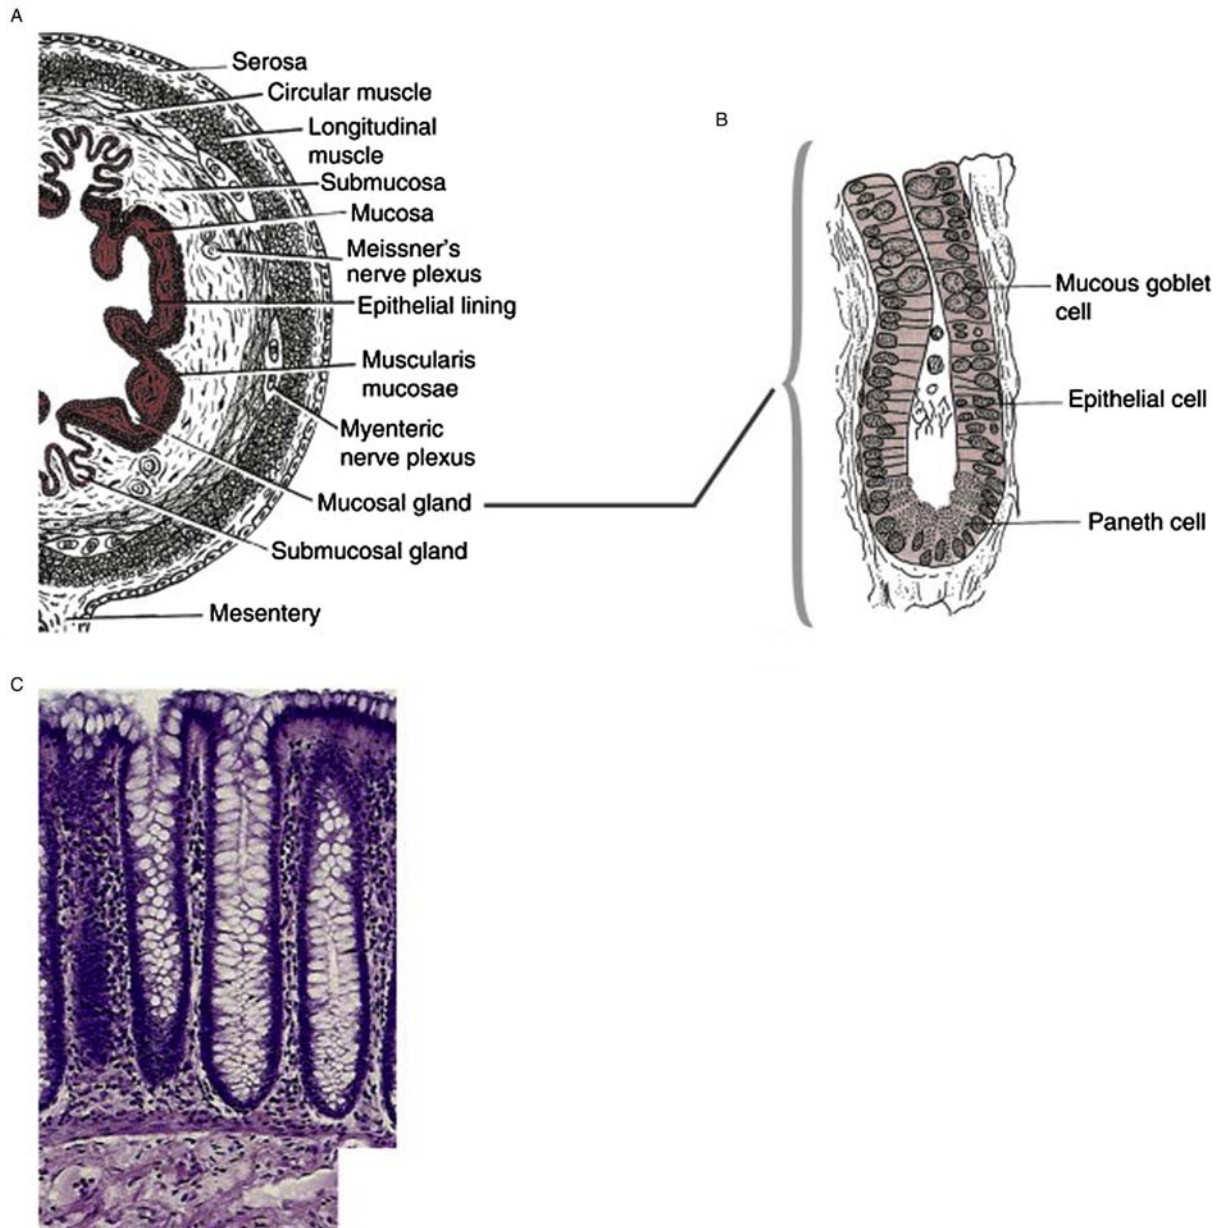

**Fig. 1** Mucosa and musculature of the large intestine. Reproduced from Netter, F., 1995. Atlas of Human Anatomy. Geneva, Ciba-Geigy, with permission from Anatomy Atlas.

### Innervation

Parasympathetic innervation to the proximal colon is provided via the vagus nerve; the distal colon and rectum are innervated via pelvic parasympathetic fibers. The sympathetic nervous system innervates the proximal colon via lower thoracic fibers, and the distal colon and rectum via lumbar fibers. Prevertebral sympathetic vertebrae receive fibers from neurons projecting out of the gut.

## Histology

Cross-sectionally, the intestinal wall is divided into four layers, with the serosa, a monolayer of mesothelial cells comprising the outermost, followed by the muscularis externa. These muscle layers comprise an external longitudinal layer and an internal circular layer. Sandwiched in-between these two layers lies Auerbach's (myenteric) plexus. The submucosa is the next more medial layer; a rich admixture of cells, including structural elements such as fibroblasts and dense connective tissue, immunologically important cells (plasma cells, lymphocytes, macrophages, eosinophils, mast cells) in addition to vascular tissue and innervation to Meissner's plexus (ganglion cells), and lymphatics comprise this layer. The muscularis mucosa, a thin sheet of smooth muscle, separates the deeper submucosa from the mucosa. The lamina propria runs interior to this layer, and is composed of connective tissue, and is lined by the luminal epithelium (Fig. 2A).

**Fig. 2** (A) and (B): Cross sections of the gut and a colonic crypt. Reproduced from Guyton, A.C., 1991. Textbook of Medical Physiology, eighth ed. Philadelphia, WB Saunders Company. (C) H and E stain of a typical colonic crypt. Reproduced from Burkitt, H.G., Young, B., Heath, J.W., 1993. Wheeler's Functional Histology, third ed. London, Churchill Livingstone.

**Table 1** Colonic cell types.

<i>Cell type</i>	<i>Location</i>	<i>Function(s)</i>
Stem cells	Crypt (base) <ul style="list-style-type: none"> <li>• Nonmigratory until differentiated</li> </ul>	Pluripotent
Undifferentiated crypt cell	Crypt	Secrete water and chloride into intestinal lumen
Paneth cells	Crypt base <ul style="list-style-type: none"> <li>• Nonmigratory</li> <li>• Basophilic cytoplasm</li> <li>• Proximal one-third of colon only</li> </ul>	<ul style="list-style-type: none"> <li>• Growth factor secretion and digestive enzyme synthesis</li> <li>• Antimicrobial peptide synthesis and release</li> </ul>
Goblet cells	Colonic crypt <ul style="list-style-type: none"> <li>• Most common cell type in the colon</li> </ul>	Mucin release
Enteroendocrine cells	Mostly in small intestine	Receptor-mediated epithelial cell function modulators
Enterocytes	<ul style="list-style-type: none"> <li>• Basolateral membrane</li> </ul> Predominantly small intestinal; present in the colon	<ul style="list-style-type: none"> <li>• Digestive enzyme synthesis (small intestine)</li> <li>• Ion transporters and channels involved in fluid and electrolyte transport</li> </ul>
M cells	Small and large intestines	Bind, process, and present antigens to components of the mucosal lymphoid immune system
Intraepithelial lymphocytes	<ul style="list-style-type: none"> <li>• Overlying lymphoid follicles</li> </ul> Small and large intestines <ul style="list-style-type: none"> <li>• Basolateral membranes</li> </ul>	<ul style="list-style-type: none"> <li>• Memory T cells</li> <li>• Mucosal immune defense</li> </ul>

The intestinal epithelium is a tight monolayer of cells that functions to absorb nutrients, electrolytes, and liquids, as well as to secrete mucus and fluids. The epithelial surface is punctuated by numerous tightly packed crypts, which contain epithelial precursor cells, enteroendocrine cells, other undifferentiated cells, and Paneth cells. Goblet cells, which secrete mucin, are also located in the crypt (Fig. 2; Table 1). As undifferentiated and precursor cells mature, they migrate superiorly to the surface and to the monolayer of absorptive cells present in crypts. The average lifespan of a colonocyte is 3–6 days.

The absorptive colonocyte develops short microvilli while in the colonic crypt, which elongate during its migration to the surface. The hydrophobic lipid bilayer of the colonocyte epithelium prevents passive transport of charged particles. The epithelial membrane contains specific protein transporters, carrier proteins, and channels allowing electrolyte transport. The electrochemical gradient formed by active transport facilitates passive flow across cell membranes.

## Function

### Electrolyte transport: ion channels

Fluids and electrolytes are absorbed via one of two pathways, transcellular vs. paracellular. Active and passive transport systems exist via both these pathways.

There is a clear polarity to the distribution of protein transporters, channels, and pumps distinguishing the apical from the basolateral membrane. Active transport utilizes transcellular, energy-driven protein pumps or channels to facilitate passage of electrolytes from an area of low concentration to one of high concentration/electrochemical gradient. A prime example of this is the Na-K-ATPase pump, the principal pump present along the basolateral membrane. The net effect of the three Na ions expelled for every two K ions accepted into the cell is a lowered intracellular Na content, and resultant net negative charge. The negative charge formed by this active transport creates an electrochemical gradient facilitative to the passive flow for other ions across the cell membrane, a process known as secondary active transport (Figs. 3 and 4).

Ion transporters may be additionally subclassified into symporters, in which ions move in the same direction, or antiporter, in which case ions move in opposite directions across the cell membrane. Cotransport of ions with other molecules, such as that of Na and glucose. The intracellular concentration of glucose is regulated both by uptake at the apical surface as well as by exit through the basolateral membrane, allowing for conditions favorable to uptake from the lumen. The Na-glucose transporter system allows for therapeutic interventions, such as the use of oral rehydration solution (ORS) in cases of severe diarrhea related to cholera or other processes. Similar cotransporters exist linked to the transport of bile salts and amino acids (Table 2).

Although sodium is the primary cation involved in ion transport, short-chain fatty acids (SCFAs) constitute the primary anion in the colon and primary metabolic fuel for colonocytes. Their transport is postulated to be linked to Na-H transporters and pH, specific bicarbonate linked transporters, and the concentration gradient across cell membranes. Chloride transport occurs via both active and passive processes, and is the major intestinal anion involved in the intestinal secretion of fluids.

Colonic smooth channels also possess ion channels, and are involved in active and secondary ion transport processes involving calcium. The electrochemical gradient formed by the activity of these ion channels facilitates the function of smooth muscle action potential generation on depolarization. With the generation of smooth muscle action potentials attaining threshold voltage, contractility of the smooth muscle is possible. The efflux of calcium into these active transport channels activates the process of

**Fig. 3** Electrolyte transporters and the cell membrane.

**Fig. 4** Electrolyte transport at the colonocyte level.

contraction. Interaction with the enteric nervous system (ENS) stimulates the release of calcium ions stored in intracellular stores. The function of ion channels can be modified by calcium channel-blocking drugs. This contractile activity, when occurring in a coordinated fashion and modulated by neurotransmission, effects peristalsis and colonic motility, which are discussed in this article.

### Fluid transport

There is an evident heterogeneity to the mucosal epithelium dependent on location in the alimentary canal, in several aspects. The type, variety, and number of ion transporters, channels, and carrier proteins vary from region to region, i.e., from jejunum to colon. Additionally, the nature of interepithelial cell junctions varies from the proximal to distal intestinal tract, influencing the “leakiness” of the respective regions. Finally, a clear gradient in cell composition and function between colonic crypt cells and those on the surface exists. Physiologic heterogeneity follows the aforementioned patterns, defining tissue function in these respective areas. For example, the colonic crypts have more of a secretory function, whereas the villus structures seen most notably in the jejunum exhibit a greater absorptive function. This heterogeneity is key in understanding changes in intraluminal osmolality and fluid shifts that occur in the intestine.

Approximately 98% of the daily fluid load handled by the intestine is reabsorbed—approximately 9 L day<sup>-1</sup>. Of this, the jejunum absorbs 85% and the colon absorbs approximately 13% or 1.5 L.

**Table 2** Electrolyte transport: examples.

<i>Ion</i>	<i>Transporter</i>	<i>Location</i>	<i>Type</i>	<i>Function(s)</i>
Na	Na, K-ATPase	Basolateral membrane	Active; antiport	Principal ion involved in water absorption
	Na-H exchangers	Apical and basolateral membrane	Secondary; antiport	
Na and Cl	NaCl Protein channel	Apical	Antiport; passive; electrochemically neutral	Principal ion involved in water secretion Basal rate of secretion influenced by several mediators (endocrine, paracrine, neural, luminal, etc.)
Cl	Protein channel	Apical	Diffusion; passive (secretion) and some active transport proteins at the apical surface (absorption and secretion), including CFTR	
Cl	Protein channel			
K	Protein channel		<ul style="list-style-type: none"> <li>• Antiport active transport (basolateral membrane)</li> <li>• Active secretion at the apical membrane; linked to Cl transport function</li> <li>• Absorptive active apical K-ATPase pumps in distal colon</li> </ul>	
HCO <sub>3</sub>		Apical and basolateral channels;	<ul style="list-style-type: none"> <li>• Alkaline phosphatase linked</li> <li>• Passive transport mechanisms</li> <li>• Na-HCO<sub>3</sub> cotransporter postulated</li> <li>• CFTR-synchronized apical channel and Cl-HCO<sub>3</sub> exchanger postulated</li> </ul>	
Short-chain fatty acids	Apical		<ul style="list-style-type: none"> <li>• Postulated link to Na-H ion transport</li> </ul>	Principal anion of the colon

CFTR, cystic fibrosis transmembrane conductance regulator.

Passive reabsorption of water occurs in the intestines, regulated primarily by electrolyte transport, i.e., following an osmotic gradient. Na-driven/related transport mechanisms are the primary driving force allowing water absorption. This osmotic gradient facilitates water absorption via both transcellular and paracellular pathways.

Transcellular water transport mechanisms such as aquaporins, or water channels, have been described. The paracellular pathway of water transport has been studied extensively, a process often described as “solvent drag” (Fig. 5).

The leakiness of paracellular pathways that varies by location in the lower alimentary tract (more prominent in the jejunum, with subsequent decrease distally), and the magnitude of the osmotic gradient (also effected by dietary Na content) are important factors affecting solvent drag. The nature of the intercellular junctions in a particular region of the colon determines the permeability, or

**Fig. 5** Intercellular junctions and fluid transport across the cell membrane.

“leakiness” of that particular epithelial area. Several intercellular structures have been described, including the *zona occludens* (tight junction), desmosomes (connections between cells), and the *zona adherens*, the latter function in cell adhesion and therefore contribute to maintaining cellular polarity across the membrane. *Zona occludens* are more apical in location and form junctional complexes between cells. It has been postulated that these junctional complexes may be more dynamic than previously believed, responding to signaling mechanisms and subject to regulation, thereby influencing their function and resultant permeability characteristics (Fig. 5).

### The ENS and gastrointestinal motility

The ENS operates both in conjunction with and independent of the peripheral nervous system. Nerve plexi exist within the bowel wall, with Auerbach’s plexus sandwiched between longitudinal and circular muscle layers, and Meissner’s plexus located more medially in the submucosa.

The ENS is the largest component of the autonomic nervous system, based on nerve cell number.

Interstitial cells of Cajal, a cell type unique to the alimentary tract, are present medial to the inner smooth muscle layer. These specialized cells interact with myenteric neurons, and are thought to exhibit independent electrical activity, generating and transmitting slow waves to smooth muscle, functioning as pacemakers for colonic motility. The ENS is capable and does functions independent of the central nervous system (CNS), with reflex activity, in response to luminal stimuli, including muscle contraction and coordination—i.e., motility, blood flow, and glandular secretion. Modulation of the ENS is via the sympathetic and parasympathetic nervous system.

### Colonic motility

The colon functions to delay passage of luminal contents to allow for water absorption, and to allow for mixing of luminal contents with the mucosa, to store fecal matter before defecation, and to propel contents forward during defecation.

The frequency and duration of propagative, high-pressure waves in the colon in part is determined by pressure exerted by the intraluminal contents (mechanical) and degree of stretch stimulation, (chemical) composition of the contents, and by other stimuli interacting with the colon.

The gastrocolic reflex, an anterograde postperistaltic process, occurs following a meal, originating proximally and propagating anterograde. Both the caloric content and the fat composition of the meal bear influence on colonic peristalsis. Likewise, gastric distention by food contents, water, or gas also has a stimulatory effect. Gastrointestinal hormones secreted in response to a meal, such as cholecystokinin, are thought to mediate peristaltic responses to a (fatty) meal. Irritant laxatives also stimulate peristalsis, even when administered rectally. Opiates are known to inhibit the ENS, and, as a consequence, retard peristalsis. Colonic motility diminishes significantly during sleep, resuming on awakening.

Motor activity varies by colonic region, in degree, frequency, amplitude, velocity, being propagative vs. nonpropagative (the latter are more common in the distal colon than the former), relative distance of propagation, and direction of propagation (anterograde vs. retrograde, the latter most commonly seen in the proximal colon). Approximately one-third of these colonic peristaltic waves are propulsive, and the ones associated with propulsion of stool tend to be slower, yet greater in amplitude.

### Defecation

Defecation involves the integration of peristaltic activity in most colonic regions, and not solely in the anorectal region. In the pre-defecatory phase, approximately an hour before actual defecation, the majority of the colon exhibits an increase in propulsive peristaltic waves, first in the proximal colon, then advancing distally.

The sensation of defecatory urge is not evident until approximately 15 min before defecation. At that time, there is a marked increase in propagative peristaltic activity, originating more distally in the colon. Each of these late propagative waves successively originates “proximate” to its preceding one, with “greater” amplitude, and present over a “greater” distance of colonic length.

Stool contact with the receptors in the upper anal canal can effect relaxation of the inner anal sphincter. In addition, stretch receptor stimulation of the rectal-vault walls results in the urge to defecate. Failure of relaxation of the external anal sphincter (which is under voluntary control) results in retrograde passage of stool into the rectum, with subsequent diminishing of more proximal peristaltic propagative waves, thereby maintaining continence when immediate defecation is not desirable or convenient.

Evacuation of the rectum and defecation require correcting the angle of the anal canal in the anterior–posterior plane; this is accomplished by assuming a squatting position. Contraction of the abdominal musculature and of the diaphragm, with a relaxed pelvic floor facilitates defecation, even in the absence of colonic peristalsis.

Stool size and consistency vary based on diet and water intake, and transit time determines size and consistency of the stool, as well as bacterial content (a major component of stool). Higher water content tends to result in larger, softer stools. The more fusiform-shaped the stool is, the less likely that its passage is associated with straining. The transit time through the colon is inversely related to the stool’s water content and, hence, its consistency (Fig. 6).

**Fig. 6** Fecal composition.

### Colonic immune function and colonic microflora

The immune system of the gastrointestinal tract functions in defending against infection (bacterial, viral, and parasitic) and luminal antigens ingested/formed by bacteria. Nonspecific and specific mechanisms exist.

The mucin secreted by colonic goblet cells functions as a barrier for the mucosal surface. Mucosal integrity serves an important barrier to luminal pathogens. Interepithelial cell junctions function both to control permeability as pertains to fluid and electrolyte absorption, as well as to preventing pathogen access beyond this layer.

The enteric immune system is vast and complex; it functions to interact with the rest of the immune system, as well as with luminal contents. Gut-associated lymphoid tissue consists of both discretely organized tissue, such as Peyer's patches (lymphoid follicles with proliferative potential in response to antigen presentation) containing M cells, and the more diffuse lymphocytes and macrophages distribution among the submucosa, mucosa, and lamina propria. M cells function in antigen sampling of intraluminal contents by binding antigens, endocytosis, antigen processing, and subsequent interaction with lymphocytes and macrophages within Peyer's patches, eliciting host responses. The lymphocyte complement of Peyer's patches originates in either the bone marrow or the thymus, enters the systemic circulation to migrate to Peyer's patches, interacts, returns to the intestinal mucosa or, via mesenteric lymph nodes, reenters the systemic circulation to reach other organs.

The gastrointestinal tract houses up to 80% of the body's immunoglobulin-producing cells. Intraepithelial T lymphocytes, plasma cells, macrophages, dendritic cells, eosinophils, and mast cells also function in a specialized manner.

Secretory immunoglobulin A (IgA) is an important host immune-defensive mechanism. Unlike the monomeric, systemic form of IgA, intestinal secretory IgA is polymeric (specifically, dimeric) in nature. This dimeric immunoglobulin is secreted by B lymphocytes situated in the lamina propria, and contains a unique "J" chain instrumental in polymer formation. This IgA binds to the Ig receptor of the epithelial cell on the basolateral membrane, and, following endocytosis and transport across the cell, is secreted from the apical side.

Secretory IgA binds to intraluminal antigens, including dietary ones, and functions in preventing their absorption. Additionally, secretory IgA has the ability to bind to microorganisms, hence preventing adherence, colonization, and invasion. Secretory IgA is secreted in breast milk, and in the breastfed neonate and infant confers a degree of passive immunity to infection by limiting luminal contents from interacting with, or directly binding to/invasive the mucosa.

Interaction of intraluminal bacteria with the immune system may affect intestinal permeability, and may modulate the intestinal immune system. Certain bacterial species are believed to interact with other enteric flora as well as with the host immune system to effect a healthier gastrointestinal tract and enhanced nutrient digestion; organisms studied include *Lactobacillus*, *Vibrio* species, and *Saccharomyces* (commonly referred to as probiotics).

Regulation of quantity of bacteria, in addition to the specific profile of bacterial species present is dependent on a host of factors, including gastric acid output, gastrointestinal motility, luminal contents, and the milieu created therein. Additionally, the intraluminal environmental milieu is affected by the specific properties of different species of bacteria, their interactions with other luminal species, and with the host itself.

### The colonic microbiome

The colon accommodates the largest number of enteric flora, on the order of  $10^{10}$ – $10^{12}$  greater than 100,000 the number of flora and more than 100-fold greater diversity of species than any other location in the alimentary canal. Efflux of bacteria into the ileum is hindered by the ileocecal valve, which functions to restrict several of these bacterial species from entering large intestine. The majority of these colonic bacteria are anaerobic in nature (Table 3).

The enteric flora plays several important roles, including interaction with the enteric immune system, effecting cellular immune activity, associated with the size and number of Peyer's patches present, influencing intestinal motility, and nutritively important functions, including bile salt deconjugation (facilitates enterohepatic circulation of bile salts), bilirubin metabolism (deconjugation and urobilin formation, allowing excretion), mucin degradation, and lipid metabolism (generation of SCFAs). Androgens and estrogens are hydrolyzed facilitating resorption and conservation of these sterols, whereas cholesterol is processed into coprostanol, a nonabsorbed sterol. Ammoniogenesis via protein and urea degradation may play a role in hepatic encephalopathy (Table 4).

**Table 3** Colonic enteric flora.

<i>Bacterial genus</i>	<i>Prevalence (%)</i>	<i>Total count (CFUg<sup>-1</sup> or ml)</i>
Anaerobes		10 <sup>10</sup> –10 <sup>12</sup> 10 <sup>9</sup> –10 <sup>12</sup>
• <i>Bacteroides</i>	100	
• <i>Porphyromonas</i>	100	
• <i>Bifidobacterium</i>	30–70	
• <i>Lactobacillus</i>	20–60	
• <i>Clostridium</i>	25–35	
• <i>Peptostreptococcus</i>	–	
• <i>Peptococcus</i>	–	
• Methanogens	–	
Facultative aerobes		10 <sup>2</sup> –10 <sup>9</sup>
• <i>Enterococcus</i>	100	
• <i>Escherichia coli</i>	100	
• <i>Staphylococcus</i>	30–50	
• Other Enterobacteriaceae	40–80	

**Table 4** Examples of biochemical reactions by intestinal flora.

<i>Reaction type</i>	<i>Reaction</i>	<i>Example substrate</i>
Hydrolysis	Amides	Methotrexate
	Glucuronides	Estradiol-3-glucuronide
Dehydroxylation	Decarboxylation	Amino acids
	Deamination	Amino acids
	Dehydrogenase	Bile acids, cholesterol
Reduction	Double bonds	Unsaturated fatty acids
	Acetylation	Histamine

Consumption of lipids, carbohydrates, and protein also occurs by colonic bacteria, in addition to that of vitamins (vitamin B<sub>12</sub> and folic acid are consumed; vitamin K and biotin are produced by these bacteria).

The development of the colonic microbiome is influenced by many factors, including environmental factors such as site of birth (home vs. hospital, rural vs. urban hospital setting), of antibiotic exposure perinatally, of oxygen deprivation, and by mode of birth (vaginal vs. cesarian). Although it is well established that the microbiome bacterial profile is largely determined after birth and with the development of immunological tolerance within the first 2–3 day of life, with a preponderance of facultative anaerobes, it is also recognized that the dietary composition plays an important ongoing role in the maintenance and character of the microbiome. Differences in the microbiome may exist in children who are breast vs. formula fed, and the composition of the breast milk in turn is modulated by maternal dietary intake. Dietary fiber in particular is very important throughout the life cycle, as bacterial fermentation produces SCFAs, which are the preferred colonocyte energy substrate. Butyrate is one such SCFA of particular importance.

The composition of the intestinal microbiome has been associated to specific disease states, including obesity, inflammatory bowel disease (IBD), and cystic fibrosis (CF). In all these conditions, in addition to the microbiome being varied from their respective healthy counterparts, it is thought to be reduced in terms of the diversity.

In the case of obesity, a varied proportion of the intestinal microflora phyla (more Firmicutes and less Bacteroidetes) have been observed in the obese vs. lean individuals. From a microbial metagenomic perspective, these bacteria are enriched in genes associated with energy harvest. What is not clear at present is if this association is causative or reflective of being obese or not. What these observations do is to raise interesting questions regarding whether if the intestinal microbiome contributes significantly to energy balance in their respective human hosts. The intestinal microflora had previously not been considered to contribute to host energy balance in a clinically significant manner.

In IBD and CF, the microbiome differs from that of healthy individuals. In the case of IBD, there is a decrease in Bacteroidetes and Firmicutes and increase in Proteobacteria—i.e., there is a decrease in the protective flora and a corresponding increase in detrimental flora. This microbiome is thought to play a causative role in disease pathogenesis in susceptible individuals. Interestingly, in comparison to healthy individuals, the colonic butyrate production in individuals with ulcerative colitis (UC) is reduced. This may be indicative of both dietary differences between these two groups (a known risk factor for the development of IBD in genetically susceptible individuals) and possibly in the pathogenesis of the disease process.

Mucus secreted by colonic goblet cells forms a physical barrier to bacterial pathogens known as the unstirred layer, and is routinely cleared by the colon. In CF, as with pulmonary secretions, colonic secretions are underhydrated, and this renders the unstirred mucus layer thicker and less able to clear trapped bacteria, which is thought to contribute to colonic inflammation frequently seen in this condition.

Modulation of the intestinal microbiome is possible by dietary changes, the use of antibiotics, and of probiotics. In the case of IBD, the colonic microflora has often been a target for therapy, with the use of antibiotics useful as therapy for the disease, while colonic diversion is another modality sometimes used. Another strategy studied in digestive and inflammatory disorders of the colon involves use of probiotics and of prebiotics (mostly dietary oligofructose) to modulate and change the profile of the microbiome. Specifically, supplementation of single and multiple species of these probiotics has been studied in the prevention and treatment of antibiotic-associated diarrhea, bacterial overgrowth in short bowel syndrome, rotaviral infections, refractory post IBD resection-related pouchitis, irritable bowel syndrome and necrotizing enterocolitis, and for the treatment/prevention of recurrent *Clostridium difficile* colitis. In CF animal models, the use of probiotics and bowel hydration retention agents such as polyethylene glycol 3350 has been associated with a decrease in colonic markers of inflammation, suggesting that altering the intraluminal microbiome and intestinal milieu may have significant impact on health and disease states. The use of probiotics in other conditions that extend beyond the gastrointestinal system (such as allergic conditions and pulmonary disease) remains an active area of research. It is highly likely that the relationship between host and microbiome is dynamic and bidirectional, and that the effects extend beyond the colon, from a nutritional, metabolic, and immunological basis. However, many studies of probiotics have not yielded clinically significant results, and caution in interpreting these findings and in consideration to the roles and types of probiotics in use should be exercised. The human host develops immunotolerance within the first 2–3 days of life, and so if probiotic therapy is started, it may need to be continued to maintain/sustain microbiome changes; cessation of supplementation may allow the microflora to return to its preprobiotic supplementation profile. Some specificity of the type of probiotic for different conditions may need to be considered. Probiotic use may be contraindicated in immunocompromised individuals where the risks of bacterial translocation and sepsis are increased, and are currently contraindicated for use in pancreatitis, where their use has been associated with adverse outcomes.

### **The colon and energy metabolism**

Although the role of the colon in fluid and electrolytes transport is well known, until recently, less was known about the colon and energy metabolism. The intestinal microflora-mediated fermentation of dietary fiber and utilization of SCFAs (acetate, propionate, and butyrate) are important in the maintenance of the colonic microbiome. SCFAs are also absorbed and contribute approximately 200 kcal d<sup>-1</sup> to the human host.

The role of the colon in energy retention is of increased importance in cases of short bowel syndrome related to resection, and in relation to the small bowel length. In cases of small bowel resection, hypertrophy of colonic tissue occurs which enhances fluid and electrolyte retention capacity; however, malabsorption of long-chain fatty acids and carbohydrates may still occur. Although it is understood that the sites of small bowel resection and amount of resection are important (in addition to the status of the ileocecal valve, an important antibacterial barrier for the small bowel), the role of colonic retention may also be important. In this setting, colonic energy retention of fermentable carbohydrates—dietary fiber—into SCFAs and their absorption increases. In individuals with small bowel resections, dietary modification to increase fermentable carbohydrates may be an important strategy in decreasing malabsorption and maldigestion.

### **The colon and nitrogen metabolism**

Colonic nitrogen metabolism involves both protein and nonprotein sources. Protein catabolism in the gastrointestinal tract can account for 10% of total body protein metabolism. The intestinal microbiome contributes much of the fecal matter and intraluminal nitrogen content and, as such, the majority of fecal nitrogen losses. Colonic ammonia specifically is the main nonprotein source of nitrogen in the colon. This ammonia is obtained by the hydrolysis of urea by colonic bacteria, and is utilized for bacterial protein synthesis. Intraluminal ammonia is also enterohepatically recirculated, and is reconverted to urea by the liver. Interestingly, increasing dietary protein intake does not increase fecal nitrogen excretion; however, increase in dietary fiber is associated with increased luminal bacterial utilization of the nitrogen (ammonia) for protein synthesis, thereby increasing fecal nitrogen excretion.

Altering the intestinal nutrient exposure, bacterial load, and pH can disrupt this enterohepatic recycling of urea and trapping it in the intestinal lumen. This is a desirable strategy employed in liver failure to decrease blood and hepatic ammonia levels. Specifically, lactulose, a nonabsorbable sugar is enterally administered to lower intestinal pH and to drive bacterial fermentation and protein synthesis, thereby trapping the nitrogen in the fecal material.

## Disorders of the colon

### Diarrhea

Diarrhea is defined as either a decrease in stool consistency or an increase in stool frequency and volume. It results from a complex interplay between colonic epithelial cell function, luminal factors, intestinal motility, and other factors.

Intestinal motility also influences stool volume and consistency. The ENS, with some modulation by the autonomic nervous system, is the primary regulator of gastrointestinal motility. Neuropeptides, gastrointestinal hormones, and luminal stimuli, such as dietary factors and interactions with bacteria, influence colonic motility. Disruptions in these systems can and do influence stool consistency and frequency.

Mechanisms of diarrhea can also be viewed from the perspective of absorptive capacity of the small intestine and colon; diarrhea results when this threshold is exceeded.

From a pathophysiological perspective, four mechanisms of diarrhea are traditionally described as of one of the following four types:

- Osmotic
- Secretory
- Motility
- Inflammatory

A degree of overlap occurs between these different types of diarrhea.

Osmotic diarrhea occurs when there is a failure to absorb a solute (usually a carbohydrate) in the proximal small intestine, thus not rendering the fluid isotonic, as would regularly occur, but, rather, hypertonic. Although electrolytes may be reabsorbed, the carbohydrate is not; rather, a portion of it is metabolized by enteric flora to SCFAs, carbon dioxide, hydrogen, and methane. With sodium and other electrolytes absorbed readily by the colon, and resultant low sodium concentration in the lumen, compounded by the presence of nonabsorbed carbohydrate, the high osmotic gradient draws fluid into the lumen and results in diarrhea. This type of diarrhea is characterized by a significant osmotic gap that can be calculated; an additional clinically significant feature of this type of diarrhea is that it diminishes on cessation of enteral intake. Malabsorbed carbohydrate and its metabolites also effect a lowering of the pH of the stool. Lactose deficiency is a good example of osmotic diarrhea in both children and adults. Ingestion of nonabsorbable sugars, such as sorbitol, can also lead to osmotic diarrhea. Excessive intake of carbohydrate-rich and, in particular, simple-sugar-rich beverages can contribute to osmotic diarrhea in children, and can exacerbate pre-existing diarrheal disease. Osmotic diarrhea resulting from excessive carbohydrate and/or simple sugar intake usually improves to resolves with reduction to cessation of dietary intake of these particular nutrients.

Secretory diarrhea occurs when the net secretion of fluids and electrolytes from the colon exceeds their absorption. This type of diarrhea exists independent of eating, and is not influenced by fasting or bowel rest. The prototypical example of pure secretory diarrhea (i.e., in the absence of inflammation or blood present in the stool) is of congenital chloride transport defects, and of gastrointestinal hormonal disorders, such as in Zollinger–Ellison syndrome and in disorders of vasoactive intestinal peptide or in other neuroendocrine tumors (Fig. 7).

**Fig. 7** Diarrhea and chloride transport across the small intestine epithelium.

Cholera occurs when the toxin interacts with the colonocyte stimulating chloride, potassium, and bicarbonate secretion, via toxin A stimulation of cyclic adenosine monophosphate (cAMP); some degree of inflammation may accompany this. ORS, which contributes fluid, sodium, and glucose relies on cellular mechanisms to effect rehydration, and is the mainstay of therapy.

Motility disorders influence intestinal function as pertain to absorption; whereas decreased transit enhances absorption of nutrients, significant decreases in motility can result in stasis. Deconjugation of bile acids by enteric flora can result in malabsorption and inflammation. Increases in motility can occur in the clinical picture of an inflamed colon, which can occur in infants and adults alike. Acute hormonal influences are more common in the adult population, such as those seen with thyrotoxicosis and carcinoid syndrome. Pharmacological agents or substance abuse can also influence motility.

Inflammatory diarrhea results in secretion of mucus, and, typically, with the presence of blood in the lumen, which in itself is a cathartic agent. The integrity of the epithelial barrier is often compromised, with resultant exudation of water and proteins. Bacterial invasion of the mucosa may occur, and is one example of inflammatory diarrhea. Additional disorders that can cause inflammatory diarrhea include allergic colitis and IBD.

Lastly, diarrhea can be categorized clinically into acute and chronic forms, with the latter being defined in persistence of symptoms for more than 3 weeks. Each type of diarrhea can be further clinically divided based on age with respect to likelihood of cause.

### Protein losing enteropathy (PLE)

Albumin is the main protein maintaining oncotic pressure in the vascular compartment. Intracellular fluid status is maintained by an equilibrium of the oncotic pressure and hydrostatic pressure. Under normal circumstances, intact mucosal barrier and intercellular junctions function to prevent protein losses from the extracellular spaces. Protein losses can occur via the intestines, and can be categorized as conditions associated with mucosal disruption (functional or structural), or those with lymphatic obstruction plus increased hydrostatic pressure in the lymphatic vessels driving the process. The conditions associated with mucosal disruption can be further subdivided into inflammatory, infectious, and noninfectious processes. Another way to characterize these conditions are whether or not they are associated with normal vs. low serum albumin levels; specifically, low albumin states occur in conditions where protein synthesis cannot maintain equilibrium with turnover and needs. Stool alpha-1 antitrypsin status determination is the preferred method of diagnosis of PLE, as it is a protease inhibitor, which is not absorbed by the intestine, but is secreted into the gastrointestinal lumen, where it is not degraded by the intestinal microflora, and is readily measureable and quantifiable. Examples of conditions associated with PLE are presented in [Table 5](#).

### Infections and enteric parasites

In order for viral and bacterial agents to cause inflammatory disease involving the gastrointestinal tract, nonspecific host defense factors of gastric acidity, gastrointestinal motility, enteric flora, barrier functions of mucus secretion and mucosal integrity (in some cases), and of specific enteric mucosal immunity and systemic immune mechanisms have to be overcome.

**Table 5** Classification of PLE.

- |   |
|---|
| <ul style="list-style-type: none"> <li>• Inflammatory             <ul style="list-style-type: none"> <li>• Non-infectious                 <ul style="list-style-type: none"> <li>- Eosinophilic gastroenteropathy</li> <li>- Cow's milk protein allergy/intolerance</li> <li>- Celiac disease</li> <li>- Graft vs. host disease</li> <li>- Crohn's disease</li> <li>- Intestinal polyposis syndromes</li> <li>- Necrotizing enterocolitis</li> <li>- Malnutrition</li> <li>- Anastomotic ulceration</li> </ul> </li> <li>• Infectious                 <ul style="list-style-type: none"> <li>- CMV gastritis (Menetriere's disease)</li> <li>- Rotavirus</li> <li>- <i>Helicobacter pylori</i></li> <li>- Giardia lamblia</li> <li>- <i>Clostridium difficile</i></li> <li>- <i>Salmonella</i></li> <li>- <i>Strongyloides stercoralis</i></li> </ul> </li> <li>• Lymphatic obstructive                 <ul style="list-style-type: none"> <li>- Lymphangiectasia</li> <li>- Cardiac disease/postsurgical (Fontan)</li> </ul> </li> </ul> </li> </ul> |

**Table 6** Bacterial pathogens grouped by pathogenic mechanism.

<i>Adherent</i>	<i>Invasive</i>	<i>Toxigenic</i>	<i>Cytotoxic</i>
Enteropathogenic <i>E. coli</i>	<i>Shigella</i>	<i>Shigella</i>	<i>Shigella</i>
Enterohemorrhagic <i>E. coli</i>	<i>Salmonella</i>	Enterotoxigenic <i>E. coli</i>	Enteropathogenic <i>E. coli</i>
Enterocytotoxic <i>E. coli</i>	<i>Yersinia enterocolitica</i>	<i>Yersinia enterocolitica</i>	Enterohemorrhagic <i>E. coli</i>
Diffuse-adherent <i>E. coli</i>	<i>Campylobacter jejuni</i>	<i>Aeromonas</i>	<i>Clostridium difficile</i>
	<i>Vibrio parahaemolyticus</i>	<i>Vibrio cholerae</i>	

These infections can result in symptoms of vomiting, diarrhea, and abdominal pain, in addition to systemic effects such as fever. Clinical symptoms vary according to the pathogen.

Bacterial virulence is facilitated by enterotoxin secretion (which may be site specific in its action, secreted before introduction, or while within the lumen), adherence and invasion of the mucosa, and cytotoxin production, which function to disrupt mucosal and cellular function.

Bacteria can be classified based on their pathological mechanism (Table 6) as well as by their site of activity, and the nature of clinical signs and symptoms manifested. Signs and symptoms vary significantly by pathogen and age at presentation, with some forms presenting as crampy abdominal pain with watery diarrhea of relatively short duration, to frankly bloody diarrhea, and systemic signs and symptoms of inflammation with frank sepsis and shock possible. Common bacterial, viral, and parasitic infections involving the colon are outlined in Tables 7 and 8.

### Polyps

Intestinal polyps are intraluminal protuberant tumors characterized by their gross morphological appearance, location(s), numbers, size, and presence (pedunculated) or absence (sessile) of the stalk (Fig. 8). Additional salient features include specific histological features used to discriminate between types and aid in predicting malignant potential. Extraintestinal manifestations are also associated with specific polyposis syndromes. Age at occurrence is important with respect to clinical significance and malignant potential; family history of polyps or of polyposis syndromes can also be predictive of disease evolution and aid in screening and surveillance of family members.

In children, juvenile polyps are the most frequently occurring kind, accounting for approximately 90% of colonic polyps. There are also many other types of polyps and polyposis syndromes, which are reviewed in Tables 9 and 10. The age of the subject, family history and inheritance patterns, number and location of polyps, and histology guide to the frequency of surveillance colonoscopy. Symptoms of rectal bleeding usually bring these patients to the attention of a physician. Polyps can cause clinically significant—yet often painless—bleeding so as to cause anemia, and can be linked to abdominal pain, rectal prolapse, or lead points associated with intussusceptions.

### IBD

The phrase IBD encompasses UC and Crohn's disease. Indeterminate colitis is a diagnosis attributed to a condition in which a clear distinction cannot be made between the two aforementioned forms of IBD, as opposed to a heterogeneous group of diseases that present a wide clinical and histological spectrum.

### Epidemiology

IBD presents in a bimodal fashion as pertains to age, first in late adolescence or early adulthood, and a smaller peak in the fifth decade of life. Overall, the sexes are equally affected for UC; in adults, the incidence of Crohn's disease is 20–30% higher in women.

The second half of the 20th century has seen the incidence of UC remain stable over time; Crohn's disease has demonstrated a marked increase across all age groups since 1950. Although IBD can affect all races, Caucasians are affected markedly more than Africans, or people of African origin. Ashkenazi Jews have a markedly increased risk of IBD compared with other Jewish groups. The incidence in the Ashkenazi Jewish population roughly parallels that of the respective geographical community in which they reside, albeit at a level which can be three-to four-times that of that general population, suggesting a genetic predisposition. The majority of individuals affected by both disorders are in North America and Northern Europe. The remainder of Europe, Latin America, and Australia has lower incidence rates, with rare cases occurring in Africa and Asia.

### Etiology

The exact etiology of IBD is unclear and is an area of active research. A multifactorial interaction between genetic predisposition, environmental stimuli, endogenous triggers, immunological dysregulation, and modifying factors is postulated, and is discussed below.

### Genetics

A positive family history in a first-degree relative confers significant risk, between 10% and 20% risk of disease occurrence of either disease type in a first-degree relative. Northern European, North American populations, and in particular globally the Ashkenazi Jewish population have the highest risk of the disease.

A high rate of concordance among Swedish monozygotic twins vs. dizygotic twins has been reported in Crohn's disease (44% vs. 3.8%). In the same study, the incidence rates observed in monozygotic twins for UC were (6.3%). These data, although supportive of a genetic role, show less than 100% penetrance, suggesting that whereas genetics are more important in Crohn's disease than in UC, environmental influences play a significant role. Simple Mendelian models of inheritance are inadequate to address the complex inheritance patterns of IBD. Candidate gene studies have suggested modest HLA associations, which differ in different populations. Systemic genome searches more recently employed in families with several members have IBD employing linkage analyses. Evidence of the *NOD2* gene on chromosome 16 being involved with cases of Crohn's disease has led to it being labeled as the IBD1 gene locus. This gene is involved with the encoding of a protein associated with monocyte nuclear factor- $\kappa$ B; this protein and pathway are involved with the interaction of monocytes with bacterial peptidoglycans. Note that only approximately 30% of individuals with Crohn's disease test positive for this particular gene mutation.

**Fig. 8** Endoscopic view of a colonic polyp.

### Environmental influences

The rapid increase of Crohn's disease over the past 50 years, increasing trends in immigrant populations, as well as incomplete genotype–phenotype associations have promoted attention to environmental factors. In particular, the search to identify an antigenic trigger to the enteric immune system has been pursued by several investigators. Postulated microbial intraluminal triggers have included mycobacterium and viruses. Dietary antigens or toxins have not been identified; diet westernization has been explored and remains an active area of research. Environmental exposures early in the life cycle such as birth environment, nutritive factors (breast vs. formula fed, with the former thought to have a protective effect) may alter the risk for developing disease in susceptible individuals/groups. Additional modulating factors include smoking and the use of oral contraceptives.

The incidence and prevalence of IBD are more in the developed world, and the global distribution is inverse to that of where geohelminthic worm infections are endemic.

**Table 9** Hamartoma to us intestinal polyps.

<i>Syndrome</i>	<i>Location of polyps</i>	<i>Pathology</i>	<i>Extraintestinal abnormalities</i>	<i>Cancer risk</i>

Inflammatory polyposis	Colonic: pseudopolyps	• Pleomorphic regenerative tissue	• Systemic signs and symptoms of inflammation (Section IBD)	• Colonic; risk of cancer from inflammatory bowel disease

Furthermore, there are nutritional factors also implicated in the increasing incidence and prevalence of IBD in the developing world. Transition from traditional to the modern western diet has been identified as a risk factor for many noncommunicable diseases, including IBD. In particular, decreasing fruit, vegetable, and fiber intake, increasing terrestrial animal protein intake, and decreased marine and plant-based protein intake, and changing profiles of types and amount of dietary fat intake (i.e., less  $\omega$ -3 polyunsaturated fatty acids, higher intakes of  $\omega$ -6 polyunsaturated fatty acids) are among implicated risk factors for the development of IBD in susceptible individuals.

### Pathogenesis

The interactions between the enteric immune system and the intestinal lumen are dynamic; some degree of inflammation in response is ever present in the normal mucosal lamina propria of the colon and small intestine, which see a very large antigenic load daily. An intact mucosal barrier, in addition to normally functioning immunoregulatory mechanisms prevent this interaction progressing to the level at which tissue injury occur.

Current chronic, inflammatory relapsing disease processes may represent either an inappropriate persistent immune response to a luminal antigen/stimulus, vs. an appropriate immune response to a persistent, abnormal stimulus, vs. perhaps a prolonged immune response to a ubiquitous stimulus.

Enteric flora may play a role in this process, although no evidence to date points strongly to a single pathogen. Defective mucosal barrier function and increased intestinal permeability—the latter being documented in patients with IBD and in up to 10% non-affected first-degree relatives—may also be involved.

The immune response is primarily T-cell mediated, of a Th-1 nature. Abnormalities of interleukin-12 (IL-12), interferon gamma (INF- $\gamma$ ), and tumor necrosis factor alpha (TNF- $\alpha$ ) have also been implicated in the immunological pathogenesis of this disease. White blood cells respond to these inflammatory mediators and proliferate the immune response. These recruited cells synthesize agents such as arachidonic acid metabolites, platelet activating factor, proteases, free radicals such as reactive oxygen species—all of which can and do cause direct injury to cells and the mucosa.

### Pathology

Pathology differs between these two disorders, both in terms of anatomical distribution and tissue involvement.

#### Ulcerative colitis

UC is limited to the colon and rectum, usually beginning distally in the rectum and extending to varying lengths proximally, by definition, in a continuous fashion (Fig. 9). Usually, a clear distinction can be made where disease ends and normal mucosa can be appreciated grossly, or endoscopically. The gross appearance of the mucosa is dependent on the severity of the disease process. Mild disease presents with a diffuse erythema and loss of the characteristic appearance of the vasculature. Numerous small, superficial ulcerations, exudates, and bleeding are seen in moderate disease; larger, deeper ulcerations increased exudates, and the development of pseudopolyps, loss of normal gross architectural landmarks such as the folds diminish. Microscopically, UC is limited to the mucosa; with more severe disease, deeper layers may show a degree of involvement, with inflammatory cell infiltrates, shortening, branching, and decreases in the number of crypts as well as crypt abscesses can also be seen (Fig. 10).

#### Crohn's disease

Crohn's disease can involve any part of the alimentary tract from the mouth to the anus, and frequently does so in a discontinuous fashion, leaving "skip areas"—regions which are grossly and histologically normal (Fig. 11); in the colon, this lends a cobblestoned appearance. Macroscopically, wall thickening is evident in long-standing disease. This disease, by definition, is a transmural process (Fig. 12). With chronic disease, fibrostenosis occurs, narrowing the intestinal lumen. Strictureing disease may follow fibrosis of superficial and deeper layers of the intestinal wall, which are evident on radiographic studies (Fig. 13).

The mesentery may also demonstrate inflammation, with adhesion and fixation of the colon a consequence of the transmural inflammatory process. Adjacent loops of bowel may become matted together. As luminal diameter narrows, intraluminal pressure may increase; in the face of unabating inflammation, this transmural process may lead to fistula formation. Enteroenteric fistulas are limited to the bowel; enterovaginal, enterovesicular, and enterocutaneous fistulization may occur. Inflammatory intra-abdominal masses called phlegmons may also form by this fistulization process.

**Fig. 9** Distribution of ulcerative colitis.

**Fig. 10** The mucosa in ulcerative colitis. Reproduced from Kelly, D.A., Booth, I.W., 1996. *Pediatric Gastroenterology and Hepatology*. London, Mosby-Wolfe.

**Fig. 11** Distribution of Crohn's disease.

The endoscopic appearance of Crohn's disease varies both by location and by time relative to the disease evolution. Intestinal Crohn's disease may initially present with aphthous ulceration overlying Peyer's patches in the colon. Ulcerations eventually grow in diameter and progress in depth, with frankly friable, exudative lesions.

Histological findings of affected areas include intense inflammatory cell infiltrates extending into the crypts, with shortening and forking of these structures, and associated abscesses. The inflammation is transmural; fibrosis and histiocyte proliferation are also seen. Noncaseating granulomatous submucosal and mucosal lesions, which are a hallmark of this disease, are not found in a majority of biopsy specimens. Granulomas can also be seen in intestinal infections such as in intestinal tuberculosis and sarcoidosis.

Even macroscopically normal-appearing tissue may yield histological findings of inflammation compatible with Crohn's disease, thus indicating that examination of the entire alimentary canal with surveillance biopsies is required before arriving at a diagnosis.

#### ***Inflammatory bowel disease and the terminal ileum***

The terminal ileum is one of the most commonly involved sites in the intestine for Crohn's disease, originating often at the lymphoid follicle; strictures may form. A phenomenon of ileal involvement has been postulated in cases of apparent UC that

**Fig. 12** The mucosa in Crohn's disease. Reproduced from Kelly, D.A., Booth, I.W., 1996. *Pediatric Gastroenterology and Hepatology*. London, Mosby-Wolfe.

**Fig. 13** Small bowel stricturing noted on small bowel follow through series in a child with Crohn's disease. Reproduced from Kelly, D.A., Booth, I.W., 1996. *Pediatric Gastroenterology and Hepatology*. London, Mosby-Wolfe.

involve the ileum, in which cecal inflammation is postulated to “backwash” into the ileum; this finding being consistent with UC is controversial.

### **Extraintestinal manifestations**

Extraintestinal manifestations are common in both Crohn's disease and UC, including ophthalmologic (uveitis), joint involvement (arthralgias and arthritis of the large joints), the skin, hepatobiliary system, pancreas, renal system, and vascular system, most commonly. Anemia and weight loss are common at the time of presentation. Growth and pubertal delay are very common at the time of presentation in children; short stature occurs in up to 50% of children. Some of these findings relate to the inflammatory process itself; others are linked to malnutrition associated with IBD.

Perianal disease with fistulization and skin tags are perhaps the most common extraintestinal abnormality associated with Crohn's disease.

### Nutritional consequences of inflammatory bowel disease

Malnutrition includes acute weight loss, partly attributable to anorexia associated with inflammation, and partly to the disease process itself, i.e., inadequate intake as well as of excessive (malabsorptive) losses. An example delineating all of these mechanisms is of anemia, which can result from frank blood loss from associated gastrointestinal bleeding, anemia of chronic disease mediated by the inflammatory mediators, anorexia with decreased dietary iron intake, and, as in the case of duodenal and jejunal disease activity (as can occur in Crohn's disease), with decreased absorption.

Intestinal disease can result in both decreased nutrient absorption as well as disruption of the mucosal barrier resulting in exudation of proteins, a process known as PLE. The latter can result in hypoalbuminemia; third spacing of fluids as a result of decreased intravascular oncotic pressure can occur. Increased energy expenditure as a consequence of inflammation is noted, particularly in the febrile state, or with sepsis. Inflammation and discomfort also contribute to decreased enteral intake—factors contributory to a catabolic state.

In addition to iron, other mineral and trace element deficiencies are noted in IBD. Iron deficiency has been discussed above. Zinc is intimately associated with gut mucosa, and is susceptible to deficiency; low albumin levels resulting from PLE and increased intestinal epithelial cell turnover probably represent a significant source of zinc depletion. Vitamin B<sub>12</sub> and folic acid deficiencies have also been documented among the water-soluble vitamins, particularly when the terminal ileal disease is noted. Vitamin D deficiency is the most common among the fat-soluble vitamins.

### Treatment of IBD

Medical approaches: Several *anti*-inflammatory treatment modalities have been employed in the treatment of IBD. Their use is dictated by disease type, location, extent, and severity. Steroids provide the cornerstone of initial therapy for acute inflammation. Five aminosalicylate derivatives, use of antimetabolites such as azathioprine and 6-mercaptopurine methotrexate, and newer biological agents including *anti*-TNF- $\alpha$  are currently employed.

Nutritional therapies including exclusive to near exclusive enteral nutrition have a role in inducing and maintaining remission of Crohn's disease involving the small bowel in particular, both when used as monotherapy as well as an adjunct therapy. Although enteral therapy is not considered a first-line therapy for UC at the present in the USA, its use as such is popular in Europe and Canada, and allows for steroid sparing/avoidance. The time to onset of remission using enteral therapy in Crohn's disease is much less with steroids than with enteral therapy, however, with the former occurring typically within 2 weeks, the latter taking usually 6–8 weeks to achieve similar clinical remission. Smaller studies have been conducted employing low-fat diets, lower processed sugar foods, and employing polyunsaturated fatty acids, such as in fish oils, which may play a role in the treatment of disease. The data regarding use of  $\omega$ -3 fish oil supplements for the treatment of IBD currently do not support routine use as a main-line therapy, but may have an adjuvant role in maintaining disease remission.

Surgical treatment is indicated in UC when acute, fulminant disease does not respond to medical therapy, or persistent chronic disease which is refractory to medical (steroid) therapy and when the diagnosis has been confirmed, i.e., that Crohn's disease has been ruled out. Colectomy is curative in such instances.

Crohn's disease is more complex, and surgical intervention, limited to involved segments only, is not curative. Failure of medical therapy to reduce inflammation, critical stenosis of the involved segments with fibrosis leading to obstruction, perforation, fistulization, and abscess formation not amenable to medical therapy and frank gastrointestinal hemorrhage are indications for surgical intervention. Reactivation of disease can occur postoperatively, at the site of anastomoses or elsewhere.

The natural history of IBD is such that long-standing disease increases the risk of colonic dysplasia, particularly in the case of UC, besides being a curative intervention, making the case for colectomy more attractive in older patients. Ileoanal continuity can be achieved by means of surgical anastomoses. Pouchitis secondary to bacterial overgrowth, smoldering pockets of disease activity that may not have been resected or have become evident after resection, and loss of continence are common complications of these procedures.

### Conclusion

The term "microbiome" refers to organisms and their genomes/functions, whereas "microbiota" refers to the organisms themselves. The difference is very subtle, and sometimes they are used interchangeably. The metabolome specifically refers to the collection of metabolites that organisms produce.

Dietary intake influences the intestinal luminal environment, and there is dynamic interplay between this intestinal substrate and the microbiota. These differences occur in the neonatal period, with differences in the metabolome developing between breastfed and formula-fed infants (Saavedra and Dattilo, 2012). Breastfed infants support a microbiome rich in Bifidobacterium, which has *anti*-inflammatory properties thought to against Crohn's disease in particular (Joossens et al., 2011; Imaoka et al., 2008; LoCascio et al., 2010). Diets high in animal fat and low in fiber have increased concentrations of Bacteroides species, whereas those diets rich in carbohydrates and low in fat have predominance of Prevotella species. This is suggestive of a bidirectional relationship between the microbiota and nutrition, further influenced by host genetic susceptibility from an immune regulation and/or intestinal barrier function perspective (Sartor, 2012; Goldsmith and Sartor, 2014; Ray and Dittel, 2015). Short-chain fatty acids, including butyric acid, are the preferred energy source for colonocytes and are produced by the bacteria clostridia, which ferments dietary fiber. This is the preferred substrate for Firmicutes. A lack of dietary fiber results in less fermentation of this substrate by gut

bacteria to short-chain fatty acids. Furthermore, lack of fiber ingestion results in intestinal bacteria targeting an alternative substrate in the absence of fiber, namely the unstirred mucus layer. The unstirred mucus layer serves a barrier between the lumen and enterocytes. When the unstirred mucus layer is targeted and permeated, this contributes to inflammation of the mucosa that is exposed underneath. Emulsifiers found in the diet also impact the intestinal unstirred mucus layer and permeability to *E. coli*, which may drive inflammation (Lock et al., 2018).

In patients with IBD, the composition of the gut microbiome is altered. There is decreased species diversity and richness in the IBD microbiota. There is a decrease in Firmicutes (including clostridia), *Faecalibacterium prausnitzii*, *Bilophila wadsworthia*, and *Bifidobacterium adolescentis* and an increase in Actinobacteria and enterobacteriaceae proteobacteria, including adherent invasive *Escherichia coli*. These microbiota profiles are different than unaffected individuals within the same geographic populations (Fujimoto et al., 2013; Tawfik et al., 2014). Furthermore, there are some differences in the microbiota in patients with UC vs. Crohn's (Schaffler et al., 2016). It remains unclear if these changes to the microbiota are causative or correlated with having IBD (Ni et al., 2017). Composition of dietary intake can influence risk for IBD (Amre et al., 2007). Additionally, the diet can be modified to effect/modulate intestinal microbiota in a manner that may reduce IBD related inflammation (Ananthakrishnan et al., 2013).

## Definition and Etiology

Cystic fibrosis (CF) is a multisystem autosomal recessive disorder caused by the mutation of a single gene on the long arm of chromosome 7 that codes for the CF transmembrane regulator (CFTR). This protein regulates the passage of chloride through the membrane of secretory epithelia, the dysfunction of which results in an altered composition of epithelial secretions. Clinically, CF is characterized by chronic pulmonary infection with periods of acute exacerbation, pancreatic insufficiency, and excessive losses of sweat electrolytes. The latter forms the basis for the diagnostic test. The mutated gene was identified in 1989 and since then more than 800 CFTR mutations have been reported, the most common of these being  $\Delta F508$ .

## Prevalence

Approximately 5% of the Caucasian North European and North American populations are carriers of the gene defect causing CF, leading to an approximate incidence of 1 in 2500 live births. This inheritance is illustrated in [Figure 1](#). The incidence of CF in non-Caucasians is much lower and estimated to be approximately 1 in 100 000 in Oriental populations.

**Figure 1** Mode of inheritance of CF: A Mendelian-inherited recessive characteristic. Reproduced from Figure 16.3 in Gibney MJ (ed.) (2005) *Clinical Nutrition. Nutrition Society Textbook Series*. Blackwell publishing. ISBN 0-632-05626-6, with permission from Wiley.

## Prognosis

The median age of survival has dramatically risen from approximately 2 years in the 1940s to nearly 30 years in the 1990s. A current survival estimation following diagnosis is approximately 40 years. This improved prognosis can be attributed to a combination of factors, including aggressive management of infections, effective antibiotics, improved nutritional management, modern physiotherapy techniques, and the centralization of treatment in specialist centers. The survival age for females with CF would appear to be less than that for males. This may be related to poorer nutritional status among female CF patients. Expert management started immediately after an early diagnosis of CF by neonatal screening results in an important beneficial effect on outcome and may be critical to the clinical course of the condition and long-term prognosis. Although optimized nutrition, antibiotics, and chest physiotherapy remain the mainstay of CF management, new approaches to treatment are being developed that may add to the traditional medical therapy for CF. As prognosis and survival improves, nutrition-related issues become more prevalent, including the effective management of pregnancy, diabetes, osteoporosis, and transplantation.

## Clinical Features

The clinical features of CF are listed in [Table 1](#).

### Pathogenesis of Lung Disease

Pulmonary disease can be demonstrated within the first few months of life. Bacterial infection is characterized by high levels of neutrophils and mediators of infection in the form of interleukin 1, interleukin 8, and elastases. Mucous glands become dilated

**Table 1** Clinical features of respiratory features of CF

Respiratory features of CF	
Atelectasis	Incomplete expansion of a lung or part of a lung due to airlessness or collapse
Bronchiectasis	Chronic dilatation of the bronchi associated with coughing and expectoration of purulent mucus
Bronchitis	Inflammation of one or more bronchi
Pneumonia	Inflammation of the lungs with air spaces becoming filled with exudates
Pneumothorax	Accumulation of air in the pleural space
Gastrointestinal features of CF	
Cholelithiasis	The presence or formation of gallstones
Cirrhosis	Liver disease characterized by loss of normal liver tissue and fibrosis
Distal intestinal obstruction syndrome	Blockage of the bowel with feces, mucus, and undigested food
Gastroparesis	Paralysis of the stomach or delayed gastric emptying
Malabsorption	Impaired intestinal absorption of nutrients
Maldigestion	Impaired intestinal digestion of nutrients
Meconium ileus	Blockage of the bowel with meconium
Osteoporosis/osteopenia	Reduction in bone mass
Pancreatic insufficiency	Reduction of enzyme production from the pancreas
Portal hypertension	High pressure in the portahepatic artery
Rectal prolapse	Protrusion of the rectal mucous membrane through the anus
Splenomegaly	Enlargement of the spleen

leading to obstruction, secondary infection, and progressive lung damage. Frequent periods of respiratory infection and exacerbation are common in CF patients with increased cough, increased sputum production, and shortness of breath. The immune response appears to be of great significance. Chronic inflammation has been cited as the cause of considerable lung damage seen in CF. Steroidal anti-inflammatory drugs have been shown to be beneficial but have nutritional side effects, such as hyperglycemia and osteoporosis. Nonsteroidal anti-inflammatory drugs, such as ibuprofen, have been used in some centers with positive results, but their long-term effect on renal function is not yet known. The impact of malnutrition on lung disease and respiratory muscle function has been extensively studied in patients with CF. Malnutrition and deterioration of lung function are interdependent. Prevention of malnutrition from the time of diagnosis is associated with better lung function and improved survival.

### Gastrointestinal Complications

Individuals with CF can develop a variety of gastrointestinal (GI) disorders related to the pathophysiological changes associated with CF. Pancreatic insufficiency, which is present in most CF patients, leads to many of the GI manifestations of CF, including steatorrhea, abdominal pain, distal intestinal obstruction syndrome (DIOS), and rectal prolapse. Gastroesophageal reflux occurs frequently in CF patients due to decreased lower esophageal sphincter pressure and is usually treated by proton pump inhibitors. In patients with advanced lung disease, vomiting is common after strenuous bouts of coughing and this over time may lead to decline in nutritional status. Peptic ulcer disease, pancreatitis, and intussusception also occur at varying degrees in patients with CF. Crohn's disease and celiac disease occur more frequently in the CF population than in controls; and GI tumors, although rare, have an increased incidence in CF.

Meconium ileus is the presenting complaint in up to 15% of infants with CF. This is a condition in which the small intestine is blocked with tenacious meconium and surgical intervention is required to correct it. Excessive mucus in the small bowel of patients with CF can provide a physical barrier to the absorptive surface. Undigested or unabsorbed food in association with this mucus, and possibly a reduced gut motility, can lead to a partial or complete obstruction of the GI tract in older children and adults known as meconium ileus equivalent, or more accurately DIOS. This is a condition specific to CF. The usual clinical presentation is one of abdominal pain, abdominal distension, and constipation. It can be precipitated by dehydration, change in eating habits, change in enzyme brand or dose, or immobility. DIOS is treated with a laxative regime and should have a diet and enzyme review.

### CF-Related Diabetes Mellitus

Diabetes requiring insulin is the most common comorbidity in CF. The islets of Langerhans are the last cells to be damaged in the process of fibrosis of the pancreas. The incidence of diabetes in CF has been reported to be 8–15%, but this may be underestimated due to lack of screening. It is estimated that 50% of patients older than 30 years will have some degree of glucose intolerance. The primary cause of CF-related diabetes mellitus (CFRD) is insulin deficiency secondary to pancreatic fibrosis. Diagnostic criteria for CFRD are the same as for non-CFRD. Glucose metabolism is also affected by many factors, including infection, malabsorption, abnormal intestinal transit time, and steroid use, all features of CF. Although CFRD shares many of the characteristics of both type 1 and type 2 diabetes, it is itself a distinct clinical condition. Hyperglycemia may adversely influence weight and pulmonary function; and as the age of survival increases, it may lead to the development of microvascular complications. Retrospective studies have shown that in those individuals presenting with overt diabetes mellitus, deterioration in weight and respiratory status for 2 years before diagnosis are reversed once insulin therapy is instituted. A program of multiple daily insulin injections and self-monitoring of blood glucose with the aim of normoglycemia is the preferred treatment with regular follow-up with the Endocrinology team. All patients with CF should be screened annually for CFRD using the oral glucose tolerance test. Minimal dietary restrictions are imposed on this group of patients in an attempt to maximize nutritional intake. See the Section on [Dietary Management of CF](#).

### Liver Disease

Another complication associated with increased longevity in CF is liver disease, which affects between 2% and 37% of adults with CF. The development of liver disease in patients with CF has been attributed to the blockage of small bile ductules with thick secretions and the subsequent development of progressive cholestasis, biliary fibrosis, and eventually biliary cirrhosis and portal hypertension. The persisting acidic conditions in the upper small bowel lead to bile salt precipitation and defective lipid emulsification. Unhydrolyzed fat and other products of maldigestion may interfere with bile acid reabsorption in the terminal ileum, thereby reducing the total bile salt pool. Fecal losses of primary and secondary bile acids lead to an imbalance of bile salts, which further increases the viscosity of the already tenacious bile. Treatment with ursodeoxycholic acid has led to an improvement in bile excretion and liver function tests. Complications of liver disease, including ascites, gastric, and esophageal varices may further exacerbate a patient's nutritional status. In a small number of patients, liver failure may require liver transplantation. See the Section on [Dietary Management of CF](#).

## Nutritional Management

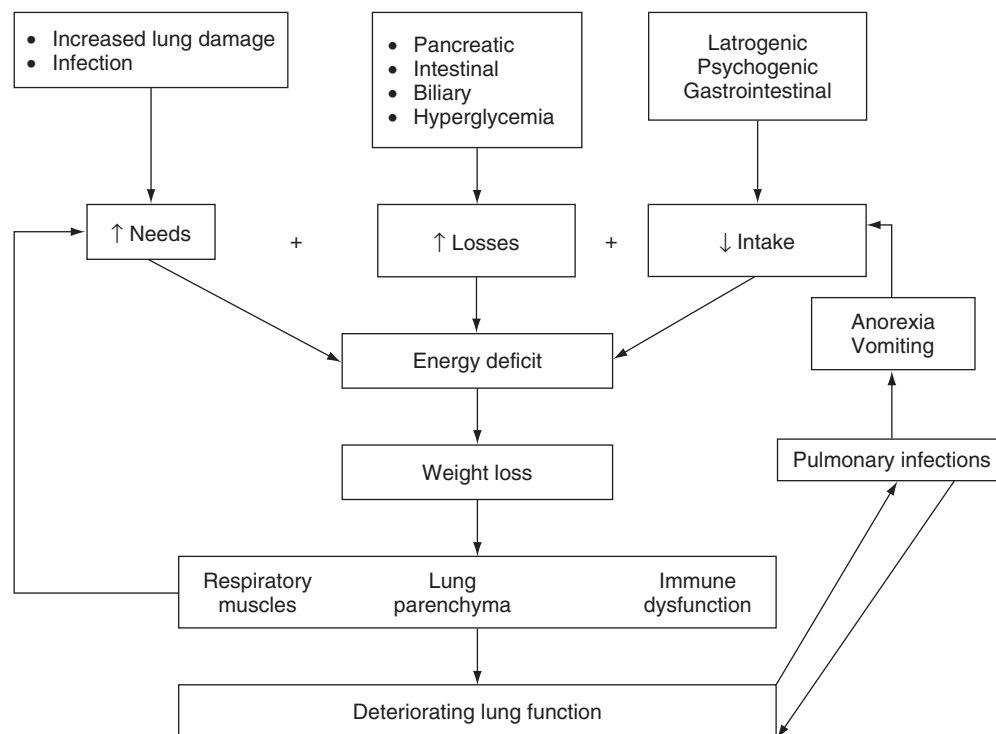

Aggressive nutritional management of patients with CF is key in their overall management. Nutritional management of CF involves maximizing dietary intake; minimizing malabsorption and maldigestion; monitoring vitamin intakes and serum levels; and adapting eating patterns in the event of diabetes, osteoporosis, DIOS, or liver disease. Nutritional support in the form of nocturnal gastrostomy feeding may be necessary if nutritional failure persists (body mass index (BMI) lower than  $18.5 \text{ kg m}^{-2}$ ). It is well recognized that the malnutrition seen in CF patients is due to an energy imbalance caused by three main factors: decreased dietary intake, increased energy requirements, and increased energy losses. There appears to be a direct association between the degree of malnutrition and the severity of pulmonary disease, affecting overall prognosis. Many patients are capable of balancing these factors effectively and have a normal growth velocity and good nutritional status. However, as lung function deteriorates, energy requirement increases and appetite decreases leading to a loss of energy stores and lean tissue further contributing to progressive deterioration of lung function (see Figure 2).

### Decreased Dietary Intake

People with CF are advised to consume a diet high in energy with no fat restriction. Before the development of enteric-coated enzymes in the mid 1980s, patients with CF were advised to follow a low-fat diet in an attempt to minimize fat malabsorption and steatorrhea. Unfortunately, older patients continue this practice as they have developed an aversion to fatty foods after many years of avoiding them. Decreased dietary intake secondary to anorexia is common in CF patients and can become more of a problem during recurrent chest infections. There has also been an increased number of reports of eating disorders and abnormal eating behavior in the CF population. In addition, polypharmacy, repeated exacerbations of CF, organomegaly, GI problems, food intolerance, and poor social circumstances can reduce oral intake.

### Increased Energy Requirements

Energy requirements are increased during periods of infection by catabolism and fever and continue to increase with advanced pulmonary disease. It has been estimated that CF patients require 120–150% of the estimated average requirement of energy. As pulmonary function deteriorates, mobility also decreases and, as a result, overall energy expenditure is reduced. Owing to the heterogeneity of CF, the energy requirements of individuals will vary and should be assessed on an individual basis. Energy losses through sputum may also be significant in a patient with a marginal energy intake. Salbutamol, often used as a bronchodilator in CF, can increase basal metabolic rate.

**Figure 2** Interdependent factors that may give rise to progressive energy deficit as lung function deteriorates.

## Increased Energy Losses

Pancreatic changes are caused by the obstruction of small ducts with thick secretions and cell debris. Functional tissue becomes replaced with fibrotic tissue leading to pancreatic exocrine insufficiency when more than 90% of the normal structure of the pancreas is lost. Pancreatic insufficiency is the most common GI manifestation in CF, occurring in at least 95% of patients. The production of pancreatic secretions, including enzymes and bicarbonate, is reduced, necessitating pancreatic enzyme replacement therapy (PERT). PERT is supplied in the form of gelatin capsules containing microspheres, which are swallowed whole with food. The capsule dissolves within the stomach and releases the microspheres, which are protected from the gastric acid by an enteric coating. Enzymes should be taken immediately before or during a meal to maximize their efficacy. The microspheres mix with the stomach contents and pass through the pylorus into the duodenum where they become activated. Microspheres should be less than 1.5 mm in diameter to ensure that they leave the stomach with food. Fibrosis of the pancreas tends to be a progressive process, so increasing amounts of oral enzyme supplements are often required as patients get older. All people with CF have some level of pancreatic dysfunction but requirements of enzymes are variable and must be assessed individually. Clinically, the aim of PERT is to correct symptomatic steatorrhea, relieve any abdominal pain, reduce the mass and frequency of stool passed, and achieve weight gain within normal limits.

The enteric coating on enzyme supplements is designed to dissolve at pH 6, the optimal pH for pancreatic enzymatic action. Owing to the reduced production of bicarbonate and the resulting lower pH of the duodenum in patients with CF, the enteric coating of the enzyme may fail to dissolve so that the enzyme does not become activated at the absorptive surface of the small bowel. Increasing the duodenal pH by taking proton pump inhibitors may improve absorption. Changing the brand of enzyme may also improve absorption as dissolution characteristics of the enteric coating and proportions of enzymes contained within the microspheres vary. Patients should be dissuaded from chewing enzymes as this breaks the enteric coating and leads to deactivation in the acid medium of the stomach. Even with maximal PERT, it has been estimated that between 10% and 20% of ingested fat will be malabsorbed. Colonic strictures known as fibrosing colonopathy (FC) in CF populations receiving high-potency enzymes with a more concentrated dose of lipase and protease per capsule have been reported. The etiology of this FC remains unclear. Recently, it has been suggested that FC may be related to the presence of methacrylic acid copolymer coating present in some preparations rather than actual enzyme strength. Some adult patients continue to take high-dose enzymes and are advised to do so within recommended levels. The working group on PERT use recommends that no more than 10 000 units of lipase per kilogram body weight should be taken per day.

## Dietary Management of CF

Patients with CF are encouraged to consume a diet providing 150% of the recommended intake for age and sex. However, this is only a guideline, because in practice, the energy requirement for a patient with CF is that which maintains their ideal body weight when malabsorption has been controlled. Maximizing energy intake from everyday foods should be the initial step in the promotion of a high-energy diet. As fat is the most concentrated source of energy in the diet, liberal use of fat should be encouraged; this can best be achieved by recommending frequent consumption of high-fat meals and snacks, including confectionery, desserts, and cakes. PERT should be dosed accordingly.

## Dietary Supplements

The energy intake of many patients with CF is commonly suboptimal. Many patients find it difficult to eat sufficient food daily to attain or maintain their ideal body weight. During a respiratory exacerbation of CF, energy requirements are at a maximum, but appetite is often reduced. Dietary supplements in the form of sip feeds can be a useful adjunct to a high-energy diet. Care should be taken to ensure that supplements are used in addition to a diet and not as a substitute for normal foods.

## Enteral Feeding

When diet and oral dietary supplements are undesirable or ineffective and nutritional failure persists, i.e., BMI lower than  $18.5 \text{ kg m}^{-2}$ , enteral feeding should be considered. Research has demonstrated a sustained weight gain and a slowing decline in respiratory function associated with supplemental enteral feeding. Artificial nutritional support can be provided via nasogastric or gastrostomy tube depending on patient's preference. Gastrostomy feeding is becoming more popular, whether passed endoscopically or under fluoroscopic guidance. The introduction of low-profile gastrostomy feeding tubes or 'button' tubes have made this method of nutritional support more acceptable to patients. The type of feed used and the PERT given with it varies between centers. Feeds are usually administered overnight in an attempt to provide 30–50% of energy requirements and to allow for maximal oral intake during the day. Gastrostomy feeds can be used over longer periods during acute pulmonary infection, loss of appetite, or in a severely malnourished patient. Patients with a history of poor intake should be monitored for refeeding syndrome.

## Specific Dietary Considerations

There are some medical complications of CF that warrant particular nutritional attention.

### Liver Disease

Patients with liver disease as a complication of their CF may have ascites, gastric, or esophageal varices, all of which may affect nutritional status and options for nutritional support. Dietary management of the patient with CF and liver disease centers on maximizing energy intake and is best achieved by encouraging small, frequent, energy-dense meals, snacks, and drinks. Suboptimal oral intake can arise in patients with hepatomegaly or splenomegaly, who often have a feeling of fullness after eating, 'a condition' referred to as the 'small stomach syndrome.' The benefits of gastrostomy insertion should be carefully weighed in a patient with gastric varices or splenomegaly due to risk of bleeding. A moderate sodium restriction may alleviate ascites. If coagulation is impaired, supplementation with vitamin K may be indicated.

Treatment of liver disease in CF is with ursodeoxycholic acid, which has a positive effect on liver enzymes. Whether this improvement is associated with improvement in nutritional status is unknown.

### CF-Related Diabetes Mellitus

The dietary treatment of CFRD varies from standard diabetic dietary advice. The principle of the diet centers on maintaining caloric intake while ensuring glycemic control. The treatment of CFRD should enhance rather than impair a patient's nutritional status. This is done by encouraging a high-fat diet and confining the intake of refined carbohydrate to mealtimes. Insulin doses should be increased so as to maximize the flexibility of the diet, particularly in those patients who are already nutritionally compromised. Patients taking oral nutritional supplements and/or overnight gastrostomy feeds need to have their insulin doses carefully monitored and adjusted accordingly.

### Bone Disease in CF

Osteopenia and osteoporosis are now widely recognized in the CF population. There are a number of contributing factors to this early development of bone disease, including steroid usage; malabsorption of calcium and, more importantly, vitamin D; poor nutritional status; decreased levels of physical activity; and a reduced peak bone mass in CF patients compared with healthy individuals. Assessment of bone health is by dual-energy X-ray absorptiometry scanning and there are a variety of treatment options available depending on the severity of disease ranging from dietary calcium and vitamin D supplementation to the use of bisphosphonate drugs, which aim to halt the progression of bone loss and promote bone formation.

### Fertility Issues

As the number of people with CF of a reproductive age increases, so does the incidence of pregnancy in this group. Although almost all males with CF are infertile owing to the absence of the vas deferens, most females are fertile. Pregnancy in women with CF requires special nutritional attention with regular monitoring, particularly with respect to adequate weight gain, and vitamin and mineral status.

### Body Composition Studies in CF

Studies of body composition in CF patients have shown deficits in total body mass, lean body mass, and body fat, which affect body density. As skinfold thickness percentiles are derived from body density, it has been suggested that the assessment of the body fat content of children with CF using, or derived from, body density, such as skinfold thickness, is invalid. Muscle function indices have been shown to respond to refeeding in malnourished patients with CF before body composition or biochemical indices of protein status improved, and so appear to be sensitive markers of nutritional status.

### Assessment of Nutritional Status

Malnutrition in CF remains a major clinical problem. Growth and nutritional status should be monitored at each clinic visit to ensure early detection of any deterioration and to prompt appropriate nutritional intervention. The many factors that complicate nutritional status in CF are shown in [Table 2](#).

When weight falls to a BMI of less than  $18.5 \text{ kg m}^{-2}$ , nocturnal enteral feeding should be considered. At diagnosis and when the patient shows clinical deterioration, the following should be determined: electrolytes, serum albumin and other liver function tests, oral glucose tolerance test, full blood count, serum retinol, and  $\alpha$ -tocopherol. If there is any evidence of iron deficiency, iron status

**Table 2** Factors affecting nutritional status

- 
- Variation in gene mutation
  - Frequency of pulmonary exacerbations
  - Gastroesophageal reflux
  - Distal intestinal obstruction syndrome
  - Pancreatitis
  - Liver disease
  - Diabetes mellitus
  - Drug therapy
  - Dietary dislikes and misconceptions
  - Psychological problems/eating disorders
  - Pregnancy
  - Transplantation
- 

should be assessed. Other medical disorders should be considered in the evaluation of nutritional failure. These include diabetes mellitus, liver disease, Crohn's disease, celiac disease, chronic abdominal pain, DIOS, and esophagitis.

## Vitamin Status in CF

At least 85% of CF patients have some level of pancreatic insufficiency leading to a degree of fat malabsorption. For this reason, unless supplemented, most patients are at risk of developing either clinical or subclinical deficiencies of the fat-soluble vitamins, vitamin A, D, E, and K. Those most at risk appear to be individuals with poorly controlled malabsorption, poor adherence to treatment, liver disease, bowel resection, or following a late diagnosis.

### Vitamin A

Vitamin A should be supplemented at a dose of 4000–10 000 IU day<sup>-1</sup>. However, low-serum levels of retinol have been noted even at this dose. If retinol levels are persistently low despite adequate supplementation, an assessment of compliance, retinol-binding protein (RBP), and zinc levels should be checked. Special care should be given to vitamin A supplementation during pregnancy as high levels are reported to be teratogenic.

It is important to consider hepatotoxicity with large supplemental doses of vitamin A in a patient who may store vitamin A in the liver, yet shows low-serum levels of retinol, and who may display ocular signs of deficiency. The free alcohol retinol is almost entirely attached to RBP, which is synthesized in the liver. Decreased levels of RBP, which may occur in up to 25% of patients with CF, may be due to an abnormality in its production by the liver, zinc deficiency, or protein–energy malnutrition. Even with adequate vitamin supplementation and PERT, up to 20% of patients may have ocular signs of deficiency of retinol. Xerosis may improve by increasing the dose of vitamin A alone or combined with zinc. It has been suggested that there may exist a specific defect in the handling of retinol in the GI tract of people with CF unrelated to the level of fat malabsorption. A correlation has been demonstrated between low levels of vitamin A and poor lung function.

### β-Carotene

β-carotene is one of the carotinoids present in plasma and a precursor of vitamin A. It is effective as an antioxidant at lower oxygen saturation states than vitamin E. It has a biological role as a lipid-soluble chain-breaking antioxidant in biomembranes. Routine supplementation with β-carotene could diminish lipid peroxidation and improve essential fatty acid status.

### Vitamin D

Vitamin D deficiency may be caused by malabsorption, underexposure to sunlight, or defects in metabolism due to liver disease. Although skin exposure to sunlight is the major source of vitamin D, serum concentrations will vary between individuals depending on endogenous production in the skin. Rickets as a result of vitamin D deficiency is rare but has been described in CF patients. Osteopenia and retarded bone maturation have been reported in a number of CF patients, even with supplementation to recommended levels. Bone density has been shown to be significantly decreased in all sites compared with that of normal young adults. Other variables such as activity levels and nutritional status have not been adequately researched, although the incidence of osteoporosis was found to be higher in those patients with severe respiratory disease. To attain and maintain normal serum levels, a daily dose of 400–2000 IU is generally required in adults.

## Vitamin E

Cholestasis and a reduced enterohepatic circulation of bile acids contribute to the malabsorption of fat-soluble vitamins from the small intestine. Vitamin E is highly lipophilic and its deficiency correlates with a degree of fat malabsorption. Subclinical neuroelectrophysiological abnormalities are already present in approximately 40% of patients by 2 months of age. Neurological signs of vitamin E deficiency are responsive to supplementation if initiated early, but are irreversible if treatment starts after the neurological lesions are present. As circulating  $\alpha$ -tocopherol is transported in the blood attached to lipid, it should be expressed as a ratio to total lipid to be correctly interpreted. Current recommendations are to monitor serum vitamin E levels annually and adjust supplementation accordingly. A daily dose of 400 IU day<sup>-1</sup> should achieve normal serum levels in adults.

## Vitamin K

A review of the literature providing conflicting opinions in the area of routine supplementation of vitamin K as the prevalence of vitamin K deficiency has not been established. Theoretically, the risk factors for patients developing vitamin K deficiency are pancreatic insufficiency, severe liver disease, extensive small bowel resection, and chronic broad-spectrum antibiotic use. Monitoring the coagulation system is advised, as vitamin K estimations are not generally routinely available. It seems prudent to prescribe vitamin K supplements to patients with the above-mentioned risk factors. Vitamin K has recently been shown to play an important role in bone health. There are no specific guidelines on supplementation, but doses of 5–10 mg appear to be a prudent guide. Annual monitoring of fat-soluble vitamin levels should be carried out and doses of vitamins altered as appropriate.

## Water-Soluble Vitamins

Supplementation with water-soluble vitamins is, in general, thought to be unnecessary in CF. In cases where dietary intake is poor or unbalanced, supplementation of vitamin C is advised. Supplementation with other water-soluble vitamins is not routinely recommended.

## Mineral Status in CF

Fat malabsorption can lead to the formation of insoluble fatty acid complexes with minerals in the gut, leading to a reduction in their absorption. CF may also be associated with intestinal mucosal defects, which may further retard the absorption of nutrients. Suboptimal levels of zinc, selenium, manganese, and iron have all been described in CF. Routine iron supplementation is not recommended as it has been suggested that *Pseudomonas aeruginosa* grows in tissues with a high concentration of iron. In addition, levels of iron may be suppressed as a normal body response in times of infection, and attempting to correct this is potentially harmful. Sodium and chloride do not need to be supplemented unless in very hot climates or during excessive exercise.

## The Oxidant/Antioxidant Imbalance in CF Patients

Patients with CF frequently exhibit increased oxygen free radical generation from activated neutrophils due to chronic lung inflammation. This, coupled with antioxidant deficiencies due to exocrine pancreatic insufficiency, results in an oxidant/antioxidant imbalance. Consequently, free radical attack on unsaturated fatty acids of lipid structures occurs leading to lipid peroxidation. An efficient antioxidant supply is suggested to control tissue damage by restoring the oxidant/antioxidant balance.

## Conclusions

There is a complex relationship between physiological, environmental, and genetic variables leading to a great variability in energy requirements among individuals with CF. Despite advances in the treatment of CF, the need for good nutritional strategies in CF will continue. Individually tailored nutritional advice for each patient with CF by a dietitian experienced in the area of CF is essential.

## Key points

- Understand the physiology of body water balance and pathophysiology of dehydration.
- Recognize the different clinical and laboratory abnormalities in isotonic, hypotonic, and hypertonic dehydration.
- Know how to manage dehydration.

## Glossary

**Hyper/hypotonic** Increased/decreased concentration of solutes (most typically sodium) in the blood

**Hypo/hyponatremia** Low/high plasma sodium concentration

**Osmolality** A measure of solute content in the blood. Dehydration tends to raise blood osmolality

**Tonicity** Measure of the osmotic pressure gradient between two solutions

## Introduction

Water is essential for the maintenance of life. As part of regular homeostasis, body water is lost mainly through the kidneys as urine but also through skin, lungs and the gastrointestinal tract. Dehydration results when water losses from the body exceed water replacement. It implies loss of water from both extracellular (intravascular and interstitial) and intracellular spaces. Dehydration alters circulatory hemodynamics and may result in disruption of the delicate electrolyte and acid-base balance needed to maintain healthy cells and tissues. The most common causes of dehydration result in both salt and water loss from the extracellular space of

which diarrheal diseases are the primary example, in contrast, pure water loss occurs due to conditions resulting in excessive sweating or in kidney diseases like diabetes insipidus, resulting in intracellular water loss. Management of dehydration depends on the severity and the precipitating medical conditions. In mild-to-moderate cases, oral rehydration with adequate fluid solutions may be sufficient. In severe cases, or when gastrointestinal function is severely impaired, intravenous fluids may be required, along with appropriate electrolyte replacement.

## Physiology of water balance

After oxygen, water is the most essential nutrient needed to sustain human life and it is responsible for connecting the diverse physiological functions of the body, some of which are shown in [Table 1](#).

### Distribution of water in the body spaces

Water is distributed across various fluid compartments in the body. For the average 70 kg man, 60% of the total body weight is comprised of water, equaling 42 L. The average adult woman is made up of 55% water because women naturally have more fatty tissue than men. The body's fluid separates into two main compartments: Intracellular fluid (ICF) and extracellular fluid (ECF). Using the average man as an example, of the 42 L of water found in the body, two-thirds of it is within the intracellular space, which equates to 28 L, forming the ICF. The ECF, which makes up one-third of the total body water, equivalent to 14 L is comprised of two components: the interstitial fluid (ISF), three-fourth of the ECF or 10.5 L and plasma volume (PV), one-fourth of the ECF or 3.5 L. Representational image is shown in [Fig. 1](#).

### Kidney and body fluid balance

The maintenance of the osmolality of body fluids within a narrow physiologic range is made possible by homeostatic mechanisms that control the intake and excretion of water. Significant fluctuations of solute and water intake fail to disrupt the total solute concentration of body fluids which remains virtually constant and the serum osmolality is maintained between the physiological range of 285–290 mOsm kg<sup>-1</sup> H<sub>2</sub>O. In a normal adult, approximately 130 L–180 L of fluid are filtered across the glomerular capillaries each day. More than 98%–99% of the filtrate is then reabsorbed by the tubules, resulting in a urine output averaging 1–2 L day<sup>-1</sup>. Urine volume can be as little as 0.5 L day<sup>-1</sup> during water deprivation to 20 L day<sup>-1</sup> during water loading ([Nielsen et al., 2007](#)).

Volume and electrolyte changes in response to decreased blood water content (increased osmolality) trigger the hypothalamus to stimulate arginine vasopressin (AVP) release from the posterior lobe of the pituitary gland. AVP acts on the kidney to increase tubular water resorption and maintain plasma volume. Decreased plasma volume also results in a complex series of events resulting in the release of renin from the kidneys and the subsequent formation of angiotensin II and the mineralocorticoid, aldosterone. Angiotensin II is a potent vasoconstrictor and stimulator of thirst. The osmotic threshold for thirst usually occurs at 290–295 mOsm kg<sup>-1</sup> H<sub>2</sub>O and is above the threshold for AVP release. Aldosterone promotes sodium resorption, which allows the blood to retain more water. AVP also increases distal nephron reabsorption of urea and its recycling to improve the efficiency of water reabsorption. The net result of these regulatory mechanisms is concentrated urine and maintenance of the plasma volume, provided that exogenous fluid intake increases proportionally. If fluid intake is not increased, dehydration will result ([Fig. 2](#)).

### Gastrointestinal tract and body fluid balance

In an adult, during a normal day, 8000 mL of fluid enters the small bowel; 500 mL as saliva, 1200 mL as gastric fluid, 600 mL as bile, 1200 mL as pancreatic juice, 2000 mL as small bowel secretion, and the remainder as ingested fluid. Almost 1.5 L is reabsorbed in the small intestine, and 1.4 L is reabsorbed in the colon. Only 100 mL is normally lost in the feces per day. With gastrointestinal diseases like vomiting or diarrhea, large volumes of water and electrolytes may be lost to the outside or, in the case of intestinal obstruction or ileus, pooled in the gut and lost to the functional compartments.

**Table 1** Major physiological functions of water.

Function	Example
Waste product removal	Excretion by kidneys
Solvent for chemical reactions	Glycolysis in the cell cytosol
Transport medium	Blood
Lubrication	Synovial fluid of joints
Shock absorber	Disks between vertebrae of spinal column
Temperature regulation	Evaporative sweat loss

**Fig. 1** Distribution of body fluids.

**Fig. 2** Water and sodium physiology: mechanisms controlling body water gain and loss. As water is lost from the body via sweat, urine, respiration, and feces: (1) Plasma osmolality increases and plasma volume decreases with water loss. (2) The increase in osmolality acts on the “thirst center” in the hypothalamus to secrete AVP and stimulates the conscious desire for water. (3) The release of AVP from the pituitary gland increases tubular resorption of water by the kidney. (4) Aldosterone is formed via a series of reactions involving renin, which is released from the adrenal cortex in response to decreased blood pressure, and a plasma protein, angiotensinogen. Aldosterone promotes sodium resorption by the kidney to maintain plasma volume. (5) These events conserve water and result in the production of concentrated urine.

### Sweat and thermoregulation

Water absorbs heat produced at the cellular level and transfers it to the surface of the skin, where it can be dissipated to the external environment. Approximately 500 mL of sweat is lost per day under average ambient environmental conditions. Such obligatory water loss occurs without visible or tactile sensations and is termed “insensible” sweat. However, given a sufficient thermal challenge, humans are capable of producing approximately 10 L of “sensible” sweat per day. Sweat is hypotonic (sodium concentration 15–65 mmol L<sup>-1</sup>).

### Respiration related water loss

Insensible loss from the respiratory tract is also about  $400 \text{ mL day}^{-1}$  in an unstressed adult. The water loss here is variable: it is increased if minute ventilation increases and can be decreased if inspired gas is fully humidified at a temperature of  $37^\circ\text{C}$  (Newburgh and Johnston, 1942).

In summary, under normal physiological conditions, the body is able to regulate its water content tightly over a 24 h period (approximately  $\pm 200 \text{ mL}$ ) with the help of various feedback mechanisms (Fig. 3).

### Pathophysiology of dehydration

Dehydration explicitly refers to the loss of total body water producing hypertonicity but it is often used interchangeably with volume depletion, which refers to a deficit in extracellular fluid volume. The distinction between these two conditions is important as it will determine the type of fluids used for treatment.

### Tonicity and osmolality

Tonicity i.e., the measure of the osmotic pressure gradient between two solutions, is a physiologic term that refers to the volume of cells in a solution; cell volume tends to expand as body fluids become hypotonic or shrink as surrounding fluids become hypertonic.

Hypertonicity usually results from a disproportionate fall in total body water relative to total body sodium producing hypernatremia. With pure water loss, extracellular tonicity rises and draws fluid from the intracellular compartment. Hypertonicity thus results in intracellular volume contraction, while volume depletion results in blood volume contraction. Neurons are particularly sensitive to hypertonicity. Extreme pure water losses resulting in serum  $\text{Na}^+ > 170 \text{ mEq L}^{-1}$  cause hemodynamic alterations but significant neurologic manifestations become apparent much before this level is reached (Bhave and Neilson, 2011).

The homeostatic response to hypertonicity is AVP-mediated urinary water conservation and stimulation of thirst seeking water. AVP release and thirst are much more sensitive to hypertonicity compared to hypovolemia (Stricker, 2004). Decreased urine output is evident early in hypertonicity ( $< 5\%$  increase over set point), while appearing late in hypovolemia as deficits of at least 10% of the blood volume are required to stimulate AVP release and raise urine osmolality.

Osmolality depends upon only the total solute concentration, while tonicity is determined by how it affects cell volume, which depends not only on the solute concentration but also on the solute permeability of cell membranes. Plasma osmolality can be easily determined by directly measuring or can be calculated from the formula: Plasma osmolality =  $2 \times \text{Na} + \text{Glucose (mg dL}^{-1})/18 + \text{BUN (mg dL}^{-1})/2.8$ . The effective plasma osmolality is determined by those solutes in the plasma which do not freely permeate the cell wall and act to hold water within the ECF. So, lipid soluble solutes such as urea which can cross the cell membrane do not contribute to the osmotic pressure gradient between ECF and ICF. Effective osmolality =  $2 \times \text{Na (mEq L}^{-1}) + \text{Glucose (mg dL}^{-1})/18 \text{ (mOsm Kg}^{-1})$ .

Normal serum osmolality is  $285\text{--}295 \text{ mOsm kg}^{-1} \text{ H}_2\text{O}$ . Serum Osmolality  $> 295 \text{ mOsm kg}^{-1} \text{ H}_2\text{O}$  can be considered to suggest impending dehydration. Pure water losing dehydration results in an elevated serum osmolality.

Fig. 3 Fluid intake and loss over 24 h.

## Blood volume

Fluid lost via the gastrointestinal tract, renal or via third spacing into the interstitial space is usually slow enough to draw from the ECF compartment although initially the fluid is derived from the plasma volume. Acute hemorrhagic fluid loss is mostly derived from the plasma volume. When net fluid loss is isotonic, it draws completely from the ECF and thus the volume of fluid loss exactly equals the volume deficit. Changes in heart rate or blood pressure do not become evident in normal subjects until 15–20% of blood volume is removed acutely (Knopp et al., 1980). Assuming a 15% fall in blood volume as a minimal threshold for clinically detectable volume depletion, a non-hemorrhagic, isotonic loss of about 15% of ECF amounting to 7% of total body water is required. In contrast, a pure water deficit equivalent to 15% of total body water is needed to reach the same hemodynamic threshold. Consequently, isotonic losses are about 2-fold more potent than pure water losses at depleting blood volume. Isotonic losses alter systemic hemodynamics, reduce blood volume and GFR, and leave body tonicity unchanged. Conversely, an equivalent pure water deficit does not measurably alter blood volume or GFR, while hyponatremia and hypertonicity are prominent.

## Dehydration and heat illness

Dehydration also adversely affects the body's ability to regulate temperature. If water loss due to sweating is not replaced during exercise, plasma volume and sweat rate will be decreased (Fig. 4). The combination of reduced peripheral blood flow for heat exchange and reduced sweat volume for evaporative cooling leads to an overall reduction in the ability to dissipate heat (Sawka et al., 2000).

The consequence of impaired heat dissipation is hyperthermia. Without evaporative cooling, human core temperatures can elevate  $5^{\circ}\text{C h}^{-1}$  during moderate intensity work. The heat production is proportional to the intensity and duration of work, ranging from  $75\text{ kcal h}^{-1}$  (314 kJ) at rest to  $300\text{ kcal h}^{-1}$  (1256 kJ) during moderate exercise and  $600\text{ kcal h}^{-1}$  (2512 kJ) for maximal sustained work. Brief periods of intense exercise can generate heat at the rate of  $900\text{ kcal h}^{-1}$  (3768 kJ).

Hyperthermia can lead to serious or even life-threatening heat injury if left unchecked. Heat injury can result if the rate of heat production is greater than the rate of cooling. When fluid losses are not replaced during activity, heat dissipation mechanisms are compromised. The buildup of heat in blood and tissues adversely affects various physiological systems. Minor heat injury syndromes include prickly heat (skin rash resulting from plugged sweat glands), heat syncope (light headedness due to pooling of blood in the extremities), and heat cramps (muscle cramps related to electrolyte loss). These heat illnesses are of concern but not life-threatening. Major hyperthermia syndromes involving dehydration are heat exhaustion which can progress to life threatening heat stroke that requires immediate medical treatment (Cheshire, 2016).

**Fig. 4** The influence of water loss by dehydration (hypohydration) on the sweating response to exercise following normal hydration (0%) and dehydration equal to 3%, 5%, and 7% of the body weight. The primary stimulus for sweating is the increase in core temperature (thermal drive). Note that dehydration reduces the sweating rate at any given level of thermal drive. Hypohydration compromises exercise by reducing sweat rate and evaporative cooling and increasing body core temperature. Reproduced from Sawka, M.N., Young, A.J., Francesconi, R.P., et al., 1985. Thermoregulatory and blood responses during exercise at graded hypohydration levels. *J. Appl. Physiol.* 59: 1394–1401, with permission from APS.

## Groups at risk for dehydration

### Infants and children

According to the WHO, diarrheal disease is the second leading cause of death in children under 5 years old, and is responsible for killing around 525,000 children every year. Infants and young children are especially vulnerable because they lack the ability to convey their thirst to caregivers or to access fluids on their own. They also have increased insensible losses due to a higher body surface area.

### Old age

With aging, there is a decline in total body water, in both the extracellular and intracellular fluid volume. There is also decreased fluid intake related to decreased thirst due to a higher osmotic operating point (the point at which the thirst sensation is triggered). Aging is also associated with a reduced glomerular filtration rate, increased proximal tubular renal absorption and a decline in maximal tubular fluid concentrating ability (Thomas et al., 2008).

The normal nocturnal rise that occurs with AVP is blunted with aging resulting in nocturia. These physiological changes that occur with aging place older persons at major risk for dehydration.

Certain behavioral factors may also influence drinking patterns in older adults who may wish to avoid the physical difficulty associated with trips to the bathroom. Dehydration also alters the effective dosage of medications through plasma volume changes, leading to further medical complications in the elderly. Dehydration in the elderly often accompanies or results from clinical conditions and/or medications.

### People who work or exercise outside

When the weather is hot and humid, risk of dehydration and heat illness increases. When the air is humid, sweat can't evaporate and cool as quickly as it normally does, and this can lead to an increased body temperature and the need for more fluids.

### Predisposing factors for dehydration and heat illness

Obesity (extra exertion, heat production, and sweating are required to move a larger mass), insufficient heat acclimation (associated with reduced sweating and evaporative cooling and increased cardiovascular and renal stress), socioeconomic barriers to cooling methods (fans, air conditioners, etc.), pyrexial illness (fever), drug and alcohol abuse (interferes with fluid balance and thermoregulation), physical work in environments that contribute to dehydration (heat: sweating; cold: respiratory water loss and diuresis; altitude: respiratory water loss and diuresis), and athletic competition and training (if athletes do not replace sweat loss).

### Identifying types of dehydration

Dehydration usually occurs along a continuum of fluid and electrolyte loss. The ratio of water to electrolyte loss determines the type of dehydration present. A classification of the types of dehydration, their characteristics and likely causes is shown in [Table 2](#).

### Clinical features and diagnosis

Thirst is not a good short-term regulator of fluid balance. Humans frequently lose up to 2% of their body weight as water before the thirst mechanism is activated but one of the first symptoms of dehydration is thirst. Mild dehydration can also cause dry mouth, headaches, tiredness, lack of energy and feeling faint on standing up. Another early sign of dehydration is urine that is darker yellow in color than usual. Monitoring the urine color has been suggested as a noninvasive way to measure hydration status, where light, pale yellow urine generally indicates a favorable hydration status. Assessing urine color may be a simple method to assess hydration status, but it can also be artificially influenced by dietary intake (i.e., nutritional supplements). Moderate dehydration results in dizziness, muscle cramps, pale and dry skin, and sunken eyes. Severe dehydration results in confusion or disorientation.

In common with most diagnoses, that of dehydration depends mainly on the history and examination. A detailed history of fever, diarrhea (duration, frequency, consistency, presence or absence of mucus or blood), vomiting (duration, frequency, consistency), medication history (e.g., recent antibiotic use, diuretics, laxatives); exposure to heat and/or cold; weight loss; and potential ingestions (e.g., drugs) should be taken.

Physical examination findings, although frequently nonspecific, may help support a diagnosis of dehydration and include: altered mental status, decreased capillary refill, decreased skin turgor which is tested on inner aspect of thighs or the skin overlying the sternum, and is less reliable in older patients due to decreased skin elasticity with age, dry mucous membranes of the tongue and oral mucosa, orthostatic hypotension, which is determined by taking supine blood pressure after the patient is lying for 5–10 min, and then taking the blood pressure as soon as the patient sits or stands up, and again in this position after two to 3 min. A drop in systolic blood pressure  $\geq 20$  mm Hg or a drop in diastolic blood pressure  $\geq 10$  mm Hg from supine indicates orthostatic hypertension.

**Table 2** Types of dehydration.**Hypertonic dehydration**

Water loss exceeds salt loss e.g., inadequate water intake, fever, excessive sweating, osmotic diuresis and diuretic drugs

There is osmotic shift of water from the ICF to the ECF

Elevated blood osmolality and hypernatremia may be seen

Symptoms include thick, doughy texture to skin (tenting is uncommon), tachypnea, intense thirst

**Isotonic dehydration**

Isotonic loss of both water and solutes from the extracellular fluid (ECF) e.g., vomiting, diarrhea or inadequate intake

No osmotic water shift from the ICF to the ECF

Blood electrolytes usually normal

**Hypotonic dehydration**

Sodium loss is higher than water loss e.g., in some instances of high sweat or gastro-intestinal fluid losses or when fluid and electrolyte deficits are treated with water replacement only

Characterized by an osmotic shift of water from the ECF to the ICF

Lethargy and irritability are common and vascular collapse can occur early

Laboratory testing for mild dehydration is not usually necessary, especially when the underlying cause is apparent. For moderate to severe cases of dehydration, blood investigations including complete blood count, electrolytes, blood urea nitrogen, creatinine, acid-base status, glucose, and urinalysis (specific gravity, hematuria, glucosuria) may be considered. Measurements of plasma osmolality and urine-specific gravity and osmolality can be used to assess the relative dehydration if baseline (euhydrated) values are known. However, due to significant interindividual variation, the use of absolute specific gravity and osmolality values for the diagnosis of dehydration remains questionable. The plasma sodium concentration gives no clue to the total body sodium content, unless water balance is also known. It merely reflects the relative proportion of sodium and water in the extracellular space. Thus, with pure water deficit, the plasma sodium concentration increases. With a mixed deficit of sodium and water, the plasma sodium reflects the relative proportion of the two that are lost. Sodium levels in moderate-to-severe dehydration are useful to determine the type and speed of fluid repletion. An acute change in body weight is the most common and practical method used to assess hydration status. It is assumed that the short-term body weight loss is primarily the result of water loss.

The history and physical examination combined with a knowledge of the natural history of the presenting condition, provides the main clues to the presence of salt and/or water depletion, the likely evolution of the condition and the necessary treatment.

**Table 3** gives the American Academy of Pediatrics guidelines for the assessment of dehydration in children ([American Academy of Pediatrics Provisional Committee on Quality Improvement, 1996](#)).

## Management of dehydration

### Goals of treatment

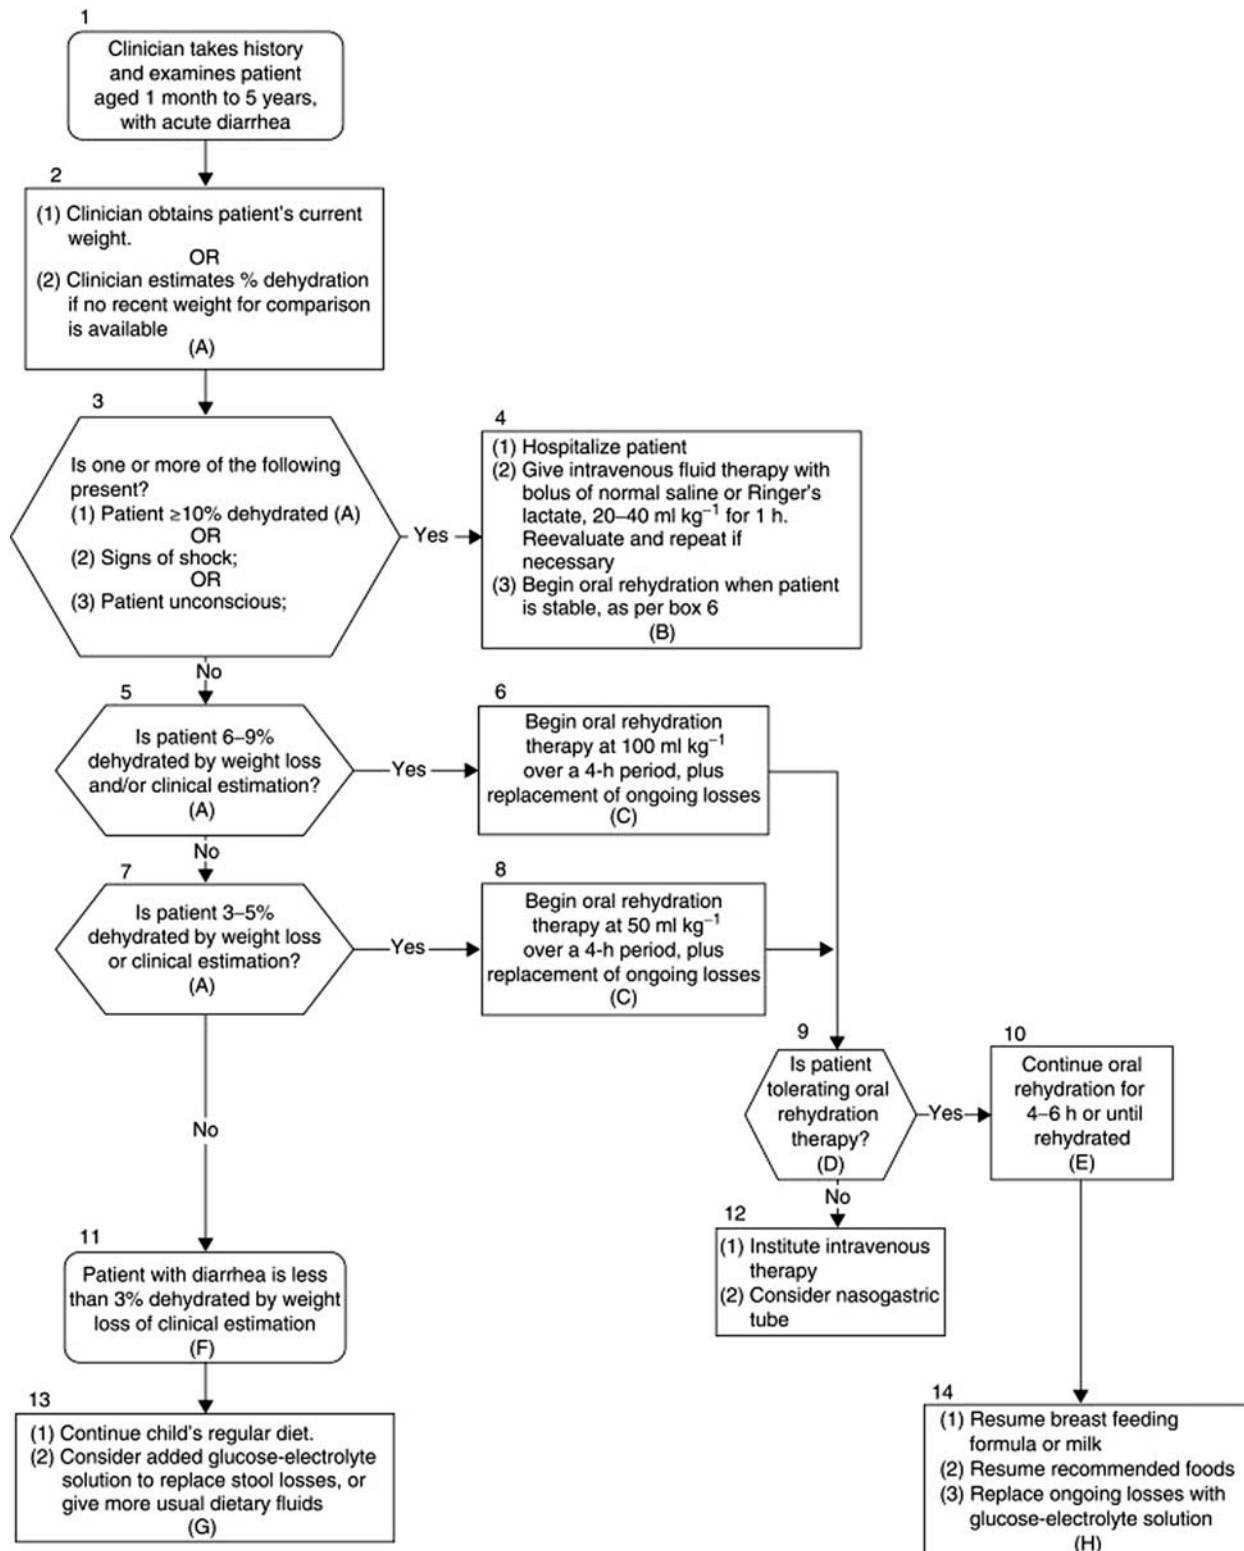

The primary goals of immediate treatment are to estimate the fluid and/or electrolyte deficit, rehydrate the patient at the earliest which involves, replacement of fluid and electrolyte deficits, maintenance needs and ongoing fluid losses.

The American Academy of Pediatrics has published guidelines for oral rehydration therapy of infants and children younger than 5 years old with acute gastroenteritis. An algorithm for the treatment and hydration of children with acute diarrhea is shown in [Fig. 5](#).

**Table 3** Guidelines for the assessment of dehydration.<sup>a</sup>

Variable	Dehydration		
	Mild, 3–5%	Moderate, 6–9%	Severe, ≥10%
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Moderately decreased
Heart rate	Normal	Increased	Increased, severe cases bradycardia
Skin turgor	Normal	Decreased	Decreased
Fontanel	Normal	Sunken	Sunken
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits	Deeply sunken orbits
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Urine output	Slightly decreased	<1 mL kg <sup>-1</sup> h <sup>-1</sup>	≤1 mL kg <sup>-1</sup> h <sup>-1</sup>
Thirst	Slightly increased	Moderately increased	Very thirsty or too lethargic to indicate

<sup>a</sup>The percentages of body weight loss and their corresponding categorization sometimes vary depending on the author.

**Fig. 5** Algorithm for children with dehydration from acute diarrheal disease. The letters at the bottom of the decision boxes refer to the following: (A) See Table 3 for guidance in the assessment of the degree of dehydration. (B) Restoration of cardiovascular stability is critical and is accomplished by giving bolus i.v. therapy. In the patient who does not respond, consider the possibility of an underlying disorder. When the patient is in a stable condition and has achieved satisfactory mental status, oral rehydration therapy (ORT) can be implemented. (C) Solutions containing 45–90 mmol L<sup>-1</sup> sodium should be given in a volume of 100 mL kg<sup>-1</sup> for moderate dehydration and 50 mL kg<sup>-1</sup> for mild dehydration. Giving the child these volumes requires patience and persistence, and progress must be monitored frequently. (D) Intractable, severe vomiting, unconsciousness, and ileus are contraindications to ORT. Persistent refusal to drink may require a trial of i.v. therapy. (E) The rehydration phase usually can be completed

### Treating different types of dehydration

In the majority of simple, mild dehydration cases, plain water is an adequate rehydration solution. However, there are instances (e.g., children younger than 5 years of age dehydrated by vomiting and diarrhea) when water containing sodium and potassium is the proper hydrating agent. The most effective way of preventing and treating mild to moderate dehydration in infants and children with acute diarrhea is the oral administration of oral rehydration solutions (ORSs). An oral rehydration solution can be made at home with table salt and sugar using the following ingredients, 1/2 teaspoon of salt, 6 teaspoons of sugar, 4 cups (1 L) of water. There are also a number of commercially available ORSs. These solutions are designed to replace fluid and electrolytes when both the water and food intake have been restricted or compromised by diarrheal disease. The World Health Organization recommends the ORS shown in [Table 4](#) for individuals afflicted with diarrheal disease and vomiting. Oral modes of fluid and electrolyte administration are always preferred in mild (3–5%) to moderate (6–9%) dehydration; however, intravenous fluids may be required in cases of severe dehydration ( $\geq 10\%$ ) and vomiting or if the patient is in a comatose state. When i.v. fluids are administered, 0.45% saline with 5% dextrose is an effective hydrating agent.

The Holliday-Segar calculation approximates daily fluid loss, therefore the daily maintenance fluid requirements for 24 h is as follows: 100 mL  $\text{kg}^{-1}$  for the first 10 kg of wt, 50 mL  $\text{kg}^{-1}$  for the second 10 kg of wt, 20 mL  $\text{kg}^{-1}$  for the remaining wt. The 24 h number is often divided into approximate hourly rates for convenience, leading to the “4-2-1” formula. 100 mL  $\text{kg}^{-1}$  24 h $^{-1}$  = 4 mL  $\text{kg}^{-1}$  h $^{-1}$  for the first 10 kg, 50 mL  $\text{kg}^{-1}$  24 h $^{-1}$  = 2 mL  $\text{kg}^{-1}$  h $^{-1}$  for the second 10 kg, 20 mL  $\text{kg}^{-1}$  24 h $^{-1}$  = 1 mL  $\text{kg}^{-1}$  h $^{-1}$  for the remainder. e.g., 70 kg patient would require 1500 mL plus 1000 mL for maintenance in a 24 h period). Add maintenance requirements plus replacement requirements for losses (vomiting, urine, etc.). A rough guide for adults is 200–400 mL for every loose stool, for children 200 mL per motion, and for infants 1–1.5 times the usual feed. If the patient is eating, calculate fluid replacement at 75% of total. If the patient is diagnosed with hypotonic or isotonic dehydration, calculate total fluids (maintenance plus replacement) for the first 24 h, and give half this amount over the next 8 h, and the other half over the next 16 h. In hypertonic dehydration, correct the fluid deficits slowly over 48 h ([Holliday and Segar, 1957](#)).

In most instances involving heavy sweating, plain water containing 1.25 g of NaCl L $^{-1}$  is a suitable rehydration solution. Increasing the concentration of NaCl to 5 or 6 g L $^{-1}$  may promote the rate of rehydration but may not be palatable for some individuals. Most commercial sports drinks contain 1.2–1.8 g NaCl L $^{-1}$  and are also good rehydration solutions, especially when both fluid and electrolytes have been lost through sweating. Fruit juices can also provide fluid, energy, and electrolytes (e.g., fresh orange juice contains approximately 10 mg of sodium and 2000 mg of potassium L $^{-1}$ ) but may be too concentrated and delay gastric emptying. Diluting fruit juices 1:3 with water may yield a more appropriate rehydration solution. The inclusion of carbohydrate in the rehydration solution provides energy for the intestinal sodium pump, which facilitates sodium transport across the intestinal cell wall into the blood, where it in turn exerts a positive osmotic effect on water absorption from the gut. Commonly used beverages, such as apple juice, tea, ginger ale, colas, and chicken broth, are inappropriate to use for rehydration because they do not contain the correct sodium and glucose ratio to promote salt and water reabsorption across the intestinal lumen. Glucose and electrolyte sports beverages are useful rehydration solutions for sporting activities but are not a good choice for children with diarrhea because these beverages have lower electrolyte and higher carbohydrate concentrations than recommended ([Wilk et al., 1998](#)).

### Prevention of dehydration

Dehydration resulting from non-disease causes can be easily prevented provided that people are inclined to drink and have access to cool, safe sources of fluids. Drink flavoring, beverage temperature, and sodium chloride content are important promoters of fluid intake in active children. Education of athletic coaches, the general public, and health care providers is necessary to increase awareness of the importance of proper hydration. The American College of Sports Medicine has issued a set of guidelines for fluid replacement ([Table 5](#)).

Simple methods, such as recording body weight before and after exercise to determine fluid loss and observing the color of urine or the turgidity of skin, can be useful for monitoring hydration status. The simplest insurance against dehydration is to consume fluids before and during physical activity or heat exposure to match water loss. The amount of fluid needed to maintain a favorable hydration status is variable between individuals but often necessitates drinking in the absence of thirst. Excess fluid consumption is rarely a problem. However, caution should be used to avoid dilutional hyponatremia from overzealous hydration. Humans can acclimate to work in a hot environment and enhance their ability to thermoregulate and conserve fluid, but they cannot adapt

in 4 h; reevaluation should occur every 1 or 2 h. See referenced text for guidance to decide when rehydration has been achieved. (F) The type and intensity of therapy will vary with the individual clinical situation. (G) Often, a child has diarrhea but remains adequately hydrated. The parent can be reassured but should be taught to assess hydration and to identify a worsening condition. If the stool output remains modest, ORT may not be required if early, age-appropriate feeding is instituted and increased consumption of usual dietary fluids is encouraged. More significant stool losses can be replaced with an oral rehydrating solution at the rate of 10 mL  $\text{kg}^{-1}$  for each stool. (H) Breast-feeding should be resumed. Nonlactose formula, milk-based formula, or milk may be given, although a small percentage of children will not tolerate lactose-containing fluids. Lactose-containing solutions seem to be tolerated better when combined with complex carbohydrates in weaned children. Children who are eating foods may resume eating, although certain foods are tolerated better than others. Recommended foods include complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruit, and vegetables. Avoid fatty foods and foods high in simple sugars (including juices and soft drinks). Supplement feeding with an oral electrolyte solution, 10 mL  $\text{kg}^{-1}$  for each diarrheal stool and the estimated amount vomited for each emesis.

**Table 4** Composition of recommended WHO/UNICEF oral rehydration solution.

<i>Solute</i>	<i>Content (mmol L<sup>-1</sup>)</i>
Glucose	75
Sodium	75
Chloride	65
Potassium	20
Citrate	10
Total osmolality	245

**Table 5** Fluid replacement: summary of recommendations of the American College of Sports Medicine.

It is recommended that individuals consume a nutritionally balanced diet and drink adequate fluids during the 24 h period before an event, especially during the period that includes the meal before exercise, to promote proper hydration before exercise or competition.

It is recommended that individuals drink approximately 500 mL of fluid approximately 2 h before exercise to promote adequate hydration and allow time for excretion of excess ingested water.

During exercise, athletes should start drinking early and at regular intervals in an attempt to consume fluids at a rate sufficient to replace all the water lost through sweating, or consume the maximal amount that can be tolerated.

During exercise lasting less than 1 h, there is little evidence of physiological or physical performance differences between consuming a carbohydrate–electrolyte drink and plain water.

Inclusion of sodium (0.5–0.7 g L<sup>-1</sup> of water) in the rehydration solution ingested during exercise lasting longer than 1 h is recommended since it may be advantageous in enhancing palatability, promoting fluid retention, and possibly preventing hyponatremia in certain individuals who drink excessive quantities of fluid. There is little physiological basis for the presence of sodium in an oral rehydration solution for enhancing intestinal water absorption as long as sodium is sufficiently available from the previous meal.

to dehydration. Acute dehydration can decrease physical performance and thermoregulation ability and increase the risk of heat illness. Chronic dehydration can reduce the metabolic and thermoregulatory efficiency and increase predisposition to kidney disease. The deleterious effects of dehydration on physiological function are summarized in Fig. 6.

## Conclusion

Dehydration is common in infants, children and elderly, especially following gastrointestinal illnesses. Oral rehydration can be safely and effectively accomplished in those with mild-to-moderate dehydration. Individuals with severe dehydration or with

**Fig. 6** Progressive physiological effects of dehydration on physical performance and pathophysiology of hypohydration. The onset, magnitude, and severity depend on the workload, level of physical fitness, ambient temperature, relative humidity, and degree of heat accumulation of the individual. abnormal serum sodium values should be treated with intravenous infusions. Early identification of the precipitating cause and determining the correct fluid and electrolyte solutions to meet the individual's maintenance, deficit and ongoing losses will help prevent serious complications. Prevention by adequate education is especially important in non-disease related dehydration in individuals at risk.

## Key points

- There is a global consensus for the diagnosis of diabetes.
- The definition/classification of prediabetes or intermediate hyperglycemia is not globally agreed.
- Newer data-driven, hypothesis free classification systems to discern diabetes heterogeneities are emerging.

## Introduction

Diabetes Mellitus is a debilitating and costly disease. Although pathogenic pathways to diabetes include defects in insulin action, pancreatic  $\beta$ -cell function, or both, destruction of or dysfunctional  $\beta$ -cell function is the culminating pathway that can lead to a metabolic imbalance responsible for the development of the disease. Because type 2 diabetes mellitus (T2DM) may be prevented or delayed with various prevention modalities, early and accurate identification of individuals at high-risk of developing diabetes at the prediabetes or intermediate hyperglycemia stage is crucial (Haw et al., 2017). In this article, the definition and classification of diabetes will be discussed, and various diagnostic criteria will be outlined. Subsequently, we will also summarize the heterogeneity of diabetes and novel data-driven approaches to decipher different diabetes subtypes.

## Definition

### Type 2 diabetes

Accurate diagnosis of diabetes with reliable and inexpensive tests for screening and early identification of T2D has historically been challenging. Figure depicts the evolution of diabetes diagnosis. The present diagnostic cut points for diabetes (fasting plasma glucose (FPG)  $> 7.0$  mmol/L (126 mg/dL), 2 h post oral glucose load (OGTT) plasma glucose (2 h PG)  $> 11.1$  mmol/L (200 mg/dL), or HbA1c  $> 6.5\%$  (48.0 mmol/mol)) are derived based on glycemic levels above which a substantially increased risk of

diabetes-associated microvascular complications is apparent, particularly diabetic retinopathy. These criteria exploit the observation that there appears to be a linear association between glycemia and diabetic complications, and there was a clear glycemic threshold separating persons at high and low-risk diabetic-specific retinopathy. An individual-level pooled analysis of cross-sectional data from nine studies from five countries with 44,623 participants aged 20–79 years with diabetes-specific retinopathy from DETECT-2 collaborators suggests that the current FPG level for diagnosis of diabetes should be lowered to 6.5 mmol/L (117 mg/dL) and that an HbA1c of 6.5% (48.0 mmol/mol) is a suitable alternative diagnostic criterion. Each assessment provides pivotal information about glucose metabolism and reflects different physiological mechanisms. The FPG reflects post-absorptive glucose homeostasis, while the 2 h PG primarily reflects the disposal of an exogenous glucose load. The HbA1c level strongly correlates with overall glycemia, reflecting the average glucose over 2–3 months. The FPG strongly correlates with HbA1c in the nondiabetic range as elevations in the FPG concentration are present throughout the day. In contrast, postprandial hyperglycemic excursions are transient, occurring 3–4 h after each meal, while 2 h PG is more strongly associated with elevations in HbA1c with increasing overall glycemia. Therefore, it is not surprising that the HbA1c has a stronger correlation with the FPG than the 2 h PG.

### Intermediate hyperglycemia/prediabetes

The development of T2DM is preceded by an intermediate prediabetic or hyperglycemia stage (impaired glucose tolerance (IGT) and impaired fasting glucose (IFG)) in which blood glucose level is elevated when compared to normal but is below diabetic thresholds. Prediabetes is a risk state that may last for several years and increases the risk of developing diabetes. However, it should be noted that only ~30–40% of those with prediabetes eventually develop T2DM. In a meta-analysis of prospective studies, when compared to normoglycemic individuals the relative risk for diabetes was: 5.52% in people with isolated IGT; 7.54% in people with isolated IFG and 12.13% in people with both IFG and IGT (combined glucose intolerance). In a separate study, prediabetes as identified by HbA1c criteria (5.7%–6.4%) identified lower proportion of individuals (20.4%) than FPG (30.2%) as high-risk for diabetes, the ability to predict progression to diabetes over 5-years was stronger for HbA1c than IFG criteria.

Identification of the prediabetic stage (IGT, IFG, or HbA1c) has been used to identify individuals with high risk for T2DM. Indeed, all the major landmark primary prevention studies that have evaluated intervention strategies for preventing T2DM have recruited individuals with IGT for assessing the benefits of intervention strategies (Haw et al., 2017). However, in large, prospective, epidemiological studies, only ~30–40% of the individuals with IGT/IFG develop overt T2DM eventually. Furthermore, ~40% of individuals who develop T2DM have normoglycemia at baseline. This limits the use of IGT/IFG as the sole means to identify individuals at high risk for T2DM.

### Diagnostic cut-points for diabetes diagnosis

#### Oral glucose tolerance test

For over a century, the oral glucose tolerance test (OGTT) has been the mainstay for the diagnosis of diabetes (Jagannathan et al., 2020). Over the years, there was substantial evolution in the conduct of OGTT with respect to the glucose loadings for testing (50, 75, or 100 g), using plasma glucose instead of whole/capillary blood, the timing and number of the sample (0, 30, 60, 90, 120 min) required for diagnosis, and the terminology for diagnosing dysglycaemia (e.g., prediabetes, intermediate hyperglycemia, chemical, borderline, subclinical, latent or overt diabetes). In 1980, the world health organization (WHO) endorsed global standardization of the OGTT with a 75 g glucose load which is still in practice (WHO Expert, 1980). Conversely, data from cross-sectional studies showed a strong association between FPG and 2 h PG values with diabetic-specific retinopathy, which led to a commonly agreed-upon protocol, endorsed by the US National Diabetes Data Group (NDDG) (National Diabetes Data Group, 1979) and the world health organization (WHO) (Report of the Expert, 1997) for the diagnosis of diabetes (FPG  $\geq$  7.8 mmol/L (140 mg/dL) and 2 h PG  $\geq$  11.1 mmol/L (200 mg/dL)) (Fig. 1).

#### Fasting plasma glucose

In the late 1960s, it was generally acknowledged that the FPG test was suboptimal for the diabetes diagnosis. Before 1997, diabetes was diagnosed based on FPG levels  $>7.8$  mmol/L (140 mg/dL), arbitrarily determined to represent the upper threshold of normal FPG. In 1997, the ADA Expert Committee revised the criteria by lowering the FPG cut-point from 7.8 mmol/L (140 mg/dL) to 7.0 mmol/L (126 mg/dL) and retained the 2 h PG value for the diagnosis of diabetes (Fig. 1). The revision of the FPG cut-point was primarily owing to the poor agreement in diabetes diagnosis between the 2 h PG and FPG and/or an FPG  $< 7.8$  mmol/L (140 mg/dL) as well as to simplify the diagnostic procedure (FPG vs. OGTT). The ADA Expert Committee reasoned that as the association between FPG and diabetes-related complications follows a continuum, then at an FPG  $> 7.0$  mmol/L (126 mg/dL), then diabetes must exist. Although the 2 h PG cut-point is justified based on diabetic-specific retinopathy studies, the optimal value for the diagnosis of FPG is inadequately standardized. Congruently, in 1999, the WHO also revised the cut-point of FPG  $> 7.0$  mmol/L (126 mg/dL) and retained the 2 h PG threshold for diagnosing diabetes.

The OGTT based criteria were the mainstay for the diagnosis of diabetes between 1980 and 2010. The HbA1c as a diagnostic tool was recently added around a decade ago.

### Non-agreement of FPG and 2 h PG

The existing glucose-centric diagnostic tests, FPG, and the 2 h PG derived from the OGTT have well-known limitations with increased inter-individual variability (FPG (coefficient of variation (CV: 5.7%; 2 h PG (CV: 16.7%)). Due to these discrepancies and poor reproducibility, ADA and WHO agencies recommended repeated testing within a “short period of time”, albeit without specifying the actual time frame to confirm the diagnosis, with the goal of reducing the probability of a false-positive diagnosis. As a result, in 1997, the ADA favored the FPG and precluded the use of 2 h PG from the OGTT (Selvin et al., 2018). Subsequently, the WHO adopted similar approach but was less restrictive about the use of the OGTT. Several observational studies showed that the association between FPG and 2 h PG with diabetes and/or diabetic-specific retinopathy was highly variable and affected by diabetogenic risk factors such as age, obesity status, sex, and ethnicity. For example, the optimal cut-points for identifying diabetic retinopathy were lower in Pima Indians, Egyptian and in US population, whereas the threshold was lower in Asian population. Therefore, revising the diagnostic criteria proposed by the latest ADA criteria resulted in the secular increase in the prevalence of diabetes and increased personal and healthcare costs. Recently, Selvin et al. proposed a clinical utility of diabetes diagnosis from a single-sample determinations of FPG and HbA1c to confirm the diabetes diagnosis (Agarwal, 2015). Performing both tests concurrently from a single sample may streamline T2DM diagnosis in resource-limited settings by eliminating the need for a second clinical visit for confirmatory testing.

### Glycated hemoglobin

Glycated Hemoglobin (HbA1c) was first discovered in 1969, and in the 1980s, it was introduced in the clinical management for diabetes (as it reflects 60–90 days average of glycemia) and has become a cornerstone of clinical practice (Jagannathan et al., 2020). In 2009, the International Expert Committee that included representatives of the ADA, the international diabetes federation (IDF), and the European Association for the Study of Diabetes endorsed measurement of HbA1c to diagnose diabetes, with a cut-point of  $\geq 6.5\%$  (48 mmol/mol), and the ADA formally adopted this criteria in 2010. However, it must be noted that HbA1c is not a reliable biomarker for assessing undiagnosed diabetes. For instance, analyses of the US National Health and Nutrition Examination Survey (NHANES-3) data from 2005 to 2006 indicate that, assuming universal screening of the undiagnosed, the HbA1c test cut point of  $\geq 6.5\%$  (47.5 mmol/mol) identifies one-third fewer cases of undiagnosed diabetes than a fasting plasma glucose cut point of  $\geq 7.0$  mmol.

Several reports have shown that Blacks, Asians, and Latinos have  $\sim 0.4\%$  higher HbA1c levels than Whites at similar glycemic levels. Correspondingly, the HbA1c test has been associated with the imprecise classification of diabetes in these high-risk populations than in Whites. In the NHANES (year 2005–2014) study, the false-positive rates for prediabetes or diabetes were  $\sim 3$  times for Blacks (17.6%) than Whites (6.3%). Besides, HbA1c may not be reliable among children and adolescents in diagnosis of

prediabetes or diabetes, underestimating their true prevalence. Besides, HbA1c values can be affected by numerous factors such as decreased red cell turnover (e.g., iron deficiency, vitamin B12 deficiency, certain hemoglobinopathies), advanced kidney dysfunction stages, and individuals with severe immuno-compromized conditions such as HIV, recent organ transplant, or cystic fibrosis may have HbA1c discordant with blood glucose levels, resulting in underestimating the prevalence of dysglycemia.

On the contrary, the hemodialytic condition is typically associated with falsely decreased HbA1c levels due to the uremic environment, reduced erythrocyte lifespan, treatment with erythropoietin, or intravenous iron replacement treatment. Importantly, HbA1c is a relatively expensive test compared with glucose and not standardized in most of the low- and middle-income countries. In essence, although HbA1c is a valuable screening and diagnostic tool for identifying dysglycemia, it may not be sufficient to substitute for the information derived from OGTT.

### Diagnostic criteria for diabetes in pregnant women

Identifying women at greater risk of developing gestational diabetes (GDM) is paramount since it is strongly associated with maternal (C-section, hypertension, cardiovascular diseases) and neonatal (macrosomia, neonatal hypoglycemia, and perinatal death) outcomes (Chung et al., 2020). A gold standard test for the screening and diagnosing of GDM is lacking, with the various testing options and thresholds are currently available (Jagannathan et al., 2020).

At present, there are two different two-step glucose thresholds criteria available to diagnose GDM, such as those defined by the Carpenter and Coustan (Agarwal, 2015), National Diabetes Data Group (NDDG) and Canadian Diabetes Association (National Diabetes Data Group, 1979; Report of the Expert, 1997). On the other hand, a one-step GDM screening approach is recommended by the International Association of Diabetes and Pregnancy Study Groups (IADPSG) (Harper et al., 2016). There has been a debate on the clinical applicability of the one-vs. two-step GDM screening test. One pragmatic randomized controlled study of 23,792 women assessed the efficacy of one-vs. two-step approach for GDM screening on perinatal and maternal outcomes (International Association of Diabetes et al., 2010). The study found that even though the one-step approach diagnosed 16.5% of women with GDM and the two-step approach diagnosed 8.5% of women with GDM, there were no differences in maternal or perinatal outcomes.

Although the HbA1c has preanalytical advantages as described in the previous section, its clinical utility in GDM has several inadequacies. A retrospective analysis from the US data showed that HbA1c in the range of 5.7%–6.4% (39–46 mmol/mol) measured at <20 weeks after gestation identified individuals at heightened risk of GDM. On the other hand, findings from New Zealand and Israel retrospective studies noted a lower HbA1c cut-off for predicting incident GDM. Therefore, more robust, prospective studies are warranted for the establishment of universal screening criteria for GDM.

### Diagnostic criteria for intermediate hyperglycemia/prediabetes

Both WHO and ADA render guidance on screening for prediabetes or intermediate hyperglycemia. While the thresholds for IGT definition are the same to both guidelines, the ADA suggests a lower threshold for IFG compared to the WHO guidelines (IFG-ADA: 100–125; IFG-WHO: 110–125 mg/dL) in an effort to improve the agreement between IFG and IGT prevalence estimates.

In 2010 ADA also recommended assessing HbA1c to screen for prediabetes or intermediate hyperglycemia; however, it is to be noted that the WHO does not endorse this recommendation. These tests do not necessarily identify prediabetes or intermediate hyperglycemia in the same people, and according to ADA recommendation, abnormal results from any of the tests are adequate for prediabetes or intermediate hyperglycemia diagnosis. The most appropriate biochemical test for identifying individuals with a high risk of developing diabetes is currently unclear. The Atherosclerosis Risk in Communities (ARIC) study demonstrated that prediabetes or intermediate hyperglycemia definitions using HbA1c were more specific and provided modest improvements in risk discrimination for clinical complications. Congruently, IFG, as defined by ADA guidelines, was more sensitive diagnostic marker and HbA1c for identifying high-risk individuals. However, several other studies, disputed this finding and demonstrated the superiority of 2 h PG in predicting CVD events and mortality over other biochemical tests.

With a range of diagnostic criteria available, it is unsurprising that individuals with prediabetes or intermediate hyperglycemia identified by each biochemical method vary widely in their phenotypes and have limited overlap. In the US Diabetes Prevention Program, Blacks had higher HbA1c levels than Whites, despite similar FPG and 2 h PG levels. Similar findings were also reported in other ethnicities. Besides, prediabetes or intermediate hyperglycemia as identified with the OGTT criteria have more severe metabolic abnormalities and diabetic-complications than when by the HbA1c criteria alone. These discrepancies in screening criteria for prediabetes or intermediate hyperglycemia may result in inaccurate diagnoses, leading to some being unnecessarily treated and others being left without treatment to prevent or delay the onset of overt diabetes. Similarly, it is arduous to estimate the global burden of prediabetes.

### Classification

Around a century ago, Dr. Elliot Joslin's have made several observations such as "... It is well known that diabetic patients come too late for treatment. If the disease is detected early, it is far more susceptible to diet ... Therefore, more energy must be exerted to discover this disease. One must hunt for it."

**Table 1** Diabetes classification according to the ADA (American Diabetes Association, 2020).

Type	Definition
Type 1 diabetes	Autoimmune pancreatic $\beta$ -cell destruction exacerbates to rapid loss of insulin deficiency.
Type 2 diabetes	Progressive loss of adequate insulin secretion, compounded by deteriorated insulin sensitivity.
Gestational diabetes	Diagnosed in the second or third trimesters, in mothers without overt diabetes prior to gestation.
Monogenic diabetes	There are two subgroups: MODY and neonatal diabetes
Diseases of the exocrine pancreas	Examples: pancreatitis and cystic fibrosis
Chemical or drug-induced	Caused by glucocorticoids, HIV/AIDS drugs, COVID-19, organ transplantation (immunosuppressive) drugs

The current classification of diabetes recognizes the significant forms of type 1 diabetes (T1D), T2D, GDM, and other uncommon types, such as monogenic diabetes (e.g., MODY), diseases of the exocrine pancreas (e.g., cystic fibrosis-related diabetes), or drug-induced diabetes (Table 1).

Distinguishing between T1DM and T2DM can be difficult. T1DM has classically been known to occur at a younger age and present with absolute insulin deficiency. T2DM, on the other hand, was classically described as occurring in older, obese individuals. However, T2DM is becoming more prevalent in younger age groups. Further, some people with diabetes present with diabetic ketoacidosis (DKA), also called ketosis-prone diabetes. People with ketosis-prone diabetes initially present with diabetic ketoacidosis at onset of diabetes (Vellanki and Umpierrez, 2017). Ketosis-prone diabetes is well described in people of African and Hispanic origin and obesity, has a high male to female prevalence and a low prevalence of pancreatic autoimmune antibodies. However, unlike patients with T1D, with intensive insulin treatment, ~70% of patients are able to discontinue insulin with glycemic control and maintained off all medications or on oral antidiabetic agents. Over the long-term, most people with ketosis-prone diabetes have a clinical course with decreasing beta-cell function similar to that of T2DM.

Thus the heterogeneity of diabetes has been the subject of considerable interest recently given the complexity of classifying diabetes and the availability of the extensive population-based databases. In the remaining chapter, we will describe the pathophysiology of diabetes “through the prism of heterogeneity” within and between diabetes types.

## Heterogeneity in T1D

The temporal rise in the incidence of T1D suggests an interplay between gene-gene, gene-environment, and environment–environment interactions resulting in overt T1D. Several epidemiological and genome-wide association studies have identified over 60 risk regions across the human genome, marked by single nucleotide polymorphisms (e.g., PTEN, PTPN22, ERBB3, SH2B3, INS) and its potential interaction with environmental factors such as Enterovirus B, height, BMI, and waist circumference on the exacerbation of T1D onset. Currently, there is a debate on the definition of subtypes within T1D which may have implications for personalized treatment. Distinct histological phenotype associates with destructive insulinitis on pancreatic  $\beta$ -cells, altered insulin processing, and the onset of T1D at a young age. Harnessing the systems biology approaches and multi-omics approach has significantly improved our understanding of various forms of T1D endotypes, and it will pave the way for a tailored therapy to the specific pathophysiological processes.

## Heterogeneity in T2D

Dysregulation of many biological pathways leads to the development and progression of T2DM (Jagannathan et al., 2020). The measurement of glucose alone cannot reflect the complexity of metabolic disorders arising from a combination of excessive adipose tissue, peripheral insulin resistance, dysfunctional pancreatic  $\beta$ -cells, increased free fatty acids, impaired incretin effects, and obesity-induced inflammation. Hence, it is imperative to cluster individuals with T2D based on perceived phenotypic characteristics (Ahlqvist et al., 2020). Recent efforts have proposed phenotype-based approaches that take advantage of modern computational capabilities and clustering techniques. These strategies have the potential to highlight underlying disease pathophysiology, enhance prognostication, and refine treatment regimens.

In 2018, Ahlqvist et al. (Ahlqvist et al., 2020), in a Scandinavian population ( $n = 8980$ ), studied six variables (glutamic acid decarboxylase [GAD] antibody, age, BMI, HbA1c, HOMA- $\beta$  (pancreatic  $\beta$ -cell function), and insulin resistance (HOMA2-IR)), assessed at the time of diagnosis with any form of new-onset diabetes. By employing k-means and hierarchical clustering algorithms, the study population was classified into five reproducible phenotypes: (1) a severe autoimmune (capturing T1D and latent autoimmune diabetes of adults (LADA)) group; (2) a severe insulin-deficient group; (3) a severe

insulin-resistant group; (4) a mild obesity-related form, and (5) a mild age-related form. The study investigators further investigated whether the subgroups differed regarding the intensification of therapy or diabetes-related complications; indeed, there were significant between-group differences, including diminished time to sustained insulin use in the severe autoimmune and severe insulin-deficient phenotypes increased risk of CKD in the severe insulin-resistant phenotype (Ahlqvist et al., 2020). Since then, several groups have replicated the findings of Ahlqvist et al. including in more ethnically diverse populations for identifying different heterogeneous clusters to identify the subgroup of individuals at high risk of developing diabetes and its associated complications.

## Conclusion

A shift to diagnosing high-risk individuals for diabetes or prediabetes even earlier than current screening modalities enables the opportunity for reducing progression to diabetes and its associated complications. However, the currently available diagnostic tests, as the FPG, 2 h PG, and HbA1c, have performance limitations and are inadequate to classify high-risk individuals owing to the multi-factorial nature of the diseases. Integrating our knowledge of genomics, immunology, and metabolic data will improve our understanding of the pathophysiology of diabetes heterogeneity and the ability to use precision medicine to tailor treatments and improve health outcomes (Chung et al., 2020).

### Key points

- The successful treatment of diabetes mellitus starts with a healthful diet, although specifics will vary depending on the type of diabetes, medications, and individual circumstances and lifestyle.
- There is no one-size-fits-all diet for diabetes, rather approach should be individualized working with a registered dietitian.
- Individualization is a cardinal principle of medical nutrition therapy for diabetes, facilitating individual lifestyle and behavior changes that will lead to improved metabolic control
- Medical nutrition therapy goals include promoting and supporting healthful eating patterns, emphasizing a variety of nutrient-dense foods in appropriate portion sizes, to achieve individualized targets for HbA1c, blood pressure, and cholesterol, achieve body weight goals, and delay and prevent diabetes complications.
- There are many different eating patterns that support a healthy eating style for persons with diabetes, such as the Mediterranean meal pattern, the DASH diet, intermittent fasting, and the myplate method.
- There continues to be no clear evidence of benefit for trace element, herbal or vitamin and mineral supplementation for people with diabetes without underlying deficiencies.

The successful treatment of diabetes mellitus starts with a healthful diet, although the specifics of the diet may vary depending on the type of diabetes being treated, medications taken and the individual circumstances and lifestyle. Since each person with diabetes will have unique needs and challenges, individualization is the cornerstone of medical nutrition therapy in diabetes treatment. Because approximately 90–95% of all people with diabetes have type 2 diabetes, and 80% of them also have overweight or obesity, weight reduction is often the main therapeutic goal. Many individuals will also require directed treatment of comorbidities such as hypertension or dyslipidemia. People with type 1 diabetes usually require far more attention to exact the quantity and type of carbohydrate they eat and how their food intake aligns with their insulin dosages and physical activity level. In all cases, education of the patient by a trained nutritionist is essential. Diabetes is rarely well controlled unless patients have at least a basic understanding of what they should eat and why.

## Overall objectives in the management of diabetes

### Control of blood glucose level

The goal of blood glucose control in diabetes is to achieve blood glucose levels that reduce the risk of diabetes complications while minimizing adverse effects of medications. Some individuals with type 2 diabetes can control their blood glucose without needing medications, or cure their diabetes, defined as having blood glucose levels below the diabetes range without needing diabetes medications or treatments for over one year. However, type 2 diabetes is a progressive disease and most patients will need medications to lower blood glucose. Therefore, for most patients with diabetes, the goal is not to normalize blood glucose but to lower it to a level where the harms of hyperglycemia are minimized, balanced against the potential harms of diabetes medications, such as hypoglycemia.

Elevated blood glucose is predominantly asymptomatic. To cause symptoms, hyperglycemia usually must be quite high, averaging >180–200 mg/dL. These symptoms include increased urination (polyuria), thirst (polydipsia), hunger (polyphagia), and blurry vision. In the most severe cases in which hyperglycemia becomes profound and remains unchecked for a long period, it can result in Hyperosmolar Hyperglycemic Syndrome characterized by dehydration, electrolyte imbalances, coma, or death. Most patients with diabetes are diagnosed while asymptomatic on the basis of hyperglycemia on laboratory testing.

Chronic hyperglycemia of any level increases the risk of long-term consequences of diabetes, also called diabetes complications. These complications are divided into microvascular and macrovascular complications: organ damage as a result of damage to small and large blood vessels, respectively. Microvascular complications are retinopathy (eye disease), nephropathy (kidney disease), and neuropathy (nerve damage). Macrovascular complications include heart disease, stroke, and peripheral vascular disease. A combination of neuropathy and vascular disease can result in damage to the extremities which may lead to amputation. Elevated blood glucose levels are more strongly associated with microvascular than macrovascular complications, the latter having a number of other strong metabolic risk factors such as hyperlipidemia, hypertension, and smoking. In studies assessing the benefits of reducing glucose levels to tight control (near-normal levels) versus more permissive levels, there are more significant benefits on microvascular complications, and only small macrovascular benefits. The benefits of tight glycemic control take years to accrue.

To determine the efficacy of treating glycemia, blood glucose must be monitored. There are three ways to assess glucose control: self-monitoring of blood glucose (SMBG), laboratory monitoring of hemoglobin A1c (HbA1c), and continuous glucose

monitoring (CGM). SMBG, done by obtaining a drop of blood and using a small handheld meter, measures the blood glucose at the time the measurement is taken. It is done only as often as necessary to inform decisions about diabetes medication adjustment, or before an insulin dose is administered for patients using insulin. CGM is a device with a small sensor worn on the body that measures blood glucose continuously throughout the day and night. HbA1c is a laboratory test that reflects glycemic control during the previous 60–90 days, and this value is what is most commonly followed for diabetes management in clinical practice. HbA1c less than 5.7% is the normal range. HbA1c of 5.7–6.4% is prediabetes which is mildly elevated glucose with an increased risk of developing diabetes. HbA1c of 6.5% and higher is diagnostic of diabetes. The treatment target for most people with diabetes will be HbA1c less than 7.0%, but this target should be individualized based on a patient's, age, comorbidities, health status, and other factors.

### **Prevention or control of comorbidities**

Morbidity and mortality among people with diabetes are rarely due to acute hyperglycemia or diabetic ketoacidosis. Rather, the long-term complications are either specific to diabetes (e.g., diabetic retinopathy or nephropathy) or accelerated by diabetes (e.g., atherosclerosis). Diabetes significantly increases the risk of coronary artery, cerebrovascular, and peripheral vascular disease, with these cardiovascular complications being the most common cause of death among people with diabetes. Prudent dietary management of diabetes therefore often requires concurrent dietary management of cardiovascular disease risk factors such as hypertension and dyslipidemia. All people with diabetes should follow best practices for dietary control of their comorbidities, such as a low sodium DASH diet in patients with hypertension. In addition, weight loss of 5% or more of initial body weight is recommended for most patients with diabetes and overweight or obesity.

### **Minimum intrusion on quality of life**

For individuals with diabetes, one of the most challenging areas of treatment is determining what to eat and how to incorporate healthy changes. Meals are an integral part of our lives and most patients will not totally abandon their lifetime dietary habits, such as forgoing favorite ethnic flavors and socially available foods. Meal patterns versus “strict diets” enable more flexibility in food choices and preferences. There is no “one size fits all” diet for persons with diabetes as every person has unique personal preferences and lifestyles. Rather, the prescribed diet that intrudes least on a person's quality of life and can be maintained is the most successful nutrition plan. Dietitians should work to identify exactly what changes are required and what favorite dishes, spices, or food groups can be built into a good nutrition prescription.

## **Principles of dietary management of diabetes**

### **Medical nutrition therapy for diabetes**

Medical nutrition therapy (MNT) is an evidence-based process aiming to treat or manage a disease through nutrition. Its components are comprehensive and include assessment of nutritional status and provision of nutritional diagnosis, diet modifications, counseling, and specialized nutrition therapies, provided by a Registered Dietitian Nutritionist (RDN) or a nutrition professional. Systematic reviews have found strong evidence that MNT can effectively improve HbA1c levels, medication use, and quality of life for people with type 1 and type 2 diabetes. Diabetes-focused MNT is usually reimbursed by insurance plans. It is recommended that people with type 1 or type 2 diabetes be referred to diabetes-focused MNT at diagnosis and then as needed throughout the life span in order to achieve optimal treatment goals. The American Diabetes Association recommends specific goals for MNT for persons with varying types of diabetes geared toward more flexibility and patient-centered (Table 1).

### **Nutrition assessment**

The first step for planning an appropriate nutrition plan is a full assessment of the patient with diabetes. Every person has unique needs and circumstances, therefore a deep understanding and assessment is key to developing a more successful and individualized management plan. Recommended nutrition assessment components for patients with diabetes are included in Table 2.

### **Individualization**

Individualization is a cardinal principle of medical nutrition therapy for diabetes, facilitating individual lifestyle and behavior changes that will lead to improved metabolic control. As no one diet fits all, a standard “diabetic diet” is neither evidence-based nor realistic for the prevention or management of diabetes. Rather, people with diabetes should be evaluated by a registered dietitian or other nutrition specialist who is able to take account of individual variations and provide personalized, diabetes-focused MNT. The nutrition intervention plan should be driven by the diagnosis, pharmacologic treatment, lifestyle, and treatment goals. Important consideration is given to dietary preferences, socioeconomic factors, and the patient's ability to understand and implement instructions. Some patients will need instruction on fine points such as carbohydrate counting and nutrition label reading; others will benefit from broader prescriptions, such as minimizing concentrated sweets and deep fried foods and avoiding

**Table 1** Goals of medical nutrition therapy for persons with diabetes mellitus.

- To promote and support healthful eating patterns, emphasizing a variety of nutrient-dense foods in appropriate portion sizes, to improve overall health and specifically to:
  - Achieve individualized targets for HbA1c, blood pressure, and cholesterol
  - Achieve and maintain body weight goals
  - Delay or prevent diabetes complications
- To address individual nutrition needs based on personal and cultural preference, health literacy and numeracy, access to healthful food choices, willingness and ability to make behavioral change, barriers to change.
- To maintain the pleasure of eating by providing nonjudgmental messages about food choices while limiting food choices only when indicated by scientific evidence.
- To provide practical tools for daily meal planning rather than focusing on individual macronutrients, micronutrients or single foods.

Adapted from [Lifestyle Management \(2019\)](#).

**Table 2** Recommendations for diabetes nutrition assessment.

#### Biomedical information

- Type of diabetes, glycemic control, lipid profile, blood pressure
- Presence of key comorbidities: Hypertension, hyperlipidemia, chronic kidney disease, cardiovascular disease, or other chronic illnesses significantly affecting health or function
- Prescriptions, use of over-the-counter medications, complementary or alternative medications
- Adherence to medications

#### Nutrition-focused physical findings

- Height, weight, BMI, waist circumference
- Weight management goals (weight loss, gain, or maintenance)
- Lower extremity edema
- Injection site for insulin or other injectable medications

#### History

- Demographic information, education, occupation
- Food insecurity and access
- Cultural dietary preferences
- Family nutrition-related medical history
- Health literacy and numeracy, knowledge, beliefs, attitudes
- Previous experiences with nutrition care services
- Motivation, readiness to behavior changes, self-efficacy
- Physical activity patterns

#### Food and nutrition-related history

- Food/beverage nutrient intake, including energy intake, portion sizes, meal-snack spacing and patterns, types and amounts of macronutrients, micronutrient intake, alcohol use
- Experience with cooking/preparing food, eating environment, access to healthy foods, frequency of eating out

Adapted from [Franz et al. \(2017\)](#).

sugar-sweetened beverages. **Table 3** presents several examples of nutritional goals that may need accommodation among different people with diabetes.

## Nutritional instruction

To achieve successful nutritional outcomes, there are several key educational factors that must be communicated with patients. Basic survival skills for the patient include understanding the relationship between food intake, activity level, and insulin; healthy weight loss goals; healthy dietary patterns for blood glucose, blood pressure and lipids; and a healthy macronutrient balance. Meal planning education should include types and amounts of food, incorporating dietary fiber, understanding serving sizes and nutrition labels, management of eating out and special occasions, as well as incorporating favorite recipes. Patients should also be instructed on how to modify food intake during brief illnesses and changes in food intake based on activity level. For those requiring a more comprehensive approach, carbohydrate counting, nutrition label reading, and self-monitoring blood glucose levels are also vital factors. In addition, patients using high hypoglycemia risk medications (insulin, sulfonylureas, or meglitinides) should be instructed on managing hypoglycemic episodes including the definition of hypoglycemia (blood glucose <70 mg/dL), common symptoms, treatment (ingesting carbohydrates), and avoidance of driving with hypoglycemia.

**Table 3** Examples illustrating the variable clinical factors affecting people with diabetes and the resulting diversity of their nutritional needs.

Patient	1	2	3	4
Type of diabetes	Type 1	Type 1	Type 2	Type 2
Age (years)	14	38	56	76
Duration of DM (years)	6	26	6	6
BMI	18	23	27	34
Physical activity	Vigorous	Moderate	Mild	Minimal
Prone to hypoglycemia	Yes	Yes	Yes	No
Blood lipids	Normal	Normal	High LDL cholesterol	High TG and low HDL
Blood pressure	Normal	High	Normal	High
Dietary preferences	Likes sweets and snacks	Healthy, little carbohydrate awareness	Spicy foods and irregular meals	Fried foods and sweets
Pharmacologic therapy	Multiple-dose insulin	Multiple-dose insulin	Oral agents plus long-acting insulin	Oral agents
Major nutritional considerations	Adequate caloric intake for growth Recognize carbohydrate portions, Low salt, high vegetable for regularize carbohydrate intake, Minimize concentrated sweets  Learn factors causing hypoglycemia  Healthy heart diet	Stabilize carbohydrate intake, count carbohydrates Low salt, high vegetable for hypertension (DASH diet)	Mildly hypocaloric  Hypolipidemic diet (low saturated fat) Regularity of meals, consistency of carbohydrate and fat intake	Moderately hypocaloric  Hypolipemic diet (low saturated fat) Low salt, high vegetable for hypertension (DASH diet) Control of dietary carbohydrate, especially high-energy concentrated sweets

BMI, body mass index; DM, diabetes mellitus; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

## Dietary approaches to diabetes

### Total energy intake

It is important to start with a personalized total energy requirement calculation. This may be for overall weight management, whether weight loss, maintenance and in some cases, weight gain. As one starts to make changes to their diets, it essential to start with one's total energy requirement or total daily calories. The total energy requirement to maintain constant body weight may be calculated using an estimating equation, taking into consideration the patient's activity level. The weight-maintaining requirement is then adjusted according to the therapeutic objective—to accomplish weight loss, weight maintenance, or weight gain. Examples of how to calculate one's caloric requirements using the Mifflin–St Jeor equation are shown in [Table 4](#). These calculations do not apply to childhood growth and development, pregnancy, malabsorption, or patients with nutritional deficiencies.

### Distribution of energy intake

Macronutrients, including carbohydrate, protein, and fat, are the main sources of energy in one's diet. Current literature indicates that there is no ideal macronutrient distribution of an eating pattern for managing diabetes. Individuals with diabetes typically consume 45% of their daily calories from carbohydrate, 16–18% from protein, and 36–40% from fat. This intake pattern is similar to the Acceptable Macronutrient Distribution Ranges (AMDR) recommended by the National Academies for the general public to reduce risk of chronic diseases while getting enough intakes of essential nutrients ([Table 5](#)). While the AMDR or other Dietary Reference Intakes (DRIs) serve as general guidelines, there are many healthy eating patterns that fall outside of these specific macronutrient distributions; these are discussed later in this chapter. Any specific recommendations regarding distributions of macronutrients should be individualized based on the patient's therapeutic objectives, personal preferences, and food availability.

Besides macronutrient distribution, the distribution of energy intake throughout the day may also vary. Patients who require insulin, for example, may need a more evenly distributed energy intake, even including a bedtime snack to avoid hypoglycemia while sleeping. For those on fixed insulin doses, it is important to maintain consistent carbohydrate intake to avoid glucose excursions. Reduced or absent energy intake for prolonged periods is dangerous for patients using any glucose lowering medication because this may result in hypoglycemia, though it is most dangerous for patients taking insulin.

### Different eating patterns for the management of diabetes

An eating/dietary pattern is a combination of different foods and food groups. There will always be varying expert opinions on which eating pattern is the best. With carbohydrate being the main dietary influence on postprandial blood glucose, some experts

**Table 4** Sample calculations of energy requirement in differing circumstances using the Mifflin–St Jeor formula to determine caloric requirements for adults.

**Caloric requirements = basal metabolic rate × activity factor**

*Basal metabolic rate (BMR)*

For men:  $BMR = 10 \times \text{weight (kg)} + 6.25 \times \text{height (cm)} - 5 \times \text{age (years)} + 5$

For women:  $BMR = 10 \times \text{weight (kg)} + 6.25 \times \text{height (cm)} - 5 \times \text{age (years)} - 161$

**Multiply BMR by one of the following activity factors:**

*Activity factors*

1. Sedentary (little or no exercise):  $BMR \times 1.2$

2. Lightly active (light exercise/sports 1–3 days per week):  $BMR \times 1.375$

3. Moderately active (moderate exercise/sports 3–5 days per week):  $BMR \times 1.55$

4. Very active (hard exercise/sports 6–7 days per week):  $BMR \times 1.725$

5. Extra active (very hard daily exercise/sports and physical job or 2x day training):  $BMR \times 1.9$

*To achieve caloric requirements for weight loss, use the above calculated formula and subtract by 500 calories (this is for a recommended 0.5–1 pound of weight loss per week):*

Caloric requirements – 500 calories per day = modified caloric requirements for weight loss

**Table 5** Acceptable Macronutrient Distribution Ranges (AMDR) for adults defined by the Institute of Medicine of the National Academies ([Institute of Medicine of the National Academies, 2002/2005](#)).

Macronutrient	AMDR (percent of total daily energy intake)
Fat	20–35%
Omega-6 polyunsaturated fatty acids	5–10%
Omega-3 polyunsaturated fatty acids	0.6–1.2%
Carbohydrate	45–65%
Protein	10–35%

recommend an eating pattern with a lower carbohydrate and higher fat intake, particularly of unsaturated fatty acids. Others advocate for a lower fat diet for its cardiovascular health benefits. The American Diabetes Association (ADA) and other expert groups support several different healthy eating patterns for managing diabetes. Healthy eating patterns for diabetes in general emphasize non-starchy vegetables and whole foods, and minimizing added sugars, refined grains, and ultra-processed foods. Current evidence does not support any eating pattern to be optimal for diabetes. However, there is evidence suggesting that reducing overall carbohydrate intake, when incorporated in different eating patterns based on individual preferences, is an effective approach to improving glycemia for people with diabetes. Regardless of which eating pattern to follow, one must take into consideration that each nutrient plays a unique role in the body metabolism, and limiting intake of any nutrient to an extreme may result in adverse health consequences. For example, carbohydrates are an important source of fiber, vitamins, minerals, and energy, and fat is an important source of fat-soluble vitamins and essential fatty acids. This is particularly true for omega-3 fatty acids, found in fatty fish such as salmon. Fat and protein intake also have satiating effects that can help with distributing meals during the day. Below, we discuss a list of eating patterns and summarize the evidence of their potential benefits on diabetes management.

### USDA Dietary Guidelines for Americans

The Dietary Guidelines for Americans have provided science-based advice on what to eat and drink to promote health, reduce risk of chronic disease and meet the nutrient needs of the general population. The guidelines focus on dietary patterns with the understanding that nutrients and foods are not consumed in isolation. Rather, people consume them in various combinations over time—a dietary pattern. The USDA emphasizes a variety of vegetables as well as fruits, especially whole fruits; grains, at least half of which are whole intact grains; lower-fat dairy; a variety of protein foods; and oils. This eating pattern limits saturated fats and *trans* fats, added sugars and sodium. These dietary recommendations can be illustrated by the use of the Plate method shown in [Fig. 1](#). Half the plate should consist of fruits and vegetables, while the other half is divided between whole grains and lean sources of protein, with a serving of low- or non-fat dairy to complete the meal. These general guidelines for macronutrients are easy for patients to remember and are appropriate for adults with diabetes.

### Mediterranean-style diet

The Mediterranean-Style diet is based on the traditional diet in the Mediterranean region and is rich in unsaturated fats from plants and seafoods, with olive oil being the primary source of dietary fat. It emphasizes fresh fruits, vegetables, nuts, whole grains, seafoods, with moderate amounts of dairy products (yogurt and cheese), eggs, and wine. It includes very small amounts of red meat and concentrated sugars. Large randomized controlled trials have demonstrated that a Mediterranean-Style diet results in better

**Fig. 1** The USDA Dietary Guidelines for Americans illustrated using the Plate method. Half the plate consist of fruits and vegetables, while the other half is divided between whole grains and lean sources of protein ([Dietary Guidelines for Americans, 2020–2025](#)).

glycemic control for people with type 2 diabetes, compared to a lower-fat eating pattern. The Mediterranean-Style diet is also considered a heart healthy diet and has also been shown to reduce the incidence of cardiovascular disease which is a major complication of diabetes.

#### ***Dietary approaches to stop hypertension (DASH)***

The DASH diet was initially investigated as a dietary intervention to manage high blood pressure. It focuses on foods high in potassium, magnesium, calcium, fiber, and protein (fruits, vegetables, low-fat dairy) while limiting the amount of saturated fats, total fats, cholesterol, and added sugars (red meat, snacks, sweets). Combining the DASH diet with sodium restriction at the national recommended level (2300 mg/day) or at an even lower level (1150 mg/day) results in additional blood pressure lowering. Currently there is limited research on the effect of the DASH diet among people with diabetes. Some evidence suggests that the DASH diet may improve HbA1c, cholesterol levels, and weight loss in people with type 2 diabetes, but long-term, large-scale clinical trials among patients with diabetes are needed to clarify this.

#### ***Low-carbohydrate and very low-carbohydrate***

The low-carbohydrate eating pattern is the most extensively studied eating pattern for type 2 diabetes due to the direct impact of dietary carbohydrate on postprandial blood glucose and insulin levels. A low-carbohydrate diet refers to an eating pattern with no more than 45% of calories from carbohydrate, typically no more than 100 g of carbohydrate per day. One meta-analysis shows that a low-carbohydrate diet, especially when carbohydrate is limited to 26% or less, can effectively reduce HgbA1c and the need for diabetes medications for people with type 2 diabetes in the short term (<12 months). A very low-carbohydrate diet, also known as a “ketogenic diet”, contains even lower amount of carbohydrate, typically less than 50 g per day or 5–10% of total calories, with the majority of calories coming from fat (>70%) and the remaining from protein. Our central nervous system relies on glucose from dietary carbohydrates for fuel. When intake of carbohydrate is extremely low, the body will respond by increasing metabolism of fat and production of ketone bodies as an alternative fuel source (i.e., ketosis). Ketogenic diets were originally developed for the treatment of drug resistant epilepsy, but there is growing evidence suggesting their benefits in glycemic control. One systematic review concludes that a ketogenic diet can be even more effective in type 2 diabetes management in terms of improving blood glucose control, lowering body weight, and reducing medication needs when compared to a low-carbohydrate diet. Due to the carbohydrate-targeting nature of insulin and many antihyperglycemic medications, those who plan to adopt a low carbohydrate or ketogenic eating pattern should consult a provider to adjust insulin and medication dosing to prevent hypoglycemia. Furthermore, a very low-carbohydrate eating pattern may not be recommended to people with chronic kidney disease, disordered eating, and women who are pregnant due to theoretical concerns.

#### ***Low-fat and very low-fat***

In contrast to a low-carbohydrate eating plan, the low-fat eating pattern focuses on limiting the amount of total fat in one’s diet. There is no standard definition for a low-fat eating pattern. In most clinical trials utilizing a low-fat diet intervention, the amount of total fat is less than 30% of total calories, with the majority being lower than 25%. Some evidence suggests that lowering fat intake may help lower the risk of developing diabetes. However, for people with existing type 2 diabetes, most literature indicate that a low-fat eating pattern is not effective at improving glycemia or cardiovascular risk factors. It is also worth noting that most studies of low-fat diets are combined with calorie restriction or weight loss programs, making it difficult to disentangle the effect of dietary pattern from these other factors. A very low-fat diet (Ornish or Pritikin eating patterns) usually consists of only 10% of calories from fat and more than 70% from carbohydrate. Some small-scale, nonrandomized studies suggest that making comprehensive lifestyle changes including eating a very low-fat diet with no calorie restriction may improve fasting glucose levels, weight, blood pressure,

and need for antihyperglycemic medications for people with type 2 diabetes. From a safety standpoint, the World Health Organization and the current dietary reference intakes recommend the minimum fat intake of 20% of total calories to ensure adequate consumption of energy and essential fatty acids, facilitate absorption of fat-soluble vitamins, and preserve HDL cholesterol. Considering the restrictive nature of the eating plan and the lack of evidence, a low-fat or very low-fat eating pattern may not be recommended for the management of diabetes. Low fat and very low-fat diets tend to be very high in carbohydrates since protein intake tends to stay around 15–20% and from the authors' opinion, we would not recommend diets that emphasize greater than 60% of total calories from carbohydrates.

### **Vegetarian or vegan**

A vegetarian eating pattern refers to a diet that does not include meat, fowl, seafood, or products containing these foods. There are several variations of the vegetarian diet, including lacto-ovo-vegetarian (eats dairy products and eggs), lacto-vegetarian (eats dairy but excludes eggs), and vegan vegetarian (excludes all animal-derived foods and food products). One systematic review concluded that vegetarian diets were related to significant reduction in HbA1C levels in people with type 2 diabetes, compared to an omnivorous diet or a conventional diet for diabetes. Another more recent meta-analysis also suggests that vegetarian diets can effectively improve glycemic control, weight, and non-HDL cholesterol levels in people with type 2 diabetes, supporting the inclusion of such dietary patterns for diabetes management. However, for people who follow a vegetarian or vegan diet, it may be necessary to monitor and supplement certain nutrients including vitamin B-12, vitamin D, calcium, zinc, and long-chain fatty acids as these nutrients are mostly present in animal products.

### **Intermittent fasting**

Intermittent fasting is technically not an eating plan but a way of eating that focuses on the timing rather than the type of foods. Fasting means consuming very little to no calories for a period of time. There are different approaches to intermittent fasting, and most common regimens include time-restricted feeding (limiting the "eating window" to 6–8 h every day), alternate day fasting (one day of fasting and one day of ad lib feeding), and periodic fasting (fasting for 1–2 days a week). With the growing interest in intermittent fasting among the public, more researchers have been examining the effects of intermittent fasting on type 2 diabetes. Current literature shows consistent evidence that intermittent fasting can help achieve weight loss (by means of caloric restriction), but there have been mixed results for improvements in HbA1c, insulin sensitivity, and other glycemic control markers. While more research is needed on this topic, intermittent fasting can be recommended to people who wish to achieve desired body weight, as weight loss is also commonly recommended for type 2 diabetes management. While intermittent fasting does not provide guidelines on the type of foods to consume, people can incorporate a healthy eating pattern as discussed above into their intermittent fasting regimen to ensure the quality of their diets. Again, people who intend to follow this eating method should work closely with a professional to match insulin and medication dosing with their eating/fasting periods to achieve optimal glycemic control. Although water and non-caloric liquids are allowed during fasting periods, many people tend to drink less total fluid on their fasting days. Therefore, in order to prevent dehydration and hypotension, patients should be advised to drink adequate liquids or reduce their diuretics and anti-hypertensive medications during fasting periods.

### **Supplements: herbal, trace elements, vitamins, and minerals**

Herbal and micronutrient, such as vitamin and mineral supplementation are always of interest for the general population. However, there continues to be no clear evidence of benefit for people with diabetes without underlying deficiencies. There has been recurrent interest in whether the routine use of herbal and micronutrients, such as cinnamon, magnesium, vitamin D or chromium, improve glycemia in people with diabetes. There is insufficient evidence of efficacy and possibly concern over long-term safety. It would obviously be attractive if simple oral supplements could facilitate normoglycemia. In addition, since herbal and vitamin and mineral supplements are not regulated, the purity and advertised amounts of the active ingredients of many dietary supplements have been questioned. Further research is needed to adequately establish the role of herbal medicines in diabetes management. The evidence, though, is slim and unconvincing that supplementation of any of these herbal or micronutrient elements has a beneficial effect except when there is a true deficiency. Vitamin and mineral supplementation is indicated when vitamin deficiency is suspected or likely. For example, populations such as the elderly with poor dietary intake, those pregnant or lactating, strict vegetarians, or those on a calorie-restricted diet may require vitamin supplements. Folate supplementation is well documented to improve the outcome of pregnancy, with or without diabetes. However, there is no clear evidence that supplementation is helpful for those eating an adequate diet. In addition, long-term use of metformin may cause vitamin B12 deficiency, and some experts recommend periodic testing of vitamin B12 levels, particularly in those with anemia or peripheral neuropathy.

In summary, evidence is weak that vitamin or trace element deficiencies occur due to diabetes. Supplementation in more normal circumstances has little or no role in the control of diabetes, and general nutritional guidelines for vitamins and trace elements should be followed. This may be particularly the case with vitamin D, because deficiencies have been reported in many populations due to decreased sun exposure, aging, and lactose intolerance as well as vitamin B12 for those taking metformin.

## Effects of ingested nutrients on blood glucose

### Carbohydrate

Carbohydrate ingestion causes blood glucose to increase and is one of the major determinants of postprandial glucose levels. In the intestine, dietary carbohydrates are rapidly hydrolyzed into sugars (approximately 75% glucose, 22% fructose and 2% galactose) by specific enzymes. The breakdown of dietary carbohydrates into sugars is so rapid that the rate-limiting step is not how fast these carbohydrates can be digested, but rather how quickly the resulting free sugars can be absorbed into the portal venous system. In people without diabetes, the normal increase in blood glucose in response to a meal is approximately 0.5–2.8 mmol/L (10–50 mg/dL) above baseline, returning to baseline within 1–3 h. The pancreatic hormonal response to dietary carbohydrate mediates the return to normal. Insulin is the central mediator of energy metabolism and is released from the pancreatic beta cells in response to the presence of carbohydrate in the intestine and after glucose passes through the liver into the peripheral circulation. The resulting level of circulating insulin is a signal for the liver to store glucose as glycogen and to reduce glucose production; it also stimulates skeletal muscle to rapidly remove glucose from the circulation, where the glucose is stored as muscle glycogen. The basics of insulin-dependent energy metabolism in the fed and the fasting states are depicted in [Fig. 2](#).

Dietary fiber is a unique type of carbohydrate that is not digested in the small intestine. Rather, it enters the large intestine and gets fermented by the gut microbiota. Since it is not absorbed into the blood stream as glucose, ingestion of dietary fiber will not raise blood glucose levels like other carbohydrates do. There is also evidence suggesting that dietary fiber can slow down the absorption rate of other carbohydrates in the meal, lowering postprandial plasma glucose and plasma insulin in people with type 2 diabetes.

Although carbohydrate intake plays the major role in postprandial blood glucose, there are other factors to consider. Diet is not the only source of glucose in blood; hepatic gluconeogenesis maintains blood glucose in the absence of dietary intake such as when a person is not eating due to an illness. Sick-day instruction is essential for people with diabetes so that they do not simply stop their treatment if they are not eating well, although medication doses may need to be modified. Pharmacologic therapies (insulin or oral agents), of course, also affect blood glucose. A long-standing debate has surrounded the optimal proportion of intake from carbohydrate, fat, and protein. People with diabetes, especially when insulin is administered, will discover that if they hold back carbohydrate their blood glucose does not increase as much. However, holding back carbohydrate unless the diet is hypocaloric, inevitably leads to a high-fat diet, and carbohydrate restriction leaves insulin with no substrate to act on. In our experience, this can cause blood glucose levels to be more unstable, susceptible to swings of hypoglycemia and hyperglycemia. We recommend that for people with type 1 diabetes a lower limit of 130 g of carbohydrate per day unless they are following a low carbohydrate diet under supervision.

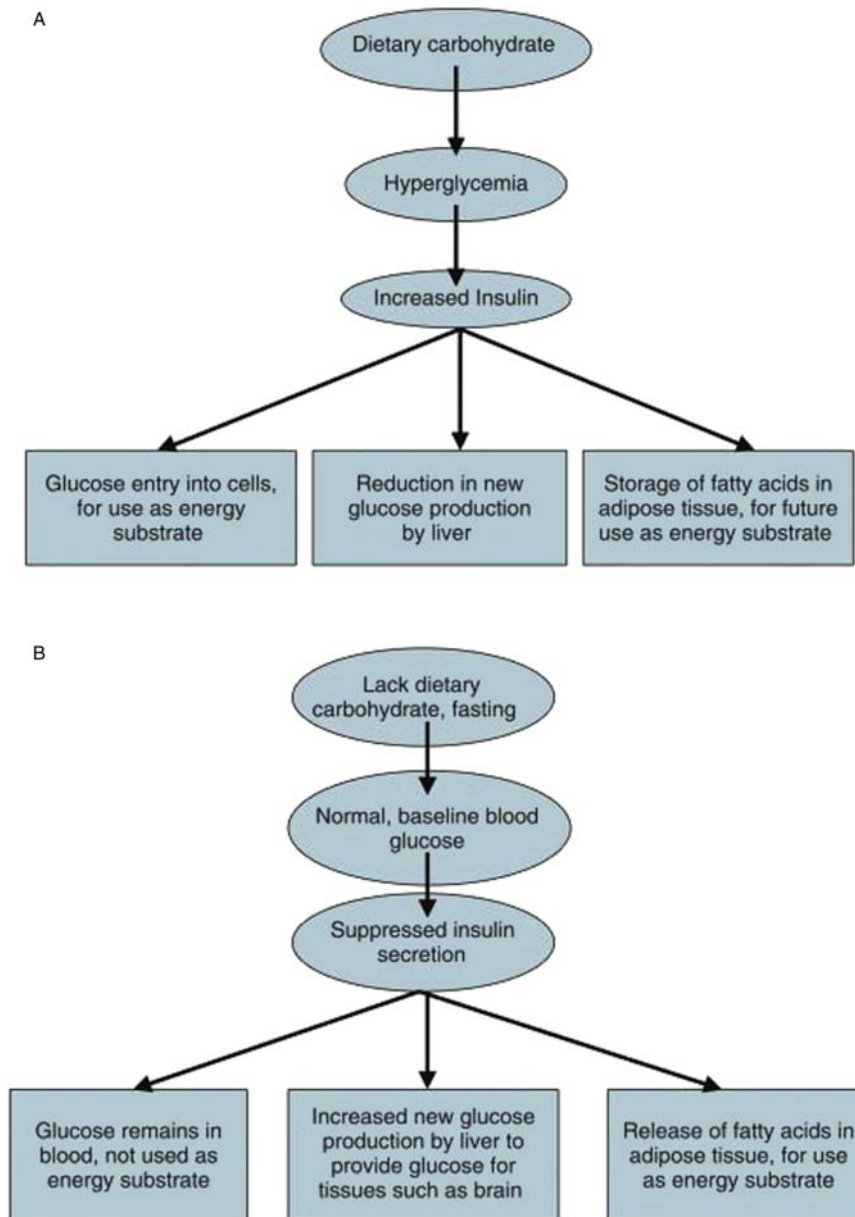

### Sucrose versus complex carbohydrate

Careful metabolic studies suggest that, gram for gram, sucrose does not increase blood glucose more than complex carbohydrates, either acutely or over a matter of weeks. In these studies, sucrose was isoenergetically substituted for other carbohydrates, mostly under carefully defined research ward conditions in which precise substitutions can be made. Because complex carbohydrates and sucrose are both digested to monosaccharides before they are absorbed, it is not unexpected that each should cause the same glycemic excursion if administered in the same number of grams. It does run counter, however, to the traditional advice that people with diabetes should avoid concentrated sweets.

A number of organizations have cited these research studies in support of a recommendation that allows ingestion of concentrated sweets. The caveat, in the words of the American Diabetes Association, is that “sucrose should be substituted for other carbohydrate sources in the food/meal plan.” In the authors’ view, there is a practical fallacy in this recommendation: People are unlikely to substitute sucrose for complex carbohydrates in equal amounts. Owing simply to taste, concentrated sweets are likely to be taken in far greater quantity than the more filling and less sweet starches. Thus, in reality, people who routinely eat concentrated sweets are likely to have greater and less predictable glycemic excursions than those who stick to complex carbohydrates. There is also the significant risk that excess concentrated sweet intake will cause weight gain (as well as dental caries). However, if a person with diabetes can include a fixed amount of concentrated sweet in his or her diet and can demonstrate that his or her diabetes is well controlled and the postmeal glycemia is not excessive, there is no reason to deny the person the sweet. The other consideration is that complex carbohydrates are superior sources of fiber, vitamins, and minerals, and therefore, should be the larger portion of carbohydrate intake.

### Glycemic index

The glycemic index (GI) is defined as the area under the 2 h curve of blood glucose after the ingestion of a set amount of carbohydrate compared with ingestion of the same amount of carbohydrate from a reference food (white bread or glucose). The glycemic load (GL) is an additional measure in which the amount of carbohydrate in a typical portion is taken into account. A high GI food is considered greater than 70 and a low value is less than 55. For glycemic load values, a high GL is considered >20 and low <10. However, it’s important to note that there are a number of factors that can affect the glycemic index and glycemic load of foods. Among these are the fat and fiber content of the meal, cooking method and duration, the patient’s absorptive rate, and micronutrient content. Further, it may be difficult to use reported GI and GL for single foods to determine the blood glucose response to meals which contain mixtures of different foods. Below are some basic guidelines to some low, moderate and high glycemic index examples.

**Fig. 2** Influence of insulin on basic energy metabolism. (A) With dietary carbohydrate intake, hyperglycemia induces insulin secretion that acts to enhance glucose entry into cells for utilization as metabolic fuel. Simultaneously, insulin decreases new glucose production in the liver, as dietary glucose is already available and excess stored in liver as glycogen, and stores the remaining excess caloric intake in adipose tissue as fat. (B) With lack of dietary carbohydrate, as in fasting, the reverse occurs: With lower blood glucose, insulin secretion is suppressed. This minimizes entry of glucose into cells but stimulates enough new glucose production from the liver to provide for obligate glucose-using tissues such as the brain. Meanwhile, low insulin concentration promotes fatty acid release from adipose tissue to serve as an alternate fuel for metabolism.

Low glycemic index (GI of 55 or less): Most fruits and vegetables, beans, minimally processed whole grains, whole grain pasta, low-fat dairy foods, and nuts.

Moderate glycemic index (GI 56 to 69): White and sweet potatoes, corn, white rice, couscous, breakfast cereals such as Cream of Wheat and Mini Wheats.

High glycemic index (GI of 70 or higher): White bread, rice cakes, most crackers, bagels, cakes, doughnuts, croissants, most packaged breakfast cereals.

Diets emphasizing low GI/GL have had inconsistent effects on diabetes and cardiovascular risk factors. In the authors' opinion, the concept of GI is valid in a research sense: certain carbohydrates, gram for gram, do raise blood glucose levels more, or with different glycemic patterns, than others. However, basing nutrition plans on the GI and the GL of foods is usually too much of a burden for people with diabetes, and may make it difficult to adhere to a healthy dietary pattern. It is more practical to encourage people to learn their own glycemic response to different foods from experience. Patients with type 1 diabetes may learn, for example, that far more insulin is needed before eating pizza or a bagel; they may learn to avoid certain "desserts." A general awareness of what preferred foods, in what amounts, raise blood glucose may be more practical than memorizing GI or GL.

### Non-nutritive sweeteners

Sweeteners are important for the quality of life of people with diabetes. An essential distinction is to differentiate those with from those without significant energy content, i.e., nutritive and non-nutritive sweeteners, respectively. [Tables 6 and 7](#) provide many of the available non-nutritive and nutritive sweeteners. Non-nutritive sweeteners can be consumed without concern about their effect on blood glucose. They have been determined to be safe when consumed within the daily intake levels established by the Food and Drug Administration (FDA).

Many "diet" sweeteners, such as sorbitol or fructose-based snacks, do cause at least some degree of hyperglycemia. Sugar alcohols (polyols) such as sorbitol, mannitol, and xylitol are classified as hydrogenated monosaccharides, hydrogenated disaccharides, and oligosaccharides. They do contain calories, but because they are only partially absorbed in the small intestine, they have a reduced energy value per gram. A few randomized controlled trials studied gastrointestinal effects of polyols/sugar alcohols and consistently found that in moderate doses of up to 10–15 g/day, polyols/sugar alcohols are tolerated. At high doses (>30 g/day), consumption of some polyols/sugar alcohols (including lactitol, isomalt, and xylitol) may result in significant gastrointestinal discomfort such as increases in flatulence, defecation frequency and loose/watery stools. It is important for people with diabetes to understand these distinctions because many calories can be ingested with foods labeled as "diet" under the false assumption that they are without effect on blood glucose.

### Protein

The average protein intake for people of all ages in the United States is between 16% and 18%. In most diets, approximately 50–100 g protein is ingested per day, compared with approximately 200–300 g carbohydrate. Therefore, protein is a calorically less significant part of the diet and far less important in regulating blood glucose. The effect of protein ingestion on blood glucose is far less pronounced than the effect of carbohydrate ingestion. Although protein ingestion affects postprandial blood glucose significantly less than carbohydrate, high-protein diets are not recommended particularly in anyone with diminishing renal function. Those with chronic kidney disease (with albuminuria and/or reduced estimated glomerular filtration rate) should target dietary protein intake at the recommended daily allowance of 0.8 g/kg body weight/day. Reducing the amount of dietary protein below the recommended daily allowance is not advised because it does not alter glycemic measures, cardiovascular risk measures, or the rate at which glomerular filtration rate declines. In people with type 2 diabetes, ingested protein can increase insulin response without increasing plasma glucose concentration. Thus, carbohydrate sources high in protein should not be used to treat or prevent hypoglycemia.

**Table 6** Non-nutritive sweeteners.

Type	US brand names	kcal g <sup>-1</sup>	Description
Saccharin	Sweet and Low, Sweet Twin, Sweet'N Low Brown and Necta Sweet	0	200–700 times sweeter than sucrose; noncarcinogenic and produces no glycemic response
Aspartame	Nutrasweet, Equal and Sugar Twin (blue box)	4	160–220 times sweeter than sucrose; noncarcinogenic and produces limited glycemic response
Acesulfame-K	Sunett, Sweet & Safe, and Sweet One	0	200 times sweeter than sucrose; noncarcinogenic and produces no glycemic response
Sucralose	Splenda	0	600 times sweeter than sucrose; noncarcinogenic and produces no glycemic response
Luo han guo extract	Monkfruit	0	150–300 times sweeter than sucrose; intended as a tabletop sweetener, a food ingredient, and a component of other sweetener blends
Stevia	Stevia	0	250 times sweeter than sucrose general use; heat stable for cooking and baking

Adapted with permission from [Fitch et al. \(2012\)](#).

**Table 7** Nutritive sweeteners.

Type	kcal g <sup>-1</sup>	Description
<b>Monosaccharide polyols or novel sugars</b>		
Sorbitol	2.6	50–70% as sweet as sucrose; some people experience a laxative effect from a load $\geq 50$ g
Mannitol	1.6	50–70% as sweet as sucrose; some people experience a laxative effect from a load $\geq 20$ g
Xylitol	2.4	As sweet as sucrose
Erythritol	0.2	60–80% as sweet as sucrose; also acts as a flavor enhancer, formulation aid, humectant, stabilizer and thickener, sequestrant, and texturizer
<b>Disaccharide polyols or novel sugars</b>		
Isomalt	2	45–65% as sweet as sucrose; used as a bulking agent
Lactitol	2	30–40% as sweet as sucrose; used as a bulking agent
Maltitol	2.1	90% as sweet as sucrose; used as a bulking agent
<b>Polysaccharide polyols</b>		
HSH	3	25–50% as sweet as sucrose; other names include hydrogenated starch hydrolyzates and maltitol syrup

Adapted with permission from [Fitch et al. \(2012\)](#).

## Fat

Dietary fat alone has little, if any, immediate effect on blood glucose concentration because the constituent fatty acids do not produce new glucose and the glycerol moieties are insignificant in their contribution to blood glucose. However, there is considerable evidence that fat reduces early glucose response (first 2–3 h) and delays peak blood glucose due to delayed gastric emptying. The delayed delivery of carbohydrate to the circulation can cause a late, slow postprandial rise in blood glucose. In some cases, fat can lead to late postprandial (>3 h). Evidence suggests that meals containing carbohydrates and that are high in dietary fat cause sustained late postprandial hyperglycemia. This is important to understand, especially for those who consume higher fat diets and are also taking insulin. Insulin dosing may need to be adjusted based on meal composition rather than on carbohydrate content alone. People who do not self-monitor frequently are unlikely to be aware of this effect of dietary fat. Although fat has little contribution to blood glucose, persons with diabetes must be aware that fat gram for gram contributes more than twice as many calories as carbohydrates or protein.

## Special considerations for diabetes subtypes

### Type 1 diabetes

Individuals with type 1 diabetes have essentially no endogenous insulin secretion due to autoimmune destruction of the insulin-producing beta cells of the pancreas. Therefore, patients with type 1 diabetes lose the body's finely tuned insulin secretory mechanism that continually provides insulin "on demand" to precisely match energy intake. This is replaced by administering exogenous insulin given in multiple daily injections, or using an insulin pump, a device that administers insulin subcutaneously on a continuous basis. However, it is difficult to precisely match exogenous insulin to glucose needs, so it is common for patients with type 1 diabetes to have episodes of hypoglycemia or hyperglycemia. Further, missing insulin for even a short period can result in significant hyperglycemia or diabetic ketoacidosis, a life-threatening condition requiring hospitalization. Advances in technology have improved the ability of patients with type 1 diabetes to keep their blood sugar within the normal range, including automated insulin delivery systems (also called artificial pancreas systems) that continuously monitor glucose levels and administer insulin automatically in response. These technologies continue to evolve rapidly and give individuals with type 1 diabetes more control over their disease.

### Major objectives

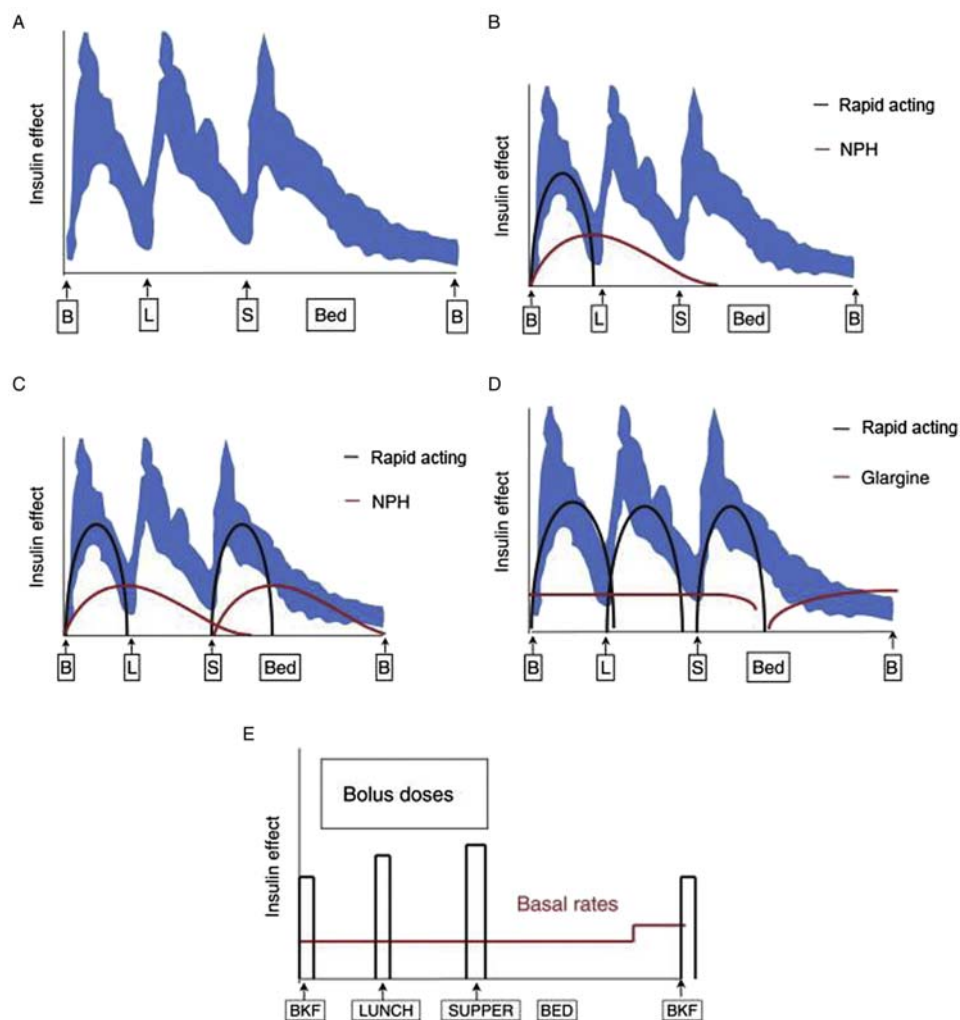

Generally, the treatment objectives in type 1 diabetes are controlling blood glucose within an acceptable range, controlling other cardiovascular risk factors, and thus avoiding long-term complications. This requires close attention not only to diet but also to its interrelationships with insulin dose and timing, physical activity, stress, and other psychosocial factors. This also includes addressing obesity and related diseases which often coexist with type 1 diabetes. Individuals with type 1 diabetes need to learn how to match their caloric intake with their exogenous insulin needs. If carbohydrate, in particular, varies significantly from day to day and meal to meal, the person must learn to adjust insulin doses to match the changed intake. Therefore, comprehensive nutrition education, including how to monitor carbohydrate intake, is recommended for all individuals with type 1 diabetes.

It is useful for the nutritionist to understand the various insulin regimens that are used to treat people with type 1 diabetes. Typically, insulin for individuals with type 1 diabetes is administered as a combination of basal insulin which provides a continuous low level of insulin, and prandial (also called bolus) insulin, which provides a rapid peak in insulin level to cover meals. Insulins that can be used for basal coverage include long acting insulins (insulin glargine, detemir, or degludec) which last for approximately a full day or longer, and intermediate acting insulin (insulin NPH) which lasts for approximately half a day. Rapid acting insulins (insulin aspart, lispro, or glulisine) have a rapid onset of action and last for several hours. Sometimes, regular insulin is used as a rapid acting insulin, this lasts for about 5–8 h. Several different typical regimens, with comments on the dietary implications, are shown in Fig. 3.

In addition to carbohydrate awareness, dietary fat intake should be taken into consideration. Dietary fat is often the main determinant of serum lipids and contributes significantly to total energy intake and thus body weight. It also delays gastric emptying, prolonging the glycemic response to dietary carbohydrate.

Very few people continue to measure and weigh food, but weighing is a useful tool during the instruction phase. Ultimately, people with type 1 diabetes should become proficient in estimating the carbohydrate content of food so that their food selection becomes habitual.

**Fig. 3** Aligning insulin regimens with nutritional intake. (A) The normal insulin response to three meals: breakfast (B), lunch (L), and supper (S). Note that insulin increases sharply after ingestion of a carbohydrate-containing meal, declining to baseline within several hours. (B) When a combination of rapid-acting and intermediate-acting insulin given only at breakfast, the normal response to breakfast is reproduced and the intermediate-acting insulin "covers" lunch. (C) When an intermediate-acting insulin is given at breakfast and supper, there is better "coverage" of the supper meal, but the intermediate-acting insulin peaks near bedtime and the middle of the night, so a bedtime snack may be necessary. (D) Long-acting insulin given at bedtime provides "basal" coverage, lasting the full 24 h, while rapid-acting insulin provides mealtime coverage. (E) Use of an external insulin pump infuses insulin at a precise basal rate, and the patient signals the pump to deliver bolus doses of insulin with each meal.

Energy intake distribution will depend on the type of insulin, the number of injections, and the aggressiveness of glycemic targets. Often, small changes in food ingestion can make a significant difference. If, for example, a patient tends to develop hypoglycemia at approximately noon, the skillful dietitian can either emphasize the necessity of eating lunch regularly before noon or suggest the patient consume some of the lunch carbohydrates as an 11 a.m. snack. These changes may eliminate the need to change insulin dose. Alternatively, if weight loss and caloric restriction are desired, then the prebreakfast insulin dose can be decreased. Especially with intensive insulin therapy (three or four daily injections or an external insulin pump), there is some flexibility in the timing of the meals but also a need for more accurate assessment of meal content. Some patients will learn their own ratio of grams of carbohydrate to insulin dose necessary to maintain blood glucose in a good range.

Eating disorders pose a serious problem to the management of type 1 diabetes. Presumably because people with diabetes are often diet conscious, the prevalence of eating disorders is surprisingly high among teenagers with diabetes. The problem is especially dangerous because young people may skip insulin injections in order to induce glucosuria, a sort of “metabolic purging.” These conditions clearly require prompt professional help.

### **Growth and development**

The total daily energy intake of a person with type 1 diabetes should be calculated to maintain normal growth and development in a child and normal weight in an adult. Examples of these calculations are provided in **Table 4**. As most people with type 1 diabetes are not overweight, they do not need low-energy diets. In fact, underfeeding is a poor way to maintain blood glucose control. The energy needed to establish and maintain normal weight should be matched with the insulin needed to control glycemia. There is no need for a thin or normal-weight person with type 1 diabetes to be perpetually hungry.

### **Carbohydrate counting**

Carbohydrate counting and calculations using food labels give the patient more freedom and flexibility with more choices. Food labels make the calculation of specific fat and carbohydrate content easier. The trend, therefore, is to emphasize the total carbohydrate in gram amounts or by carbohydrate “choices,” where one choice is equal to 15 g of carbohydrate. Examples of 15 g carbohydrate choice include a slice of bread, one-third cup of pasta or rice, or a small apple. If using a food label, one can count the amount of “net carbohydrate” by subtracting fiber from total carbohydrate, as dietary fiber does not affect glycemia. For example, if a food has 22 g of total carbohydrate and 3 g of fiber per serving, this food contains 19 g net carbohydrate. Fat intake should also be addressed with more emphasis on the types of fats, saturated versus mono- and polyunsaturated. This shift in teaching allows for more emphasis on specific carbohydrate and fat awareness rather than lumping mixed foods together in exchanges.

### **Gastroparesis**

An extremely difficult clinical challenge is posed by the patient with diabetic gastroparesis. This condition, a severe autonomic neuropathy reducing gastric motility and gastric emptying time, can sometimes be difficult to diagnose by standardized testing, such as gastric emptying studies. Gastroparesis causes symptoms of early satiety, nausea, vomiting, and abdominal pain, which can result in markedly variable food ingestion. Along with pharmacologic management and good glycemic control, the dietary prescription for diabetic gastroparesis should include small, frequent feeding as tolerated. Rarely, the condition can progress to the point that any oral intake is difficult, and tube feeding or a gastrostomy is required. Fortunately, diabetic gastroparesis tends to wax and wane in severity.

### **Type 2 diabetes**

Approximately 90–95% of all people with diabetes have type 2 diabetes. The prevalence of type 2 diabetes has increased substantially over the last two decades and has paralleled rising rates of obesity. There are two pathophysiologic mechanisms underlying type 2 diabetes: the body's cells are resistant to the action of insulin (insulin resistance), and the pancreas is unable to secrete enough insulin to overcome that resistance (relative insulin insufficiency). There is a complex interaction between these two processes, and their relative contribution to diabetes pathogenesis and progression over time may vary from individual to individual. Insulin resistance is strongly associated with overweight or obesity, although only a minority of people who are overweight or obese have diabetes, so there are clearly other processes at play. Persistent insulin resistance in type 2 diabetes, together with deteriorating pancreatic insulin secretion over time, sometimes results in patients with longstanding type 2 diabetes requiring exogenous insulin therapy. This does not change the diagnosis to type 1 diabetes, which is a disease of entirely different pathogenesis.

### **Major objectives**

The cornerstone of type 2 diabetes treatment is medical nutritional therapy which emphasizes a healthy diet, physical activity, and weight loss for individuals with overweight or obesity. For most patients with diabetes, a goal weight loss of  $\geq 5\%$  of their body weight is recommended. It should be noted that to achieve and maintain this weight loss goal, intensive interventions are needed, meaning that patients have frequent (at least monthly) contact over a period of at least several months; shorter and less intensive interventions are may be minimally effective. Intensive lifestyle interventions for patients with type 2 diabetes have demonstrated beneficial effects on weight, blood glucose, kidney function, long-term disability, and other benefits, although no benefits were found on cardiovascular outcomes. The best dietary strategy for accomplishing and maintaining weight loss is unclear and may vary from person to person depending on their individual eating patterns, preferences and nutritional needs. It should also be noted

that weight loss strategies for patients with type 2 diabetes should include consideration of pharmacologic therapy for weight loss and metabolic surgery, the latter being the most effective means of achieving weight loss and, for many individuals, remission of type 2 diabetes.

### Coexisting risk factors

Obesity, dyslipidemia, and hypertension are especially prevalent in type 2 diabetes and contribute to cardiovascular risk. Given that the majority of people with type 2 diabetes die of cardiovascular causes, it is critical for medical nutrition therapy for type 2 diabetes to address these cardiovascular risk factors. In fact, most evidence suggests that the management of coexisting risk factors, particularly hypertension, dyslipidemia, and smoking cessation, is more important than the treatment of hyperglycemia in preventing cardiovascular morbidity and mortality. Fortunately, the same intensive lifestyle changes that benefit blood glucose also improve these comorbidities. Medical nutritional therapy should target these comorbidities, such as by using a low sodium DASH diet and moderation of alcohol intake in patients with hypertension. In addition, medical management with antihypertensives and cholesterol lowering medications is often needed to achieve treatment targets.

### Other types of diabetes

Gestational diabetes, or elevated glucose that occurs during pregnancy, is relatively common, occurring in nearly 10% of pregnancies, and substantially increases the risk for developing subsequent type 2 diabetes. The management of gestational diabetes has many aspects unique to pregnancy and is not discussed here. Among non-pregnant adults, the vast majority of diabetes is due to type 2 diabetes and type 1 diabetes. Other types of diabetes are uncommon and include pancreatectomy-induced diabetes, diabetes due to chronic pancreatitis, cystic fibrosis, iron infiltration of the pancreas (hemochromatosis), or rare syndromes of insulin resistance. When there is widespread destruction of pancreatic cell mass, as with cystic fibrosis, pancreatectomy, or extensive cancer, the exocrine as well as endocrine functions are affected, leading to malabsorption and impaired glucagon secretion. Malabsorption causes steatorrhea and may require pancreatic enzyme replacement to avoid marked variability in carbohydrate as well as fat absorption.

## Diabetes medications and other non-nutrient factors that regulate blood glucose

No element of diabetes management exists in a vacuum, so it is essential to consider how dietary therapy interacts with other elements of glucose regulation and diabetes treatment. Besides glucose-lowering medications, other non-nutrient factors that affect blood glucose include specific medications (e.g., glucocorticoids), acute illnesses, and changes in physical activity. Some of these non-nutrient factors are discussed below.

### Insulin

As the two major types of diabetes (type 1 and 2) differ in pathogenesis, so the use of insulin differs for each. In type 1 diabetes the insulin doses must be closely matched to the meals ingested. As described earlier, insulin is administered for multiple purposes: basal insulin provides a continuous low level of insulin, and prandial insulin covers the increase in glucose with a meal. Prandial insulin may be given at prespecified doses (for example, 5 units with each meal) or be based on carbohydrate intake. In addition, patients may administer correctional insulin: rapid acting insulin given to cover high glucose levels, typically per a sliding scale (Table 8). Patients with type 1 diabetes typically will use all three of these types of insulin, for example 15 units of long-acting (basal) insulin at bedtime, and with each meal 1 unit of rapid acting (prandial) insulin per 15 g of carbohydrate plus an additional 1 unit of rapid acting (correctional) insulin for every 30 mg/dL blood glucose above 120 mg/dL. Alternatively, they may use an

**Table 8** Example of an insulin regimen for a patient with type 1 diabetes based on blood glucose level before each meal.

Meal	Insulin type	Units of insulin per blood glucose level (mg/dL)					
		<150	150–199	200–249	250–299	300–349	≥350
Breakfast	Rapid acting prandial	4	4	4	4	4	4
	Rapid acting SS	0	1	2	3	4	5
Lunch	Rapid acting prandial	4	4	4	4	4	4
	Rapid acting SS	0	1	2	3	4	5
Dinner	Rapid acting prandial	6	6	6	6	6	6
	Rapid acting SS	0	1	2	3	4	5
Bedtime	Long acting	14	14	14	14	14	14

SS, sliding scale.

**Table 9** Types of available insulin by onset, peak, and duration of action.

Category	Insulin generic name	Approximate onset	Approximate peak (h)	Approximate duration (h)
Rapid acting	Aspart	10–20 min	1	3–5
	Lispro	15–30 min	0.5–2.5	3–6.5
	Glulisine	25 min	1	4–5
Short acting	Regular	30–60 min	2–4	5–8
Intermediate acting	NPH	1–3 h	4–10	12–16
Long acting	Glargine	3–6 h	“Peakless”	11 – >24
	Detemir	3–4 h	3–9	6–23
	Degludec			

insulin pump or automated insulin delivery system. Many people with type 1 diabetes learn to adjust their insulin dose according to both the blood glucose at the start of a meal and the estimated amount that a unit of insulin will reduce their blood glucose—some people may be more sensitive to insulin than others, thus, the relationship between carbohydrate intake and insulin dose needs to be individualized.

For patients with type 2 diabetes, insulin is a medication of last resort. Of all classes of diabetes medications, it is the most dangerous with by far the highest risk for hypoglycemia. Hypoglycemia is a potentially serious complication that is associated with vascular events, falls, cognitive impairment, and mortality. Hypoglycemia also imposes a substantial burden on patients and their family and caregivers, and leads to worse medication adherence and glycemic control. Insulin also imposes significant practical burden on patients from injections, blood glucose monitoring, and sometimes also psychosocial burdens.

Therefore, insulin in type 2 diabetes is generally reserved for situations where blood glucose cannot be lowered by lifestyle change and other classes of diabetes medications, or there are contraindications or barriers to access other diabetes medications. Although nutritionists do not usually prescribe or adjust insulin, it is useful to know the various types of insulin available (Table 9) and patterns of insulin action (Fig. 3). In addition to those listed, there are also premixed insulin products, such as 70% NPH and 30% regular insulin, which provide a mixture of each insulins' action.

### Diabetes medications other than insulin

Diabetes medications other than insulin are the primary treatment for type 2 diabetes, and may also be used by some patients with type 1 diabetes who have developed insulin resistance. The number of available non-insulin diabetes medications has expanded dramatically over the past two decades, now including 11 medication classes and over 25 compounds, not to mention combination products and all of the generic and brand names of these products. Some of these medications are oral and others injectable. Here we will give brief overview of each medication class, but for more details about the selection, administration, and monitoring of these medications, refer to a reference such as the American Diabetes Association Standards of Medical Care in Diabetes.

**Metformin** is the first line medication for all patients with type 2 diabetes, as it has the most evidence of benefiting long-term outcomes. It is an oral medication that acts by decreasing hepatic glucose production and increasing insulin sensitivity. It may cause some modest weight loss, but is mostly weight neutral. Its major contraindication is low renal function, though it may be used safely in many patients with chronic kidney disease. Common side effects are diarrhea and nausea that are often worst when first starting the medication, and can be decreased by using long-acting metformin formulations. Long-term use of metformin may cause vitamin B12 deficiency, so some experts recommend monitoring vitamin B12 levels routinely.

**Sulfonylureas** (glipizide, glyburide, glimepiride) are older diabetes medications that are commonly used because they are inexpensive, easy to administer, and have few contraindications. They are oral medications that act by stimulating pancreatic insulin secretion. They cause significant weight gain, and their major side effect is hypoglycemia, although the risk is substantially lower than insulin. Of note, they interact with a number of antibiotics that can increase the effective dose of the sulfonylurea and cause hypoglycemia, so it is important to caution patients using sulfonylureas about these interactions.

**Thiazolidinediones** (pioglitazone, rosiglitazone) are older, effective diabetes medications that are not commonly used due to concerns about rare but serious side effects which include bone fractures and bladder cancer. They are oral medications that act by increasing insulin sensitivity. They are weight neutral and generally well tolerated. They are not recommended in patients with chronic kidney disease or heart failure because they can cause fluid retention.

**DPP-4 inhibitors** (sitagliptin, linagliptin, other -gliptins) are newer diabetes medications that are very well tolerated but relatively weak in their blood glucose lowering effect. They are oral medications that act in gut hormone pathways to stimulate glucose-dependent insulin secretion and slow gastric emptying. They are weight neutral, have few side effects, and some can be used without dose adjustment in chronic kidney disease. Unlike other newer classes of diabetes medications, they have not been demonstrated to have cardiovascular or renal protective benefits.

**GLP-1 receptor agonists** (liraglutide, dulaglutide, other -glutides) are newer diabetes medications that are being used increasingly due their cardiovascular and renal benefits and potential to cause weight loss. They are injectable medications administered daily or weekly that, like DPP-4 inhibitors, act on gut hormone pathways. Some may be used safely in chronic kidney disease. Common side effects include nausea and diarrhea, and they have been associated with increased risk of pancreatitis and gallbladder issues. Of note, liraglutide and semaglutide are also FDA approved for weight loss in patients with and without diabetes and are extremely effective, lowering weight by up to 15% of initial body weight. Therefore, these medications are being used increasingly for the dual purpose of glucose lowering and obesity treatment.

**SGLT-2 inhibitors** (empagliflozin, canagliflozin, other -flozins) are newer diabetes medications that are being used increasingly due to their cardiovascular and renal benefits. They are oral medications that act by increasing glucose loss in the urine. Calories lost this way are mostly countered by increased appetite but on average they cause modest weight loss. Dose adjustment for chronic kidney disease is required. They are also effective diuretics and have been shown to improve outcomes among patients with heart failure, although they are not approved solely for that purpose in patients without diabetes. Common side effects include genital mycotic infections, volume depletion and hypotension. In some studies, SGLT-2 inhibitors have been associated with rare but serious adverse events including bone fractures, amputations, diabetic ketoacidosis, and Fournier's gangrene (a life-threatening infection of the perineal area).

**Other diabetes medication classes** are used very infrequently. They are meglitinides,  $\alpha$ -glucosidase inhibitors, bile acid sequestrants, dopamine-2 agonists, and amylin mimetics.

### Physical activity

The effects of exercise on blood glucose levels are complex and sometimes unpredictable. Although moderate, extended aerobic exercise generally causes progressive lowering of blood glucose, intense exercise may transiently increase the blood glucose. Also, exercise can cause a drop in blood glucose 6–12 h later which may cause hypoglycemia for individuals who are treated with insulin. In general, it is recommended to modify diet to accommodate exercise, rather than changing the dose of diabetes medications, because the duration and intensity of exercise may be unpredictable. However, reducing insulin dosage in anticipation of exercise does work best for many individuals.

### Stress

Stress in normal life is difficult to quantify or study, but the usual experience is that blood glucose control deteriorates under stress. This is most likely due to changes in their diet such as eating for stress relief, rather than physiologic changes. Especially for patients with type 1 diabetes, it is important to counsel patients to maintain consistent eating habits in times of stress. It is common for patients with diabetes to have clinical eating disorders, and counseling by behavioral specialists or therapists specializing in eating disorders may be helpful.

### Dietary prevention and management of comorbidities

People with diabetes have a higher prevalence than the general population of important chronic conditions that require their own dietary considerations. These conditions include diabetes complications: cardiovascular disease and chronic kidney disease, as well hypertension and dyslipidemia that are risk factors for these complications. Dietary considerations for these comorbidities are discussed briefly in this section; for more detailed information refer to other chapters in this Encyclopedia of Human Nutrition, or other appropriate references mentioned below. In addition, smoking is a major contributor to all of these risk factors and complications, and for patient who use tobacco or e-cigarettes, smoking cessation counseling should be provided and the patient referred to smoking cessation resources.

#### Cardiovascular disease

For both primary and secondary prevention of cardiovascular disease, dietary approaches are aimed at addressing hypertension and dyslipidemia, the major cardiovascular risk factors discussed below. These risk factors contribute to the development of atherosclerotic cardiovascular disease which is the most common cause of death among people with diabetes. For individuals with failure and resultant propensity for fluid retention, it is important to follow a low sodium diet and avoid dietary indiscretion to sodium which can precipitate a heart failure exacerbation.

#### Dyslipidemia

Dietary control of dyslipidemia focuses on eating patterns that are low in saturated fats and *trans*-fat, and high in fiber and omega-3 fatty acids. Dietary patterns that achieve this include the Mediterranean diet and the DASH diet, discussed above. Increased physical activity is also important to reduce cholesterol and reduce cardiovascular risk: the American Heart Association recommends 150 min of physical activity of moderate intensity or greater per week for maximal cardiovascular benefit. It is important to note

that genetics explains approximately 40% of individual variation in lipid levels, so there is a limit to what changes in diet and lifestyle can accomplish. Patients should be encouraged to take and adhere to lipid lowering medications if they are indicated as these medications are well tolerated and effective at achieving dramatic lowering of LDL cholesterol and resultant prevention of cardiovascular disease and mortality.

### Hypertension

Dietary changes can make a dramatic impact on blood pressure, especially among people with elevated blood pressure, such that diet can reduce or eliminate the need for blood pressure lowering medications for some people. The two major dietary factors that contribute to blood pressure are sodium intake and the overall dietary pattern. A low sodium diet of less than 2300 mg per day of sodium is recommended for people with diabetes and hypertension, and lower sodium intake may be even more effective. In terms of dietary pattern, the DASH diet has been shown to be effective at lowering blood pressure in multiple clinical trials, and is more effective when used in combination with a low sodium intake. Details of the DASH diet are described above.

### Chronic kidney disease

Chronic kidney disease is a microvascular complication that occurs in 20%–40% of people with diabetes. Chronic kidney disease is defined and staged according to an individual's level of kidney function (glomerular filtration rate) and the presence and degree of protein loss in the urine. Dietary management of chronic kidney disease is complex, and further details can be found in guidelines specific to chronic kidney disease. Important factors to consider in dietary management are the stage of chronic kidney disease, use of renal replacement therapy (such as hemodialysis), degree of urinary protein loss, electrolyte balance, calcium and vitamin D levels, and use of medications with dietary implications such as phosphate binders or warfarin. For patients who have diabetes and chronic kidney disease stage 3 or greater, but are not on dialysis, a protein-restricted diet of approximately 0.8 g of protein per kg body weight per day is recommended as this has been demonstrated to slow the decline in kidney function. Patients who are on dialysis may need a higher level of protein intake as many patients who are on dialysis struggle with malnutrition. As in patients with heart failure, sodium restriction will be important for patients who have a tendency toward fluid accumulation. As chronic kidney disease progresses, electrolyte disturbances become more common, and in some patients a low potassium diet may need to be implemented to control potassium levels.

### Conclusions

Medical nutrition therapy is essential to all people with diabetes, of whatever type or severity. A healthy diet should contain important components, including foods containing carbohydrates from whole grains, fruits, vegetables, vitamins, and low-fat dairy products. Although blood glucose control and management of coexisting risk factors are overall goals, the implementation of dietary management is a highly complex and individualized process. Principles of medical nutrition therapy that generally apply to all diabetes, and specific features that apply to the various types of diabetes, have been discussed; but it must be emphasized that good nutritional management requires the close interaction of each individual patient with a knowledgeable expert in dietetics.

## Key points

- Diabetes Mellitus is a chronic multifactorial metabolic disorder characterized by a dysregulation in glucose metabolism leading to hyperglycemia and long-term complications, with a projection to affect 700 million people in 2045.
- Several types of diabetes have been classified by the WHO including T1DM, T2DM, GDM, and Maturity Onset Diabetes of the Young (MODY). Despite the heterogeneity of the disease, they all share hyperglycemia and defective insulin secretion or sensitivity.
- T1DM is an autoimmune disease characterized by the lack of insulin resulting from the destruction of pancreatic  $\beta$  cells on the islets of Langerhans. It is marked by its early onset and the presence of islets-specific autoantibodies (GADA, IA-2A, ZnT8). The key genetic risk factor is located on the Major Histocompatibility Complex (MHC or HLA) known as HLA-DR and HLA-DQ. Other non-MHC genes are involved in the development of T1DM, including *PTPN22*, *IFIH1*, *INS*, *CTLA4*, and *IL2RA*.
- T2DM is the most commonly diagnosed form of diabetes. T2DM is characterized by insulin resistance and/or insulin deficiency, making this disease heterogeneous in nature. The advancement in technologies has allowed recent genetic studies to discover five distinct subgroups of T2DM, which all have hyperglycemia in common, yet have different etiologies, and potentially different prognosis. This discovery will play a major role in advocating for a patient-centered treatment approach to prevent the possible complications.
- GDM is the third common type of diabetes diagnosed during the second half of pregnancy, and usually resolving with delivery. The main cause of GDM is the inability of pancreatic  $\beta$  cells to respond to increased glucose levels and insulin resistance. This form of diabetes is quite similar to T2DM, including the genes involved in its development.
- MODY are a cluster of heterogeneous autosomal dominant inherited non-autoimmune Diabetes Mellitus sharing similarities with both T1DM and T2DM. Given the early-onset of the disease, it is commonly misdiagnosed as T1DM; however, it has its own genetic etiology affecting the HNF gene family.

## Introduction

Diabetes Mellitus is a chronic metabolic disorder characterized by a dysregulation of glucose metabolism leading to hyperglycemia and long-term vascular complications. Diabetes is a leading non-communicable disease globally, with over 463 million living with the disease currently and a projected 700 million people affected by 2045 (Saeedi et al., 2019). Despite the heterogeneous etiological and clinical nature of the disease, all existing types share hyperglycemia and defective insulin secretion or sensitivity. The most commonly diagnosed, Type 1 Diabetes Mellitus (T1DM) and Type 2 Diabetes Mellitus (T2DM), are quite distinct in both their epidemiology and etiology (Saeedi et al., 2019). T2DM accounts for 90% of diabetes cases worldwide and has been shown to be heterogeneous with etiologies ranging from insulin deficiency to insulin resistance (Ahqvist et al., 2018; Saeedi et al., 2019). T1DM is an autoimmune disease characterized by a deficiency in insulin secretion from pancreatic  $\beta$  cells (Dimeglio et al., 2019; Ilonen et al., 2019). Other rarer types of diabetes are diagnosed regularly and have been classified by the World Health Organization (WHO). However, the scope of this review will mainly focus on T1DM and T2DM, with a brief overview on Gestational Diabetes Mellitus (GDM) and Maturity Onset Diabetes of the Young (MODY).

## Type 1 diabetes mellitus (T1DM)

### Prevalence

According to the International Diabetes Federation, T1DM makes up 10–15% of the global total diabetes prevalence (Katsarou et al., 2017). The prevalence of T1DM has increased at a rate of 2–3% per year (Dimeglio et al., 2019). This increase has been mainly observed in children under the age of 15 years, with a global incidence of 79,000 children per year in 2013 and 90,000 cases in 2015 (Katsarou et al., 2017; Patterson et al., 2014). About 25% of the cases were diagnosed in Europe, 20% in North America and Caribbean, and 6% in Western Pacific (Patterson et al., 2014). In adults aged 15–19 years, the highest incidence was in Estonia (39.9/100,000) and the lowest incidence in Mauritius (1.1/100,000) (Diaz-Valencia et al., 2015). Those differences can be attributed to factors including genetic susceptibility, environmental exposures, and socio-economic status (Dimeglio et al., 2019).

### Etiology

T1DM is a chronic disease characterized by the lack of insulin resulting from the destruction of pancreatic  $\beta$  cells on the islets of Langerhans (Dimeglio et al., 2019; Ilonen et al., 2019). T1DM can appear at any age although it is commonly diagnosed in children or young adults before the age of 40 years (Ilonen et al., 2019).

T1DM is mainly characterized by a communication between the endocrine pancreas and the immune system (innate and adaptive) (Dimeglio et al., 2019). The main markers indicating destruction of  $\beta$  cells destruction are the appearance of islet-specific autoantibodies such as glutamic acid decarboxylase autoantibody (GADA), IA-2 antigen (IA-2A), and zinc transporter 8 (ZnT8), in addition to deficiency in insulin production (Ilonen et al., 2019; Katsarou et al., 2017). The subsequent progression to symptomatic T1DM depends on the number of expressed autoantibodies and the age at which the expression occurs. As such, those expressing more than two autoantibodies during the first three years of their lives have a higher risk of progressing into T1DM within 10–20 years (Ilonen et al., 2019; Katsarou et al., 2017). Notwithstanding, some people might express autoantibodies and yet not develop T1DM. Further, at diagnosis, people with T1DM show reduced  $\beta$  cell function, which may slightly improve with treatment over the course of the first year (known as the “honeymoon period”) (Dimeglio et al., 2019). It is speculated that the autoimmune trigger is most likely to happen during the *in-utero* phase, when the person is first exposed to those autoantibodies, especially if the mother suffered from T1DM (Ilonen et al., 2019).

T1DM can also arise from insulinitis, whereby immune cells infiltrate the pancreas and destroy  $\beta$  cells accordingly. The most commonly involved immune cells are CD8<sup>+</sup> T-cells, CD4<sup>+</sup> T-cells, B cells, and macrophages. Insulinitis is also characterized by the hyperexpression of class I human leukocyte antigen (HLA) in islet cells, which stimulates Interferon synthesis, autoantigen presentation to CD8<sup>+</sup> T-cells, and accelerates the death of  $\beta$  cells (Dimeglio et al., 2019; Ilonen et al., 2019). A third mechanism involves the inflammation of the exocrine pancreas and is characterized by an increased expression of T-cells and CD11c<sup>+</sup> (Dimeglio et al., 2019; Ilonen et al., 2019). This mechanism, more common in T1DM without elevated levels of autoantibodies, changes the physiology of the pancreatic extracellular matrix and increases vascularization (Dimeglio et al., 2019; Ilonen et al., 2019). The pathogenesis of T1DM is described in Fig. 1 below.

Another subgroup of T1DM diabetes is Latent Autoimmune Diabetes (LADA). This subgroup typically occurs in adulthood and does not require insulin treatment for the first 6 months following diagnosis. Accordingly, LADA is often regarded as a milder form of an autoimmune response with pathological features that closely resemble T2DM. With that said, LADA is a T1DM subgroup because of its resulting insulinitis and expression of IA-2A (Dimeglio et al., 2019; Ilonen et al., 2019; Pozzilli and Pieralice, 2018). On the other end of the spectrum, the genetic susceptibility of LADA seems to be less expressed than it is for T1DM. The HLA, which are very common in the young and adult onset of T1DM, are less frequent in LADA. The prevalence of LADA is higher than originally thought. In fact, LADA cases constitute 2–12% of all adult-onset autoimmune diabetes in adults, and 4–14% of T2DM cases in Europe diagnosed in adulthood are positive for T1DM-associated autoantibodies. The global prevalence of LADA differs based on the inclusion criteria and diagnostic methods applied to identify the disease (Pozzilli and Pieralice, 2018). Hence, unlike T1DM, LADA may be prevented by a healthy lifestyle such as weight regulation, healthy eating, and physical activity.

## Genetics

T1DM is a polygenic disease affected by both genetics and the environment with twin concordance varying between 30 and 70%, sibling concordance of 6–7%, and a 1–9% chance for children with at least one parent with diabetes (Dimeglio et al., 2019; Katsarou et al., 2017). The key genetic risk factor, accounting for 40–50% of T1DM, is located on the major histocompatibility complex (MHC) on the short arm of chromosome 6 (IDDM-HLA, 6p21), known as HLA-DR and HLA-DQ (Dimeglio et al., 2019; Katsarou et al., 2017; Pociot and Mcdermott, 2002; Redondo et al., 2018). Both DR and DQ consist of alpha and beta heterodimers; DRA and DRB loci encode for the alpha and beta of DR, while DQA1 and DQB1 loci encode for the alpha and beta chains of DQ (Pociot and Mcdermott, 2002). Several haplotypes of those alleles exist, varying by ethnicity, some of which are protective against T1DM (i.e., DR15-DQ6), while the commonly expressed DR3-DQ2 and DR4-DQ8 increase susceptibility to T1DM (Katsarou et al., 2017; Pociot and Mcdermott, 2002; Redondo et al., 2018). HLA alleles are associated with different autoantibodies: DR3-DQ2 was found to be associated with GADA, while DR4-DQ8 has been associated with IA-2A (Robertson and Rich, 2018). The strongest genetic association at the population level has been observed for HLA-DQ1, DQB1, and DRB1. Further, a heterozygotic inheritance of DR3-DQ2 and DR4-DQ8 has a much stronger association with T1DM than the homozygotic inheritance of either one of them (Katsarou et al., 2017; Pociot and Mcdermott, 2002; Redondo et al., 2018).

Studies suggest that the association between HLA and T1DM results from polymorphisms of genes encoding for various amino acids in the peptide-binding section of the HLA molecule. The latter impacts the binding affinity and variety of peptides that can reach T-cells, specifically, position 57 of HLA-DQB1 and position 13 of HLA-DRB1 (Redondo et al., 2018). Of the several classes of the HLA family, HLA class I and the peptide antigen complex play a major role in the development of T-cells selection in the thymus, as well as in the cytotoxicity mediated by antigen-specific T-cells (Pociot and Mcdermott, 2002).

There are also non-MHC genes associated with T1DM, though their effects are not as comparable to MHC genes (Pociot and Mcdermott, 2002; Robertson and Rich, 2018). The strongest T1DM-associated variants encoding candidate genes are *PTPN22*, *IFIH1*, *TYK2*, and *SIRPG* (Redondo et al., 2018; Robertson and Rich, 2018). They serve as important targets for direct variant-protein and function relationships. *PTPN22* on chromosome 1p13 encodes a major down-regulating protein, LYP, which in turn inhibits TCR signal transduction by the dephosphorylation of tyrosine residues on two main proteins, Lck and CD3 (Pociot and Mcdermott, 2002; Prasad and Groop, 2015; Redondo et al., 2018; Robertson and Rich, 2018). Further, functional studies on *PTPN22* have shown various novel frameshift mutations and splicing variants that change between generations. Similarly, functional studies on LYP protein showed that a new isoform of the protein reduced CD4<sup>+</sup> T-cells' response to antigens (Robertson and Rich, 2018). *IFIH1* encodes the protein melanoma differentiation-associated protein 5 (MDA5), which binds viruses and mediates the interferon response of the immune system to respond; hence, an insult to this protein reduces the capability to fight viruses and thus increases risk of T1DM (Redondo et al., 2018).

Another essential player is the variable number tandem repeat (VNTR) in the INS promoter on chromosome 11 (11p15.5) (Pociot and Mcdermott, 2002; Redondo et al., 2018; Robertson and Rich, 2018). VNTR INS regulates insulin expression in the thymus, hence modulating the negative selection of T-cells for the insulin-derived peptides. The relationship between the INS gene and the immune system has been studied in nonobese diabetic mouse (NOD), where cloned diabetes-inducing CD4<sup>+</sup> T-cells created antigenic hybrid peptides through cross-linking proinsulin peptides to other peptides in secretory granules of pancreatic beta-cells (Robertson and Rich, 2018). In humans, it has been shown that CD8<sup>+</sup> T-cells, encoded by INS mRNA, have the capacity to attack and kill pancreatic beta cells, a common islet autoimmunity pathway leading to T1DM (Robertson and Rich, 2018). The other gene modifying T1DM risk is cytotoxic T-lymphocyte associated protein (CTLA4), essential for T-cell development and acts as a negative regulator of cytotoxic T-cells (Pociot and Mcdermott, 2002; Prasad and Groop, 2015; Redondo et al., 2018; Robertson and Rich, 2018). The established relationship is at the post-transcriptional level, where an immunoglobulin protein, Abatacept (CTLA4-Ig), blocks the interaction with CD28 by selectively binding CD80/CD86, which can reduce beta-cell loss in newly diagnosed people (Pociot and Mcdermott, 2002; Redondo et al., 2018; Robertson and Rich, 2018). Other genes and variants associated with T1DM have been discovered, such as Interleukin 2 receptor subunit alpha (*IL2RA*). The latter is essential for

T-regulatory cells' function, and hence, the abnormalities caused by genetic insult to the variant lead to an imbalance between T-regulatory cells and T-effector cells, thus increasing the risk of T1DM (Prasad and Groop, 2015; Redondo et al., 2018). Genetic variants are still being discovered on a daily basis, and their expression and the risk of increased susceptibility differs between populations and ethnicities.

### Environmental/infectious factors

Over the years, T1DM diagnosis has overlapped with the seasonal spike in virus infections, mostly peaking during the colder months, as well as reported disease onset with the outbreaks of mumps and rubella (Ilonen et al., 2019). Recently, the focus has shifted to human enterovirus B (echovirus and coxsackie B), peaking late summer and early autumn. The most common explanation is the increased need for insulin, which accelerates the rate at which T1DM develops, especially in children. However, the time of birth may also be key, since exposure to maternal antibodies during fetal growth protects against viral infections and T1DM. Several studies comparing controls to T1DM people who died from the disease found that it is more common to find  $\beta$ -cell stain positive for enterovirus VP1 protein in those who had T1DM. The latter finding indicates that people with T1DM suffer from a low-grade infection in their pancreatic islets. For instance, coxsackie B virus infects monocyte-derived macrophages, which is a type of cells found abundantly in immune cells infiltrates of the pancreatic islets of T1DM patients. A controversial point in this issue is the timing of the viral infection compared to the diagnosis of T1DM. Some have found enterovirus infection to be present at diagnosis, while others, mainly in children, have found the infections to be present around the time of autoantibody seroconversion and not diagnosis (Ilonen et al., 2019). As for the mechanisms leading to  $\beta$ -cell destruction, there are several. The one with the least effect is cytolysis by productive infection, which due to its poor-replicative nature, would lead to functional deficiency in  $\beta$ -cells. Following infection, autoantigens are released from  $\beta$ -cells and transported to pancreatic lymph nodes by macrophages, where they activate autoantigen-specific T-cells. Upon this, CD8<sup>+</sup> cytotoxic T-cells are returned to the islets where the virus has increased interferon activity that presents antigens to the cytotoxic cells by increasing the expression of class I HLA, hence the start of the attack on  $\beta$ -cells (Ilonen et al., 2019).

### Treatments

Treating T1DM is a complex process with an overall objective to promote glycemic control and a healthy lifestyle to prevent metabolic (i.e., hyperglycemia, hypoglycemia, and ketoacidosis) and longer-term micro- and macro-vascular complications of diabetes.

The most common treatment is insulin with analogues having various onsets and durations of action mimicking pancreatic insulin release (Dimeglio et al., 2019; Katsarou et al., 2017). The only non-insulin medication approved is pramlintide (Dimeglio et al., 2019). Yet, some patients use metformin, glucagon-like receptor agonists, and dipeptidyl peptidase-4 inhibitors. Continuous glucose monitoring (CGM) has been used to closely examine glucose levels throughout the day to titrate dosage and to prevent episodes of hypoglycemia or hyperglycemia. The American Diabetes Association (ADA) alongside other associations, have set targets for HbA1c to 7.5% for the pediatric population and 7% for adults. Those levels can be higher or lower based on the patient's health and overall condition (Dimeglio et al., 2019).

### Current status and future

Several studies, such as the Diabetes Prevention Trial (DPP) and the European Nicotinamide Diabetes Intervention Trial (ENDIT) among others, have tried to prevent or delay the development of T1DM in predisposed individuals by administering an early regimen of insulin. Unfortunately, these trials have not yielded beneficial results. However, it is still possible that T1DM is one of the rare diseases that can benefit from primary prevention by enhancing the immune system, and thus preventing insulinitis and the start of an autoimmune response. Further understanding of the etiology of T1DM and its treatment and prevention is needed.

## Type 2 diabetes mellitus (T2DM)

### Prevalence

T2DM makes up more than 90% of diabetes cases, which also happens to be one of the most common non-communicable diseases globally. In 2017, about 462 million people were living with T2DM and this number is expected to go over 600 million by 2040 (Kaiser et al., 2018; Khan et al., 2020; Zheng et al., 2018). The major contributors to this epidemic are the shifts from low to middle income socio-economic status and the accompanying epidemiological and nutritional transitions that countries are experiencing as a consequence of urbanization and industrialization (Zheng et al., 2018). The prevalence of the disease varies widely across ethnicity and geography, with the two main epicenters being China and India. The onset of the disease in these two countries has been linked to a lower BMI and a younger age than high-income European countries (Khan et al., 2020; Zheng et al., 2018). Currently, the countries with the highest numbers of people with T2DM are China with 88.5 million, India with 65.9 million, and the US with 28.9 million. However, the countries with the highest prevalence are in the Middle East with a prevalence of 12.8%, while Africa has the lowest prevalence of 4.7% (Khan et al., 2020; Saeedi et al., 2019; Zheng et al., 2018). This large disparity

in prevalence highlights differences in socio-economic development, and the presence of environmental and genetic factors associated with the disease. As such, the prevalence of the disease differs widely between Indigenous native populations and non-Indigenous populations, with a 3–5 times higher risk in indigenous populations, and between global populations (Khan et al., 2020; Ley et al., 2009; Prasad and Groop, 2015; Zheng et al., 2018). As such, Asians Indians have an earlier onset and etiology compared to Pima Indians (Khan et al., 2020; Narayan et al., 2021; Prasad and Groop, 2015; Staimez et al., 2019; Zheng et al., 2018).

### **Etiology**

T2DM is a common multifactorial disease mainly caused by a defect in either insulin secretion or in the feedback loop between insulin secretion by pancreatic  $\beta$  cells and insulin action at the level of peripheral tissues, thus causing hyperglycemia. On one hand, reduced insulin secretion prevents the body from maintaining physiological glucose levels while on the other hand, insulin resistance leads to increased endogenous hepatic glucose synthesis and reduced peripheral (muscle and adipose tissues) glucose uptake. Those can be two separate events occurring at different times or simultaneously. However, their coexistence governs the progression to T2DM through a worsened hyperglycemia (Galicia-García et al., 2020; Zheng et al., 2018). Certain conditions associated with T2DM, like obesity, are characterized by chronic low-grade inflammation, which infiltrates the pancreatic islets, causing ER stress and oxidative stress leading to the loss of integrity of the islets. The excessive presence of free fatty acids and glucose in circulation leads to lipotoxicity and glucotoxicity, which induce ER stress through the unfolded protein response pathways (UPRP), eventually causing  $\beta$  cell damage. The activation of UPRP causes accumulation of misfolded insulin, which increases the production of reactive oxygen species, thus worsening the inflammatory status. These pathological conditions can impair communications between islet cells of the pancreas and peripheral tissue, and contribute to poor regulation of insulin release, ultimately causing  $\beta$  cell impairment (Galicia-García et al., 2020; Zheng et al., 2018). As for insulin resistance, it is characterized by a decreased physiologic response of insulin-sensitive tissues which progresses into a systemic insulin resistance. At the level of the muscles and adipose tissues, insulin resistance will lead to the reduced responsiveness of the glucose transporter GLUT4, hence hindering glucose uptake from circulation. This could also be caused by the defect in the activation of the insulin receptors (IRS-1 and IRS-2) at the surface of peripheral tissues, thus blocking the intracellular downstream signaling cascade leading to T2DM with time. The main role of insulin at the hepatic level is to stimulate glycogen storage and prevent the endogenous glucose synthesis. However, insulin resistance impairs the process, as well as increases lipogenesis and proinflammatory cytokines (leptin and adiponectin) release, which further increases inflammation and may contribute to the destruction of  $\beta$  cells in the long run (Galicia-García et al., 2020). Hence, T2DM is a complex disease requiring the presence of either impaired  $\beta$  cell function or insulin resistance, or both at different or at the same time.

### **Genetics**

Studies have shown that the concordance of T2DM in monozygotic twins (~70%) is higher compared to dizygotic twins (20–30%), highlighting the significant genetic contribution to the disease. Prediabetes traits have been also shown to be inherited, and ethnicity/race play a major role in determining susceptibility (Nair and Baier, 2015; Prasad and Groop, 2015). Nowadays, with the technological advancements and the reduced costs, scientists have been able to better understand the complexity of T2DM. Candidate-gene association studies (CGAS) and genome-wide association studies (GWAS) have shed light on the polygenic nature of the disease, showing its potential population-specific genetic etiology. The key candidate genes in T2DM reported are *KCNJ11*, peroxisome proliferator-activated receptor gamma (*PPARG*), *HNF1B*, *WFS1*, and insulin receptor substrate (*IRS1*). *KCNJ11* encodes Kir6.2, an essential subunit of the ATP-sensitive potassium channel involved in regulating glucose-stimulated insulin release from pancreatic islets. One variant, E23K, has been identified as the most potent and to be the target of the therapeutic drug sulfonylureas (Nair and Baier, 2015; Prasad and Groop, 2015). *PPARG* is mainly expressed in adipose tissues encoding for a type II nuclear receptor (PPAR- $\gamma$ ), involved in regulating fatty acid storage and glucose metabolism. Its variant P12A, causing a substitution of proline for alanine, is the target of the therapeutic drug family thiazolidinediones, aimed at improving insulin action and secretion (Nair and Baier, 2015; Prasad and Groop, 2015). Further, linkage studies have identified genes responsible for the Mendelian forms of T2DM such as *MODY*, which share a common gene with T2DM called hepatocyte nuclear factor subunit alpha 4 (*HNF4A*) (Nair and Baier, 2015; Prasad and Groop, 2015).

However, the first identified gene *via* linkage studies was cysteine protease calpain 10 (*CAPN10*) on chromosome 2q37, mainly reported in people from Mexican-American descent (Nair and Baier, 2015; Prasad and Groop, 2015). *CAPN10* is involved in glucose-stimulated secretion and action of insulin and  $\beta$  cell function through facilitating the necessary actin-reorganization; hence, its involvement in insulin resistance of T2DM (Meza-Espinoza et al., 2019). Further, an insertion/deletion variant in this gene known as *SNP-19* (*rs3842570*) has been linked to increased levels of glycated hemoglobin and obesity in T2DM people (Meza-Espinoza et al., 2019). Another gene, widely replicated for T2DM is *TCF7L2*, showing a strong linkage signal on chromosome 10q in the Icelandic population. With the exception of Pima Indians, variants of this gene have been found to be related to T2DM in most ethnic populations (mainly European), with an OR of 1.50 in non-Hispanic Whites (Nair and Baier, 2015; Prasad and Groop, 2015). *IRS1* gene encodes a protein responsible for mediating cellular processes by transmitting signals from insulin receptors to downstream signaling pathways. The *IRS1* protein is responsible for stimulating autophosphorylation of its  $\beta$  chain, which in turn phosphorylates several downstream molecules to activate insulin action. On the one hand, a mutation in this

gene involving the C allele of rs2943641 has been shown to be associated with insulin resistance. On the other hand, the variants of *IRS1* gene reduce the basal levels of IRS1 protein, which diminishes the induction of IRS1-associated downstream PI3K activity in muscles. Additionally, the substitution of glycine for arginine at position 972 in the molecule, one of the strongest mutations involved in the progression of T2DM, has been linked to insulin resistance in the majority of the population (Yousef et al., 2018). Numerous genes have been discovered thus far *via* linkage studies, GWAS, CGAS, and whole genome sequencing (WGS) in different ethnic groups, most of which have been confirmed to play a role in T2DM predisposition in most ethnicities. With the advancement in techniques and the rise of the GWAS studies, novel approaches using Illumina sequencing uncovered the presence of over 150 single nucleotide polymorphisms (SNPs) mapping to more than 120 loci. Some of the variants discovered are trans-ethnic, and hence affect people all over the globe, while a good part of the discovered variants is ethnicity-specific or population-specific (Nair and Baier, 2015; Prasad and Groop, 2015). As such, minor variants in *GLIS3*, *ITM2-R3HDM-L-HNF4A*, *ZFAND*, *PSMD6*, *MAEA*, *KCNK16*, and *PEPD* among others, were found to be specific for the East Asian population; variant in *TMEM163* specific for the North Indian origin, and variant in *SLC16A11* in Mexicans (Prasad and Groop, 2015). Despite the novel genetic discoveries in the etiology of T2DM, it explains only less than 20% of the heritability of the disease and its prediction. In fact, T2DM is a multifactorial disease that has genes influenced by the environment, intrauterine environment, and other existing health conditions (Prasad and Groop, 2015). Also, diabetes inheritance relies on which parent is affected by the disease, as such, T2DM has a higher maternal inheritance, while T1DM has a higher paternal inheritance (Prasad and Groop, 2015).

### Heterogeneity

Until a few years ago, diabetes was classified as either T1DM or T2DM (as major types). However, increased recognition of early-onset T2DM (younger than 30 years) in several populations (Fagot-Campagna et al., 2000), and growing recognition of T2DM in nonobese populations pointed to the need to explore heterogeneity of the disease (Gujral and Narayan, 2019; Gujral et al., 2018; Narayan, 2016). Thus far, the diabetes classification has relied on the presence or absence of islet-specific autoantibodies and the age of diagnosis, hence more than 80% of the cases are classified as T2DM (Ahlqvist et al., 2018; Ilonen et al., 2019). With additional variables (i.e., *PDX1*, *PAX4*, *INS*, *HNF1A*, *GCK*, etc.) (Lawlor and Stitzel, 2019), Ahlqvist et al. proposed five distinct diabetes subgroups possible (Ahlqvist et al., 2018). Two of the groups have variant traits associated with reduced  $\beta$  cell function and insulin deficiency, while the other three groups have variant traits related to insulin resistance (Ahlqvist et al., 2018; Lawlor and Stitzel, 2019). The first group, severe autoimmune diabetes (SAID), was characterized by an early-onset diabetes exhibiting relatively low BMI, poor metabolic control, insulin deficiency, and presence of GADA. The second group, severe insulin-deficient diabetes (SIID), was similar to SAID except it was GADA negative. The third group, severe insulin-resistant diabetes (SIRD), showed a severe insulin resistance and increased BMI. The fourth group, mild obesity-related diabetes (MOD), exhibited high BMI but not insulin resistance. Lastly, group five, mild age-related diabetes (MARD), was similar to group four, in addition to the late-onset of the disease (Fig. 1) (Ahlqvist et al., 2018). The replication of these clusters in certain European cohorts, such as ANDIS, SDR, ANDIU, and DIREVA, showed the same grouping pattern for newly diagnosed and existing diabetes cases (Ahlqvist et al., 2018). These results have been further replicated in several studies, and the results were in line with the initial findings (Bancks et al., 2021; Kanaya et al., 2011, 2014). It appears that the various diabetes phenotypes are present across populations, but their frequency might vary across population; for example, South Asians groups may have a higher frequency of T2DM phenotypes related to impaired insulin secretion. Furthermore, complications and disease progression were assessed for all five groups identified by Ahlqvist et al. This showed that SAID and SIID had higher  $A_{1c}$  levels, a stronger indicator for ketoacidosis, while SIRD had the highest risk of non-alcoholic fatty liver disease (NAFLD) and kidney disease (Dennis et al., 2019; Kanaya et al., 2011, 2014). The ADOPT and RECORD trials showed differences in glycemic progression and health outcomes per group, as to the ones found in the original study by Ahlqvist's team (Dennis et al., 2019). Other studies have also been conducted to highlight the differences in the subgroups of T2DM and their complications, such as the MASALA-MESA studies (Bancks et al., 2021; Kanaya et al., 2014). This discovery also allowed linking genetic variants and loci with their corresponding subgroups. As such, variant of gene *TCF7L2* was associated with SID, MOD, and MARD; another variant in gene *TM6SF2* has been associated with both SIRD and the risk of NAFLD; and variant in gene *HLA* has been associated with SAID (Ahlqvist et al., 2018). This is extremely helpful in moving diabetes treatment and diagnosis into a personalized or patient-centered approach to prevent any unwanted complications and delaying progression.

### Other factors

There are strong data linking inter-generational factors and diseases—the Developmental Origin of Health and Diseases (DOHaD) theory. The latter postulates that the structure and physiology of organs influenced during fetal growth may adapt to adverse growth conditions predisposing to diseases in adulthood. As such, poor nutrition during pregnancy may lead to structural and functional changes in key organs including the pancreas (Barker, 2004; Vaiserman and Lushchak, 2019). In fact, an unhealthy pregnancy may cause *intra-uterine* growth restriction (IUGR) and dysfunction in pancreatic  $\beta$  cells. The natural response to this gestational insult is the reduced fetal insulin synthesis by building insulin resistance, which serves as a coping mechanism for unfavorable environmental conditions postnatally (Barker, 2004; Vaiserman and Lushchak, 2019). It may also be possible that *intra-uterine* growth restriction might impair beta cell function or beta cell mass. All this has led to the thrifty phenotype hypothesis, which conjectures that any *in utero* insult (i.e., placental dysfunction, stress, and inadequate nutrients etc) may lead to adaptations aiming at an

optimal nutrient storage to maximize metabolic functions. The fetal adaptations, be it reduced peripheral insulin sensitivity or impaired pancreatic development, may accrue into adulthood in the form of reduced insulin secretion or insulin resistance, which serve as the basis of T2DM (Barker, 2004; Vaiserman and Lushchak, 2019). Further, studies have shown a U-shaped association between birth weight, which is impacted by nutritional status during gestation, and risk of T2DM later in life. As such, both low birth weight (LBW) and high birth weight (HBW) increase the risk of T2DM in adulthood. The most likely explanation for the LBW offspring is the catch-up growth in the postnatal period which causes a disproportionate gain of fat to lean mass or impaired insulin secretion. Whereas, the explanation for HBW is the increased risk of overweight/obesity starting childhood, which might grow into adulthood if not addressed early in life (Vaiserman and Lushchak, 2019). Dietary factors, weight, and physical activity also play a role in the risk of developing T2DM. When it comes to weight, it was first thought that only overweight/obesity is associated with T2DM, while in fact the heterogeneity of the disease has shown that increased body fat mass despite a low/normal BMI may be a predisposing factor (Weisman et al., 2018). The changes in dietary patterns across populations into an industrialized diet has contributed tremendously to the increase in weight and fat mass. The industrialized diet pattern relies heavily on sugar sweetened beverages and energy-dense-nutrient-poor foods, mainly based on the ease of accessibility to those items away from home, as well as their reduced prices. Energy-dense foods are generally higher in their fat content, typically saturated fats compared to unsaturated fats. Further, consumption of high glycemic index foods has also been linked to increased T2DM risk, while a diet rich in low glycemic foods and rich in fiber is associated with a lower risk of T2DM (Weisman et al., 2018). Additionally, with economic development and modernization across the globe, people have started to rely more on cars and less on walking, mechanized labor, having more desk jobs, engaging in less physical activity due to their working schedules, and to higher use of screen time. Hence, physical inactivity and sedentary have grown over time, increasing the risk of obesity and insulin resistance and thus the risk of T2DM. In fact, both resistance and endurance exercises have been shown to improve glycemic control in people with diabetes, making it an essential component of diabetes treatment (Weisman et al., 2018). Finally, T2DM disproportionately affects people with lower socio-economic status, due to several factors—access to healthy foods and exercise, stress, etc. Lower education status and lower income increase food insecurity and reduce access to health care, making it more difficult for people to get the medical attention and healthy diet they need to prevent the development of T2DM (Weisman et al., 2018). Fig. 2 summarizes some of the factors implicated in the risk of developing T2DM among different races and ethnicities.

### Treatments

The main objective of treatment is either to prevent or delay T2DM in case of pre-diabetes or mitigate the progression of the condition and its potential complications. The first objective may be achieved through the implementation of proven interventions aimed at a healthy lifestyle, including diet and exercise, or pharmacology (e.g., metformin), while the second is attained by the further addition of pharmacologic treatment to lifestyle interventions, and also attention to blood pressure and lipid control. Diet and

**Fig. 2** Factors involved in risk of developing T2DM among different racial and ethnic groups. Source: Bancks et al. (2021, JCEM).

exercise have proven to be very efficient in the prevention and treatment of diabetes; in addition to good quality and duration of sleep (Diabetes Prevention Program (DPP) Research Group, 2002; Marín-Peñalver et al., 2016). In most cases, T2DM is accompanied by excessive weight and adiposity, which are key players in increasing insulin resistance and impairing insulin secretion from pancreatic cells, and in depositing ectopic fat in places like the liver, pancreas, and muscle. Hence, a moderate weight loss (mainly fat) in those who are overweight would be beneficial to achieve optimal levels of glycated hemoglobin and blood glucose (Marín-Peñalver et al., 2016; Pi-Sunyer, 2014). This is affected through adequate caloric and nutrients intake following a personalized plan. However, for those who do not suffer from excessive weight, an isocaloric and balanced diet is still crucial; results observed in several studies including the LookAHEAD trial (Marín-Peñalver et al., 2016; Pi-Sunyer, 2014). Both aerobic and resistance exercises help improve glycemic control, in addition to regulating blood lipids and blood pressure. The recommendation is to engage in at least 150 min of physical activity per week at moderate intensity. However, it is important to note that exercise is contraindicated in case of uncontrolled hyperglycemia or hypoglycemia, as this could damage the peripheries (Marín-Peñalver et al., 2016). One of the most successful lifestyle changes intervention addressing people with diabetes is that which was tested in the DPP trial. DPP was aimed at teaching people how to build a better lifestyle using nutrition, exercise, and behavioral changes. The main two findings of the trial were the superiority of lifestyle changes over oral pharmacological agents and a 58% reduction in the incidence of T2DM (Diabetes Prevention Program (DPP) Research Group, 2002). Several other efficacy and translation trials of interventions like the DPP have been reported and meta-analyzed, as well as other sustainable interventions such as HDC, Alliance, and REACH (Galaviz et al., 2018a,b; Haw et al., 2015, 2017). Pharmacologic treatments for glucose control in people with diabetes are numerous; but the two most commonly prescribed agents are: Biguanides and Sulfonylureas. Metformin is one the most commonly prescribed biguanides as the first treatment of choice for T2DM. Metformin has the capacity of reducing intestinal glucose absorption and inhibiting hepatic gluconeogenesis through different mechanisms. Additionally, it increases insulin sensitivity, which opposes insulin resistance (Harrigan et al., 2001; Marín-Peñalver et al., 2016). Since their introduction in the 1950s, Sulfonylureas have been widely used given their stimulation of insulin release from pancreatic  $\beta$  cells and increased action. Their action is possible through the inhibition of an ATP potassium channel, which changes membrane potential by calcium influx to the cell, hence releasing insulin from secretory granules of the pancreas. In some cases, sulfonylureas and biguanides are prescribed in tandem (Harrigan et al., 2001; Marín-Peñalver et al., 2016). Other newer treatments have been introduced such as dipeptidyl peptidase-4 inhibitors (DPP4i) and sodium glucose co-transporter 2 inhibitor (SGLT2i). DPP4i targets the regulation of glucose through blocking incretins—agents that increase insulin secretion and inhibit glucagon. Generally, DPP4i are prescribed for patients with inadequate glucose control through lifestyle modifications, in combination with metformin (Harrigan et al., 2001; Marín-Peñalver et al., 2016). As for SGLT2i, they inhibit glucose renal reabsorption at the level of the proximal convoluted tubule and increase glucose excretion, hence modifying hyperglycemia. In fact, the increased glucosuria aids in weight loss and blood pressure reduction (Harrigan et al., 2001; Marín-Peñalver et al., 2016). It is important to note that despite insulin being the treatment of choice for T1DM, it is prescribed in many cases of T2DM based on onset and duration of action, as it can aid in regulating insulin release from the pancreas, especially for subgroups related to defect in insulin release from the pancreas (Harrigan et al., 2001; Marín-Peñalver et al., 2016). Finally, according to the ADA, the treatment of choice should follow a patient-centered approach based on the coexisting conditions and comorbidities.

### Future perspectives

T2DM is a heterogeneous disease affecting populations at different rates and is likely connected to the developmental origin of health and disease together with contemporary lifestyle, reflecting the complexity of the disease. Genetic research, while still in infancy, has led us to better understand the different loci and variants involved in the prognosis and various etiologies of the disease. Despite the countless GWAS, CGAS, and WGS studies, more in-depth investigations in diverse ethnic populations are needed to better understand the differences and similarities, and possible gene-gene and gene-environment interactions. It is also important to note that T2DM is a preventable disease, as it has been shown that the risk can be substantially reduced with successful lifestyle interventions through diet and exercise. Yet, understanding the etiology, probably through genetic profiling, better grasp of phenotypes and their prognosis and treatments remains crucial for a personalized treatment.

## Other types of diabetes

### Gestational diabetes mellitus (GDM)

GDM is defined as glucose intolerance first diagnosed during the second half of pregnancy (second or third trimester) without previously known diabetes (T1DM or T2DM) (Mack and Tomich, 2017). Recently, the American College of Obstetricians and Gynecologists (ACOG), has released an updated clinical diabetes management guideline in which they included a rarely diagnosed pre-gestational diabetes (American College of Obstetricians and Gynecologists' Committee on Practice Bulletins—Obstetrics, 2018). The latter is defined as diabetes diagnosed in the first half of pregnancy (before week 20 of gestation) based on standard diagnostic criteria. Pre-gestational diabetes is classified as either Type 1 or Type 2, based on the similarities they share with T1DM and T2DM, respectively. Ethnic disparities, screening standards, and diagnostic criteria influence the prevalence of GDM, with the highest being in the Middle-East and North Africa region (15.2%) and the lowest was in European countries (6.1%).

Given the physiological adaptations to meet the requirements of both the mother and the growing fetus, the need for hepatic glucose production increases by 30%. In a normal pregnancy, the pancreatic compensation can match the increased needs to maintain euglycemia. However, in GDM pregnancy, the pancreas is unable to respond to the increased level of glucose, leading to an exhaustion of the pancreatic  $\beta$  cells and development of diabetes (Mcintyre et al., 2019). This is possibly due to the release of hormones opposing insulin action (human placental lactogen, progesterone, placental growth hormone, cortisol); and inflammation through the increased release of tumor necrosis factor (TNF) which interferes with insulin signaling cascade (Mcintyre et al., 2019). GDM shares similar genetic traits with T2DM, as it is seen in the variants on loci of the genes *TCF7L2*, *GCK*, *KCNJ11*, *MTNR1B*, and *CDKAL1*, all of which are major players in regulation of insulin sensitivity and glucose metabolism regulation (Mcintyre et al., 2019).

The main risk factors associated with GDM include maternal age, ethnicity, pre-pregnancy weight, GDM diagnosis in a previous pregnancy, and family history of GDM. It has been proposed that women older than 40 years are twice at risk of developing compared to women younger than 30 years of age (Mcintyre et al., 2019; Szmulowicz et al., 2019). Overweight or obesity ( $\text{BMI} \geq 25 \text{ kg/m}^2$ ) before pregnancy, in addition to a sedentary lifestyle during and prior to pregnancy are important risk factors for developing GDM. Furthermore, some environmental (endocrine disruptors and pollutants) and psychosocial (stress, depression, anxiety) factors may contribute to GDM development (Mcintyre et al., 2019; Szmulowicz et al., 2019). The commonly observed consequences of GDM include increased risk of cesarean delivery, shoulder dystocia, birth injuries due to the large size of the infant, and hypoglycemia of the neonate. Further, in the short-term, the mother may suffer from pre-eclampsia, polyhydramnios, and birth canal lacerations. Whereas in the long-term, women suffering from GDM may be at increased risk of developing T2DM, metabolic syndrome, cardiovascular, kidney, retinal, and liver diseases (Mcintyre et al., 2019).

The main goal of GDM treatment is to maintain fasting glucose levels  $\leq 95 \text{ mg/dL}$ ; 1 hr postprandial glucose  $\leq 140 \text{ mg/dL}$ ; and 2 h post-prandial glucose  $\leq 120 \text{ mg/dL}$ , while maintaining adequate fetal growth (Mcintyre et al., 2019). This goal could be achieved through Medical nutrition therapy (MNT), which aims at organizing and diversifying food intake to include sufficient energy, macronutrients, micronutrients, and fibers needed during this phase, while keeping blood glucose level well maintained. Additionally, it is recommended to engage in at least 30 min of moderate-intensity aerobic exercise on most days of the week (Mcintyre et al., 2019). When glycemic control is not achieved *via* MNT, pharmacological treatment including insulin or an oral agent (i.e., metformin) is initiated. Insulin is the first treatment of choice, as it does not significantly cross the placental barrier; while the use of oral agents is still controversial with lacking long-term data on the offspring. Post-partum treatment depends on maternal glucose level after delivery, as in most cases, GDM resolves after birth (Mack and Tomich, 2017; McIntyre et al., 2019).

### Maturity onset diabetes of the young (MODY)

MODY are a cluster of heterogeneous autosomal dominant inherited non-autoimmune Diabetes Mellitus. The main features of MODY include its early onset (before the age of 35), and the presence of a family history of autosomal dominant inheritance of diabetes contrasting with both Type 1 and Type 2 Diabetes Mellitus (Naylor et al., 2018). Several genetic etiologies exist for MODY causing a dysfunction in pancreatic  $\beta$  cells starting at birth (Peixoto-Barbosa et al., 2020). The most common defects are GCK-MODY (MODY2) and HNF1A-MODY (MODY3), each accounting for 30–60% of all MODY cases, followed by HNF4A-MODY (MODY1) and HNF1B-MODY (MODY5) constituting 10% of all MODY cases (Naylor et al., 2018; Prasad and Groop, 2015) (Table 1). The defective insulin secretion in MODY2 is caused by a mutation to the gene encoding glucokinase (GCK), a key enzyme involved in the absorption and metabolism of glucose at the hepatic level, as well as stimulating insulin release from the pancreas (Sternisha and Miller, 2019). MODY1, MODY3, and MODY5, are caused by insults to the hepatocyte nuclear

**Table 1** Major subgroups of maturity onset diabetes of the young.

Subgroup name	Gene	Chromosome	Frequency	Clinical features	Frequency of microvascular complications	Treatment
MODY1	<i>HNF4A</i>	20q12-q13.1	5–10%	<ul style="list-style-type: none"> <li>• Large at birth.</li> <li>• Mild neonatal hyperinsulinemia/hyperglycemia.</li> </ul>	Common	Insulin/sulfonylureas
MODY2	<i>GCK</i>	7p15-p13	30–60%	<ul style="list-style-type: none"> <li>• Progressive insulin secretory defect.</li> <li>• Mild fasting hyperglycemia at birth.</li> <li>• Generally asymptomatic.</li> </ul>	Rare	Exercise/diet
MODY3	<i>HNF1A</i>	12q24.2	30–60%	<ul style="list-style-type: none"> <li>• Mild neonatal hyperinsulinemia/hyperglycemia.</li> <li>• Progressive insulin secretory defect.</li> </ul>	Common	Insulin/sulfonylureas
MODY5	<i>HNF1B</i>	17q12	<5%	<ul style="list-style-type: none"> <li>• Renal glucosuria.</li> <li>• Renal anomalies.</li> <li>• Pancreatic hypoplasia.</li> <li>• Intrauterine growth restriction.</li> </ul>	Common	Insulin/sulfonylureas

factors (*HNF*) family ( $4\alpha$ ,  $1\alpha$ , and  $1\beta$ , respectively), all of which are crucial in the development and function of the pancreatic  $\beta$  cells (Peixoto-Barbosa et al., 2020; Prasad and Groop, 2015). The clinical manifestations associated with MODY differ based on the type and genetic origin of the disease, which ultimately influences the treatment regimen. As such, some of them could be treated by dietary therapy alongside insulin or medication, while others require pure pharmacological treatment. For instance, people suffering from MODY3 can benefit from sulfonylureas, while those suffering from MODY1 are sensitive to this treatment, and those with MODY5 require insulin treatment. As for MODY2 patients, the treatment is not quite clear, and it may be only required during pregnancy depending on the fetus' genotype (Naylor et al., 2018). As for the microvascular complications, they are also dependent on the subgroup of MODY and its severity. Among the most common MODY types, MODY2 is the only one with very rare microvascular complications, while the others (MODY1, MODY3, and MODY5) exhibit them commonly. Those complications are mainly at the level of the kidneys in the form of renal cyst that may eventually lead to renal failure (Naylor et al., 2018).

## Conclusions

Diabetes Mellitus is a chronic multifactorial metabolic disorder characterized by a dysregulation in glucose metabolism leading to hyperglycemia and long-term complications, projected to affect 700 million people in 2045. Despite the common traits shared by all major forms of diabetes, T1DM, T2DM, GDM, and MODY, the disease is known for its heterogeneity. T1DM is an autoimmune disease leading to the destruction of the pancreatic  $\beta$  cells of islets of Langerhans; while T2DM can be caused by either an insulin deficiency or resistance, or both, hence the different subgroups. On the other hand, GDM is generally a transient form of diabetes diagnosed during the second half of pregnancy and resolving with delivery; yet, if not well-controlled it could continue into T2DM. Finally, MODY is a cluster of non-autoimmune diabetes, yet, it could be misdiagnosed as T1DM given its early onset and the similarities shared with T1DM. Given the heterogenous nature of the disease and different etiologies, it is important to apply a patient-centered and personalized approach for treatment in the aim of preventing the disease or any major complications that may arise.

### Key points

- To give an overview of the global burden of diarrheal diseases
- To discuss the relationship between diarrheal disease and childhood malnutrition
- To give a brief summary of the causes of diarrhea, both infectious and non-infectious
- To discuss the treatment and prevention of diarrheal disease and provide a summary of the current evidence for public health interventions aimed at reducing the burden of diarrheal diseases in low-income countries

### Introduction

Diarrhea is commonly defined as an increase in the frequency of bowel movement with increased fluidity of stool relative to usual patterns in an individual. There is a wide variation in the literature in the definition of a diarrhea episode, ranging from mothers' perceptions to operational definitions based on the frequency of loose stools in 24 h. The operational definitions vary but require at least three watery or loose stools in 24 h.

Diarrhea can be classified in a number of ways: duration of an episode (acute duration—less than 14 days; persistent—14 days or more), type of stool (watery or bloody), consistency of stool (loose, liquid, and watery), dehydration status (dehydrated, nondehydrated), pathophysiologic mechanism (inflammatory, secretory, osmotic), or based on causative agents (e.g., *Escherichia coli*, cholera, rotavirus, *Shigella*, etc.). Dysentery refers to acute bloody diarrhea resulting from infective colitis with bleeding from ulceration. In terms of overall burden of diarrhea, acute infectious diarrhea is by far the greatest contributor as almost every human being experiences it at some point in a lifetime.

## Pathophysiology of diarrhea

During diarrhea there is an increased frequency of bowel movement and alteration in stool consistency. Normal fluid and solute movement across the intestinal membrane is altered resulting in increased loss of water and electrolytes (particularly sodium, potassium, chloride, and bicarbonate). Four mechanisms have been postulated to be responsible for these alterations: decreased fluid absorption, increased intestinal secretion, increased luminal osmolality, and altered intestinal motility. Inflammatory diarrhea probably results from a combination of all four. It has been suggested that a common mechanism exists in cases of bacterial, viral, and parasitic diarrhea where levels of cyclic nucleotide are enhanced. Loss of fluids and electrolytes may lead to dehydration, acidosis, hyponatremia, and hypokalaemia. The degree of dehydration depends on the net amount of fluid lost. World Health Organization (WHO) classifies the grades of dehydration as none, some, or severe dehydration. The estimated fluid deficits in the different types of dehydration are no dehydration (not enough signs to classify as some or severe dehydration), some dehydration (two or more of the following: restlessness, irritability; drinks eagerly, thirsty; sunken eyes), and severe dehydration (two or more of the following: lethargy/unconsciousness; sunken eyes; unable to drink/drinks poorly; skin pinch goes back very slowly). However, the most reliable measure of volume depletion in an adult is postural hypotension, and this important sign should be sought in all but the most trivial cases.

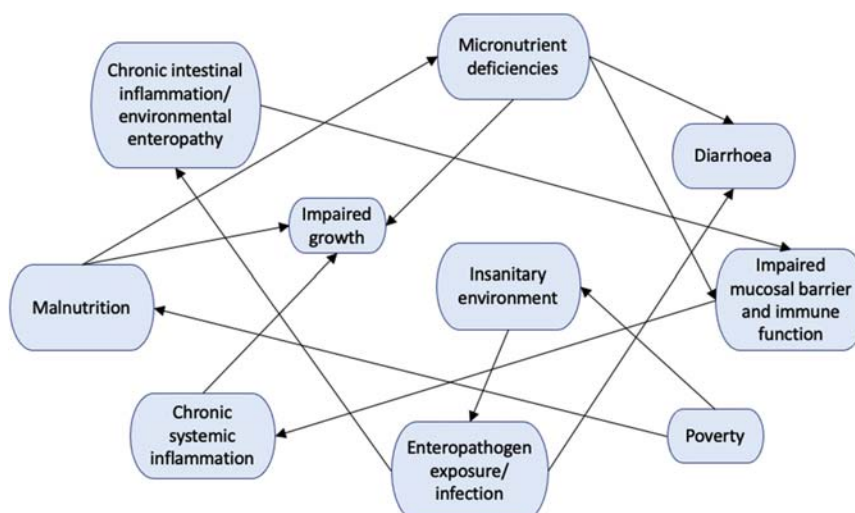

## Global overview

Diarrhea remains the second leading cause of death in under-5s globally, with over 0.5 million children dying annually of diarrheal disease. The majority of these deaths are in children under the age of 2. Children in low-income countries (LICs) under the age of 3 have on average 3 episodes of diarrhea annually, which may have implications for nutritional deficits and growth faltering. The Global Enteric Multicenter Study (GEMS), which analyzed the burden and etiology of diarrheal disease in children across seven sites in Africa and Asia, found that the majority of cases of moderate-to-severe diarrhea were caused by just four pathogens: rotavirus; *Cryptosporidium*; enterotoxigenic *Escherichia coli* producing heat-stable toxin; and *Shigella*, and that children with moderate-to-severe diarrhea were significantly more likely to have linear growth faltering during the follow-up period (Kotloff et al., 2013). However, the carriage of enteropathogens does not necessarily lead to diarrhea, and it is likely that this is a reflection of the balance between the intensity of infection, often itself a consequence of size of inoculum, and host defense. A recent study in Zambia showed that children with stunting excreted up to 11 enteropathogens concurrently despite not having intercurrent diarrhea. These children also had a severe degree of enteropathy demonstrated on small bowel biopsies and this is likely to represent an adaptive response to constant enteropathogen exposure with the outcome of reduced microbial translocation (Amadi et al., 2021). The aforementioned enteropathy is known as environmental enteropathy or environmental enteric dysfunction and refers to abnormalities of small intestinal structure and function seen in populations living in unsanitary conditions. Changes include villous blunting, crypt hypertrophy, epithelial breaches, mucosal inflammation and increased mucosal permeability, resulting in systemic inflammation and nutrient malabsorption. This lesion in itself plays a central role in childhood growth failure. These data from Zambia are consistent with data from the Malnutrition and Enteric Disease Study (MAL-ED), which set out to assess the role of enteropathogen burden and diarrhea in childhood growth at eight sites across South America, Asia and sub-Saharan Africa. This study also showed high numbers of enteropathogens being carried by asymptomatic children in association with slower linear growth (MAL-ED Network Investigators, 2017).

## Contribution of diarrhea to malnutrition

It has long been thought that diarrheal disease has a significant impact on child growth and development, however, recent evidence suggests that it is frequent exposure to enteropathogens as opposed to frequency of diarrheal disease that affects growth. Although the negative short-term association between diarrheal episodes and weight-for-age is widely accepted, several studies in recent years have examined the relationship between childhood diarrhea and nutrition in more detail, particularly with regards to longer-term impact on linear growth, with varied results. Data from multi-study analyses suggest that there is a multiplicative effect on growth with each diarrheal episode/day of diarrhea over the first two years of life. A pooled analysis of 1393 children from 9 studies across 5 countries (Peru, Brazil, Ghana, Guinea-Bissau and Bangladesh) found that the odds of stunting at 24 months of age increased by 1.13 when cumulative diarrheal incidence over the first 24 months of life increased by 5 episodes (Checkley et al., 2008). A more recent analysis of 7 longitudinal cohort studies from Peru, Brazil, Guinea-Bissau and Bangladesh, where data on diarrhea and anthropometric measures were available, found that a child with the average age-specific monthly diarrhea burden (equivalent to 23 days/year) was 0.38 cm shorter at 24 months than a child with no diarrhea. This deficit was reduced to 0.2 cm if the number of days of diarrhea/year was halved (Richard et al., 2013).

The MAL-ED study found no significant long-term relationship between diarrheal morbidity and linear growth, however, higher rates of enteropathogen detection in non-diarrheal stools were found to have a negative impact on linear growth. *Campylobacter* in particular was found to be negatively associated with growth rates for both length and weight (MAL-ED Network Investigators, 2017).

**Fig. 1** Diagram demonstrating the complex interplay of factors linking diarrhea and malnutrition.

If it is indeed the case that luminal enteropathogen exposure contributes to malnutrition as opposed to diarrheal disease in itself, then interventions aimed at reducing enteropathogen burden in children might reasonably be expected to have a positive effect on childhood growth (**Fig. 1**). The WASH benefits trial was a cluster-randomized trial in which pregnant women in villages in rural Bangladesh and Kenya were randomized to one of seven interventions aimed at improving sanitation and nutrition. This showed that interventions aimed at improving sanitation alone did reduce childhood diarrhea in Bangladesh, however only interventions that included a nutrition element were seen to be associated with an improvement in linear growth ([Luby et al., 2018](#)). Sanitation interventions did not appear to have an impact on childhood diarrhea or on growth in Kenya ([Null et al., 2018](#)). The Sanitation Hygiene Infant Nutrition Efficacy (SHINE) trial, a cluster-randomized trial of water, sanitation and hygiene (WASH) and improved infant and young child feeding (IYCF) interventions in rural districts in Zimbabwe, showed that neither of these types of interventions reduced the prevalence of childhood diarrhea, and while IYCF interventions did increase linear growth, the combination of WASH interventions with IYCF did not provide any additional benefit ([Humphrey et al., 2019](#)). It is likely that the WASH interventions in these trials were not of sufficient intensity to result in improvement in child health outcomes, as enteropathogen burden remained high in the intervention groups. Interventions are needed that are more effective at reducing (and ideally excluding) fecal contamination of the domestic environment (**Fig. 2**).

Zinc deficiency is widespread among populations of LICs, and this may be both a consequence of and a contributor to diarrheal disease. Zinc is absorbed in the small intestine and decreased absorptive capacity of the gut may contribute to deficiency in LICs, where environmental enteric dysfunction is known to be widespread and reduced fractional absorption of zinc has been demonstrated in children. Fecal losses of zinc occurring in chronic or frequent diarrheal disease also contribute to deficiency. Zinc

**Fig. 2** View of a high-density residential area in Lusaka, Zambia, typical of unplanned settlements in LICs where lack of proper drainage leads to regular flooding which contributes to insanitary conditions.

deficiency may lead to malabsorption through the impairment of digestive enzymes in the small intestine, hence perpetuating the cycle of enteropathy and zinc deficiency. The World Health Organization (WHO) recommends that zinc supplements at a dosage of 20 mg/day for 10–14 days are given to all children with acute diarrhea, and this has been shown to reduce the duration and severity of symptoms as well as the risk of subsequent episodes in the short-term.

The nutritional consequences of chronic non-infectious diarrhea should also be considered. Specific nutritional deficits will depend on the site of the gastrointestinal disease, for example, Crohn's disease often involves the terminal ileum hence vitamin B12 deficiency is common as this is the only site for absorption of this vitamin. Nutritional deficits relating to specific conditions will be discussed in the section "Non-infectious causes of diarrheal disease".

## Infectious causes of diarrheal disease

Infectious causes of diarrhea can be subdivided according to whether the causative agent is bacterial, viral or parasitic, and we will discuss some of the commonest causes in each of these categories.

### Bacterial

Common bacterial causes of diarrhea include *Campylobacter jejuni*, several pathotypes of *E. coli*, *Shigella*, *Vibrio cholerae*, nontyphoidal *Salmonella* species, *Clostridioides difficile* (previously *Clostridium difficile*), and *Yersinia enterocolitica*. *Vibrio cholerae* will be discussed below under "Cholera." All of these can present with bloody diarrhea although *Shigella* is the predominant bacterial cause of this.

*C. jejuni* is the most common cause of bacterial diarrhea worldwide and was found to be responsible for 7.5 million disability-adjusted life years in the 2010 Global Burden of Disease Study. This is a foodborne infection which in high-income countries is usually sporadic as opposed to causing outbreaks. In low- and middle-income countries (LMICs), *C. jejuni* is hyperendemic and spread via contaminated drinking water and food (e.g., poultry). Infection is usually only symptomatic in children, who can be infected multiple times.

There are 6 diarrheagenic *Escherichia coli* (DEC) pathotypes: enteropathogenic (EPEC); enterotoxigenic (ETEC); enteroaggregative (EAEC); Shiga toxin producing or enterohaemorrhagic (STEC/EHEC); enteroinvasive (EIEC); and diffusely adherent (DAEC), with ETEC being the principal pathotype in LMICs and in returning travelers. ETEC causes diarrhea through heat stable (ST) and heat-labile (LT) toxins which, like cholera toxin, open chloride channels after activation of secondary messenger signaling. EPEC causes diarrhea through complex processes initiated by intimate adherence. EIEC is invasive, with a similar pathogenesis to *Shigella*, while EHEC is usually akin to an EPEC which additionally carries a nephrotoxic cytotoxin gene. A study from Guatemala found that by the age of 36 months, cumulative seroprevalence of antibodies to ETEC was 83% (Steinberg et al., 2004). In addition to being one of the four most common pathogens causing moderate-to-severe diarrhea in children in LMICs, ETEC producing heat-stable toxin (ST-ETEC) as well as typical EPEC are associated with a higher risk of mortality in infants than other enteropathogens (Kotloff et al., 2013).

Nontyphoidal *Salmonella* species are a major cause of food-related outbreaks of diarrheal disease, usually related to undercooked poultry or eggs, and are also an important cause of diarrhea in returning travelers. In immunocompetent individuals, typical nontyphoidal salmonellosis causes self-limiting diarrheal disease and treatment with antimicrobial agents is not generally recommended as this can prolong bacterial shedding. Bacteremia secondary to invasive nontyphoidal salmonellosis can occur in high-risk groups (extremes of age, HIV- or malaria-infected, malnourished) with the majority of these cases occurring in Africa. *Salmonella enterica* serovars typhimurium, Dublin and Enteritidis are most commonly associated with invasive disease with the Typhimurium sequence type 313 being of particular concern as this demonstrates multidrug resistance to antimicrobial agents and may not require an animal reservoir. It is important to note that typhoid (due to *Salmonella enterica* serovar typhi) is not primarily a diarrheal disease and is not considered in this article.

*Clostridioides difficile* is one of the most common nosocomial infections worldwide and the most common iatrogenic cause of diarrhea. It is a spore-forming bacillus with infection usually occurring as a result of spore ingestion, as these are able to survive on fomites for several months. For this reason, measures including handwashing, glove wearing and decontamination of medical devices and patient environment as well as antimicrobial stewardship are important in the prevention of *C. difficile* infection (CDI) in healthcare settings. CDI is often associated with antibiotic use in hospitalized patients, particularly in the elderly or immunocompromised, as this depletes the intestinal microbiota and disrupts the protective mucous layer. There is a range of clinical presentations, from asymptomatic carrier status to pseudomembranous colitis with potential complications of toxic megacolon, bowel perforation, and death. Although antibiotics including metronidazole, oral vancomycin and fidaxomicin are often used as first line treatments for symptomatic CDI, there is increasing evidence that fecal microbiota transplantation is an extremely effective treatment.

*Yersinia enterocolitica* is a zoonotic infection, with pigs being the most common animal reservoir, and is usually transmitted to humans through ingestion of undercooked or raw pork products, although foodborne outbreaks have also been associated with contaminated water, milk, bean sprouts and tofu.

## Cholera

Cholera typically causes epidemic outbreaks in LMICs and represents a major public health burden for some of these countries. There have been seven pandemic cholera outbreaks in the past, with the first six outbreaks originating on the Indian subcontinent during the nineteenth century and the seventh originating in the 1960s. Prior to the 19th century, epidemic cholera had largely been confined to Asia as it was in the Bengal river deltas that this formerly free-living estuarine bacterium acquired its virulence genes. *Vibrio cholerae* causes diarrhea through the cholera toxin, which is produced by *V. cholerae* serogroups 01 and 0139 and consists of an A subunit and 5 B subunits. The B subunit binds to monosialoganglioside GM1 receptors on the luminal surface of enterocytes and following endocytosis travels through retrograde transport from the plasma membrane to the trans-Golgi network and thence to the endoplasmic reticulum where the active portion of the A subunit (the CTA1 subunit) is unfolded. CTA1 stimulates adenylate cyclase activity through ADP-ribosylation, leading to increased cAMP production and efflux of chloride ions, and subsequently to secretory diarrhea with massive fluid and electrolyte losses. Treatment of cholera was revolutionized by the advent of oral rehydration solution (ORS) which came into widespread use in the 1970s. An inexpensive solution of glucose and electrolytes, ORS can in fact be used to treat acute watery diarrhea regardless of the etiology and has enabled reduction in mortality in cholera outbreaks from over 60% to less than 1%.

## Viral

Rotavirus is the leading cause of severe acute diarrheal disease in children globally, with approximately half of deaths due to rotavirus occurring in just four countries: India; Nigeria; Pakistan; and the Democratic Republic of the Congo. Deaths have reduced significantly since the introduction of rotavirus vaccines in the early 21st century, however, unfortunately oral rotavirus vaccinations underperform in LICs where they are most needed, possibly due to the ubiquity of environmental enteropathy in these settings. Rotavirus causes an inflammatory diarrhea with a secretory component due to a viral enterotoxin encoded in the viral genome.

Adenovirus can cause a range of clinical presentations in addition to acute diarrheal disease including febrile upper and lower respiratory tract infections, hepatitis, keratoconjunctivitis, meningoencephalitis, cystitis and myocarditis. It usually causes a mild self-limiting clinical picture in the immunocompetent host however infection can be of particular significance in the context of immunosuppression, for example, in post-transplant patients.

Norovirus (previously known as Norwalk virus) usually presents with nausea and vomiting, diarrhea, and fever. It is highly transmissible due to the small infective dose (<100 viral particles) and was originally termed “winter vomiting sickness” before the causative organism was known as it tended to occur in seasonal outbreaks in healthcare settings such as hospitals and nursing homes in the Northern hemisphere. There is some evidence for a high prevalence of noroviruses in LMICs (a rate of 8% among healthy controls is cited in one review), albeit with a significant level of asymptomatic infection, and in tropical regions infections seem to correlate with the rainy season.

Sapoviruses cause a similar clinical presentation to norovirus albeit generally milder, with self-limiting diarrhea and vomiting, both in outbreaks and sporadic cases worldwide. Sapoviruses are thought to account for 5.9–22.6% outbreaks where samples are negative for norovirus and pathogenic bacteria.

## Parasites

Parasitic causes of diarrhea include protozoa: *Entamoeba histolytica*, *Giardia intestinalis*, *Cryptosporidium*, *Cystoisospora belli*, *Cyclospora cayetanensis*, and some helminths including *Strongyloides stercoralis*, *Trichuris trichiura* (whipworm), and *Schistosoma mansoni*. These are discussed further in the article on “Parasitism.” Cryptosporidiosis in particular is a leading cause of childhood diarrhea in LMICs and is known to be associated with growth faltering even in the absence of symptoms of diarrhea. In the MAL-ED study, the presence of *Giardia* (although not associated with increased risk of acute diarrheal illness) was associated with increased intestinal permeability and worse growth outcomes at 24 months. Parasitic infections of the gastrointestinal tract can lead to specific nutritional deficits, for example, hookworm infection (*Necator americanus* and *Ancylostoma duodenale*) does not usually present with diarrheal disease but can lead to iron deficiency anemia as the adult worms attach to the mucosa of the small intestine leading to chronic blood loss. The question of whether worm infections (specifically the soil-transmitted helminths *Ascaris lumbricoides*, whipworm and hookworm) contribute to growth faltering in children remains controversial however a cluster-randomized trial of periodic deworming in 1 million pre-school children in India showed no significant effect on growth (Awasthi et al., 2013).

## Human immunodeficiency virus (HIV)

Although HIV infection in itself does not cause diarrhea, immunocompromized individuals are more at risk of opportunistic infections causing diarrhea including *Cryptosporidium*, *Cystoisospora belli*, cytomegalovirus, *Mycobacterium avium* complex and *C. difficile*. Several antiretroviral drugs prescribed in HIV can also cause diarrhea.

### Intestinal tuberculosis

*Mycobacterium tuberculosis* infection of the gastrointestinal tract may present in a non-specific way with chronic diarrhea with or without blood, abdominal pain, fever, and weight loss, and may be difficult to distinguish from inflammatory bowel disease (IBD), particularly Crohn's disease, as these are both inflammatory granulomatous conditions. Similarly, to Crohn's disease, it may affect any part of the gastrointestinal tract however has a predilection for the ileocecal region. Not all patients with intestinal TB will have concurrent pulmonary disease, with active pulmonary TB only being found to be present in a quarter of patients with intestinal infection.

### Whipple's disease

Caused by infection with the bacteria *Tropheryma whipplei*, this rare multisystem disease can present with diarrhea and weight loss and can be diagnosed through histopathological analysis of duodenal biopsies or through PCR detection of *T. whipplei* in tissue. Classic Whipple's disease typically occurs in Caucasian individuals and, although carriage of *T. whipplei* seems to be common in native African and Asian populations, resulting disease is rare.

### Tropical sprue

This condition, which manifests clinically as chronic diarrhea and weight loss, was previously commonly described in South Asia and the Caribbean and is now rarely diagnosed. It has been listed under infectious causes of diarrhea as it now seems likely that reports of this condition in the past were due to infections which were either not known about or which it was not possible to exclude with diagnostic techniques available at the time. For the traditional method of diagnosis of this disorder, it is necessary to exclude infectious causes, and to demonstrate evidence of enteropathy on small bowel biopsies (villous blunting, lymphocyte infiltration and increased crypt depth) as well as evidence of malabsorption of fat, vitamin B12 and xylose. However, in the present day it is difficult to arrange tests of fat and xylose absorption hence demonstration of enteropathy in the presence of folate and vitamin D deficiency in the absence of any other demonstrable cause should be accepted as sufficient for diagnosis of tropical sprue.

### Non-infectious causes

There are many causes of non-infectious diarrhea, including the inflammatory bowel diseases ulcerative colitis and Crohn's disease (autoimmune conditions leading to intestinal inflammation and usually presenting with diarrhea) as well as malignant causes including colorectal cancer, neuroendocrine tumors and lymphoma. Drugs are also an important cause of non-infectious diarrhea, with common causative agents being antibiotics, proton pump inhibitors, H2 receptor antagonists, and metformin. Radiotherapy targeting cancers in the abdomen or pelvis can also result in enteropathy leading to chronic diarrheal disease. Celiac disease is another important cause of chronic diarrheal disease, as is malabsorption secondary to pancreatic exocrine insufficiency. Hyperthyroidism can also present with diarrhea. Specific nutritional deficiencies associated with several of these conditions are discussed below.

### Inflammatory bowel disease

Although malnutrition can occur in both of the predominant forms of IBD, ulcerative colitis (UC) and Crohn's disease, it is more common in Crohn's as this condition can affect the small intestine and hence has greater capacity to disrupt the absorptive function of the gut. As previously discussed, vitamin B12 deficiency is common in Crohn's for this reason, as well as other micronutrient deficiencies including folate, iron, zinc, selenium, and vitamin D. These should be screened for routinely and supplementation prescribed as required. Low bone mineral density is also common in IBD due to both reduced absorption of calcium and vitamin D as well as corticosteroid use in these patients. Due to the inflammatory nature of IBD, patients with active disease are in an increased catabolic state and hence have greater protein requirements (1.2–1.5 g/kg/day in adults) than the general population where an intake of 1 g/kg/day is recommended. There is little evidence to support that energy expenditure in general is greater in IBD patients, with the possible exception of severe acute UC, in which state electrolyte losses (particularly  $K^+$  and  $Mg^{2+}$ ) are also common due to high volume diarrhea. Hypokalaemia may also be exacerbated by use of intravenous hydrocortisone in these patients.

### Celiac disease

This is an immune-mediated gluten-sensitive enteropathy caused by antibodies against gluten peptides in genetically susceptible individuals. Treatment consists of lifelong dietary exclusion of gluten. In untreated celiac disease there is villous atrophy and inflammation with loss of small intestinal surface area as well as loss of disaccharidase activity, leading to carbohydrate maldigestion and malabsorption. Individuals with celiac may present with diarrhea, weight loss, abdominal bloating, iron deficiency, and poor

growth in children. Other nutritional deficiencies which are reported in untreated celiac disease include vitamin B12, folic acid, vitamin B6 (pyridoxine), vitamin D, calcium, zinc, and less commonly, magnesium.

### Pancreatic exocrine insufficiency

Failure of the exocrine pancreas usually occurs as a result of chronic pancreatitis however can also be secondary to pancreatic malignancies, resection, cystic fibrosis, and less commonly diabetes mellitus. Maldigestion and malabsorption occur as a result of loss of functioning pancreatic parenchyma and hence reduced secretion of pancreatic enzymes, and affected individuals present with symptoms including diarrhea, steatorrhea, weight loss, abdominal pain and bloating. Nutritional deficiencies seen in pancreatic exocrine insufficiency include fat soluble vitamins (A, D, E and K), micronutrients including magnesium, trace elements and plasma proteins.

### Intestinal failure (often due to short bowel syndrome)

Intestinal failure is the reduction of gut function below the minimum absorptive capacity required to maintain health and/or growth. Short bowel syndrome, which refers to the physical loss of or loss of function of a portion of the small bowel resulting in a reduced ability to absorb nutrients, is the most common cause of intestinal failure. This condition may be congenital or acquired as a result of the following: surgical resection, for example, following abdominal catastrophe such as infarction, trauma, or volvulus; extensive small bowel mucosal disease usually secondary to Crohn's disease; or radiotherapy for intraabdominal cancers. Fluid and electrolyte loss can be very high in this condition, particularly in the acute phase, when patients with jejunostomy may lose as much as 8 L/day. Depending on the length of remaining small bowel and whether or not the colon is in continuity, these patients may require intravenous supplementation with fluid, electrolytes, and in some cases parenteral nutrition.

## Diagnosis

Diagnostic approach to the patient with diarrheal disease depends on the duration of symptoms, with acute diarrhea being more likely to be due to an infectious agent, and cases with a duration of greater than two weeks warranting investigation for non-infectious causes. All cases of persistent diarrhea and all cases of dysentery should have stool cultures and examination for ova, cysts and parasites on three separate stool samples. In most settings, investigation of acute watery diarrhea would only be indicated in specific circumstances such as outbreaks.

## Prevention and treatment

General population-based preventive measures recommended by the WHO to reduce the burden of diarrheal disease include increasing access to clean drinking water, improved sanitation and handwashing with soap, improved food hygiene, rotavirus vaccination and exclusive breastfeeding for the first six months of life. The WHO recommends that oral cholera vaccines should be used as a reactive strategy during outbreaks and for prevention in high-risk areas. Currently available vaccinations for diarrheal diseases are summarized in [Table 1](#).

The WASH Sustainable Development Goal set by the UN is for "universal access to safe and affordable drinking water and adequate and equitable sanitation and hygiene for all by 2030." Despite the seemingly obvious benefits inherent in this goal, it should be noted that three recent major trials of WASH interventions in LICs (WASH-Benefits Bangladesh, WASH-Benefits Kenya, and Sanitation Hygiene Infant Nutrition Efficacy (SHINE)) found no effect of these interventions on childhood growth and mixed effect on diarrheal disease. Interventions in these trials included increased chlorination of drinking water and increased access to improved pit-latrines and to handwashing stations with soap, and uptake of interventions was reported to be high. Although these

**Table 1** Available vaccines for diarrheal diseases.

Type	Disease	Vaccine constituents	Route	Protection
Live, attenuated	Cholera	<i>V. cholerae</i> (CVD103-HgR, <b>Vaxchora</b> )	Oral	67% over 3 years
	Rotavirus	Attenuated virus ( <b>Rotarix</b> ; GSK)	Oral	85–100%
	Rotavirus	Human-bovine reassortant viruses ( <b>RotaTeq</b> ; Merck)	Oral	74% over one season, 94.5% vs. severe disease
Inactivated	Cholera	Heat-killed <i>V. cholerae</i> + CTB ( <b>Dukoral</b> ; Chiron)	Oral	80–90% over 6/12, 60% at 2 years
	Cholera	Vc O1 Inaba and Ogawa plus O139 (Euvichol, Shanchol)	Oral	40% over 6 months

interventions had no effect on diarrhea in children in Kenya and Zimbabwe, a 40% relative reduction in diarrheal disease was seen in Bangladesh, which may reflect differing baseline levels of contamination between environments. An expert meeting convened by the WHO and the Bill and Melinda Gates Foundation to discuss these results concluded that the household interventions in these trials were not sufficiently intensive to achieve clear benefits, and in fact community-level interventions such as providing a piped, microbially safe supply of drinking water to each household or a community-level sewerage sanitation system may be required in order to impact childhood diarrheal disease and stunting.

Specific treatments for diarrheal disease will depend on the underlying cause, for example, targeted antimicrobial treatment in infectious diarrhea where the causative organism is known. However supportive treatments can be used regardless of the etiology of the diarrheal disease, including ORS, replacement of electrolytes, zinc supplements, and appropriate nutritional support.

## Conclusions

Although the burden of diarrheal diseases remains significant particularly in LICs due to limited access to clean drinking water and sanitation, the advent of simple interventions such as ORS has reduced mortality particularly in the setting of outbreaks. It seems that the relationship between diarrhea and childhood malnutrition is indirect, with enteropathogen exposure as opposed to diarrhea itself responsible for limiting growth. Large scale community-level interventions to improve sanitation and water supply are required to address this problem in LICs.

### Key points

- Dental caries of the permanent teeth is the most common of all chronic diseases.
- Dental caries is caused by high intakes of free sugars. The availability of fluoride in the mouth helps to prevent dental caries, however the link between free sugar intake and caries development remains also when fluoride is present.
- WHO recommends to restrict free sugar intake to less than 10% of total energy intake.
- Dietary choices are influenced by the wider social and commercial environments people live in.
- Policy strategies to reduce free sugar intake need to create supportive environments through a combination of upstream, midstream, and downstream strategies, including the regulation of industry activities.

### Introduction

Despite being largely preventable, oral diseases are the most common conditions of mankind, with a significant impact on the individuals affected and their wider communities. Oral diseases are highly prevalent across the entire life course from early life to old age. Globally, diseases of the teeth and mouth affect 3.5 billion people, nearly half of the world's population ([G.B.D. Oral Disorders](#)

Collaborators, 2020). In 2015 oral diseases accounted for an estimated US\$ 357 billion in direct costs (such as treatment expenditures) and US\$ 188 billion in indirect costs (such as productivity losses due to absence from work or school) (Righolt et al., 2018). Oral diseases disproportionately affect the poor and vulnerable in society with stark and persistent oral health inequalities evident globally.

In recognition of the global public health importance of oral diseases, in May 2022 the World Health Organization (WHO) agreed a new landmark Global Oral Health Strategy, which highlights the need for prevention and health promotion to combat oral diseases and reduce oral health inequalities (WHO, 2022). The WHO strategy also recognizes the importance of adopting an integrated approach to prevention through tackling the shared causes of oral diseases and other non-communicable conditions, including diet and nutrition.

This article will present an epidemiological overview of oral diseases with the main focus on dental caries, the most common oral condition, and will outline the need for a comprehensive range of policy measures to reduce free sugars consumption, the principal cause of dental caries.

## Background

The World Health Organization defines oral health as “the state of the mouth, teeth and orofacial structures that enables individuals to perform essential functions, such as eating, breathing and speaking, and encompasses psychosocial dimensions, such as self-confidence, well-being and the ability to socialize and work without pain, discomfort and embarrassment” (WHO, 2022). Oral health is clearly a very important and integral element of overall health and wellbeing enabling essential daily functions. The mouth and teeth are also a fundamental feature of personal identity (Peres et al., 2019).

A wide range of diseases and disorders can affect the mouth and teeth, but the main oral diseases of global public health significance include dental caries (tooth decay), periodontal (gum) disease and oral cancers.

Dental caries is the localized destruction of dental hard tissues (enamel and dentine) by acidic by-products from the bacterial fermentation of free sugars (Pitts et al., 2017). Dental caries is a chronic condition that can affect individuals across the life course from early childhood to later life.

Periodontal diseases are chronic inflammatory conditions that affect the tissues surrounding and supporting the teeth. Initially, periodontal disease presents as gingivitis, a reversible inflammation of the periodontal soft tissues which causes gum bleeding and swelling. In a proportion of susceptible individuals, gingivitis progresses to periodontitis. Periodontitis involves the destruction of the periodontal tissue support including the bone surrounding the teeth and can ultimately lead to tooth loss. Severe periodontal disease is largely restricted to middle aged and older people.

Oral cancer is a broad term that is mostly used to refer to oral cavity cancer i.e., cancers of the lips, tongue, gums, floor of mouth, palate, and cheeks (ICD codes C00-C06). Some definitions include throat cancers, i.e., oropharyngeal cancer (ICD codes C07-C14). Squamous cell carcinoma is the most common type of oral cancer. The prevalence of oral cancers increases with age.

## Impact of oral diseases

Oral diseases have a considerable impact on individuals and societies (Fig. 1). The mouth is the site of fundamental human functions, such as eating and communicating, and an integral part of the self (Peres et al., 2019). Dental caries, periodontal disease, and their endpoints of tooth loss affect quality of life of children and adults due to the associated pain and discomfort, by reducing the ability to eat and enjoy a variety of foods, and by affecting self-esteem and willingness to socialize. In children, severe levels of caries can impact sleep, concentration, performance at school, and even growth and development. Very young children may require extraction of carious teeth under general anaesthesia. Because most dental treatments are provided by highly skilled dental professionals and require specialist equipment, the economic costs of oral diseases are also high. In many countries, out-of-pocket expenditure for dental treatment places a significant burden on individuals and families, with poorer households disproportionately affected. Societal costs are significant as well: due to the high prevalence of oral diseases, the costs of dental care in high-income countries exceed the treatment costs of other common non-communicable diseases (NCDs) such as cancer and respiratory diseases. In many low-income countries, the available healthcare budgets cannot accommodate these costs and oral diseases remain largely untreated.

## Epidemiology and etiology of diet-related oral diseases

### Dental caries

#### Prevalence and trends

Dental caries is the most common of all chronic NCDs. Despite an overall decline in caries levels between 1990 and 2017, the global prevalence remains unacceptably high. The Global Burden of Disease study estimated that in 2017, untreated dental caries of the permanent teeth affected 2.3 billion people worldwide, corresponding to an age-standardized prevalence of 29.4%, while dental caries in deciduous (milk) teeth affected 523 million children globally (G.B.D. Oral Disorders Collaborators, 2020). The distribution of dental caries is highly skewed toward more disadvantaged population groups, following clear social gradients among both

**Fig. 1** Impact of oral diseases (Heilmann et al., 2015).

children and adults. At a global level, there is concern over the increasing burden of dental caries in many low- and middle-income countries (G.B.D. Oral Disorders Collaborators, 2020).

### ***Etiology of dental caries***

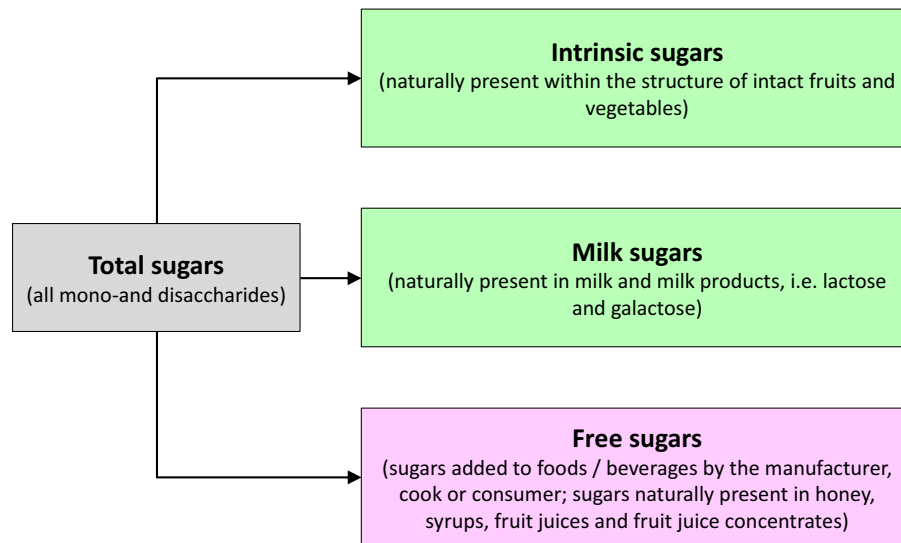

Dental caries is inextricably linked to diet—the main cause of caries is the consumption of free sugar. Caries develops through the interaction between acid-producing bacteria that are present in dental biofilms or plaque (these are mainly mutans streptococci, but also other groups of acidogenic and acid-tolerating species) and dietary free sugars (Pitts et al., 2017).

Not all dietary sugars are considered cariogenic—the sugars of concern are the so-called free sugars, defined by the WHO as “sugars added to foods or beverages by the manufacturer, cook or consumer; as well as sugars naturally present in honey, syrups, fruit juices and fruit juice concentrates” (WHO, 2015). Intrinsic sugars (those naturally present within the structure of intact fruits and vegetables) and milk sugars (naturally present in milk and milk products i.e., lactose and galactose) are not considered to increase caries risk. The WHO classification of sugars is shown in Fig. 2 (WHO, 2015; Heilmann et al., 2021).

When free sugars are consumed, they are fermented by oral bacteria, a process which produces acid and causes the pH in the dental biofilm to fall, resulting in the demineralization of the dental hard tissues, i.e., the enamel and dentine. The critical pH at which demineralization occurs is about 5.5 for enamel and about 6.0 for dentine. The main acid involved in the caries process is lactic acid. During demineralization, mineral ions (calcium and phosphate) that are part of the enamel and dentine are released from the surface layer of enamel. This process is reversible—after the sugars are cleared from the mouth, the pH slowly rises again due to the buffering capacities of the saliva. Lost minerals are redeposited back into the enamel structure and remineralization occurs. As long as there is a balance between demineralization and remineralization, the tooth can remain intact. However, if free sugars are ingested too frequently and/or in high amounts, the repeated acid attacks can shift the balance toward demineralization and a carious lesion can develop (Pitts et al., 2017).

Given that acid-producing bacteria are ubiquitous in humans, free sugar consumption is considered the key causal factor in the development of dental caries. The associations between the amount of free sugars consumed and levels of dental caries were examined and confirmed by a systematic review of the evidence that informed the 2015 WHO guideline on sugars intake for adults and children (Moynihan and Kelly, 2014). In view of this evidence, and the body of evidence linking free sugar intake and unhealthy weight gain, the WHO guideline recommends that for both adults and children, sugar intake should be restricted to less than 10% of total energy intake (strong recommendation). A further reduction to less than 5% of total energy intake is given as a conditional recommendation (WHO, 2015).

Free sugar intake is in large parts driven by the consumption of ultra-processed foods and drinks. The term “ultra-processed” refers to manufactured foods and drinks that underwent a series of industrial processes to create products that are hyperpalatable, cheap, and ready to consume. They are made mostly from derived substances and have long lists of ingredients that

**Fig. 2** WHO classification of sugars (Heilmann et al., 2021; WHO, 2015).

include additives such as flavors, colors, sweeteners, emulsifiers, and processing aids, while containing little or no intact (unprocessed) foods. Ultra-processed foods and drinks are energy-dense, often devoid of nutrients, and their free sugar content is generally much higher than that of unprocessed or minimally processed foods. Examples are sugar-sweetened beverages (SSB), breakfast cereals, sweets and biscuits, sugared milk products, instant sauces, and many baby products (Monteiro et al., 2018).

A question often asked is about the relative importance of frequency versus amount of free sugars consumption. Both factors play a role in the caries process; however, as they are highly correlated in human diets, the practicability and usefulness of attempting to disentangle them may be questionable. Given that the amount of sugar intake is important from a general health point of view, caries prevention strategies taking a Common Risk Factor Approach should aim to reduce the amount, while usefully highlighting that this might be achieved by reducing the frequency of intake.

The relationship between free sugar intake and dental caries is moderated by a number of other factors. These include salivary flow, the anatomy of the tooth, and most importantly, the availability of fluoride ions in the mouth (Pitts et al., 2017). The presence of fluoride in the mouth inhibits demineralization and enhances remineralization, moving the balance in favor of caries prevention. This means that the caries inhibiting effect of fluoride is mainly topical rather than through systemic uptake during the development of enamel, as was originally believed. Given its widespread use, accessibility and high acceptability, fluoridated toothpaste is considered the most important vehicle for getting topical fluoride into the mouth. The effectiveness of fluoridated toothpaste has been studied extensively in randomized controlled trials. The Cochrane review on the topic estimated that twice daily toothbrushing with fluoridated toothpaste prevents about 24% of caries lesions among children and adolescents. However, even with the widespread use of fluoride toothpastes and other forms of fluoride delivery, the link between free sugar intake and caries development remains (Moynihan and Kelly, 2014).

## Periodontal disease

### Prevalence and trends

Periodontal disease (gum disease) is another highly prevalent oral disease—according to the Global Burden of Disease study it is the sixth-most prevalent chronic condition in the world. Its prevalence increases with increasing age. The global age-standardized prevalence for severe periodontal disease was 9.8% in 2017, peaking at age 60–64 years. Like dental caries, periodontal disease is socially patterned, disproportionately affecting the more disadvantaged population groups. While the age-adjusted prevalence of periodontal disease has decreased in high-income countries since 1990, middle- and low-income countries have seen an increase over the same period (G.B.D. Oral Disorders Collaborators, 2020).

### Etiology of periodontal disease

The most important risk factors for periodontal disease are poor oral hygiene and tobacco use. However, there are also associations with dietary factors, with evidence for a role of vitamin deficiencies (mainly B vitamins, vitamin C, and vitamin D), calcium, and proinflammatory saturated fatty acids. A diet high in free sugars has also been implicated in the development of periodontal disease, an inflammatory disease. Dietary sugars contribute to oxidative stress, which plays a role in inflammatory processes.

## Dental erosion

### Prevalence

Dental erosion, or tooth wear, is defined as non-carious tooth surface loss. Globally, there are large variations in the reported prevalence of dental erosion due to varying methods of measurement. Available data suggest that the prevalence of dental erosion in deciduous teeth ranges between 30% and 50%, and in permanent teeth between 20% and 45%.

### Etiology

Dental erosion is caused by acids that are either intrinsic, i.e., produced in the body (most commonly through gastro-esophageal reflux disease or eating disorders that involve vomiting); or extrinsic, i.e., coming from the diet. It does not involve bacteria. Dietary sources of acid are mainly citric acid and phosphoric acid that are found in citrus fruits, fruit juices, soft drinks, vinegar and some alcoholic drinks—however, their potential to cause erosion depends not only on acidity but also on mineral content.

It should be stressed that while an excessive intake of acidic fruits has also been linked to dental erosion, the risk is far outweighed by the health benefits of a diet high in fruits and vegetables and no conflicting messages should be given to patients and the public.

## Oral cancer

### Prevalence

Oral cancers (cancers of the lip, tongue, and mouth) were the 16th most prevalent cancers worldwide in 2018, with the highest incidence occurring in South-Central Asia and parts of Oceania. Prevalence is socially graded with lower socioeconomic position associated with higher risk.

### Etiology of oral cancers

Oral cancer is strongly associated with alcohol consumption, particularly in combination with smoking. It has been estimated that alcohol and tobacco together account for 80% of all oral cancers.

On the other hand, a diet high in fruits and vegetables is thought to have a protective effect, which is attributed to anti-inflammatory and antioxidant properties of micronutrients contained in fruits and vegetables. The evidence is based mainly on case-control studies with the potential for bias due to unmeasured confounding and selective reporting, and further research is needed.

## Social and commercial determinants of oral diseases

### Social determinants of oral diseases

The previous sections emphasized the causal role of dietary behaviors—in particular, free sugar consumption—for the development of oral diseases. It is important to recognize that health-related behaviors such as diet are not taking place in a vacuum but are influenced by the wider environment people live in—the social determinants of health. These include distal factors such as the political and economic context in a given society, the extent of structural inequality, and degree to which people's socio-economic position affects their living and working conditions and ability to access health services. These wider determinants shape individual behaviors through material and psychosocial pathways as shown in [Fig. 3](#) ([Peres et al., 2019](#)).

The importance of socio-economic factors for good oral health is reflected in the stark social gradients that are seen within and between countries. [Fig. 4](#) shows the stepwise increase in the prevalence of any caries experience with increasing levels of area-level deprivation among 5-year-olds in England in 2019 ([Public Health England, 2020](#)).

Moreover, oral diseases share common risk factors with general diseases. A diet high in free sugar increases the risk of dental caries, as well as obesity and type-2 diabetes. Alcohol consumption is not only linked to a higher risk of oral cancer but is also a leading cause of global morbidity and mortality from a range of other cancers and conditions. Addressing these common risk factors, which include the wider social determinants described above, to prevent oral diseases will therefore also help to prevent other chronic diseases. The implication is that oral and general diseases should be tackled together in an integrated manner.

More recently, the concept of the commercial determinants of health has been introduced. These refer to strategies used by the private sector to promote products and choices that are detrimental to health ([Kickbusch et al., 2016](#)). Sugar is a prime example for the way commercial determinants of health operate. The commercial determinants of sugar consumptions and implications for policy strategies aiming to improve oral and general health by reducing sugar intake are discussed in the following sections.

### Commercial determinants of sugar consumption

Ultra-processed foods and drinks are the primary sources of free sugar intake in the population. They are cheap and readily available worldwide in both urban and rural settings. The sugar industry uses complex strategies to promote high sugar consumption.

The strategies used by the industry that have negative impacts on population health include advertising, lobbying (influencing legislators and policymakers to favor corporate goals), corporate social responsibility (social and environmental actions such as

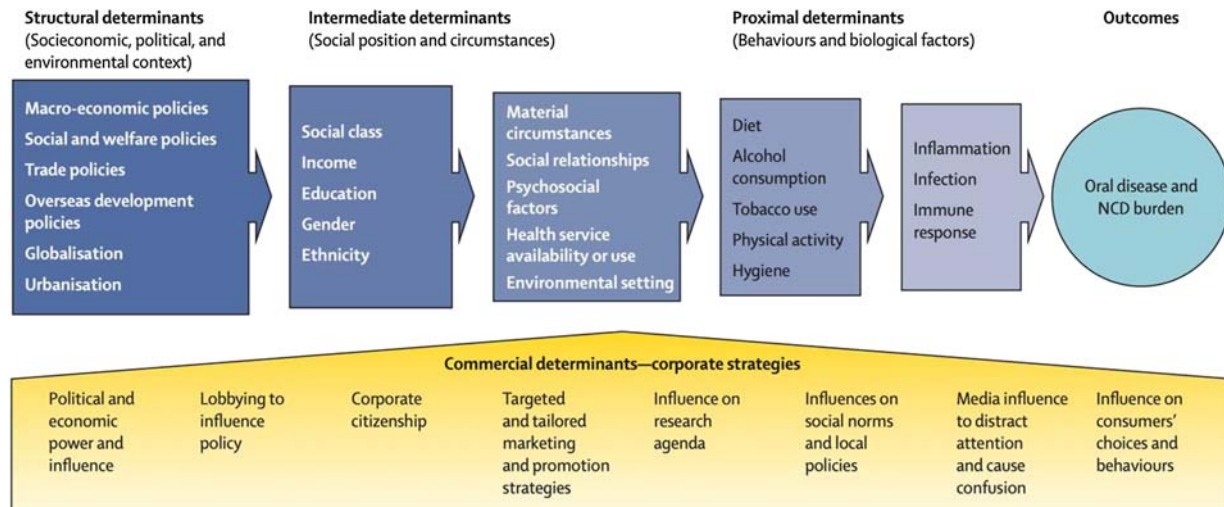

Fig. 3 Social and commercial determinants of oral diseases (Peres et al., 2019).

promoting sports or donating to charities) to increase social acceptability, and extending their supply chains, i.e., their manufacturing and distribution networks (Kickbusch et al., 2016). As a result, transnational sugary foods corporations have significant political and economic influence on the international landscape. Evidence shows how industry has used its power to protect their interests by frustrating public health initiatives. When the policy agenda does not suit industry interests, policies are less likely to be implemented, and if implemented, they are more likely to fail. One of the best-documented cases of industry interference with public health policymaking is when the Sugar Association (which brings together prominent sugar industry actors) pressured the US Congress to get the 2004 WHO Global Strategy on Diet, Physical Activity and Health withdrawn. The association demanded that the Congress withdraw US funding of WHO, if WHO did not remove from the guideline their recommendation to restrict added sugar intake to 10% of daily energy consumption.

The sugar industry has also opposed initiatives to reduce sugar consumption at the national level. As a result, policies to introduce the taxation of SSB and food labeling have faced substantial barriers in their implementation. The industry uses misleading arguments as well as their political and economic power to influence the discourse, including the setting up and funding of opposition groups.

The sugar industry spends billions of dollars on advertising and marketing with sophisticated strategies such as gamification, product placement in films, social media campaigns, and the use of celebrities to endorse their products. Industry spending on advertising to promote their unhealthy products far surpasses the funds available to WHO and national governments to promote healthy diets. Particularly concerning are the marketing campaigns directly targeting children, which often promote products that are touted as being “healthy” but are very high in free sugar.

Fig. 4 Prevalence of caries experience in 5-year-olds in England, 2019 by national Index of Multiple Deprivation (IMD) 2019 quintiles (Public Health England, 2020). Error bars represent 95% confidence limits.

The WHO has acknowledged these commercial determinants and the need for public health actions to respond, and has recently initiated an action program to strengthen the evidence, develop tools, increase capacity, raise awareness, and help build partnerships to address the commercial determinants of health.

### Policy strategies to reduce free sugar consumption

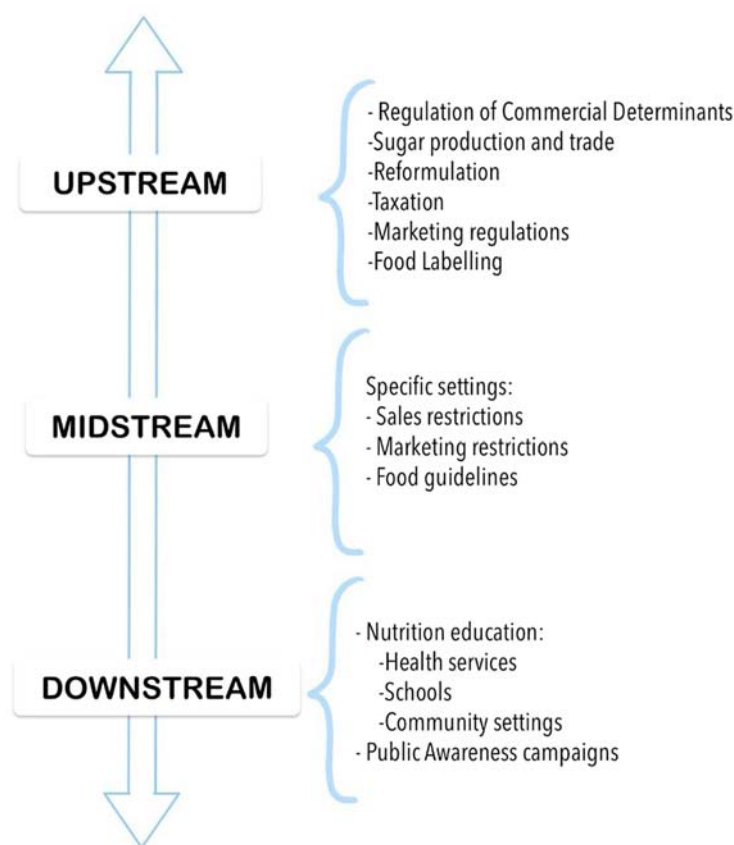

From a public health perspective, policy strategies that regulate the amount of free sugars present in foods and drinks are key to reduce sugar consumption at the population level. These strategies can range from upstream approaches aimed at structural changes to the food environment, to downstream approaches aiming to change individual dietary behaviors. Policy efforts need to be coordinated and implemented at international, national, and local levels. A summary of the most common policies currently used by different countries is shown in Fig. 5.

#### Upstream strategies

Upstream approaches aim to target the causes of disease at their source and can be highly effective. Key upstream strategies are regulation and fiscal policies, i.e., taxation.

#### Regulation of industry influence on policy development

The need to regulate the food industry has been highlighted as a critical upstream policy strategy to promote healthier eating, and governments worldwide have implemented a range of different policy measures. Examples include transparency mechanisms, managing conflicts of interest, monitoring corporate practices, and managing interactions with industry. However, there are currently no strategies directly regulating the sugar industry. Moreover, most of the strategies targeting different types of industries do not establish limits to curb their influence over policy-making processes, which is highly relevant in relation to the sugar industry. Thus, more robust regulation of industry policy influence is needed.

**Fig. 5** Policy strategies to reduce free sugar consumption.

### ***Sugar production and trade***

Policies focusing on sugar production and its trade shape the availability of sugar at the population level and indirectly impact health outcomes. Agricultural diversification and alternative uses for sugar crops fall within this group of policies. For example, India has local programmes to promote the growing of traditional crops and use of sugarcane for ethanol production instead of refined sugar. Additionally, regulating the sugar trade can shape access to free sugars and their use by manufacturers of processed foods such as soft drinks and confectionery. Several countries have tariffs on importing sugars. However, agricultural and trade policies are usually based on economic arguments, particularly in countries where the sugar production industry and the sugar manufacturing industry generate many jobs and are a central part of the national economy.

### ***Voluntary agreements to achieve reformulation***

Several countries have used voluntary agreements to encourage manufacturers to reformulate their products and reduce their free sugar contents for better population health. Voluntary agreements with the industry exist in places such as Australia, Europe, and Southeast Asia. For example, Singapore's top seven soft drinks manufacturers pledged to reduce the sugar content of their products by 12% by 2020. However, voluntary efforts have failed to deliver significant progress due to their limited scope and lack of ambitious goals. An evaluation of the Public Health Responsibility Deal in England (a public–private partnership involving voluntary pledges between government, industry and other organizations to improve public health) concluded that it had largely failed. These failures of voluntary agreements with the food industry have highlighted the need for mandatory regulatory policies.

### ***Taxation***

Price is a major determinant of sugar consumption and fiscal measures such as taxation of sugary products can be highly effective. Taxation of SSB is increasingly popular because of their low nutritional value and high intake in many countries. According to the WHO Global Database on the Implementation of Nutrition Action, 84 member states have implemented SSB taxes. An important advantage of these strategies is that they do not require consumers to change their behavior. Evidence suggests that a 20% increase in price is needed for a significant reduction in SSB consumption. In some countries where taxation policies have been implemented, the industry responded with reformulation schemes to avoid price increases. For example, after announcement of the 2018 implementation of the soft drinks industry levy in the UK, the proportion of drinks with more than 5 g sugar per 100 mL fell by 34% points.

### ***Advertising restrictions***

The sugar industry spends billions on complex marketing strategies to promote its products. Because of this, national authorities have found themselves in need of stricter marketing regulations. Advertising restrictions can apply to media such as TV, radio, movies, or the internet, with additional rules to protect children. For example, several countries have introduced policies prohibiting TV adverts for sugary products before 9 p.m.

In Chile, cartoons, toys, or prizes as incentives to sell unhealthy foods to children are banned. Thus, cereal mascots cannot be used to promote breakfast cereals, and chocolate eggs with hidden toys cannot be sold in the country. Bans of industry sponsorship of community and sports events, and advertising bans on transport systems such as the Transport for London Network also fall within this category. However, these strategies are not widely implemented due to strong opposition from industry actors.

### ***Labeling***

Food labeling provides straightforward information about food composition to consumers. Food labeling systems such as traffic lights are simple and easy to understand by most people. However, the labeling of free sugars is inconsistent and often confusing. The industry's voluntary efforts have focused on using 'healthy stamps' systems to identify healthier products. Their effectiveness in changing purchase patterns is however low. More recently, countries such as Chile, Mexico, Peru, and Israel have implemented mandatory "high in sugars" warning signs for all processed foods. Early evaluations have shown these mandatory policies to be easily understood by consumers and more effective in reducing purchases of sugary products.

### ***Midstream strategies***

Midstream strategies aim to reduce free sugars consumption by creating healthy and supportive environments using a settings approach. For these strategies to be successful, joint action with actors such as businesses, public and private institutions, and communities is fundamental.

An important strategy in this group are mandatory food guidelines in institutions such as schools, nurseries, healthcare services and workspaces, to improve the quality of the food provided to students and staff. Examples are the replacement of fruit juices and soft drinks with water, or sugary desserts with fruit or sugar-reduced alternatives. In addition, policies banning the marketing and sale of sugary products in schools, workplaces, and healthcare settings have been proven effective in reducing sugar intake.

Sales restrictions in supermarkets and other retailers have also been implemented. For example, some supermarkets in the UK have replaced confectionery and sugary snacks usually sold at checkouts with healthier options. More recently, the UK has implemented restrictions on price promotions for foods high in sugars such as "buy one, get one free" offers.

## Downstream strategies

The strategies that are most frequently implemented by local governments and/or health professionals are downstream policy strategies that target individual behavior change. They focus on the provision of dietary advice including individual support by health professionals and have been implemented with different degrees of success. Examples include nutrition education in health settings, schools, or community spaces. Evidence shows that these activities have modest results in reducing sugar intake. The types of nutritional education that are more likely to be effective are those focusing on healthcare workers, schoolteachers, or social care workers who can act as health champions in the community, and initiatives that teach skills such as cooking and growing foods.

Finally, there is a varied group of strategies aimed at providing information on healthy eating to consumers. Most countries have implemented public awareness campaigns at the national or regional level. However, research has shown that giving non-tailored, general advice on healthy eating can raise knowledge on the topic but does not lead to long-term behavior change. A disadvantage of downstream approaches is that they can widen oral health inequalities, because the messages are more likely to reach and benefit the more advantaged population groups.

## Conclusions

Oral diseases, and dental caries in particular, pose significant global public health problems that affect a large proportion of the world's population. The main cause of dental caries is the consumption of free sugars. A range of upstream, midstream, and downstream actions are therefore urgently needed to reduce free sugars consumption to prevent dental caries. Upstream legislation, regulation and fiscal action should be implemented whenever possible to effectively and sustainably reduce free sugars consumption at a population level.

### Glossary

**Bruxism** Grinding of the teeth which can cause the teeth to wear and damage the tooth enamel through time.

**Chromosome** One of the thread-like structures in a cell nucleus that carry the genetic information.

**Cystathionine  $\beta$ -synthase** Enzyme that catalyses the first step of the transulfuration pathway from homocysteine to cystathionine.

**Lipid peroxidation** Refers to the oxidative degradation of lipids. It is the process whereby free radicals oxidize lipids in cell membranes resulting in cell damage.

**Nonstarch polysaccharide (NSP)** Complex carbohydrates other than starches found in foods. Contribute to dietary fiber in the diet. Insoluble NSP found in wheat, maize and rice and have a stool bulking effect. Soluble NSP found in oats, barley, rye and beans, can help lower blood cholesterol.

**Osteoporosis** Condition resulting in loss of bone tissue resulting in bones becoming brittle and liable to fracture.

**Purine** A nitrogenous compound with a two-ring molecular structure. Examples are adenine and guanine which occur in DNA structure, and uric acid.

**Superoxide dismutase** An enzyme which catalyses the dismutation of superoxide into oxygen and hydrogen peroxide. It is an important antioxidant defense in nearly all cells exposed to oxygen.

**Trisomy** A condition where there is one extra chromosome present in each cell in addition to the normal pair.

Down's syndrome, named after John Langdon Down, is a most widely recognized chromosomal disorder found in humans and falls into a category of chromosomal disruptions known as trisomies, hence, the other term for the condition; Trisomy 21. People with Down's syndrome vary widely in their abilities, but the syndrome is the most common genetic cause of intellectual disability.

More than 90% of Down's syndrome individuals have a total of 47 chromosomes in cells instead of the usual 46. The remaining cases are mainly either translocations, where there is a rearrangement of fragments of chromosomes, or mosaics in whom there are both normal and trisomic cells, that is, mosaic trisomy 21. There is a relationship between the frequency of Down's syndrome births and age, with both very young mothers and older mothers having a higher incidence of affected infants. It has been suggested that

nutrition may be implicated in the nondisjunction of the chromosomes. The additional chromosomal material in Down's syndrome usually comes from the mother, but it can, on occasion, come from the father. This observation may be indicative of hormonal changes in the older mother that reduce the likelihood of spontaneous abortion in an abnormal pregnancy.

The incidence of Down's syndrome is approximately 1 in 600–1000 live births. Prevalence is rising as life expectancy has improved over recent years with advancing medical knowledge and higher standards of care. In addition, women are having children at the older age and the incidence of Down's syndrome is increasing with increasing maternal age, although there are significant differences between various racial and social groups.

Physical defects common in Down's syndrome include congenital anomalies of the gastrointestinal tract (e.g., duodenal atresia and intestinal aganglionosis), which occur in approximately 12% of infants with Down's syndrome. Most of these anomalies require the neonate to be operated on immediately to allow nutrition. Congenital heart disease occurs in approximately 40% of infants with Down's syndrome. Children with congenital heart disease may present with failure to thrive, but after surgical repair of heart defects these children usually improve. Immune dysfunction, increased susceptibility to leukemia, and premature ageing with Alzheimer-like changes in the brain are major features of the syndrome.

Thyroid dysfunction is more common in people with Down's syndrome with the incidence increasing with age. Hypothyroidism is most frequently reported but hyperthyroidism can also occur. Correction of the thyroid function is essential to allow normal learning processes to take place and to help weight control.

There are many biochemical anomalies associated with the syndrome, mainly quantitative rather than qualitative. It is presumed that the overexpression of genes on chromosome 21 contributes to both the structural and functional pathology. Overdose effects of the genes already mapped to chromosome 21 are thought to alter pathways controlling the production of monocarbons, purines, pyrimidines, tubulins, and myelin.

The nutritional complications associated with Down's syndrome are summarized in [Table 1](#).

## Nutritional Status

It is debatable how relevant reference data from normal groups are for people with Down's syndrome.

## Dietary Assessment

In children with Down's syndrome, conflicting reports have shown energy intake to be less than, similar to or greater than age-matched comparison groups, with a small percentage of children exceeding the recommended daily intake by more than 50%. However, as children with this syndrome tend to be shorter than age-matched children, energy intake comparisons need to be calculated per unit of body height.

Lower than recommended intakes of nonstarch polysaccharide coupled with higher than recommended consumption of protein and fats have also been reported. Researchers have reported low intakes of calcium, particularly in preschool and school-age children who refuse or limit milk consumption. Iron intakes have been reported to be low, particularly nonhem iron. Vitamins A and C intakes are limited in those who have a poor intake of fruit and vegetables. Intake of vitamin B has also been reported as low.

## Laboratory Assessment

### Carbohydrate metabolism

Fasting blood glucose levels are usually in the normal range, but the glucose tolerance curve has been reported to be flatter and often with a double humped curve, suggestive of delayed absorption. There is an increased incidence of both Type 1 (insulin dependent) and Type 2 diabetes in Down's syndrome. Studies have shown increased insulin resistance in obese and overweight females and adults with Down's syndrome but further research is required.

**Table 1** Nutritional complications of Down's syndrome

Physical	Problems with muscle tone, oral health and dentition, chewing and swallowing
Metabolic	Anomalies in carbohydrate protein and lipid metabolism Increased demands on antioxidant defence system and methylation pathways Increased incidence of diabetes, celiac disease, obesity and thyroid disorders and leukaemia Growth retardation
Behavioral	Food consumption and exercise choices

## Protein Metabolism

Disturbances in protein metabolism are common in Down's syndrome. An increased level of immunoglobulin A and immunoglobulin G antibodies to food antigens has been reported, and several studies have reported an increased prevalence of celiac disease. Abnormal levels of fasting plasma and urinary amino acids have been reported.

## Lipid Metabolism

One study reported no significant differences between study and control groups, drawn from within the same families, in levels of total cholesterol, low-density lipoprotein, apolipoprotein B, and the apolipoprotein B to apolipoprotein A-I ratio. Triacylglycerol levels were significantly increased and serum high-density lipoprotein cholesterol to total cholesterol ratio significantly decreased in Down's syndrome. This suggests increased risk for coronary heart disease. The results of this and other studies reporting no difference between Down's syndrome and comparison groups in atherosclerosis, contrast with early reports that suggested a decreased incidence of coronary artery disease in Down's syndrome. It is not clear whether the differences reflect nutritional variables or population variable changes reflecting the increased survival rate in infancy.

There is evidence of increased lipid peroxidation in Down's syndrome.

## Vitamins

Some studies have reported biochemical evidence of deficiency of thiamin, nicotinic acid, pyridoxine, cobalamin, folate, ascorbic acid, retinol,  $\beta$ -carotene, and  $\alpha$ -tocopherol in patients with trisomy 21. Vitamin D metabolites have been reported to be in the normal range in a Spanish study that demonstrated wide seasonal variation linked to intensity of solar radiation.

## Minerals

Low iron, calcium, manganese, and zinc blood concentrations have been reported in patients, and the iron to copper ratio has been reported to be decreased. Recent studies reported that intracellular zinc in blood mononuclear cells was approximately 47% lower than normal controls and it is possible that this could play a role in thyroid dysfunction, immunodeficiency, retarded growth, and faulty DNA repair. Low zinc status may contribute to the chemical disturbances that usually appear with ageing in individuals with Down's syndrome. Further research is required to determine whether zinc supplements are beneficial and if so at what dose. Supplementation with selenium aimed at increasing levels of the selenium-dependent enzyme glutathione peroxidase is reported to have led to a decrease in initially high blood mononuclear cell levels of copper, but did not affect iron or zinc.

Vitamin and mineral levels have been held to reflect not just nutrient intake, but also abnormal metabolism. Assessments of antioxidants and of oxidation by-products are useful indicators of nutritional status in people with Down's syndrome. The over-expression of the superoxide dismutase system, the purine synthesis pathway and cystathionine  $\beta$ -synthase are thought to create extra demands for antioxidants and for folate, but despite gene dosage effects the many biochemical anomalies that have been reported in people with Down's syndrome show a great deal of individual variation.

## Anthropometric Assessment

Growth delay is one of the main characteristics of Down's syndrome but impaired growth velocity is particularly evident at certain stages of development.

The fetal growth has usually been reported to be relatively normal and the length of the neonate is often within normal limits, allowing for gestation. Some studies have reported the prenatal growth delay and a major Italian study comparing neonatal length, weight, head circumference, and weight/length squared reported all percentiles of growth variables lower in Down's syndrome infants except for weight/length squared percentiles.

At approximately 6 months of age, when growth starts to become regulated by growth hormone, growth velocity usually begins to show a marked reduction from normal levels. Although for the Down's syndrome child the period between birth and 2 years and the period between 6 years and 10 years of age are times of accelerated growth, the deviation from normal levels remains significant. Slow growth velocity is also a particular feature of adolescence, although there is a pubertal growth spurt. The deviation of adult stature from the means of reference groups is greater than the deviations in early infancy.

The short stature in Down's syndrome seems to be mainly the result of the impaired growth of the long bones of the leg, as sitting height measurements show that the growth of the vertebral column is closer to normal.

Why there is growth delay in Down's syndrome is not entirely clear, and several hypotheses have been advanced. Both human growth hormone therapy and zinc sulfate supplementation of the diet have been reported to accelerate the growth.

Children with Down's syndrome tend to be not only shorter, but also heavier than reference children. Charting the height and weight of a child with Down's syndrome using reference norms from the general population, will show the abnormality of the growth pattern. However, it is more useful clinically, to compare the height and weight of an individual against syndrome-specific norms, as that will show up any deviation from the growth patterns of children with Down's syndrome.

Italian percentile charts have been drawn up for neonates with Down's syndrome based on a large sample of consecutively born infants. The specific growth charts for children with Down's syndrome have been constructed based on anthropometric assessments of US children, Sicilian children (thought to be representative of southern European children) and Dutch children (thought to be representative of northern European children). On average the Dutch children were taller than the US children and the US children were taller than the Sicilians. More recently growth charts have been developed for UK children and in the US work is currently being undertaken to update growth charts to encompass current research that shows children with Down's syndrome are growing better.

## **Nutritional Requirements**

Children and adults with Down's syndrome need the same range of nutrients as the general population. Energy intake standards based on age groups are not appropriate for children with Down's syndrome. Energy intakes in both children and adults need to be tailored to height and weight and to the physical activity.

## **Nutritional Therapy**

In the 1970s and 1980s hopes were raised that megadoses of vitamins and minerals would boost intelligence in children with Down's syndrome, but rigorous studies have shown these doses lead neither to higher intelligence nor to better health. In addition, there is anxiety about possible side effects, particularly of the fat-soluble vitamins.

As more has been learned about the genes on chromosome 21, interest shifted to targeted nutritional intervention aimed at correcting the metabolic anomalies that are common in Down's syndrome owing to genetic overexpression, with the emphasis on nutrients to maintain health and prevent disease. Targeted nutritional supplementation with vitamins, minerals, amino acids, digestive enzymes, and essential fatty acids remains controversial. Clinicians have reported differences between children treated and not treated in health, growth, and cognitive and speech functions but few well-designed studies have been performed.

## **Dietary Management**

### **Dietary Guidelines**

Dietary recommendations are as for the general population until research proves otherwise. There are, as yet, no specific dietary guidelines for the woman pregnant with a Down's syndrome child. Periconceptual folic acid supplements of 400 µg daily in addition to folate-rich foods may be beneficial in decreasing risk of Down's syndrome, as well as neural tube effects. There are also indications that antioxidant and essential fatty acid intake may be particularly important, but at present dietary advice is the same as for other pregnant women.

The situation is similar for infant feeding. Brain lipids in the human infant are known to change with changing intakes of fatty acids. The needs of a newborn with Down's syndrome for the long-chain polyunsaturated fatty acids docosahexenoic acid and arachidonic acid have not yet been determined. Because breast milk contains the preformed dietary very long-chain fatty acids that seem to be essential for the development of the brain and the retina, it seems prudent to encourage breast-feeding.

The antioxidant defense system has a particularly important role in Down's syndrome and parents and caregivers can be advised on providing a diet rich in antioxidants. Dietary intakes need to be considered for the sulfur amino acids (which are needed for glutathione synthesis), of fat-soluble vitamins A, C, and E, water-soluble vitamins B<sub>6</sub>, B<sub>12</sub>, and folic acid, and of the minerals selenium and zinc. In latitudes where no vitamin D is synthesized in the winter months, it is particularly important to ensure exposure to sunlight during summer months to maintain adequate stores of the vitamin throughout the year as recent studies indicate an increase in the incidence of osteoporosis in Down's syndrome. Those who are housebound or have poor mobility may benefit from a vitamin D supplement.

## **Feeding Behavior**

Feeding skills tends to be delayed in the young child with Down's syndrome, but the sequence of the emergence of the skills is the same as with other children if appropriate learning opportunities are provided.

Infants with Down's syndrome have a smaller oral cavity, which makes it easier for liquids to spill from the sides of the mouth. If a child is hypotonic, the tongue is likely to flatten out when the child sucks instead of forming a groove round the nipple, so the child will have a weak suck, may gag, and milk will leak from the mouth. Feeding will be exhausting, and particularly where the child has a cardiac defect, the child may have difficulty taking in enough milk to meet energy requirements. Tube feeding may be necessary until the child develops better tongue control. Feeding will be easier if the infant is wide awake and extra support for the infant during feeding, in particular supporting the infant's chin to help steady the jaw, can all help encourage intake. Because of the benefits of breast-feeding, it is essential that nursing mothers are given help and advice when their infants have initial difficulties. Breathing during feeding may be helped if the mouth and nose are cleared of mucus with a syringe before feeding.

As with other children, it is important to introduce textured food when the child is developmentally ready, and information should be provided for parents and caregivers regarding appropriate expectations and helpful feeding techniques as well as dietary

advice. In children with Down's syndrome, poor neuromotor control of the tongue may result in the continued use of pureed food. There may be slow initiation of the swallow response, possibly because of hypotonic pharyngeal muscles, and oral sensitivity problems may also make the transition to textured foods difficult. Persistent feeding problems merit multidisciplinary assessment and therapy. Impaired swallow can result in food being aspirated and contribute to respiratory problems. The presence of the tongue protrusion reflex past the age of 12–18 months can result in delayed progression to solid food and can contribute to malocclusion of teeth. Also, dental abnormalities can exacerbate difficulties with chewing and can contribute to poor nutrition, because children who have problems chewing may be offered soft often high-energy food and be given little opportunity to accept meats, fresh fruits and vegetables, which are lower in energy.

Fresh fruit and vegetables provide the nonstarch polysaccharide that can help prevent the constipation common in Down's syndrome. Fruit juices and water between meals also help with constipation. Because the hypotonia in Down's syndrome also contributes to sluggish bowel habits, this is another reason for children and adults to be encouraged to take part in physical activity. If constipation does not respond to dietary management, there should be a medical assessment to exclude gastrointestinal and thyroid problems.

### Dental Problems

Dental anomalies in Down's syndrome include changes in the tooth structure, reduced total number of teeth and delayed or abnormal eruption. Together with the physical abnormalities of the facial appearance and oral cavity, these can all impact on feeding. Dental disease is common in Down's syndrome as teeth are more at risk of wear through bruxism and decay due to fragile enamel. In addition, gum disease (gingivitis), and oral infections due to mouth breathing can lead to teeth becoming loose and falling out. A healthy balanced diet, including plenty of fruit and vegetables, low in sugar-containing fluids and fizzy drinks (including 'diet' varieties), and avoiding frequent snacks will help preserve teeth.

### Obesity

Obesity is common in Down's syndrome having been reported from different cultures and ethnic backgrounds. From Australian and North American studies it has been reported that by 2–3 years of age more than 30% of children with trisomy 21 are overweight and that by 9 years of age the average child with Down's syndrome is obese.

High rates of overweight and obesity have been reported in adults with Down's syndrome, both living in the community and at home, and more commonly in females than males. Overweight and obesity are particularly associated with living in the family home compared to supervised community units or hospital, but they are not significantly associated with the degree of learning disability.

Because excessive weight gain in childhood often leads to adult obesity, it is important to encourage healthy choices in childhood. Why children with Down's syndrome have a tendency to become fat is not clear, but probably several factors influence the weight gain. Retardation of growth resulting in short stature may be of prime importance. Obesity in people with Down's syndrome has also been linked with several physiologic features of the syndrome (Table 2).

Prepubescent children with Down's syndrome have a decreased resting metabolic rate compared to control children matched for the body mass index. Children of approximately the same body composition, whether or not they have Down's syndrome, expend similar levels of energy in the physical activity. Since obesity is negatively correlated with the motor performance, it is likely to lead to a reduction in sporting and physical recreation activities, and thus obesity has social as well as health implications, in children with Down's syndrome as in other children. However, children and adolescents with Down's syndrome have been shown to have difficulty with sustained physical exercise in both laboratory and recreational situations, and this has been attributed to physiological impairments, notably cardiovascular, as well as to lack of motivation.

Children, adolescents and adults with Down's syndrome have a deficit in isokinetic strength, and by the age of 14 years adolescents with testosterone levels in the normal range fail to show the pubertal muscle strength increase. Progressive resistance exercise

**Table 2** Factors predisposing to obesity in Down's syndrome

	<i>Increased</i>	<i>Decreased</i>
Poor eating behavior	↑	
Calorie intake	↑	
Resting metabolic rate		↓
Muscle tone		↓
Exercise		↓
Thyroid function		↓
Substrate fat oxidation		? ↓
Leptin levels	? ↑	

programs can help to build muscle strength, and regular aerobic exercise will improve exercise tolerance. Often individuals can attain high standards in competitive gymnastics and swimming. The overexpression of collagen genes on chromosome 21 affects both muscle and connective tissue, and it has been claimed that targeted nutritional treatment leads to rapid improvement in both muscle strength and joint stability.

In a cross-sectional study of men and women with Down's syndrome, the body mass index declined with increasing age. Further research is needed to clarify whether individuals lose weight as they age, or whether there is a shorter life expectancy for individuals with higher body mass indices.

## Celiac Disease

There is an increased incidence of celiac disease in Down's syndrome compared with the general population. Symptoms such as gut dysfunction (both diarrhea and constipation), abdominal bloating, dyspepsia, mouth ulceration, mood change, arthritis, general fatigue, and mild anemia may be indicators of celiac disease, although many of these are common in Down's syndrome without celiac disease. Blood tests such as antiendomysial antibodies (AEA) and tissue transglutaminase antibody status can give an indication of celiac disease but are not conclusive. Definitive diagnosis remains the identification of villous atrophy on small bowel biopsy. Quality of life can be greatly improved on a gluten-free diet so implementation following diagnosis and good compliance should be encouraged.

## Ageing

The rapid ageing that characterizes Down's syndrome is in line with the accumulating evidence that many degenerative diseases are associated with deleterious activated oxygen species reactions. Activated oxygen species can damage genetic material and inactivate membrane-bound enzymes as well as cause lipid peroxidation in cell membranes. Of particular relevance to Down's syndrome is the evidence relating to cancer, inflammatory joint disease, diabetes, degenerative vascular disorders, degenerative eye disease and senile dementia – all reported to have increased prevalence in Down's syndrome.

The gene for copper/zinc-superoxide dismutase is on chromosome 21, and copper/zinc-superoxide dismutase levels are elevated by 50% in a range of cells of people with Down's syndrome, including erythrocytes, blood platelets, leucocytes, and fibroblasts. The increase has also been reported in fetal cerebral cortical cells. Although copper/zinc-superoxide dismutase usually functions as an antioxidant it seems likely that in Down's syndrome the raised levels lead to oxidative stress. When the increased production of hydrogen peroxide through catalysis of superoxide free radicals is not matched by a sufficient increase in glutathione peroxidase to metabolize the additional hydrogen peroxide to water and oxygen, there is thought to be an increase in highly reactive hydroxyl radicals leading to increased lipid peroxidation.

Fibroblasts derived from people with Down's syndrome show elevated lipid peroxidation, and levels of thiobarbituric reaction products, which indicate extent of lipid peroxidation, have been reported to be raised in erythrocytes from Down's syndrome subjects compared to control subjects.

A reported increase in the activity of the hexose monophosphate pathway in Down's syndrome is thought to be a compensatory mechanism to deal with increased hydrogen peroxide, allowing greater production of the reduced form of nicotinamide-adenine-dinucleotide phosphate, thus improving the ability of cells to reduce oxidized glutathione. However, it has been suggested that this shift of glucose utilization from energy production to reducing power may compromise cellular cation pumps.

Among the genes so far identified on chromosome 21 is that for  $\beta$ -amyloid precursor protein. Amyloidosis is evident in the brain tissue of both patients with Alzheimer's disease and those with Down's syndrome. Studies are investigating the implications of the anomalies in the expression of the  $\beta$ -amyloid precursor protein and also of the effect on cobalamin/folate metabolism of the gene for the enzyme cystathionine  $\beta$ -synthase, also on chromosome 21. The overexpression of both these genes is believed to contribute substantially to the development of dementia. Although all people with Down's syndrome have evidence of brain pathology similar to Alzheimer's disease by their early thirties, not all show Alzheimer-like behavior changes as they age.

It may be that an increase in dietary antioxidants could delay the onset of Alzheimer's type symptoms but more research is required. However, standard dietary recommendations for healthier lifestyles (i.e., eating more fruit and vegetables and including more oily fish in the diet) may have the added potential benefits of increasing antioxidant intake. Unfortunately these are often the foods least favored by individuals with Down's syndrome.

Low vitamin E levels have been found to be associated with dementia, not only in the elderly but also in those with Down's syndrome. Vitamin E may have a potential therapeutic role in Alzheimer's like neurological changes by protecting the integrity of the muscarinic receptors. In addition, vitamin E is a strong antioxidant. Likewise, vitamin B<sub>12</sub> deficiency has been reported in cases of Down's syndrome and Alzheimer's disease; however, replacement therapy does not change the evolution of the underlying disease. Continuing research into the etiology of the Down's syndrome phenotype is expected to lead to advances in the treatment of both Down's syndrome and Alzheimer's disease.

## Care in the Community

Most people with Down's syndrome live in the community; some live with parents or caregivers, but adults often live independently or semi-independently. Many people with Down's syndrome can learn about healthy eating and manage their own diets. A dietitian's role in a community learning disability support team is likely to encompass not only individual assessment, but also teaching and educating people with Down's syndrome as well as parents, caregivers and other professionals.

## Key points

- Anorexia Nervosa (AN) is a serious psychiatric disorder associated with significant medical morbidity and higher mortality rates relative to the general population
- AN is characterized by energy restriction, fear of weight gain, behaviors to inhibit weight gain, and body image disturbance
- AN is associated with high rates of self-harm, suicidality, and co-morbid psychiatric diagnoses, in particular mood and anxiety disorders and substance abuse
- The effects of malnutrition are seen across body systems, with common findings including cardiovascular compromise (bradycardia, orthostatic hypotension, and less commonly, arrhythmias), amenorrhea, low bone mineral density (BMD), and gastrointestinal complaints.
- Treatment for AN may occur on a spectrum from outpatient to inpatient psychiatric interventions; all levels of care should include an interdisciplinary team of providers.

## Introduction

Anorexia nervosa (AN) is a serious psychiatric disorder classified under the category of Feeding and Eating Disorders in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5; [American Psychological Association, 2013](#)). The key characteristics of AN are centered on an individual's perception of their weight and subsequent behaviors to avoid weight gain resulting in low weight. Full diagnostic criteria are described below. Individuals with AN commonly present with co-morbid psychiatric disorders and physiologic manifestations of malnutrition across body systems. AN is associated with elevated risk of death compared to the general population consequent to effects of malnutrition and suicide ([Keshaviah et al., 2014](#)).

## Diagnostic criteria

AN is a distinct diagnosis outlined under the category of Feeding and Eating Disorders in DSM-5 ([APA, 2013](#)). Although an individual may be diagnosed with more than one eating disorder during their lifetime, concurrent disorders are not possible within the framework of current diagnostic criteria. Diagnosis of AN per DSM-5 criteria is focused on the following features:

- Energy restriction (restriction of food intake) leading to body weight that is significantly low for that individual by age, sex, growth trajectory, health, or what is minimally normal or expected if a child or adolescent.

- Profound fear of gaining weight or becoming fat with behavior that prevents weight gain despite low weight.
- Body image disturbance, significant self-evaluation tied to weight or shape, or poor insight into the seriousness of weight loss/low body weight

The DSM-5 was published in 2013 with notable differences from the diagnostic criteria in the previously published Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition Text Revision. First, the discrete cutoff of 85% of ideal body weight (IBW) was removed as an exemplar of low body weight and replaced with language describing “significantly low” as “less than minimally normal, or for children and adolescents, less than that minimally expected” (APA, 2013, p. 338). Additionally, the amenorrhea criterion was removed in consideration of younger adolescents who are premenarchal, those who have irregular menses or body composition (body fat) that influences menstruation, and males. Further revisions included adding persistent behavior that inhibits weight gain as an index of fear of weight gain, and replacing “denial” of the seriousness of low body weight with “persistent lack of recognition” of the seriousness of low body weight (APA, 2013).

DSM-5 describes two subtypes of AN: restricting and binge-eating/purging. Individuals with the restricting AN subtype lose weight or maintain low weight through dietary restriction and exercise and have not engaged in binge-eating or purging in the past 3 months. Alternatively, those with the binge-eating/purging subtype have experienced recurrent binge eating or purging through laxatives, vomiting, diuretics, enemas, etc. within the 3 months prior to diagnosis.

The International Classification of Diseases 11th Revision (ICD-11) also includes restricting and binge-eating/purging AN subtypes along with weight-related diagnostic qualifiers of “significantly low weight” and “dangerously low weight.” Notably, however, the ICD-11 does not provide set cutoffs for “significantly low” or “dangerously low” when evaluating weight status. Per the DSM-5, in adults severity of weight status is conceptualized using World Health Organization (WHO) classifications as follows: mild—body mass index (BMI)  $> 17 \text{ kg/m}^2$ , moderate—BMI of  $16\text{--}16.99 \text{ kg/m}^2$ , severe—BMI  $15\text{--}15.99 \text{ kg/m}^2$ , and extreme—BMI  $< 15 \text{ kg/m}^2$ . Importantly, clinicians should consider level of functioning and symptom profile, in addition to weight, when determining severity of AN. For children and adolescents, BMI percentile and percent median BMI are used, and should consider a child’s previous growth trajectory when determining severity of illness (Society for Adolescent Health and Medicine [SAHM], 2015).

Likewise, atypical anorexia nervosa (AAN) is diagnosed in individuals who meet criteria for AN with regards to energy restriction, fear of weight gain, and body image disturbance yet do not exhibit low weight as per WHO classifications for BMI described above. Those with AAN may present with significant weight loss or, in the case of youth, fail to continue on the expected growth trajectory. This presentation would fall under the DSM-5 category of Other Specified Feeding or Eating Disorder (OSFED) with the specific designation of AAN.

## Other clinical characteristics

Individuals with AN commonly present with comorbid psychiatric disorders. One survey reported that 56.2% of individuals with AN met criteria for at least one other DSM-IV psychiatric disorder, of which mood and anxiety disorders (including obsessive compulsive disorder), and substance abuse were most prevalent (Andrés-Pepiñá et al., 2020). Longitudinal studies show that over one-third of individuals (39%) who recover from AN continue to exhibit other psychiatric disorders at follow-up (17–29 years post presentation; Andrés-Pepiñá et al., 2020).

Additionally, individuals with AN experience high rates of self-harm. As many as 21% of individuals with AN engage in non-suicidal self-injury (NSSI) in their lifetime (Cucchi et al., 2016). High mortality rates in AN are due, in part, to death by suicide (Keshaviah et al., 2014), with greater risk of suicide attempt in individuals with the binge-eating/purging subtype (Mandelli et al., 2019). Moreover, suicide attempts in individuals with AN are reported to have a greater level of intent and potential lethality than those found in other eating disorder diagnoses (Guillaume et al., 2011). Suicide is the cause of death for 1 in 5 individuals who die as a result of AN; this population has been found to be 31 times more likely to die by suicide than age matched peers (Preti et al., 2011).

## Epidemiology

Lifetime prevalence of AN is estimated to be between 0.3 and 2.2% (Bulik et al., 2006; Hudson et al., 2007). The peak incidence is during adolescence, specifically 15–19 years of age and is more common in females than males (Hoek and van Hoeken, 2003). Although eating disorders are perceived to affect only white individuals, they are found across all racial and ethnic groups (Marques et al., 2011). Non-white individuals with eating disorders may present differently than white women and are less likely to receive treatment (Marques et al., 2011). Additionally, AN may be more common in sexual and gender minorities than cisgender, heterosexual peers (Nagata et al., 2020).

There is no consensus definition of recovery from AN. It has been suggested that AN exists along a spectrum from subsyndromal (body image concerns and eating restriction without changes in weight) to full syndrome, as well as a spectrum from partial remission with “minimal” restriction through full remission with no behaviors present (Steinglass et al., 2020). Commonly, recovery from AN is defined as normalization of disordered behaviors such as eating patterns, resolution of dietary restriction or binge eating,

improvement in cognitive distortions (e.g. body image disturbance), and physiologic recovery (e.g. weight) and may be episodic (Steinglass et al., 2020). It has been suggested that 46% of individuals fully recover from AN and up to 20% develop chronic illness, although studies with adolescent-onset AN show higher rates of recovery (up to 65%; Andrés-Pepiñá et al., 2020). Relapse is most common in the first 2 years following treatment discharge. Prognosis is better for those who enter treatment at a young age or those with shorter duration of illness prior to entering treatment (Andrés-Pepiñá et al., 2020).

## Pathophysiology

The development of AN is likely a complex bio-psycho-social phenomenon involving genetic predisposition in combination with environmental factors. Recent genome wide association studies of nearly 17,000 cases suggest a strong genetic influence and posit AN as a metabo-psychiatric disorder (Watson et al., 2019).

Within the environment, media-driven societal pressure to conform to the “thin ideal” (romanticized thin body type) likely contributes to the development of restrictive eating disorders. The notion that life would be better if one was thinner, or internalization of the thin ideal, and greater exposure to media sources promoting thin bodies are associated with increased eating pathology. Resultant dieting behavior in childhood is a key predictor of the onset of eating disorders (Culbert et al., 2015).

Additional environmental factors include parenting style, parental personality, and history of adverse childhood events (ACEs; (Culbert et al., 2015). Personality traits associated with eating disorder development include negative emotionality, perfectionism, drive for thinness, poor interoceptive awareness, and obsessive-compulsiveness, neuroticism, impulsivity, negative urgency, and inhibitory control have been implicated for those with binge-purge behaviors. Additionally, neurotransmitter disturbances and regulation have been suggested as contributing factors to eating disorder development (Culbert et al., 2015).

## Differential diagnoses

When considering a diagnosis of AN, primary medical and psychiatric illnesses must be ruled out. Medication use, gastrointestinal diseases, food allergies and intolerances, thyroid abnormalities, new onset Type 1 diabetes mellitus, malignancy, and HIV/AIDs can cause weight loss. Psychiatric disorders that have overlapping symptoms also should be considered, including anxiety disorders and phobias that inhibit intake, depressive disorders, and schizophrenia-related erratic eating. Additionally, drug use that suppresses appetite (e.g. stimulants, cocaine) must be ruled out.

## Screening

There are a number of instruments available to aid clinicians in screening for the presence of eating disorder pathology. These tools are not appropriate for diagnosing AN, but can be used to identify patients in need of further clinical assessment or referral to a specialist. Very brief, self- or clinician-administered screening tools, like the SCOFF Questionnaire (Morgan et al., 1999) and Eating Disorder Screening in Primary Care (ESP-PC; Cotton et al., 2003), often are used in medical settings. More thorough assessments include the Eating Attitude Test-26 (EAT-26; Garner et al., 1982), Eating Disorder Examination-Questionnaire (EDE-Q; Fairburn and Beglin, 1994), and the Eating Disorder Diagnostic Scale (EDDS; Stice et al., 2000), all of which are self-administered.

## Clinical presentation and physical examination

Presentation may vary depending on clinical setting; however, it is imperative that clinicians across settings are aware of warning signs and can identify potential cases for early intervention. Clinicians should consider an eating disorder in any individual with new or rapid weight loss, growth stunting in adolescents or children, new dieting behavior or compulsive exercise, rigid or obsessive food habits, or negative thoughts about weight or shape.

Effects of malnutrition may be seen regardless of weight or BMI. Individuals may present to care based on symptoms such as dizziness or fainting, gastrointestinal distress, and changes in menstrual patterns (amenorrhea). Clinicians might see indications of purging behavior, such as Russell’s sign (abrasion on the knuckles of the hands due to repeated self-induced vomiting), dental enamel erosion, or enlarged parotid glands. Hemodynamic instability, arrhythmias, dehydration, peripheral edema, bloating, gastric distention, xerosis, hair loss, lanugo, cold intolerance, brittle hair and nails, and subcutaneous fat loss also may be noted on exam (Westmoreland et al., 2016).

Initial assessment should include a complete history including medical, family, and social histories. Nutrition history including changes in eating patterns, weight loss, and 24 h dietary recall, and menstrual history, may elucidate warning signs as well. Growth charts for children and adolescents should be reviewed or weight history for adults. Complete physical examination including height, weight, BMI, vital signs, laboratory studies, urinalysis, and electrocardiogram (EKG) should be completed (Campbell and Peebles, 2014).

## Common laboratory findings

The effects of malnutrition can lead to a number of laboratory abnormalities and may be related to a specific behavior (e.g. hypokalemia induced by purging). Patient-specific factors such as illness severity, weight status, medications, pre-morbid or co-morbid illness, and eating disorder behaviors may guide clinicians in type and frequency of laboratory monitoring.

Chemistries frequently are monitored closely to evaluate electrolytes tied to nutritional intake and starvation status. Refeeding syndrome, or shifting serum phosphorus, potassium, magnesium, and glucose in a starved person on restarting adequate nutrition, is a rare but potentially fatal complication of AN. Refeeding hypophosphatemia is a common finding during nutrition restoration and is a hallmark of impending refeeding syndrome (O'Connor and Nicholls, 2013). Additionally, clinicians should evaluate potassium levels in relation to purging through vomiting or diuretic use, with those who are underweight and using diuretics being most at risk. Low potassium and elevated bicarbonate seen in metabolic alkalosis are indicative of vomiting and can lead to serious cardiac arrhythmias. Low serum chloride may also be seen in those who vomit frequently. Dehydration may result in a relationally elevated blood urea nitrogen (BUN), creatinine, potassium, sodium, calcium, and albumin. Dangerously low sodium can be due to diuretic misuse, and rarely in those who water load (overhydrate) prior to appointments in an attempt to falsify weight.

The most common liver complications include elevation in aspartate aminotransferase (AST) and alanine aminotransferase (ALT), which show an inverse relationship with body weight (as body weight decreases, AST and ALT increase). Less commonly, elevated AST and ALT may occur during nutrition rehabilitation, causing fat and glucose deposition in the liver leading to hepatic steatosis. Bilirubin, alkaline phosphatase, and international normalized ratio (INR) may be implicated as starvation causes liver injury at low weight. Liver glycogen stores and impaired gluconeogenesis related to starvation-mediated liver injury also contribute to hypoglycemia. Despite these weight-induced changes, albumin most often remains normal. However, pre-albumin is a reliable marker of malnutrition and has been shown to be predictive of serious outcomes in severely malnourished individuals with AN.

The complete blood count may reveal a number of abnormalities related to malnutrition. Leukopenia (low white blood cell count), anemia, and thrombocytopenia (low platelets) may be related to insufficient intake. Elevated white blood cell count is seen with infection, inflammation, stress, or anemia. Elevated red blood cell count may reflect dehydration.

Malnutrition results in alterations in the hypothalamic-pituitary-thyroid axis with resultant amenorrhea, low androgens, and low estrogen levels. Additionally, laboratory findings may show an elevated growth hormone (GH) with low levels of insulin-like growth factor-1 (IGF1), and hypercortisolemia. Thyroid stimulating hormone (TSH) may be normal or low, as well as low free T4 and T3 related to adaptation to low energy availability and metabolic rates and normalizes with weight restoration (Schorr and Miller, 2017). Parathyroid hormone (PTH) levels are commonly low, and have importance when considering calcium, PTH, and vitamin-D mediated bone health implications for this population (Lenherr-Taube et al., 2020).

## Testing

Cardiovascular complications due to nutrition-related structural changes (e.g. myocardial atrophy) as well as electrolyte imbalances may lead to serious, and potentially deadly consequences in individuals with AN. Routine electrocardiograms (EKG) are recommended to monitor for conduction and repolarization abnormalities; however, echocardiograms are not typically necessary unless EKG shows signs of pericardial or valve disease. EKGs often show bradycardia (abnormally slow heart rate), in part due to autonomic dysfunction (Sachs et al., 2016).

Low bone mineral density (BMD) is a result of malnutrition, vitamin D deficiency, low IGF1 and hypocortisolemia (Solmi et al., 2016). These effects may have long-term implications as peak bone mass is achieved during adolescence, coinciding with peak incidence of AN, and may not be recoverable later in life leading to higher rates of osteoporosis and fractures than in healthy peers. As amenorrhea and illness chronicity are associated with low BMD in this population (Solmi et al., 2016), dual energy x-ray absorptiometry measurements are recommended for those who are not menstruating or with long duration of illness.

## Management

Management of AN is best achieved with an interdisciplinary team including, at minimum, mental health, medical, and nutrition services (Ozier et al., 2011). Ideally, the treatment team communicates regularly to monitor progress and set goals in conjunction with the individual and family. As outcomes are improved for those who receive early, comprehensive care (Andrés-Pepiñá et al., 2020), identification and timely treatment are key.

Level of care for AN is on a continuum from outpatient to inpatient psychiatric hospitalization. Achieving goals while maintaining safety in the least restrictive setting is preferable to higher levels of care; however, escalating care may be necessary for individuals who fail to meet outpatient goals (e.g. weight gain, behavioral improvement), have safety concerns, or are medically unstable (Buchman et al., 2019).

In the outpatient setting, family-based treatment (FBT) is the first-line intervention for children and adolescents with AN (Buchman et al., 2019). FBT is a manualized, three phase, stepwise approach in which primary caregivers (usually parents) intervene to guide nutritional and weight restoration, slowly restoring autonomy to the adolescent and ending with a focus on the adolescent's development. For older adolescents and adults, and younger patients for whom FBT is not possible, individual psychotherapy is the

preferred outpatient treatment modality. Promising psychotherapeutic approaches for AN include cognitive behavior therapy (CBT), focal psychodynamic psychotherapy (FPT), the Maudsley Model of Anorexia Nervosa Treatment for Adults (MANTRA), and Specialist Supportive Clinical Management (SSCM), though none of these interventions has demonstrated consistent superiority to the others (Brockmeyer et al., 2018).

Intensive outpatient (IOP) treatment involves components of mental health, meal supervision, nutrition, and family therapy in a treatment center three or more days per week for a portion of the day (usually 3–5 h). Partial hospitalization (PHP) is the next higher level of intensity in which individuals attend a day-based program, returning home in the evenings and weekends. Individuals commonly attend PHP for a few to several weeks at a time. Residential level of care is an unlocked facility where participants live and receive treatment. Residents may stay at residential care for weeks to months. Finally, inpatient psychiatric or inpatient eating disorder (less common) facilities are locked units for those with significant safety concerns or uncontrolled behaviors (e.g. purging) that cannot be managed in other settings.

Inpatient medical care is intended to be short-term stabilization with the intention of returning to the individual to eating disorder care for ongoing management. Indications for inpatient medical hospitalization include hemodynamic instability (e.g. bradycardia, orthostatic hypotension), rapid weight loss, food refusal, significant electrolyte derangements (e.g. hypokalemia), or end-organ damage (SAHM, 2015).

Medication management may be utilized in conjunction with psychotherapy in some cases. However, in those with low weight, psychopharmacologic agents may be less effective. Antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants) are a commonly prescribed class of medications for those with AN, although they have not proven to significantly improve behaviors, promote weight gain, or maintain weight in this population. Olanzapine, a second-generation antipsychotic, may be used to facilitate short-term weight gain and may assist in those who experience obsessiveness (Davis and Attia, 2017). Medications to treat nutritional deficiencies, electrolyte imbalances, gastrointestinal complaints (constipation) are used as indicated. Physiologic estrogen replacement therapy for low bone mineral density has been shown to improve bone density in DXA scans and may be utilized based on DXA z-scores. Hormonal contraceptives (e.g. birth control pills) are not recommended to induce menses as they may mask resumption of spontaneous menses and have not been shown to improve DXA scores. Nutrition therapy considers the age, life-stage, laboratory findings, and historical eating patterns of the individual (Ozier et al., 2011). Nutrition therapy focuses on resolving nutritionally-based deficiencies, weight restoration, and normalization of eating patterns.

## Conclusion

AN is a serious psychiatric illness with high rates of mortality, co-morbid psychiatric illness, and medical consequences. Early identification and treatment are associated with improved outcomes, and clinicians should be aware of warning signs and familiar with appropriate screening tools. Treatment for AN occurs across a spectrum of settings dependent on individual psychiatric and medical needs.

### Key points

- BED is often a chronic and fluctuating disorder characterized by persistent and recurrent episodes of binge eating without the regular use of inappropriate compensatory behaviors
- Several methods can be used to assess BED, including standardized clinical interview and self-report measures.
- Biological, psychological, and social risk factors may interact to determine the onset and maintenance of BED, and both psychiatric and medical comorbidities, including obesity, are common.
- Evidence-informed treatments include psychosocial treatments, behavioral weight management, and pharmacotherapy.
- Treatment selection involves weighing the advantages and disadvantages of available interventions for an individual client, but more research is needed to identify personalized approaches to treatment of BED.

### Glossary

**Abstinence from binge eating** The absence of binge eating behavior for a specified period of time (usually at least one month)

**Binge eating** The ingestion of a large amount of food within a discrete period of time accompanied by a sense of loss of control over when, what, or the quantity of food that is eaten

**Compensatory behavior** Inappropriate behavior designed to counteract the effects of binge eating or prevent weight gain. Examples of compensatory behaviors include self-induced vomiting; misuse of laxatives, enemas, diuretics, or diet pills; excessive exercise; and fasting

**Eating disorder** A persistent pattern of aberrant eating or inappropriate dieting behaviors accompanied by distressing thoughts and emotions. Eating disorders are associated with significant medical morbidity, as well as physical, social, or psychological dysfunction

**Loss of control** The subjective feeling that one cannot stop eating or control when, what, or the amount of food that is eaten

**Obesity** Refers to an excess of body fat. At present, there is no clear division between normal and abnormal levels of fat. However, body mass index (BMI), a ratio of weight to height calculated by weight in kilograms divided by the square of height in meters, is widely utilized as a screening measure for obesity given its robust associations with adiposity and medical comorbidity (obesity is operationalized as a BMI  $\geq 30$ )

## Introduction

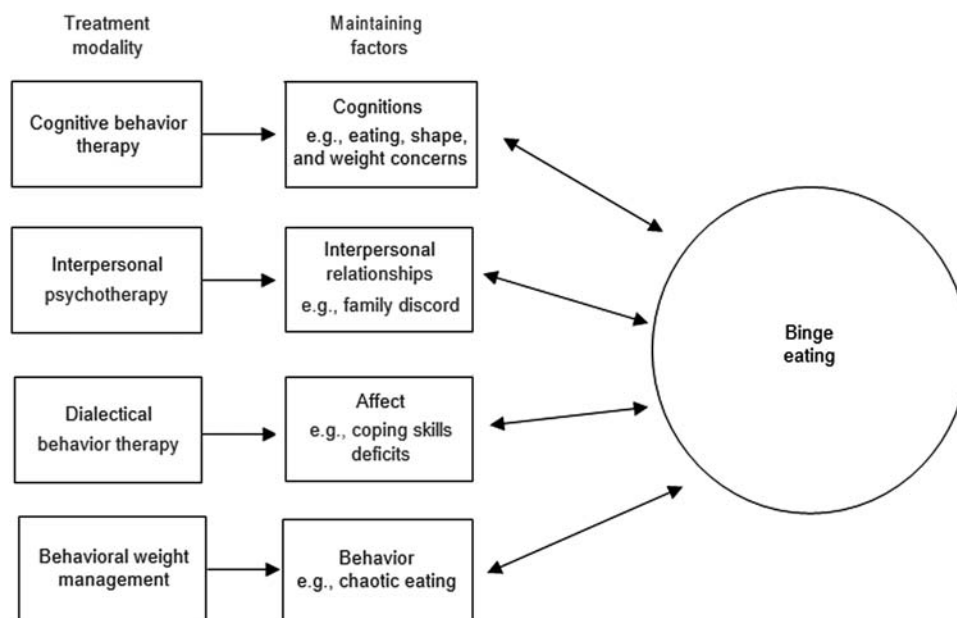

In 1959, Stunkard noted three patterns of eating behavior in patients with obesity: night eating, binge eating, and eating without satiation. However, it was not until the 1980s that binge eating received attention as a distinct clinical phenomenon. Spitzer and colleagues proposed diagnostic criteria for Binge Eating Disorder (BED) and subsequently evaluated them in two field trials in the 1990s. These initial investigations led to the inclusion of BED in the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV) as an example of Eating Disorder Not Otherwise Specified (EDNOS) and as a proposed diagnostic category requiring further study. Subsequently, BED was included as a formal diagnosis in the Diagnostic and Statistical Manual of Mental Disorders – Fifth Edition (DSM-5).

BED is characterized by persistent and recurrent episodes of binge eating without the regular use of inappropriate compensatory behaviors seen in Bulimia Nervosa (BN) and the binge eating/purging subtype of Anorexia Nervosa (AN). In this chapter, we address several findings related to BED including its assessment, epidemiology, risk factors, and comorbid conditions. Evidence-supported treatments also are reviewed, including guidelines for choice of treatment approach (Fig. 1).

## Assessment of binge eating

A binge episode is defined as the consumption of a large amount of food within a discrete period of time, accompanied by a sense of loss of control over eating. Researchers and clinicians have agreed that loss of control involves the subjective feeling that one cannot stop eating, or control what or how much is being eaten. Indeed, many observers have concluded that loss of control, rather than the amount of food ingested, is the hallmark of binge eating. There has been much less agreement about the size and duration of binge eating episodes. Specifically, there is no definitive threshold for a “large amount” of food (other than agreement that the amount of food eaten is more than others typically would eat in a similar situation), and the duration of binge eating episodes can vary widely, sometimes continuing over a period of many hours.

To receive a clinical diagnosis of BED (DSM-5), binge episodes must occur on at least one day per week for three months or more. Moreover, the binge eating episodes must be associated with three or more associated clinical features: eating much more

**Fig. 1** Psychosocial and behavioral interventions and treatment targets for binge eating.

rapidly than normal; eating until uncomfortably full; eating large amounts of food when not hungry; eating alone because of embarrassment about how much one is eating, and feeling disgusted, depressed, or very guilty after overeating.

Several methods can be used to assess binge eating and BED, including standardized clinical interviews and self-report measures. A clinical interview by a trained professional is the preferred assessment method, as it provides the opportunity to standardize definitions of key concepts such as a “large amount of food” and “loss of control.” Structured interviews include the Eating Disorder Examination (Fairburn et al., 2014) and the Eating Disorder Assessment for DSM-5 (Sysko et al., 2015). Questionnaires are easier to administer, and the use of psychometrically sound questionnaires is widespread for research and clinical screening. Self-report assessments include, but are not limited to, the Eating Disorder Diagnostic Scale (Stice et al., 2000) and the Questionnaire for Eating and Weight Patterns—5 (Yanovski et al., 2015). Interview-based assessments tend to yield ratings of binge eating that are lower, but more precise, than questionnaire-based surveys (Everett et al., 2021). Because binge eating and related psychopathology may occur across a range of behavioral phenotypes, readers may wish to consider the consensus measures for phenotypes and exposures website ([www.phenx.org](http://www.phenx.org)) for additional measures and protocols that may cut across multiple domains.

## Epidemiology and risk factors

Findings from a nationally representative sample of 36,309 US adults assessed with lay-administered diagnostic interviews based on DSM-5 criteria documented lifetime prevalence estimates of 0.80%, 0.28% and 0.85% for AN, BN, and BED, respectively (Udo and Grilo, 2018). This study also found that the lifetime prevalence of BED was more common among women, and that the rates for BN and BED were roughly comparable across racial/ethnic groups. BED is also associated with obesity and extreme obesity. Findings from the Udo and Grilo (2018) study are in contrast with previous findings based on population data from the US National Comorbidity study (Hudson et al., 2007), which reported higher rates of BED (lifetime prevalence of 2.8%), and equivalent rates of BED in men and women. The Hudson et al. (2007) study utilized DSM-IV rather than DSM-5 criteria and utilized a much smaller sample than the Udo and Grilo (2018) study. Nevertheless, future population studies are needed to resolve differences in BED prevalence rates. All available studies have documented that binge eating is more prevalent among individuals with obesity in both community and clinical samples.

Multiple potential risk factors have been implicated in the etiology of BED. Family history and twin data have documented that BED is a moderately heritable illness that aggregates in families independently of obesity. Although work focusing on the genetics of BED is preliminary, there are indications that genetic polymorphisms related to dopamine functioning associated with poor impulse control are linked to BED. Other research has documented the involvement of serotonergic genes in BED. There have been investigations suggesting the involvement genes associated with numerous other factors (e.g., ghrelin, endocannabinoid system), but results are not definitive, and findings from genome-wide association studies have not yet been reported. Overall, research has indicated that BED is characterized by elevated response to food reward as well as increased impulsivity and compulsion (Boswell et al., 2021).

Many studies have identified other putative risk factors for the development of eating disorders and binge eating disorder. These investigations have indicated that biological (e.g., childhood obesity, family history of obesity), psychological (e.g., body dissatisfaction, negative affect, perceived stress, depressive symptoms, dietary restraint), and social (e.g., repeated exposure to negative comments about shape, weight, or eating, perceived pressure to be thin) factors are implicated in the pathogenesis of binge eating.

Risk factors do not operate independently, and more recent work has investigated patterns of risk in longitudinal samples of adolescent women with body dissatisfaction (Stice and Van Ryzin, 2019). Results indicated that pursuit of the thin ideal with subsequent body dissatisfaction, dieting, and unhealthy weight control behaviors predicted the onset of binge eating disorders, and that impaired interpersonal functioning and negative affect preceded the onset of any eating disorder. Prospective risk factor studies including males and females of different racial and ethnic groups will improve our understanding of how multiple factors interact to determine the onset and maintenance of binge eating.

## Comorbidity

BED has been associated with weight gain over time and higher risk of diabetes and other metabolic dysfunction. Indeed, severity of binge eating is positively associated with degree of overweight, and there are important differences between overweight individuals with and without BED. Patients with BED report earlier onset of obesity along with a history of more severe obesity, dieting, and weight fluctuations. Moreover, when compared to equally overweight individuals without binge eating problems, BED patients report considerably less “restraint” or control over eating, lower self-esteem, more fear of weight gain, more preoccupation with food, and higher body dissatisfaction.

Although it is well documented that obesity is linked to adverse medical and psychosocial outcomes, research has indicated that BED is associated with poor health independent of the effects of comorbid obesity or psychopathology. Epidemiologic data suggest that BED is associated with type 2 diabetes, hypertension, dyslipidemias, sleep problems/disorders, and pain conditions. BED is also related to asthma and gastrointestinal symptoms and disorders, as well as menstrual dysfunction, pregnancy complications, intracranial hypertension, and polycystic ovary syndrome in women.

BED is also associated with increased risk of other psychiatric disorders and symptoms. Individuals with lifetime BED have higher rates of mood, anxiety, substance use, and other eating disorders compared to equally overweight individuals without binge eating problems. Data also suggest co-occurrence of binge eating with bipolar disorder and attention-deficit/hyperactivity disorder. Personality disorders also appear to be prevalent among patients with BED. Finally, symptoms of BED, particularly binge eating, also are associated with other psychiatric symptoms, particularly depressive symptoms.

## Treatment of binge eating

Among those who seek treatment, BED tends to be a chronic and fluctuating disorder. The clinical picture in BED often involves onset in late adolescence or the early 20s, with numerous periods of relative control over eating and weight loss alternating with periods characterized by binge eating and weight gain. Individuals with BED often seek obesity treatment rather than treatment of disordered eating *per se*.

A variety of psychosocial and pharmacological interventions can help individuals gain control over binge eating. There also is some evidence that behavioral weight management is associated with weight loss and short-term improvements in BED symptoms, although data suggest that eating disorder-focused treatments may be required to achieve longer-lasting remission from binge eating. Nevertheless, a substantial number of patients are not abstinent from binge eating after treatment, suggesting the need for clinical trials of novel therapeutic approaches as well as combinations and sequencing of treatments.

## Psychosocial treatments

Treatments for BED have been adapted from those that have been shown to be effective in reducing binge eating among individuals with BN (Linardon et al., 2017). The majority of the research on psychosocial treatments has supported two structured, focused, short-term psychotherapies, Cognitive Behavior Therapy (CBT) and Interpersonal Psychotherapy (IPT), both of which have been shown to be more effective than no treatment in decreasing the frequency of binge episodes and improving the psychopathology associated with binge eating (da Luz et al., 2020). In addition, the use of Dialectical Behavior Therapy (DBT) (Ben-Porath et al., 2020) and interventions based on Acceptance and Commitment Therapy show promise as alternative treatments for BED. Finally, evidence supports the utility of self-help interventions in the treatment of binge eating.

### Cognitive behavior therapy

Therapist-led CBT has been the most extensively studied treatment and has been shown to be associated with long-term reductions in binge eating and related psychopathology (Hilbert et al., 2020). It should be noted that many patients with binge eating do not meet full diagnostic criteria for BED or fluctuate between disorders, and thus one of the most widely-used formats of CBT is CBT enhanced for eating disorders (CBT-E), which adopts a transdiagnostic approach to binge eating. CBT-E has been found to be effective for treatment of individuals with a range of diagnoses (Atwood and Friedman, 2020).

CBT for BED is based on the premise that binge eating is maintained in the context of ongoing dietary restraint, weight concerns, negative emotions, and low self-esteem. Treatment focuses first on normalizing eating, and then on the identification and restructuring of maladaptive thoughts and beliefs, particularly those related to eating, shape, and weight.

CBT for BED has been adapted to reflect important differences between individuals with BN and BED (Fairburn, 2008). Specifically, cognitions relating to having a large body size are directly targeted in treatment. Overweight individuals with BED may be helped to accept a larger than average body size and to change unrealistic expectations for weight loss. For the majority of BED patients, a five or ten kilogram weight loss does not correspond with their desired weight, even though a modest weight loss may relate to improvements in binge eating and overall health. It is therefore important to help patients adopt realistic goals for the body weight and shape they are likely to achieve.

Another adaptation of CBT for BED relates to differences in the role of dieting between individuals with BED and those with BN. Although the treatment of BN stresses the role of dietary restraint in precipitating binge episodes, and treatment focuses on decreasing dietary restraint, patients with BED do not necessarily binge eat in response to restraint or hunger. Indeed, the preponderance of evidence suggests that increasing dietary restraint may help to ameliorate binge eating in obese individuals. Thus, CBT for BED does not stress decreased dietary restraint; rather, treatment encourages the development of a moderate, structured, healthy eating pattern.

### Interpersonal psychotherapy

Klerman and Weissman's IPT originally developed for treatment of depression has been adapted for group treatment of individuals with BED (Wilfley et al., 1998). IPT for binge eating is based on the idea that dysfunctional eating behavior is maintained in the context of interpersonal difficulties. Treatment focuses on identifying and addressing specific, problematic interpersonal patterns in an effort to ameliorate binge eating. Treatment can focus on: (1) role disputes, such as marital or family discord; (2) role transitions, such as the adjustment to motherhood or a new job; (3) grief, such as the loss of a spouse or loved one; or, (4) interpersonal

deficits, such as loneliness and social isolation. IPT for BED does not directly target eating behaviors or attitudes about eating, shape, and weight. Although the ways in which CBT and IPT conceptualize and treat binge eating differ, both appear to be effective in reducing the frequency of binge eating. Evidence suggests that IPT may be particularly effective for individuals with low self-esteem and a high level of specific eating disorder psychopathology (Wilson et al., 2010).

### **Dialectical behavior therapy**

Developed by Linehan for the treatment of individuals with borderline personality disorder, DBT has been adapted for treatment of BED (Ben-Porath et al., 2020). DBT is a comprehensive treatment program based on cognitive and behavioral principles and complemented by the use of mindfulness strategies derived primarily from Zen Buddhism. In addition to weekly individual outpatient treatment, traditional DBT prescribes a weekly group meeting in which the goal is to increase participants' behavioral skills. A group-only version of DBT for individuals with BED has been shown to decrease binge eating relative to active control eating, and wait list control; adaptations included changes to treatment format, content, and duration, and thus the effect of standard DBT cannot be determined from available studies. Nonetheless, despite its emphasis on emotion regulation, DBT has not shown superiority in reducing negative affect or enhancing adaptive affect regulation skills among individuals with BED. Thus, additional research is needed to determine the mechanisms by which DBT affects change in BED symptoms, and to evaluate the efficacy of DBT relative to CBT and IPT.

### **Guided self-help**

There is growing evidence for the efficacy of guided self-help programs, in which a therapist or other professional provides support to individuals in completing a manualized self-help intervention, in the treatment of patients with eating disorders including binge eating (Traviss-Turner et al., 2017). Guided self-help programs have some advantages over more specialized psychotherapies for binge eating in that they can be implemented by therapists with little experience in the treatment of eating disorders and may offer a cost-effective approach to treating binge eating in community settings. For example, an eight-session guided self-help program resulted in significantly greater rates of abstinence from binge eating and reductions in the cognitive correlates of disordered eating relative to treatment as usual when provided by nonspecialist clinicians in a large health maintenance organization in the USA (DeBar et al., 2011). Another report found that guided self-help based on CBT principles was more effective than behavioral weight loss in producing remission from binge eating at two-year follow-up (Grilo and Masheb, 2005). Available findings suggest that CBT-based guided self-help may be a useful first stage treatment for mild-to-moderate BED, but more research is needed (Traviss-Turner et al., 2017). Other forms of self-help, such as unguided self-help and DBT-based self-help may also be effective for some patients.

### **Behavioral weight management**

As most individuals with BED are overweight and want to lose weight, and because obesity is associated with significant medical and psychosocial consequences, weight loss is a potentially important outcome in the treatment of BED. Several reports have indicated that participation in a behavioral weight management program that focuses on moderate calorie restriction, provides education about sound nutritional principles, and promotes physical activity is associated with decreases in binge eating and improvements in mood among individuals with BED (Grilo, 2017). There is also evidence that behavioral weight management interventions produce greater weight loss among individuals with BED than do specialized psychotherapies for binge eating (e.g., CBT, IPT), which generally have been shown to have little effect on weight status. Although more widely available, behavioral weight management programs may be less effective than specialized psychotherapies and CBT-based guided self-help in producing lasting remission from binge eating. These findings indicate that psychosocial interventions that target disordered eating may be preferred in treating patients with BED, depending previous treatment history, current weight status, and personal goals for treatment.

### **Pharmacotherapy**

A number of medications have been used to treat BED. Pharmacotherapy for BED tends to lead to moderate improvements in binge eating, but a modest impact on body weight. Medications may increase access to treatment and carry less stigma than psychotherapy. Lisdexamfetamine was the first drug approved for treatment of moderate-to-severe BED by the Food and Drug Administration (FDA) in 2015, and off-label treatments include antidepressants, weight loss medications, and anticonvulsants.

Emerging insights into the pathophysiological mechanisms involved in BED influence investigations into novel pharmacologic approaches. Animal models and small clinical trials have investigated a group of potential drug targets involving neurotransmitters/hormones like dopamine, glutamate, and endogenous opioids. However, larger and more robust investigations are required to determine the safety and efficacy of novel pharmacological agents.

### Psychostimulant medication

Approved by the FDA for treatment of attention deficit hyperactivity disorder, the rationale for its use in BED was due in part to shared features of the disorders, including impulsivity, as well as the drug's side effect of decreased appetite and weight loss. Current evidence documents utility of lisdexamfetamine in reducing binge eating days per week in adults. A review documented that an initial dose of 30 mg/day titrated to 50–70 mg/day is effective and generally well tolerated for treating moderate-to-severe BED in adults, with most adverse events being mild-to-moderate (e.g., dry mouth, headache, insomnia) (Heo and Duggan, 2017). Before starting treatment, potential for abuse and dependence, as well as serious cardiovascular-related reaction, and monitored throughout treatment.

### Antidepressant medications

Because of their efficacy in ameliorating binge eating and purging behaviors in individuals with BN, antidepressants have been used widely in the treatment of BED (Davis and Attia, 2019). Early research comparing tricyclic antidepressants (e.g., desipramine, imipramine) to placebo showed greater reductions in binge eating among obese binge eaters treated with active medication than with a placebo. In subsequent research, several selective serotonin reuptake inhibitors (e.g., fluoxetine, fluvoxamine, sertraline, citalopram) have been shown to be associated with moderate reductions in binge eating in BED patients. Moreover, the effects of antidepressant treatment on binge eating are independent of any effects on mood.

### Anticonvulsant medication

Anticonvulsant medications were initially investigated for BED because they are used to treat disorders that are often comorbid with BED, such as mood and substance use disorders, and some have been associated with weight loss (McElroy, 2017). Topiramate and zonisamide have both been effective for treatment of BED, although use of both may be limited due to side effect profiles. There also is preliminary evidence that augmenting group CBT for BED with topiramate is associated with greater reductions in body weight and higher rates of remission from binge eating compared to group CBT with placebo (Claudio et al., 2007). Topiramate has been the most studied, but its long-term on binge eating and weight loss remain unknown.

### Weight loss medications

Anorectic agents used in the treatment of obesity, sibutramine and orlistat, have been investigated in BED patients with promising results, but sibutramine was withdrawn from the US market in 2010. Research has shown that adding orlistat to CBT-based guided self-help is associated with higher rates of remission from binge eating at post-treatment and greater weight loss at both post-treatment and 3-month follow-up relative to CBT-based guided self-help plus placebo (Grilo et al., 2005). Emerging data on newer anti-obesity agents (e.g., semaglutide) herald a more promising future for the use of anti-obesity agents, but the efficacy of these agents in the management of BED is not known. Nevertheless, findings suggest that augmenting psychosocial treatments for disordered eating with weight loss medications may be an effective approach to treating patients with BED and obesity.

### Selection of treatment for specific patients

No single treatment approach is effective for all patients, and additional research is needed to guide personalized treatment for individual patients with BED. Until such information becomes available, clinicians and patients must decide on a course of treatment based on a careful assessment and thorough consideration of the pros and cons of available options, including cost and access. A review found that combining certain medications with cognitive behavioral therapy or behavioral weight management produces superior outcomes to pharmacotherapy only for BED, but does not substantially improve outcomes achieved with psychosocial treatment only (Grilo et al., 2016). Recent evidence suggests, however, that weight-loss medication enhanced outcomes for adults with BED with comorbid obesity in an adaptive stepped care approach (Grilo et al., 2020). More research is needed on comparative efficacy, mechanisms through which treatments work, and complex models of care.

### Eating disorder and obesity history

A history of early onset of binge eating, binge eating in the absence of obesity, or obesity in combination with numerous bouts of weight loss and regain over time (i.e., “yo-yo” dieting), suggest a course of eating disorders treatment. Such patients can be reassured that significant improvements in the aberrant eating and eating disorder psychopathology associated with BED can be obtained without weight loss.

On the other hand, clinical experience suggests that patients who report adult onset of binge eating and obesity, and do not have a history of marked weight fluctuations, may benefit from a behavioral weight management approach. Behavioral weight management also may be indicated for patients who remain overweight after a trial of eating disorders treatment. However, weight loss

among individuals with BED is modest, and the re-emergence of binge eating can lead to weight regain, so it is important for each individual to evaluate the likelihood that he or she will be able to sustain changes in eating and exercise.

### Psychiatric status

Given the high psychiatric comorbidity in BED, a thorough evaluation is important for all patients who seek treatment. Although mild to moderate depression or anxiety is likely to improve during treatment of binge eating, the presence of marked or severe current illness suggests primary treatment of the mood or anxiety disorder. In addition, the presence of personality disorders characterized by emotional, dramatic, or impulsive behavior appears to be related to severity of binge eating. Although data indicating that co-morbid personality disorder is associated with treatment outcome, it may be that an approach like DBT, which targets emotional regulation may benefit these individuals.

### Available resources

Clinicians trained in the use of psychosocial treatments for eating disorders are likely to be found in most academic medical centers and urban areas but may not be available in rural or underserved areas. Insurance companies vary in coverage for treatment of eating disorders, and some insurance plans may pay for obesity treatment only if there is a clear medical indication (e.g., hypertension or other cardiovascular risk). Thus, clinicians may need to consider pragmatic factors such as the availability of specialty care, or patient insurance plan coverage. Guided self-help programs based on CBT principles may be a promising alternative for patients who do not have access to specialized psychotherapies. There is growing interest in the use of mHealth (e.g., apps and internet-based interventions) as a means of disseminating therapist-guided self-help for BED, and preliminary data have been encouraging. However, comorbid psychopathology and high frequency binge eating may require more intensive clinical intervention.

### Summary

BED is a fluctuating disorder and frequently chronic disorder that is common among obese individuals who seek treatment and is associated with elevated rates of psychopathology. Although the exact causes of binge eating remain unknown, available data support a multidimensional model that includes biological, psychological, and social factors. Once established, binge eating is maintained by a complex interplay among eating behaviors, cognitions, affect, and interpersonal factors. Nevertheless, available research indicates that most people who binge-eat can be helped with specialized psychotherapy for eating disorders, therapist-guided self-help programs, or behavioral weight management. Pharmacotherapy also appears to reduce binge eating, and treatment with certain medications may result in larger and more sustained weight losses when combined with psychosocial interventions than psychosocial intervention alone. A careful assessment, review of the benefits and disadvantages of the different therapies, and consideration of the availability of trained clinicians should guide the choice of treatment for an individual with BED. More research is necessary to fully understand this problematic eating disorder and to improve strategies for management and treatment.

### Key points

- Bulimia nervosa is a serious eating disorder associated with significant impairment and distress, health complications, psychiatric comorbidity, and a chronic course.
- Bulimia nervosa occurs across genders, racial/ethnic groups, and socioeconomic status.
- Treatment for bulimia nervosa should include medical management and monitoring, empirically supported psychological intervention, and, if necessary for malnourished patients, nutritional support. Pharmacotherapy is a safe and effective adjunct to psychological treatment.

## Introduction

Bulimia nervosa (BN) is a severe eating disorder characterized by recurrent episodes of binge eating, inappropriate compensatory behaviors, and overvaluation of weight and shape (APA, 2013). This article will begin by introducing the diagnostic criteria for BN. Next, we will describe the prevalence of BN, followed by a discussion of research regarding the psychopathology of BN. We will then describe the etiology of BN, followed by the nutritional and medical complications of the disorder. We will continue with a description of dietary management, psychological treatment, and pharmacotherapy, evidence for the effectiveness of each, and special considerations for future research. Finally, long-term prognosis will be discussed.

## Diagnostic criteria

Diagnostic schedules, including the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5; APA, 2013) and proposed guidelines for the International Classification of Diseases, 11th Edition (ICD-11), agree that the following features must be present for a diagnosis of BN: (1) recurrent episodes of binge eating; (2) recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting, laxative or diuretic misuse, fasting, or excessive exercise; and (3) self-evaluation that is unduly influenced by body shape and weight (APA, 2013). Importantly, BN is distinct from anorexia nervosa (AN) because one cannot be underweight and meet criteria for BN (APA, 2013). Additionally, BN is distinct from binge-eating disorder (BED), as BED includes recurrent binge eating without the presence of recurrent inappropriate compensatory behaviors or the requirement of undue influence of body shape and weight on self-evaluation (APA, 2013).

Binge eating is distinct from everyday overeating or dietary indulgence. According to DSM-5, three features must be present for an eating episode to be considered an objective binge episode: consumption of an unusually large amount of food, over a short period of time, and a subjective sense of loss of control over eating (APA, 2013). The size of binge-eating episodes varies; in laboratory studies, binge-eating episodes in BN are around 3000 calories. Notably, the literature has identified that some binge-eating episodes are considered “subjective” rather than objective. Subjective binge eating involves loss of control as with objective binge eating, but the amount of food is not deemed excessive. Importantly, the amount of food consumed is not the primary criterion for defining a binge, as both subjective and objective binge-eating episodes are associated with loss of control and thus distress.

The DSM-5 diagnostic criteria and ICD-11 proposed guidelines differ in two important ways. First, ICD-11 includes subjective binge-eating episodes to satisfy the binge eating requirement. Another key difference is in duration of symptoms: the ICD-11 criteria for BN require a shorter duration of binge eating and compensatory behaviors, 1 month, compared to the required duration of 3 months in DSM-5.

One concern of diagnostic classification experts is the prevalence of residual, “catch all” diagnoses such as the DSM-5 category, “Other Specified Feeding or Eating Disorder” (OSFED), which encompasses a wide variety of subthreshold eating disorders, including BN of low frequency (e.g., binge-eating episodes or compensatory behaviors occurring less than once per week) or limited duration (e.g., behaviors that have not persisted for three consecutive months). In studies comparing the ICD-11 and DSM-5 criteria to diagnose patients, the broader proposed criteria of ICD-11 do appear to facilitate greater clinical utility. In an investigation of 107 adults with eating disorders, the proposed ICD-11 BN criteria appeared to capture more individuals with BN than the DSM-5 criteria, leaving fewer individuals in the residual category of OSFED BN (Amorim Palavras et al., 2018). Furthermore, individuals who met criteria for ICD-11 BN but not DSM-5 BN endorsed no significant differences in severity of eating disorder psychopathology, depression, anxiety, stress, or health-related quality of life (Amorim Palavras et al., 2018), indicating that the DSM-5 criteria do not better predict distress or impairment when compared with the ICD-11 criteria.

The proposed ICD-11 diagnostic guidelines also appear to be superior to ICD-10 criteria in classifying eating disorders. In a study of 2288 clinicians using ICD-10 and proposed ICD-11 criteria to diagnose case vignettes of individuals with feeding or eating disorders, the ICD-11 diagnostic guidelines better distinguished cases of eating disorders and demonstrated higher clinical utility ratings across clinicians, who were diverse in terms of language (including Chinese, English, French, Japanese, and Spanish), indicating that the ICD-11 criteria as written appeared valid and culturally sensitive.

## Prevalence of BN

### Gender differences

Recent research indicates that the lifetime prevalence of BN among female-identified individuals is 0.46%, and among male-identified individuals is 0.08%. However, the prevalence of specific bulimic symptoms is higher in both genders; a study of college students from 11 universities revealed that 49% of female students endorsed binge eating compared with 30% of male students, but rates of compensatory behaviors were similar: 31% of female students versus 29% of male students endorsed excessive exercise, fasting, self-induced vomiting, or laxative/diuretic use to control their weight or compensate for binge eating. The average age of onset for BN is 18 years, but binge eating and compensatory behaviors in children have been documented as early as 10 years old, in boys and girls.

Although point prevalence of BN decreases across the lifespan for women, it remains constant for men, suggesting gender differences diminish over time. Women from age 20 to age 40 demonstrate higher drive for thinness and bulimia symptoms across time compared to men, which may help explain greater prevalence of BN among adolescent girls and young women.

Research on the prevalence of BN in gender minority populations is limited. However, recent findings indicate that rates of self-reported BN are higher in transgender and genderqueer individuals relative to their cisgender peers, suggesting that gender minority groups may be at heightened risk for BN (Simone et al., 2020). Further research is needed to understand this disparity.

### **Racial/ethnic differences**

Early research of racial/ethnic differences suggested that the prevalence of BN was higher in White individuals. However, in recent years, studies of eating disorder prevalence have found no significant racial/ethnic differences in rates of BN in population samples or high-risk college women, suggesting little to no difference in prevalence across racial/ethnic groups. Notably, BN samples in research studies historically have been largely White, limiting conclusions that can be drawn regarding prevalence. Research should continue to include samples diverse in terms of race/ethnicity to address the disparities of previous samples.

### **Food insecurity**

Food insecurity is defined as “limited or uncertain availability of nutritionally adequate and safe foods or limited or uncertain ability to acquire acceptable foods in socially acceptable ways”. Food insecurity is associated with high weight and overeating (Franklin et al., 2012), potentially through a pattern of dietary restriction followed by increased consumption of lower cost, low-nutrition, energy dense foods (Bruening et al., 2012). Recent studies have shown associations between food insecurity and binge eating. In an investigation of 873 adults, low and very low food security were associated with increased likelihood of BN diagnosis (Lydecker and Grilo, 2019). Individuals with food insecurity experience intermittent availability of food throughout the month, due to various factors including paycheck allocation or payments from food assistance programs, which is thought to contribute to a scarcity-induced dietary restriction and subsequent binge eating cycle. The relationship between dietary restriction and binge eating within food secure populations is well-established (Fairburn, 2008), but the relationship in the context of food insecurity may be unique due to the bidirectional process of restriction and binge eating that results from externally imposed food restriction due to financial difficulties, rather than internally motivated dietary restriction for the purpose of weight loss or maintenance. Because most studies of food insecurity and BN are correlational, further research is needed to elucidate the temporal development of BN in the context of food insecurity, and the mechanisms for the development and maintenance of bulimic behaviors in this population.

### **Associated psychopathology**

#### **Weight/shape overvaluation**

In addition to being a core symptom of BN, weight/shape overvaluation is thought to play a central role in the onset and maintenance of dietary restriction, binge eating, purging (e.g., self-induced vomiting, laxative abuse, and diuretic abuse), excessive exercise, and other eating-related concerns, all of which are evident in BN (Fairburn, 2008). Patients with BN demonstrate significantly greater levels of weight/shape overvaluation and body image disturbance when compared with patients with AN and healthy controls. Related to weight/shape overvaluation, fear of weight gain also is a prominent feature of BN; a network analysis of adults with BN revealed that fear of weight gain was central to BN psychopathology.

### **Comorbidity**

There is extensive evidence that the problems and distress associated with BN extend beyond disordered eating. As many as 74.4% of individuals with BN experience symptoms and diagnoses of concurrent mood disorders, anxiety disorders, post-traumatic stress disorder, substance use disorder, and personality disorders. BN also is associated with increased rates of suicide (Goldstein and Gvion, 2019). Substance use disorders demonstrate perhaps the most significant overlap, as 37% of individuals with BN meet criteria for a substance use disorder. Emphasizing the seriousness of this overlap, the presence of multiple comorbidities in BN is associated with inpatient hospitalization stays, a poorer prognosis, and increased mortality.

The mechanisms underlying the relationship between bulimic symptoms and comorbid psychopathology in BN warrant further investigation. Theorists have proposed that certain transdiagnostic risk factors may help to explain the overlap between symptoms. One such risk factor might be the experience of shame, an overarching negative evaluation of the self, which has been shown to predict a variety of different forms of psychopathology including bulimic behaviors, substance abuse, self-harm, depression, and anxiety.

## Etiology and maintenance

A variety of psychological, biological, and social factors are involved in the emergence of BN. We review three categories of risk: genetic, developmental, and personality-based risk.

### Genetic risk

Research on the genetic epidemiology of BN is limited when compared with AN. It appears that individuals with family members with BN are predisposed to developing BN themselves (Strober et al., 2000). The heritability of BN is estimated at 0.60 (Bulik et al., 2010). Genetic studies indicate BN is strongly correlated with AN and alcohol use disorder, supporting their phenotypic overlap.

### Developmental risk

Engagement in and exposure to dieting behavior, through parents or other family members, and childhood obesity appear to increase risk for disordered eating behaviors consistent with BN. Adverse childhood experiences also appear to increase risk for BN; across studies of patients with BN, 35% report childhood sexual abuse, 33% report physical abuse, and 81% report emotional abuse (Molendijk et al., 2017). Moreover, 49% of patients with BN report multiple forms of childhood maltreatment (Molendijk et al., 2017). Experience of childhood maltreatment among patients with eating disorders is associated with comorbid psychiatric diagnosis, increased suicidality, earlier age of eating disorder onset, and a more severe illness course (Molendijk et al., 2017).

### Personality risk

Although impulsivity historically was thought to predispose one to, and correlate with, BN, research has clarified that impulsivity is a broad term that encompasses several facets of rash behavior, and does not demonstrate reliable associations with, or prediction of, behaviors consistent with BN (Fischer et al., 2008). This said, the impulsogenic trait of negative urgency, a disposition that describes the tendency to act rashly when feeling distressed, demonstrates reliable and consistent prediction of behaviors central to BN (i.e., binge eating and purging), as well as prediction of other comorbid maladaptive behaviors and symptoms, including self-harm, substance use, and depression (Berg et al., 2015). Other personality traits that predispose one to the development of BN include heightened perfectionism, negative affect (a general dimension of negative mood), neuroticism (i.e., the tendency to experience anxiety, depression, impulsiveness, and vulnerability to stress), and avoidance motivation (the tendency to avoid harm or discomfort).

## Theories of BN maintenance

There are several established theories that seek to explain the maintenance of disordered eating behaviors within BN. Binge-eating episodes often follow periods of extreme dietary restriction or fasting (Fairburn, 2008). Restraint theory posits that dietary restriction is a risk factor for binge eating due to chronic hunger and a reliance on cognitive control of food intake, rather than physiological cues of hunger and fullness. Fasting also is thought to increase physiological and cognitive hunger drives, and deplete self-regulatory resources. Other theories attempt to incorporate the experience of difficult emotions in explanatory models of binge eating; the affect regulation model posits that binge eating is used to cope with strong negative emotions, and escape theory posits that binge eating is used to relieve or distract from subjective distress. Empirical studies support both dietary restriction and heightened negative affect as preceding binge eating in BN samples (Haedt-Matt and Keel, 2011), but evidence for relief of negative affect following binge eating is mixed, with some studies reporting alleviated negative affect following binge eating (Berg et al., 2013), and others reporting elevated negative affect following binge eating (Haedt-Matt and Keel, 2011). Further research is needed to clarify the emotional consequences of binge eating and thus the maintenance process of BN.

## Health consequences of BN

### Nutritional consequences

Binge eating often follows caloric restriction and tends to occur on consecutive days. Individuals with BN frequently report caloric restriction following a binge-eating episode, to prevent further weight gain (Fairburn, 2008). Caloric restriction can result in restrictive eating behavior that may fail to achieve the recommended energy intake, leading to nutritional deficiencies and weight loss. Although a diagnosis of BN requires that a patient not be underweight, many patients with BN are weight suppressed (i.e., at a current weight that is several pounds below pre-morbid weight). Because weight suppression has been found to maintain BN in longitudinal research, it is essential that nutritional treatment of BN seek to help the patient decrease dietary restriction by eating a larger range and greater quantity of food consistently to allow for the resumption of a normative, healthy pattern of eating and restoration to premorbid weight.

### Medical consequences

Eating disorders, including BN, are associated with increased risk of death (Arcelus et al., 2011) somewhat heightened by medical complications attributed to specific bulimic behaviors, such as purging. Importantly, purging behavior of all types can be associated with severe medical complications across all body systems (see Forney et al., 2016, for a review). Self-induced vomiting is the most frequently endorsed purging behavior in BN and research shows that the medical complications of self-induced vomiting can be extensive (Forney et al., 2016). Recurrent self-induced vomiting is associated with dehydration and electrolyte loss, including potassium. Regarding oral health, self-induced vomiting directly causes dental erosion due to the stomach acid that enters the mouth. Case studies indicate that self-induced vomiting causes parotid gland (a salivary gland between the mouth and ear) swelling, which can be painful to patients (Forney et al., 2016). Self-induced vomiting in BN also is associated occasionally with gastroesophageal reflux, retrosternal burning (heartburn), and acid regurgitation, potentially due to exposure of stomach acid to the esophagus. Of note, these symptoms are not associated with frequency of purging behavior, but instead are thought to be due to intraindividual sensitivity to esophagus damage. Rarely, cardiovascular complications occur due to purging behavior, generally when substances such as ipecac are used to induce vomiting. Given the potential severity of these symptoms, patients who vomit frequently should be educated on the medical consequences of such behavior.

Laxative and diuretic use are less common than self-induced vomiting among individuals with BN, but nevertheless associated with problems of various organ systems (Forney et al., 2016). Consequences of laxative and diuretic misuse include renal inflammation, calcium deposits, kidney stones, gastrointestinal symptoms such as bowel dysfunction and abdominal discomfort, cardiac arrest, seizures, and rhabdomyolysis (deterioration of muscle tissue) (Forney et al., 2016). Given the possibility of extensive complications, providers should be aware of laxative and diuretic abuse and intervene swiftly to avoid long-term damage to vital organ systems.

### Treatment

Below, we review the recommended components of treatment including dietetic management, psychological intervention, and pharmacotherapy.

#### Dietetic management

Practice guidelines set by the Academy for Eating Disorders recommend dietetic involvement in eating disorder treatment, including for BN. However, the recommended, manualized psychological treatments for adults and youth do not typically mention the incorporation of dietetic treatment, despite the explicit mention of nutrition-focused content in 91% of treatment manuals. This is likely because of the distinction between malnourishment and undernourishment in BN. Many patients with BN are undernourished due to dietary restriction, but not malnourished. Because restriction not leading to low body weight still can be associated with serious health complications due to the avoidance of certain food groups, basing malnutrition only on current body weight runs the risk of missing treatable complications. Moreover, BN can result in the context of a history of AN; thus, it is recommended that providers take possible malnutrition seriously to avoid a host of life-threatening problems. If a patient with BN is undernourished but not malnourished, dietetic treatment may not be indicated, as the other providers as part of the treatment team (e.g., primary care physician, therapist, psychiatrist) may be equipped to help the patient by prescribing a regular meal pattern. At all levels of care, patients with BN should be screened routinely for medical instability and nutrition deficiency to ensure safety for treatment and determine if nutrition interventions are needed.

When dietetic support for BN is necessary (e.g., in cases of medical instability or malnourishment), dietitians should follow the practice and training standards set forth by the Academy for Eating Disorders. The components of care can be divided usefully into three categories: screening, professional responsibilities, and the nutrition care process, each described in further detail below.

#### Screening

The dietitian should be aware of the groups at high-risk for disordered eating, and screen those individuals appropriately. Screening tools may include symptom checklists or clinical interviews.

#### Professional responsibilities

The dietitian should prioritize the use of a reflective practice model and demonstrate a commitment to and use of professional clinical supervision, which improves patient outcomes and ensures safe practices, as well as maintains clinical resilience. Dietitians should seek out supervision or consultation services regularly, and initiate contact with the patient's treatment team (e.g., therapist, physician, psychiatrist) early in the treatment process.

### Nutrition care process

In addition to the usual assessment procedures taken by a dietitian (e.g., thorough assessment of medical history, allergies and diseases, individual macronutrient requirements), there are several special considerations for patients with BN. The nutrition care process should include a thorough assessment of premorbid and current dietary intake, considering all aspects of intake (e.g., macro and micro nutrients, fluid, caffeine, alcohol). The dietitian should carefully assess the patient's sociocultural background and its influence on dietary preferences, the purchasing and preparing of food, flexibility of the patient's schedule, timing of the meal pattern, and the relation of these factors to eating disorder behaviors. It also is important to remain mindful of medication and supplement use, and their potential impact on weight, eating behavior, and appetite. The dietitian should gain some knowledge of the patient's beliefs regarding food, eating, and body image to allow for an understanding of the context of the eating problem. Special attention should be paid to the lived experience of the patient, including possible past harms related to weight stigma. It also is essential that the dietitian assess and take into account activity level and athlete status in prescribing recommendations for the meal pattern.

A nutrition diagnosis is formulated based on nutrition intake problems stemming from BN (e.g., over or under-hydration, avoidance of certain nutrients), and a statement is developed to inform the treatment team of the plan for treating specified problems. The dietitian should take special note of the nutrition problems related to body image disturbance, history of dieting, family history of an eating disorder, and fear of weight gain, all of which can inform the patient's approach to or avoidance of the specified nutrition rehabilitation plan. For adolescents, it is necessary to involve the patient's family in assessment, treatment planning, and treatment implementation.

The nutrition intervention should consider the patient's stage in the eating disorder treatment process and level of independence, which often is based on level of care (e.g., outpatient, intensive outpatient, hospital, residential). The recommended meal pattern for all patients is three nutritionally adequate meals per day (e.g., morning meal, mid-day meal, evening meal), and 2–3 snacks per day (e.g., snacks between the morning and mid-day meal, mid-day and evening meal, and after evening meal). A wide variety of food intake should be encouraged, as well as flexibility of food choice and an emphasis on eating for enjoyment rather than to lose or maintain weight. The dietitian should be mindful of providing education on common side effects of resuming a regular meal pattern, including gastrointestinal effects (e.g., bloating, discomfort, constipation) and topics such as gut function, appetite regulation, weight and body changes, and social eating, among others.

It is important that dietitians adapt nutrition counseling to the patient's individual level of motivation, developmental expectations, psychological treatment model, and psychiatric comorbidities. Using motivational interviewing, employing collaborative goal setting, and encouraging self-monitoring can aid in keeping the patient engaged in treatment. Importantly, the dietitian should communicate regularly with the patient's treatment team throughout the duration of nutrition counseling.

### Psychological treatment

Randomized controlled trials (RCT) show that cognitive behavior therapy (CBT), interpersonal psychotherapy (IPT), and dialectical behavior therapy (DBT) demonstrate effectiveness in reducing symptoms of BN in adults in the short- and long-term (e.g., [Agras et al., 2000](#); [Safer et al., 2001](#)). A newer treatment, integrative cognitive-affective therapy for BN (ICAT-BN) demonstrates similar effectiveness as CBT ([Wonderlich et al., 2014](#)). Research of treatment for BN in adolescents is limited, but RCTs show that family-based treatment (FBT) demonstrates effectiveness in reducing symptoms when compared with supportive psychotherapy, and CBT demonstrates some evidence in reducing binge eating and purging when compared with established treatments. We describe each treatment below and provide a brief summary of evidence for their effectiveness.

#### Cognitive behavior therapy

"Enhanced CBT" for eating disorders (CBT-E; [Fairburn, 2008](#)) is a "transdiagnostic" treatment that can be adapted for any type of eating disorder, including BN. CBT-E works by addressing the thoughts and behaviors that maintain bulimic behaviors, including overvaluation of weight and shape and unhealthy weight control behaviors (i.e., dietary restraint) that perpetuate the binge-eating/purging cycle. The conceptualization of these maintaining factors is individualized for each patient, so that the treatment is tailored to their specific eating problem. In CBT-E, the therapist and patient work together to understand the eating problem, regulate the patient's eating using a prescribed, regular meal pattern and self-monitoring, and address the maintaining factors for the individual patient. There is evidence to support CBT-E as an effective treatment for BN in adults and older adolescents. CBT-E appears to result in significantly greater post-treatment and 60-week follow-up outcomes compared to another established treatment for BN, interpersonal psychotherapy (IPT; described below) ([Fairburn et al., 2015](#)).

#### Interpersonal psychotherapy

Individuals with BN report difficulty and problems in interpersonal relationships, including hostility toward others, communication difficulties, trouble understanding others' perspectives, and overall distress about relationships. The IPT theory posits that interpersonal difficulties cause low self-esteem and negative affect which then predispose one to bulimic behaviors. IPT focuses on

addressing these interpersonal problem areas, and deficits in social skills, which are thought to maintain eating disorder behaviors. By improving interpersonal functioning (and consequently, binge eating and purging as means for coping with dysfunction), IPT can be helpful in resolving bulimic symptoms. Two RCTs demonstrate IPT's effectiveness in treating BN (Agras et al., 2000; Fairburn et al., 1991). In each trial, CBT appeared superior to IPT in terms of end-of-treatment symptom reports. However, symptom reports were similar at 1-year follow-up, suggesting IPT may have a delayed, but similarly effective, impact on bulimic symptoms.

### Dialectical behavior therapy

DBT for BN seeks to improve a patient's skills in four domains: interpersonal effectiveness, distress tolerance, emotion regulation, and mindfulness. Skill-building in these areas is thought to reduce affective lability, which in turn decreases bulimic behaviors. DBT was first developed for the treatment of chronic suicidality (Linehan, 2014), but was adapted for use with individuals with BN given commonalities in the symptom profiles of both groups (e.g., emotion dysregulation that causes engagement in impulsive behaviors such as binge-eating or self-harm). DBT is considered a "third wave" cognitive-behavioral therapy. Results from two RCTs offer preliminary evidence for DBT's effectiveness in reducing bulimic behaviors in BN. In one RCT, 28.6% of women with BN who were randomized to receive DBT reported abstinence from bulimic behaviors compared to no women in the waitlist control group, which was a statistically significant difference (Safer et al., 2001). In the other RCT, 26.9% of women with BN in the DBT condition reported abstinence from bulimic behaviors, and 61.5% no longer met criteria for BN at end of treatment, which was statistically significant difference compared to the control condition (Hill et al., 2011).

### Integrative cognitive-affective therapy

ICAT-BN is the most recently developed of all the BN treatments. This treatment focuses on reducing emotion dysregulation, improving interpersonal skills, and addressing intrapersonal factors (including self-discrepancy and nutrition). ICAT-BN is based on models of conditioning and learning, which guide its interventions of eating disorder behaviors. ICAT-BN theory posits that individuals with BN experience negative affect due to the discrepancy between their actual and ideal self, which then causes them to engage in bulimic behaviors and self-criticism. A RCT showed comparable effectiveness of ICAT-BN and CBT at end-of-treatment and 4-month follow-up (Wonderlich et al., 2014). ICAT-BN may be an acceptable alternative treatment option for individuals who do not respond to CBT and present with emotion dysregulation, interpersonal distress, and self-criticism.

### Family-based treatment

FBT-BN is used for adolescents with BN and emphasizes the role of the family in helping the adolescent normalize their eating patterns and resume healthy adolescent development. FBT was originally developed for adolescents with AN, but has been adapted for the treatment of BN, with many of the same core components of the original treatment. FBT-BN seeks to empower parents to restore their adolescent back to health, and separate the adolescent from the illness. Although FBT-BN is newer than its predecessor, FBT-AN, there is preliminary evidence for its effectiveness in reducing bulimic behaviors. FBT-BN demonstrated a statistically significant difference in rates of abstinence from eating disorder behaviors when compared with nondirective supportive psychotherapy in one RCT (Le Grange et al., 2007). In another RCT, FBT-BN demonstrated comparable end of treatment and 6-month follow-up outcomes to CBT for adolescents (Le Grange et al., 2015).

### Pharmacotherapy

Pharmacologic medication has been tested for BN (see Bello and Yeomans, 2018 for a review). Notably, pharmacotherapy can be used with or without psychotherapy, and tends to offer increased accessibility to treatment, as well as more convenient long-term management due to the low time commitment for medication management and the need for less intensive training (compared with psychotherapy training) for the treating health care professional. Pharmacotherapy can be especially helpful in addressing symptoms comorbid to BN (e.g., depression, anxiety, impulsivity), as better management of these symptoms can help patients fully engage in eating disorder treatment.

Fluoxetine is a selective serotonin reuptake inhibitor that was approved by the Food and Drug Administration (FDA) in 1994 for acute treatment and maintenance of BN. Across randomized placebo-controlled studies, there is evidence for the effectiveness of fluoxetine in treating BN. In a multi-center study of 387 women with BN, an 8-week course of fluoxetine (60 mg/day) resulted in a 67% reduction of binge-eating episodes and a 56% reduction of vomiting episodes from pretreatment; in contrast, the placebo condition resulted in a 33% reduction in binge-eating episodes and 5% reduction in vomiting episodes (Fluoxetine Bulimia Nervosa Collaborative Study Group, 1992). Findings also support that fluoxetine aids in relapse reduction; a 52-week RCT of 232 individuals with BN demonstrated that there was a significant decrease in relapse to binge eating and purging behaviors among the fluoxetine group, compared to a placebo condition. In some studies, fluoxetine is associated with minor side effects compared with placebo conditions, including insomnia, nausea, anxiety, dizziness, and decreased libido. However, other studies demonstrate few side effects. In sum, fluoxetine demonstrates both effective and safe reduction of bulimic behaviors in BN (Bello and Yeomans, 2018).

## Treatment of underrepresented populations

Most of the research on BN treatment has occurred in high SES, White, female-identified patients. This disparity may be due to a lack of diagnosis in other groups; one study showed that White individuals were more likely to be diagnosed with and receive treatment for BN, despite Black individuals and girls from low-income families being more likely to exhibit bulimic behavior than White individuals and girls from high income families (Ham et al., 2015). Consequently, it is unclear whether established assessments and treatments are effective among people of color, men, gender and sexual minority groups, and low SES groups such as individuals experiencing food insecurity. Special attention should be paid to researching treatment effectiveness in these groups, and in adapting current treatment approaches to be culturally sensitive and accessible to underrepresented and underserved populations. Of note, guided self-help versions of specialty eating disorder therapies, such as CBT (Linardon et al., 2017), have been somewhat helpful in addressing the treatment-accessibility gap, but further work is needed to improve dissemination, cost, and access to the specialty BN treatments described above, particularly in underserved populations that appear to be at comparable or heightened risk.

## Long-term prognosis

Help-seeking rates for eating disorder symptoms are quite low (13–35.6%). One review found that across studies, the average duration of untreated BN was 53 months, and it appeared that shorter duration of untreated BN was associated with greater likelihood of remission (Austin et al., 2021). Of those who do obtain treatment, symptom remission is not guaranteed; over 60% of patients fail to fully abstain from core BN symptoms, despite receiving first-line, empirically supported psychological treatments (Linardon and Wade, 2018). In terms of pharmacotherapy, post-treatment effects across medications are moderate, indicating that taking medication also does not guarantee remission. Findings such as these highlight the urgent need for research to improve the effectiveness and accessibility of existing treatments, and the development of culturally sensitive guidelines for implementing these treatments within groups historically underrepresented in the literature.

## Conclusion

BN is a serious eating disorder associated with a chronic course, psychiatric comorbidity, and impairment. BN impacts individuals of various backgrounds and identities. Treatment should be prompt, and comprehensive in terms of psychological, pharmacological, and nutrition focus, specifically for those demonstrating undernourishment. Delays in treatment may prolong illness course, emphasizing the need for improved access, particularly for marginalized groups who may be at higher risk.

### Key points

- Energy balance is the difference between metabolizable energy intake and total energy expenditure. It is strongly related to macronutrient balances, and the sum of the individual substrate balances, expressed as energy, are mathematically equivalent to the overall energy balance.
- Energy in foods is furnished by carbohydrate, proteins, fats, and alcohol; only 5–10% is lost through the feces and urine.
- The energy available to the body, called ‘metabolizable energy’, is on average  $17 \text{ kJ g}^{-1}$  of carbohydrate,  $17 \text{ kJ g}^{-1}$  of protein,  $37 \text{ kJ g}^{-1}$  of fat, and  $29 \text{ kJ g}^{-1}$  of alcohol. These figures vary slightly according to the types of carbohydrate, protein, or fat in the diet.
- The energy used in the body, or energy expenditure, is classically assessed by indirect calorimetry. It involves measuring non-invasively the oxygen consumption and carbon dioxide production by an individual.
- Short-term regulation of energy balance is poor, but (in most people) long-term regulation is relatively accurate. The exact mechanism is still unknown, but must include, in certain individuals, conscious alterations in lifestyle to correct unwanted changes in body weight.
- During long periods of energy imbalance, the weight gained (or lost) is initially glycogen plus water with an energy density of  $1.0000 \text{ kcal/kg}$ . If the imbalance continues, after a week the tissue gained (or lost) is a mixture of mostly fat, water, and proteins.
- Undernutrition leads to a decrease in energy expenditure. Part of the decrease in absolute metabolic rate is related to weight loss.
- During overfeeding, although much of the excess energy intake will be stored in adipose (fat) tissue, there are compensatory increases in thermogenesis and energy expenditure which will moderate the level of imbalance over time together with the parallel effect of body weight gain.

NEAT Non-exercise activity thermogenesis

## Introduction

To maintain physiologic functions, the human body continuously expends energy by oxidative metabolism. This energy is used to maintain chemical and electrochemical gradients across cellular membranes for the biosynthesis of macromolecules such as proteins, glycogen, and triglycerides, and for muscular contraction. Another part of the energy is lost as heat because of the inefficiency of metabolic transformations. Ultimately all the energy produced by the organism is dissipated as heat.

The energy expended by an individual can be assessed by two different techniques: indirect and direct calorimetry. The term indirect calorimetry stems from the fact that the heat released by chemical processes within the body can be indirectly calculated from the rate of oxygen consumption. Indirect calorimetry measures the heat released by the oxidative metabolic processes and direct calorimetry assesses the heat dissipated by the body. The average values of the two over a period of 24 h or more are very close in steady state conditions. A relationship exists between these two variables although they are not in strict temporal synchronization since when an acute exercise is performed during the day, the total heat loss response lags behind that of heat production, thereby resulting in a small and transient increase in body central temperature. The difference between metabolic heat production and heat dissipation represents the body "heat balance", which, over a 24 period, will be generally in equilibrium in healthy subjects without developing fever.

The total body heat losses are equal to the sum of several components, namely the non-evaporative components (i.e., the radiant heat exchange, the convective and conductive heat transfers) plus the evaporative component (i.e., heat losses through the skin and the pulmonary losses consecutive to water vapor loss during expiration).

When average total heat production is not equal to average total heat loss, the heat imbalance will indicate either a net heat *storage* when the former is larger than the latter or a net heat *dissipation* when the latter is higher than the former. As a result, core (internal) body temperature will progressively rise or decrease respectively.

## Energy balance: definition

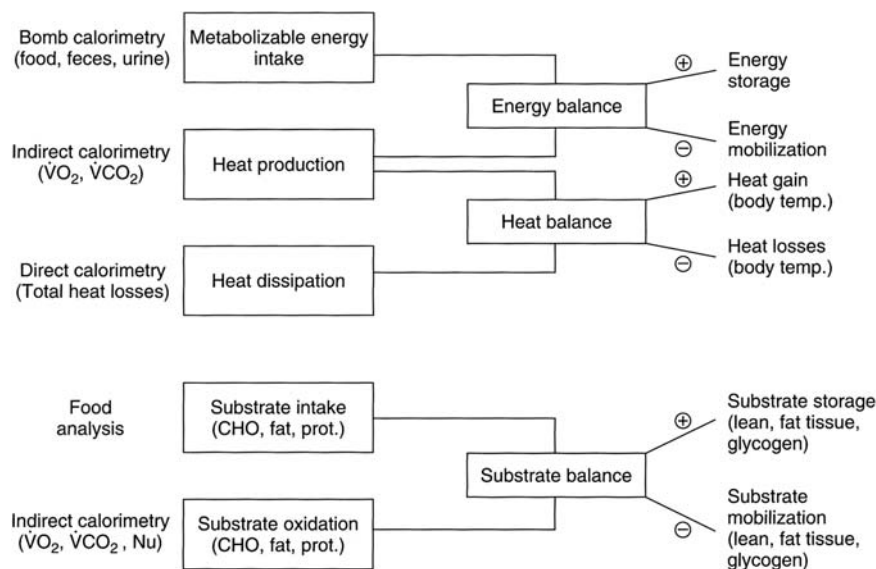

Overall energy balance is given by the following equation:

$$\text{Energy balance} = \text{total energy intake} - \text{total energy expenditure}$$

Thus, if the total energy contained in the body (as total fat, protein and glycogen) is not altered, average energy expenditure must be equal to average energy intake. In a state of positive energy balance over a long period of time, an increase in body energy stores will occur, primarily as body fat, and vice versa in a state of negative energy balance. The differences between the concepts of energy balance, substrate balance and heat balances are presented in Fig. 1.

This very simple equation has plagued nutritionists and physiologists for many decades, since it masks a number of difficulties that are of practical, methodological and conceptual nature:

- (1) The methodology to assess energy intake is much more uncertain than that assessing total energy expenditure by modern methods namely by stable non-radioactive isotopes (D<sub>2</sub>O<sup>18</sup>) or respiration (whole body) chamber.

**Fig. 1** Heat balance, energy balance, and substrate balance: three different complementary concepts measuring different things.

- (2) The inherent bias of the subject under investigation can lead to large errors in the quantitative food intake assessment. In contrast, one cannot cheat on the total energy expenditure value as it is generally inconspicuously and objectively assessed by physiological measurements.

This issue of large errors inherent to food energy intake measurement in free-living conditions has become important for the medical/nutritional scientists. As a result, it was proposed to calculate “true” energy intake indirectly (using the formula above) from total energy expenditure (TEE). As a result, the energy balance is assumed to be in equilibrium (or close to equilibrium) over a week or so, namely  $E_{in} = TEE$ .

If we accept this simplified postulate, the relative error in food energy intake assessment by classical methodology can be then estimated. Incidentally, large (non-voluntarily) under-estimation of total energy intake has been systematically reported in obese subjects/patients.

- (3) The natural variability of energy intake from day-to-day in a given subject is much greater than that of energy expenditure in free-living conditions. This is quite expected since just one day fasting (or feasting), in a time series of habitual food intakes, will drastically inflate its intra-individual coefficient of variation. In contrast, energy expenditure is never zero in a living individual but has a baseline value equal to resting post-absorptive metabolic rate and a lower minimal value during the night while sleeping.
- (4) Eating meals constitutes a discontinuous process (generally 2–5 meals per day), whereas metabolic energy expenditure is of continuous nature. Thus, when calculated over day-time, energy balance will largely be positive whereas it is compensated by a negative value during night-time, a period during which the person normally sleeps and rarely eats meals.

This rhythmic day/night pattern of energy balance occurs normally in most individuals, who are not involved in work shifts. When the 2 phases are cumulated, the 24 h energy balance can be in equilibrium, the diurnal period of positive balance is compensated by the negative one during the nocturnal period.

This emphasizes that an energy balance should be calculated over a minimum of 24 h (for example in a respiration chamber) in order to be able to assess the potential energy storage or mobilization of body tissues. However, evidence of full continuous energy equilibrium may require a longer measurement duration such as several days and even weeks (see below).

- (5) When the magnitude of energy imbalance (either positive or negative) has a large gap, this permits an appropriate interpretation of the results for comparing those values with the time course of body weight and body composition simultaneously observed.

### Model of energy balance: a dynamic state

There are multiple reciprocal direct and indirect influences of energy intake on energy expenditure and vice versa: for example, energy intake influences resting energy expenditure by increasing postprandial and dietary-induced thermogenesis, whereas changes in energy expenditure via a modification of physical activity are susceptible to influence energy intake to re-equilibrate energy balance. To ensure an accurate regulation of body stores, a double servo-control is essential (Fig. 2).

Body weight and body composition are not invariant with time, but small corrections of both input and output from day-to-day, week-to-week or more, ensure energy homeostasis. When attempting to explain the actual responses in energy balance and weight regulation in real life, we need to recognize that several factors may be operating on both sides of the energy balance equation. Compensatory adjustments occur in both intake and output sides, but unraveling their respective importance, is not an easy task in humans. Much more advanced, sophisticated and complex models of energy balance have been developed over these last decades for predicting the evolution of body weight and body composition profile, but these are outside the scope of this paper.

### Gross and metabolizable energy

The traditional way of measuring the energy content of foodstuffs is to use a “bomb calorimeter” in which the heat produced when a small representative sample of food is combusted (under high pressure of oxygen) is measured. The food is completely and instantaneously oxidized to water, carbon dioxide and small mineral incombustible residues. The total heat liberated (expressed in

**Fig. 2** Simplified conceptual model of energy balance showing the numerous feedback systems operating between energy input and energy output toward body weight regulation.

kilocalories or kilojoules) represents the gross energy value or heat of combustion of the food. The heat of combustion differs between carbohydrates, proteins, and fats. There are also important differences within each category of macronutrients. For example, sucrose has a gross energy of  $16.5 \text{ kJ g}^{-1}$ , whereas starch yields  $17.5 \text{ kJ g}^{-1}$ . The energy yield of butterfat is  $38.5 \text{ kJ g}^{-1}$  and of lard is  $39.6 \text{ kJ g}^{-1}$ . These values have been rounded off to give  $17.3 \text{ kJ g}^{-1}$  for carbohydrates rich in starch and poor in sugar,  $39.3 \text{ kJ g}^{-1}$  for average fat, and  $23.6 \text{ kJ g}^{-1}$  for mixtures of animal and vegetable proteins.

However, the gross energy value of foodstuffs does not represent the energy actually available to the body, since no potentially oxidizable substrate (macronutrients) can be considered available to the body until it is presented to the cell for oxidation. None of the foodstuffs are completely absorbed in the small intestine and some residual unabsorbed foods are excreted in the feces. Digestibility of the major macronutrients are high; on the average, 97% of ingested mixed carbohydrates, 95% of average fats and 92% of average exogenous proteins are absorbed from the intestinal lumen.

In the body, the tissues are able to oxidize carbohydrate and fat completely to carbon dioxide and water, but the oxidation of protein is incomplete since it results in the formation urea in the liver (and other nitrogenous compounds such ammonia), which are excreted in the urine with an energy equivalent of  $5.2 \text{ kJ g}^{-1}$  of protein ingested. With a mixed diet, rich in carbohydrates and fibers, the metabolizable energy of food is approximately 90% of the gross energy value (heat of combustion). The remaining 10% is mainly due to unabsorbed energy (fecal energy losses). The latter value increases with the amount of dietary (insoluble) fibers (for example, cellulose).

## Total energy expenditure and its components

Classically we simply considered energy expenditure as being made up of 3 components: the energy spent for basal metabolism or basal metabolic rate, (BMR), the energy spent on physical activity, and the increase in resting energy expenditure in response to a variety of stimuli (in particular food, cold, stress, and drugs). Additional subcomponents have been included such as the partition of physical activity into structured exercise (such as sporting activities) and non-exercise activity thermogenesis (NEAT) such as fidgeting.

For a more detailed outline of the components of TEE, refer to the chapter “Energy adaptation”.

## Basal metabolic rate and resting metabolic rate

These are the largest component of energy expenditure accounting for between half to 3/4 of total daily energy expenditure. BMR is measured under standardized conditions, that is, in an awake subject lying in the supine position, in a state of physical and mental rest, in a comfortable warm environment, and in the morning in the postabsorptive state, usually 10–12 h after the last meal. Resting metabolic rate (RMR) is measured at rest, supine but the conditions of measurements are less strict, for example in inter-prandial conditions. The distinction between RMR and BMR in the literature is not always clear. RMR could be considered almost equivalent to BMR if the measurements are made in postabsorptive conditions; the terms RMR and BMR are used interchangeably in the sections below.

It seems difficult to partition RMR into various subcomponents because the metabolic rates of individual organs and tissues are hard to assess in humans under noninvasive experimental conditions. BMR can vary up to 10% between individuals of the same age, gender, body weight, and body composition (fat-free mass), suggesting that genetic factors are also important. Day-to-day (intraindividual) variability of BMR is low in men (coefficient of variation of 1–3%) but is slightly greater in women because the menstrual cycle affects BMR. In both women and men, sleeping metabolic rate is lower than BMR by 5–10%, the difference being explained by the effect of arousal.

The major part of the whole-body RMR (~60%) stems from organs with high-metabolic activity such as the liver, kidneys, brain, and heart, although these account for a small proportion of the total body weight (5%). Per unit body weight, the kidneys, and heart have a metabolic rate more than twice as high as the liver and the brain. In contrast, the metabolic rate of muscle per unit body weight is nearly 35 times lower than that of the heart and kidneys. Since the proportion of muscle to non-muscle changes with age from birth to adulthood, the RMR per unit body weight is not constant with age. The tissue with the lowest metabolic activity per unit body weight is adipose (fat) tissue, which accounts for only 4% of the whole-body RMR in nonobese subjects. Calculations show that this value can increase up to 10% or more in obese subjects with a large excess in body fat. Skin and intestines (which have a relatively large protein mass and protein turnover), as well as bones and lungs, also contribute significantly to RMR.

Numerous studies have demonstrated that a major factor explaining the variation in RMR between individuals is fat-free mass (FFM), a heterogeneous component that can be partitioned into muscle mass and non-muscle mass. Unfortunately, there is no simple and accurate way to assess these two subcomponents. Owing to the larger variation between individuals in fat mass, as compared to FFM, and because in grossly obese women fat mass can represent a nonnegligible component of total RMR, the prediction models for RMR that include both FFM and fat mass explain significantly more variance in RMR than FFM alone. In addition, age, sex, and family membership are additional factors that should be taken into account.

The effects of gender on RMR are explained by differences in body composition. Caution should be used when comparing RMR expressed per kilogram FFM in men and women, because the composition of FFM is influenced by gender. The muscle mass of men is greater than that of women and this tends to give a lower value of RMR per kilogram FFM in men when compared to that of

women. This is explained by a greater component of tissue with a low metabolic rate per unit mass (resting muscle) in men than in women.

In clinical work, where body composition is difficult to assess, body weight, gender, and age can be used to estimate BMR and RMR, bearing in mind that many important determinants of RMR, in addition to body size, have been identified under noninvasive experimental conditions. BMR can vary up to 10% or more between individuals of the same age, gender, body weight, and FFM, suggesting that genetic factors are also important.

### Thermic effect of food or postprandial thermogenesis

The basal energy expenditure increases significantly after a meal. The so-called thermic effect of food is mainly due to the energy cost involved from the mouth to the endogenous tissues. The total thermic effect of food represents about 10% of the total energy intake over 24 h in sedentary subjects. The thermic effect of macronutrients mainly depends upon the energy costs of processing and/or storing the exogenous nutrient. Expressed as a percentage of the energy content of each macronutrient, values of about 8%, 2%, 20–30%, have been reported for glucose, fat, protein respectively, and as much as 22% for alcohol (ethanol).

For example, protein synthesis requires much energy due to the high cost of peptide bonds synthesis and biochemical processing. For the concept of altered thermic effect of food in adaptive thermogenesis, refer to the chapter “Energy adaptation”.

### Energy expenditure due to physical activity

The energy spent on physical activity depends on the type and intensity of the physical activity and on the time spent in different activities. Physical activity is often considered to be synonymous with “muscular work,” which has a classical definition in physics (i.e., force  $\times$  distance) when external work is performed on the environment (such as climbing).

During muscular work (muscle contractions), the muscle produces three to four times more heat than mechanical energy so that useful work costs more than muscle work. There is a wide variation in the energy cost of any activities both within and between individuals. The latter variation is due to differences in body size and in the speed and dexterity with which an activity is performed. To adjust for differences in body size, the energy cost of physical activities is expressed as multiples of BMR, the latter taken as baseline. The values generally range from 1 (= resting) to 5–6 for most daily habitual individual activities, but can reach values between 10 and 15 during intense exercise. In terms of daily energy expenditure, physical activity accounts for 15–40% of total energy expenditure (TEE) but it can represent up to 70% of daily energy expenditure in an individual involved in heavy manual work or competition sports. However, for most people in industrialized societies the contribution of physical activity to daily energy expenditure is relatively limited by occupation.

The energy expenditure associated with everyday life activity, which excludes structured exercise, is called non-exercise activity thermogenesis (NEAT). It plays a pivotal role in the regulation of human energy metabolism and body weight regulation. In practice, NEAT includes the energy expended while moving around (e.g., during household, occupational or leisure activities), walking back and forth (pacing) and fidgeting. It can be measured by the so-called factorial approach: each component of NEAT is quantified, and total NEAT is calculated by summing up these components. NEAT varies substantially between people of similar size in part because of the substantial variation in the amount of spontaneous physical activity they perform. Obesity is generally associated with low NEAT's, the deficit being not negligible: Obese individuals stand and ambulate significantly less and seat more than their lean counterparts.

Just as described above for a specific activity, it has been customary to express TEE relative to RMR (TEE/RMR or TEE/BMR), in order to (partially) offset the large variation in RMR among subjects of different body weight and body composition. This quotient is called physical activity level (PAL) and expressed as a the multiple of RMR measured over a 24 h period. For example, a PAL of 1.5 indicates that TEE is 50% greater than RMR (BMR) over 24 h.

### Energy balance and macronutrient balance

Since macronutrients (carbohydrate, fat, protein) are the major sources of energy (if alcohol is excluded), it is logical to consider energy balance and macronutrient balance together as the opposite side of the same coin [Schutz \(1995\)](#).

Provided the respiratory quotient, i.e., the ratio of CO<sub>2</sub> production to oxygen consumption is known, indirect calorimetry also allows an estimation of the macronutrient oxidation rates in the whole body in addition to energy expenditure.

The 3 macronutrients crude balance are defined as:

Carbohydrate balance = carbohydrate intake – carbohydrate oxidation

Lipid(Fat) balance = lipid(fat) intake – lipid(fat) oxidation

Protein balance = protein intake – protein oxidation

There is a direct mathematical relationship between total energy balance and total macronutrient balance, since the arithmetic sum of individual substrates balance (when macronutrients are expressed as energy) is equivalent to the overall energy balance. Note that the importance of lipid (fat) balance concept merits more details, given in a subsequent paragraph.

In a study composed of heterogeneous individuals (both lean and obese ones pooled), energy balance calculated over a period of weeks, was well correlated to total fat balance. This indicates that when there is an increase in body energy stores due to positive energy balance, this was mostly explained by body fat accumulation in adipose tissue rather than increase in muscles.

Total body energy stores (constituted mainly of fat stores in adipose tissue) represent a large proportion of the total daily energy ingested. For example, let's take a 60 kg non-obese woman (with 25% body fat), who is eating 2000 kcal/day<sup>1</sup>, this would represent a total adipose tissue storage (at 8000 kcal/kg for fat) of 120,000 kcal. Hence, this represents theoretically 60 days of fat available stored, whereas carbohydrate storage (as glycogen) constitutes only 3–4 days of reserve.

### The classical fat balance concept: needs to be refined under certain nutritional conditions

The definition of “crude” fat (lipid) balance described above is somehow more complex than a simple balance equation, since, in the intermediary metabolism, one substrate (or molecule) can be converted into another substrate. For example, carbohydrates can be transformed into fat in acute carbohydrate overfeeding conditions. This process is called *de novo lipogenesis*, meaning new synthesis of fat derived from another precursor that exogenous fat (Schutz, 2004).

Taken together the above considerations mean that we must distinguish 3 types of fat balance rather than only one (Fig. 3):

- (1) *Classical* (crude) fat balance, typically used in nutrition/dietetics
- (2) *Dynamic* fat balance, a very useful concept to use when energy dislocation (+ or – energy imbalance) leads to body weight gain and body weight loss respectively.
- (3) Further *sub-partitioning* of fat balance, which can be split into an exogenous component (coming from food) and that mobilized from the body (endogenous one). This more complex type of fat balance is useful when interpreting acute overfeeding (or underfeeding) conditions. It primarily concerns situations such as a surfeit of foods rich in carbohydrates or sugar dissolved in liquids (such as soda, the so-called *soda syndrome*). Note that chronic excess alcohol consumption has also lipogenic capacities.
- (4) In habitual nutritional conditions, the fat stored in adipose tissue mainly comes from dietary fat (i.e., exogenous). The best evidence of this, is that the relative composition of fatty acids in adipose tissue (expressed in % of total tissue fat) closely reflects that of fat ingested in particular the nutritionally essential poly-unsaturated fatty acids of w3 and w6 series.

The transformation of exogenous carbohydrates into endogenous fat occurs in the liver and, to a lesser extent, in adipose tissue. This has important consequences for this key organ, as the liver is a real metabolic “carrefour”, which regulates and controls a vast number of functions for maintaining metabolic homeostasis and is responsible of many biosynthesis activities.

The mechanism of *de novo* lipogenesis leading to excess endogenous fat in the liver has negative functional consequences in particular if it is associated to physical inactivity. The placidity results in a blunted mobilization of carbohydrates stored as glycogen in the liver and muscles, precluding its subsequently oxidation by the active working muscles. The progressive accumulation in the liver is subsequently converted into fat as schematically presented in Fig. 4.

### Energy imbalance and body weight relationship

Positive energy balance leads to body weight gain and negative energy balance leads to body weight loss. There is no fixed relationship between these two variables, since there could be considerable variations in the composition of the weight change in terms of fat, lean tissues and associated water stored or mobilized.

$$1) \text{ Classical nutritional (static) : Fat bal.} = \text{Fat}_{\text{in}} - \text{Fat}_{\text{ox}}$$

$$2) \text{ Dynamic fat balance (dynamic): } \Delta \text{Fat bal.} = \Delta \text{Fat}_{\text{in}} - \Delta \text{Fat}_{\text{ox}}$$

$$3) \text{ Partitioning of fat balance between exogenous/endogenous}$$

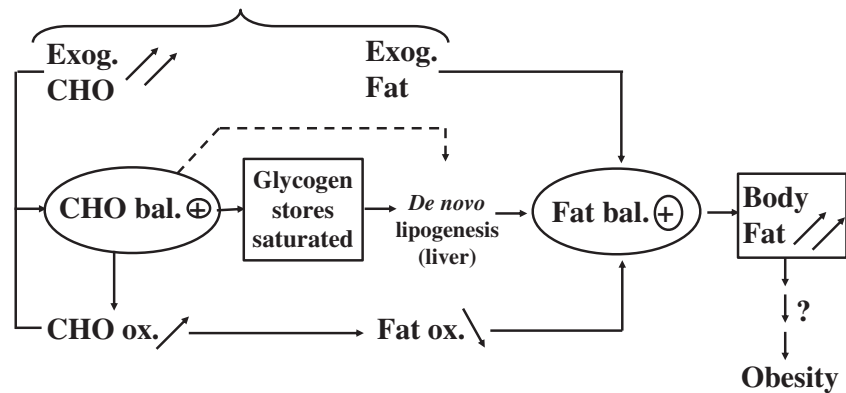

$$\text{a) Exog. Fat bal.} = \text{Fat}_{\text{in}} - \text{Fat}_{\text{ox exog.}}$$

$$\text{b) Endog. Fat bal.} = \text{de novo Fat synthesis} - \text{Fat}_{\text{ox endog.}}$$

---

$$\text{Total: (a+b)} = (\text{Fat}_{\text{in}} + \text{de novo Fat}_{\text{synth.}}) - (\text{Fat}_{\text{ox exo} + \text{endo}})$$

**Fig. 3** When macronutrients are considered, the classical fat balance is considered to be static. In dynamic conditions, during which fat storage or fat mobilization occur, *delta* fat balance will be more compatible with the independent measurement of serial body composition. In addition, the classical fat balance has to be adjusted in case of particular nutritional conditions, during which *net de novo* lipogenesis i.e., a transformation of exogenous carbohydrates into endogenous fat. The total equation considering these factors is given in the bottom line. Abbreviations: bal. = balance; in = intake; ox = oxidation;  $\Delta$  = change in; exog. = exogenous; endo. = endogenous; synth = synthesized.

**Fig. 4** The mechanism of *de novo* lipogenesis is schematically shown when surfeit carbohydrates are deliberately over consumed continuously for a period of approximately one week. In real-life situation of repeated high CHO (sugar) overfeeding on obesity risk development, the dual mechanism perpetuating a net positive fat balance accompanied by a rise in body fat stores, can be summarized: the total body fat gain is explained by (1) a drop in endogenous fat oxidation (antilipolytic effect of insulin) to which is superposed to (2) the effect of stimulation in *de novo* lipogenesis resulting from the net conversion of carbohydrates into fat notwithstanding the retention of exogenous fat of the meal (if any). Abbreviations: CHO = carbohydrates; Exog. = Exogenous; bal. = balance; ox. = oxidation; arrow up = increase; arrow down = decrease.

Over short term, relatively small energy retention or mobilization on a daily basis can cumulate over time and be accompanied by important body weight gain and vice versa. The confounding factor is the associated water retained in certain tissues in particular when glycogen storage or glycogen mobilization occur in the early phase of acute feeding or depriving carbohydrate, respectively. The calculated water dilution rate of “dry” glycogen by water in the tissue is approximately 3, indicating that each 100 g of glycogen stored/mobilized was associated to approximately 300 g of water in the glycogen-water pool displaced. Over longer term, this transient situation plays little role and cumulated energy retention (or mobilization) becomes compatible with fat retention (or mobilization), if we neglect the protein storage or mobilized.

In summary, day-to-day body weight fluctuations are generally accommodated by water retention due to changes in carbohydrate storage as well as acute sodium intake fluctuations. Body weight tend to be spontaneously maintained over middle term, despite large natural day-to-day fluctuations of macronutrients balance and body weight. The large fluctuations of CHO balance are explained by the variability of total CHO eaten from day-to-day vs that oxidized.

## Energy balance regulation

Any regulated function varies within a certain window that is largely determined by the physiological homeostasis which ultimately will favor survival [Galgani and Ravussin \(2008\)](#).

Short-term day-to-day energy imbalance is mostly accommodated by rapid changes in carbohydrate balance, whereas over a prolonged period of time, positive energy balance is mostly expressed as fat storage since carbohydrate stores remain limited to a maximum of about 1 kg. By contrast, the fact that the body weight of certain individuals varies in a very narrow range over years/decades, in spite of large day-to-day fluctuations in both the amount of food (macronutrients) consumed and also in the level of physical activity, may suggest that body weight is accurately regulated in these individuals. A critical feature of any regulated system is the metabolic response to a voluntary disturbance: the regulated variable should result in a compensatory response that tend to attenuate the initial disturbance and to restore the system to its “set” or “preferred” value or initial state. It seems important to highlight key features of energy balance and weight regulation (refer to the companion chapter on Energy Adaptation).

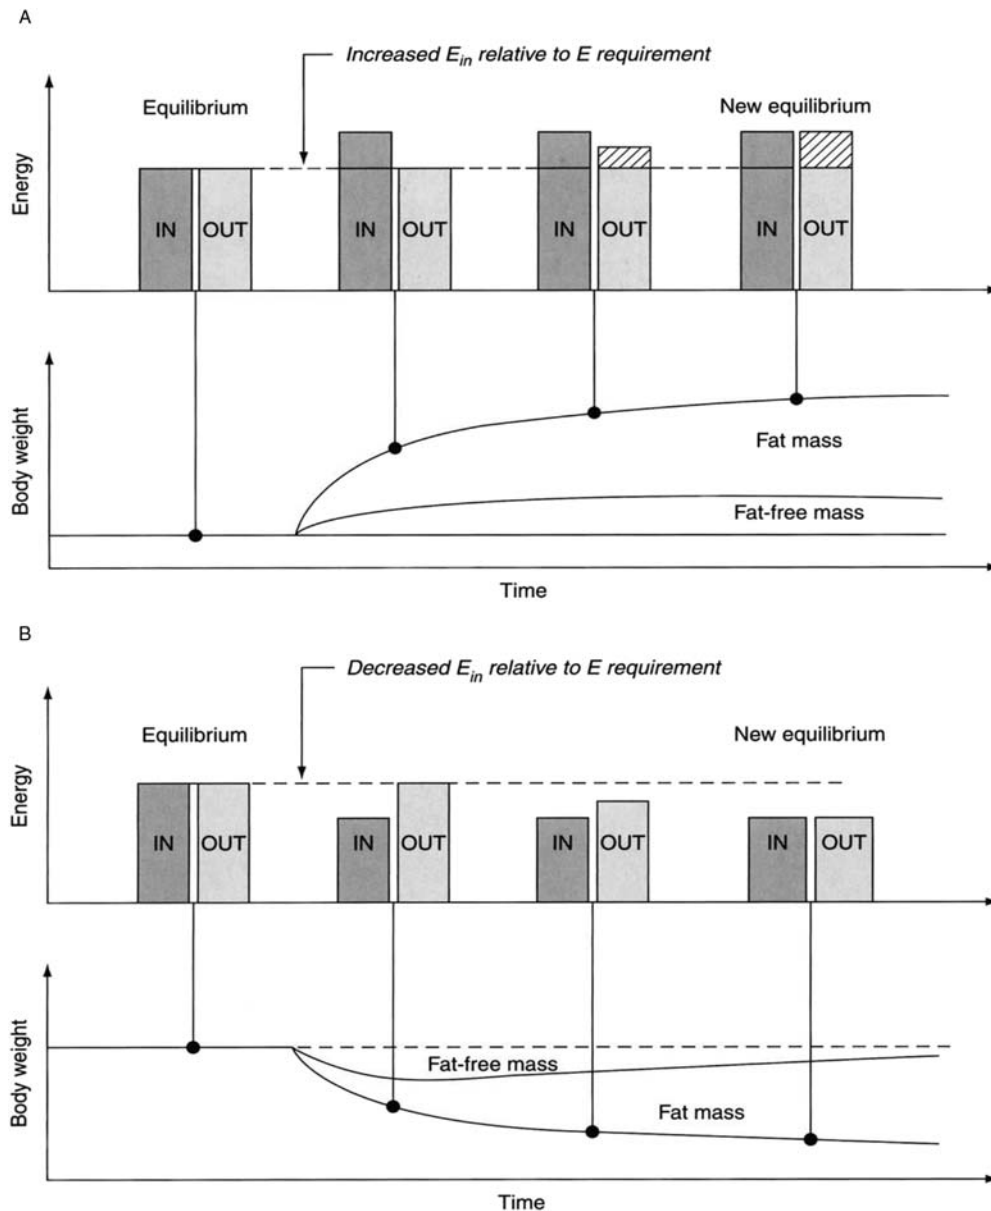

First, the energy balance spontaneously varies from day-to-day because human beings cannot precisely match total energy intake and total energy expenditure on a day-to-day basis. The changes in daily energy intake and expenditure appear relatively random and not necessarily synchronized. Positive energy balance on one day may not be spontaneously and fully compensated by negative energy balance on the subsequent day, so that it is important to consider the overall energy balance regulation over a sufficiently prolonged period of time.

Near equality of energy intake and expenditure in non-obese individuals can most often appear over a period of 1–2 weeks. Longer term research measurements (over several weeks) are technically difficult and impractical to conduct for the subjects, and also because of cumulative systematic energy measurements errors on both sides of the energy balance.

Second, this matching of long-term energy intake and energy expenditure must be very accurate in certain individuals, because a theoretical error (imbalance) of only 1% between energy input and energy output, if constant and persistent over several years and if not compensated, will lead to a theoretical gain or loss of approximately 10 kg in the first decade of imbalance if the body would be invariant.

### Dynamic and static evolution of energy balance: overfeeding and underfeeding conditions

To better understand the dynamic aspect of energy balance (i.e., in non-steady state or not) we need to stimulate the body by an acute and continuous perturbation such as overfeeding/underfeeding to demonstrate that the system is not inert and invariant; see [Bray, and Bouchard \(2020\)](#) for an extensive analysis of human overfeeding studies. As shown in [Fig. 5A](#) step (and sustained) increase in energy intake above energy requirement will lead to a gradual gain in body weight. The size of the energy imbalance will progressively diminish with time as weight is gained. The reason for this is that the expansion of FFM and fat mass (adipose tissue) will be accompanied by a rise in energy expenditure. A new equilibrium in weight is eventually reached after adaptation of each component of TEE, that is, RMR, diet-induced thermogenesis and body weight.

**Fig. 5** Dynamic change in energy balance following a step (and sustained) increase (A) or decrease (B) in total energy intake. The time required to reach a new equilibrium in energy balance is very long (several years) and depends on the magnitude of initial energy imbalance, the magnitude of adaptation of energy expenditure in response to the step change in energy intake, and on the factors related to the subject (obesity vs. leanness). Let us take the following practical example: small increase in energy intake, for example, of 100–200 kcal/day, will induce small increases in body weight, associated to a rise in energy expenditure as the mass of lean tissue increases. If these changes occur month-by-month, and if after 3–5 years the adult is still eating an excess of 200 kcal/day over the baseline value, they will now be progressively heavier. Ultimately, after a long period of adaptations (years), they will reach a new energy balance equilibrium at a higher energy intake level. As a result, their weight will tend to reach a plateau after an expected (theoretical) 8–10 kg weight gain.

In a perfectly regulated system, any increase in energy intake should be offset by a change in energy expenditure of the same magnitude and direction. However, a 100% efficient adaptive process would obviously be counterproductive, since this would signify that an increase in energy storage (required during the anabolic state of nutritional rehabilitation) or an increase in energy mobilization (required for decreasing body weight) would be very limited. Briefly, adaptation to energy imbalance occurs at the cost of increasing (or decreasing) body weight.

In fact, excess energy intakes result in an increased metabolic turnover and energy flux through the mechanism of adaptive thermogenesis. The efficiency of energy storage is not constant and depends upon several factors including the magnitude of energy imbalance, the composition of the surfeit energy fed, as well as endogenous factors.

Analysis of underfeeding experiments shows that the progressive decrease in total energy expenditure has 3 components. First, if energy intake is decreased the thermic effect of food (approximately 10% of energy intake) is similarly decreased. Second, there is a quick adaptive decrease in metabolic rate during the first week, related in part to a decrease in sympathetic activity. The magnitude of this decrease is only 5–8%. Third, there is a decrease in metabolic rate related to body weight lost: most investigators find a decrease in 10–12 kcal per day per kg weight loss.

The combined effects of all 3 processes are that a person who lost weight from, say, from 100 kg to 70 kg (a 30% reduction in weight) would experience approximately a 15% reduction in energy expenditure and hence in energy requirements for weight maintenance. Thus, a decrease in energy intake causes a reduction in body weight up to the time that a new equilibrium will be reached at which the reduced requirement will be again compatible with the reduced intake, and therefore body weight will ultimately stabilize.

Taken together, we can conclude that the efficiency of energy utilization is lower in overfeeding than in underfeeding conditions because substrate storage in tissues is energetically costly (ATP needs), whereas the process of energy mobilization requires little energy. Adaptive changes in thermogenesis attenuates the impact of excessive or insufficient food consumption on energy balance. The magnitude of adaptive thermogenesis, which shows high inter-individual variability, also varies as a function of the nature of excess substrates fed; protein has a greater effect than carbohydrate, followed by fat. As shown in a graphical form (Fig. 6) the relationship in steady state conditions between total energy intake below and above energy equilibrium (considered as energy needs) vs energy expenditure and energy balance is not quite linear, indicating an improved net efficiency of energy utilization below energy maintenance and a decreased one above energy equilibrium.

**Fig. 6** Relationship between the level of energy intake on energy balance in steady state nutritional conditions, i.e., after adaptation: from underfeeding (below energy needs) to body weight maintenance when energy needs are fully covered, up to overfeeding situations (above weight maintenance) conditions. The metabolic adaptations occur in both sides of the energy imbalance, i.e., by increased energy saving in undernutrition and increased energy dissipation in overfeeding by stimulation of diet-induced thermogenesis. Note that the straight line (where  $x = y$ ) would represent the unreal and unphysiological situations where E intake would be equal to Energy expenditure immediately no matter what is the level of E intake, without a long transient adaptation over the years, at the cost of body weight gain or body weight loss. E = energy.

## Conclusions

The magnitude of day-to-day variability of energy expenditure in a given individual under free-living conditions is substantially lower (coefficient of variation CV of around 5–10%) than that of total energy intake (CV with much larger range: 10–20%). This has consequences for the extent to which both variables can be controlled for regulating energy balance and substrate balance, and hence to maintain body weight.

Several studies have shown that the relationships between energy intake, energy expenditure vs body weight is not straightforward, since it depends upon several factors, the most important ones being the time frame under which it is considered (one day, one week, one month, or more) and the accuracy and precision with which energy intake and expenditure are measured in humans; energy intake being much more difficult to track than energy expenditure.

The metabolic energy used in the body, or energy expenditure, is classically assessed by indirect calorimetry, involving the measurement of oxygen consumption and carbon dioxide production. These validated systems, have been used as a golden standard for assessing energy needs/requirements of individuals and groups of well-defined subjects by [FAO/WHO \(1985\)](#), admitting implicitly that food energy intake failed to be accurate enough to assess energy needs in various populations.

### Key points

- Understand when Enteral Nutrition is appropriate
- Understand the benefits and complications of Enteral Nutrition
- Review the indications and components of parenteral nutrition
- Understand the complications associated with parenteral nutrition

## Part I: Enteral nutrition

### Introduction

Enteral nutrition (EN) is the modality of feeding via the gastrointestinal (GI) tract when one cannot sustain or progress their nutritional needs orally. Feeding is delivered directly into the GI tract for absorption of nutrients, fluid, electrolytes, and vitamins.

EN dates back a few thousand years, notably 100 BC when barley and wheat were provided via rectal feeds in patients who were not capable of eating orally (Vassilyadi et al., 2013; Dudrick and Palesty, 2011). It wasn't until 1598 that Capivacceus used a hollow tube placed in the esophagus to deliver liquid nutrients (Dudrick and Palesty, 2011) and Hunter in 1790 (Vassilyadi et al., 2013; Dudrick and Palesty, 2011) first used EN for therapeutic purposes to bypass the esophagus and feed directly into the stomach. The first documented case of gastrostomy tube placement was in 1876 by Verneuil (Vassilyadi et al., 2013) and early enteral feeding attempts and techniques kept evolving well into the twentieth century leading to the development and innovation of enteral nutrition that we know today. EN has been able to provide a vital avenue for patients to receive and meet their nutritional needs.

### Indications and contraindications

EN is the preferred method of feeding patients who cannot eat, absorb, or use a normal diet in the presence of a useable GI tract. Indications for EN are listed in Table 1 and should be initiated in the critically ill within 24–48 h.

EN can also be harmful if clinically used when the GI tract is not accessible, safe to use, functional or ethically don't align with a patient's goals of care. Table 2 lists common contraindications to EN.

### Types

EN requires liquid formulas to be administered through a tube in the upper GI tract. The type of feeding tube used for EN delivery can be divided into two categories: nasogastric or nasoenteral tubes, which enter the GI tract through the nose or gastrostomies and jejunostomies, which enter through the abdominal wall. In general, feedings administered through nasal tubes is indicated for

**Table 1** Potential indications for enteral nutrition.

<b>Inability to ingest food normally</b>	
Prolonged NPO (nothing by mouth)	Multiple sclerosis
Persistent nausea	Amyotrophic lateral sclerosis
Early satiety	Guillain-Barre syndrome
Dysphagia, odynophagia	Huntington's chorea
Mucositis	Parkinson's disease
Chronic abdominal pain	Respiratory failure
Head and neck surgery	Fracture of mandible
Stroke	Irradiation of head and neck
Unconsciousness, stupor, coma	Chemotherapy
Brain tumor or injury	Oropharyngeal neoplasm
<b>Gastrointestinal dysfunction</b>	
Acute pancreatitis	
Chronic liver disease	
Crohn's disease	
Ulcerative colitis	
Diabetic gastroparesis	
Enteric fistula (if access is distal to fistula)	
Esophageal stricture or neoplasm	
Gastric outlet obstruction	
<b>Psychiatric</b>	
Anorexia nervosa	
Depression	
<b>Medical</b>	
Hypermetabolic state (trauma, sepsis, burns)	
Critical illness	
Renal failure	
Cancer or cardiac cachexia	
Chronic obstructive pulmonary disease	
Cystic fibrosis	
Hyperemesis gravidarum

**Table 2***Contraindications for enteral nutrition*

Mechanical obstruction
Intractable vomiting or diarrhea that is refractory to medications
Extreme malabsorption
Short Bowel Syndrome (100 cm small bowel remaining)
Paralytic Ileus
High Output Fistula
Peritonitis
GI bleeding
Hemodynamic Instability
Inability to access GI tract
Terminal disease/Hospice

periods lasting less than 4 weeks whereas feedings that require a longer duration of time use more permanent tubes (gastrostomies and jejunostomies).

## Access

### *Nasogastric route*

Short-term feeding tubes should be used for patients who are expected to receive EN for less than 4 weeks or for whom a long-term feeding tube is not an option. Nasogastric tube placement, where a silicone or polyvinyl tube passes through the nose into the stomach, is one of the most common types of enteral access and can be used to safely administer short-term EN and or in patients who are at risk of aspiration. This procedure can be performed bedside. Nasogastric tubes vary in length from 30 to 43 in with diameters of 8–14 French. Bolus or continuous infusions can be used to administer feedings. Complications that may occur with short-term tubes include patient discomfort, sinusitis, or minor epistaxis. Both, nasogastric or nasoenteral (duodenal or jejunal), when placed with a nasal bridle to secure the tube in place decrease the risk of dislodgement and helps ensure adequate calorie delivery (Stabler et al., 2018; Seder et al., 2010).

### *Nasoduodenal or nasojejunal route*

Nasojejunal tubes are longer tubes than their nasogastric counterparts and are also used for short-term feeding (4 weeks), in patients with gastric dysmotility, nausea or vomiting, gastroparesis, and high-risk patients. A nasojejunal tube is more difficult to insert and place, particularly if blind placement of the tube occurs, where complications of misplacement into the trachea or into the lung pleura could lead to a pneumothorax. An electromagnetic placement device allows for the visualization of the placement of small-bore feeding tubes using a transmitting stylet and a receiver placed on the patient's abdomen (Powers et al., 2018). Alternatively, tubes can be advanced via endoscopic or fluoroscopic guidance. Feedings via nasojejunal route require an infusion pump for administration.

### *Percutaneous endoscopic gastrostomy (PEG), percutaneous jejunostomy (PEJ) or percutaneous endoscopic gastrostomy with jejunal extension tube (PEG-JET)*

PEG tubes are used in patients who will need long term, full, or supplemental feedings lasting more than 4 weeks. The PEG tube can be placed directly into the stomach through the abdominal wall using an endoscope. Tubes can then be advanced by endoscopic guidance into the duodenum and then brought out through the abdominal wall to provide the access route for enteral feedings. The advantages of PEG tube feeding are that they are easier to place than a jejunostomy, less expensive, and easier to maintain. Disadvantages are that it is contraindicated in patients with obstructions and there may be a moderate risk of aspiration in high-risk patients. The tube diameters commonly used range from 6 to 8 mm French units. In general, small diameter tubes should be avoided in patients with poor gastric emptying who require intragastric administration of medication. Percutaneous jejunostomy (PEJ) is also used in long-term feeding, in patients who require full or supplemental feedings for more than 4 weeks. PEJ placement requires higher skill and is more difficult to place than PEG, but can safely feed patients with gastric resection, gastric dysmotility, and patients with a higher risk for aspiration. Sometimes clinical scenarios arise when the need to both decompress the stomach while providing nutrition must occur. A combination of the two tubes via a percutaneous endoscopic gastrostomy with jejunal extension tube (PEG-JET or J-PEG) is performed either with fluoroscopy or endoscopy to achieve this (Ponsky et al., 1985; DeLegge et al., n.d.). A limitation in PEJ tubes is that the tubes are typically smaller in size and may clog more easily.

## Formula selection

Although the composition of EN formulas vary widely, almost all formulas are nutritionally complete when administered in the appropriate quantities. Factors to consider when choosing a formula depend on the nutritional needs of the patient, the

functionality of the GI tract and desired metabolic response (Rath et al., 2020). Most formulas are gluten and lactose free, with some containing Halal and Kosher designations as well as non-GMO and vegan varieties. Water comprises the majority of EN with formulas ranging between 70 and 85% water depending on the caloric density. A wide selection of EN formulas are commercially available depending on the needs of the patient and can be classified into four separate groups:

- **Standard or Polymeric formulas:** These formulas contain intact proteins from milk and soy, oligosaccharides and lipid sources primarily from lecithin and oils which contain both long-chain triglycerides (LCT) and medium-chain triglycerides (MCT). Standard formulas vary in caloric density ranging 1.0 calorie (kCal) per milliliter (mL) to 2.0 kCal/mL. Protein provision can range between 15 and 25% and is most often the deciding factor on formula selection. Standard formulas are typically well tolerated across many patient populations, including the medical and surgical intensive care units (ICU's) (McClave et al., 2016).
- **Elemental and Semi-Elemental formulas:** These formulas require less digestion than standard formulas as their components have been enzymatically hydrolyzed. They contain peptides and free amino acids with lower osmolality. They are often used for patients that have malabsorptive conditions and impaired GI function, which may include short bowel syndrome, Crohn's and/or pancreatitis. The protein in these formulas is in the form of peptides and free amino acids, while fat is provided as a combination of LCT and MCT. Carbohydrates are partially hydrolyzed starch maltodextrins. Formulas may provide 1–1.5 kCal/mL and protein can range 18–38% of total kCal.
- **Disease specific formulas:** These formulas are designed to provide specific nutrient needs based on specific illnesses. They are intended for patients who have specific metabolic requirements and may be enriched with specialized nutrients to improve patient outcomes (See Table 3).
- **Blenderized:** These formulas are defined as blended foods and liquids provided via feeding tube (Escuro, 2014) and can be commercially made or blended in the hospital and/or home environment. Blenderized foods may date back to 1949 when purified amino acids, sucrose, corn oil, starch, vitamin, and minerals were fed to study participants (Dudrick and Palesty, 2011) and has gained popularity as of recent to a subset of patient/families interested in real-food ingredients. Risks associated with its use include bacterial contamination and inconsistencies with nutrient content (Milton et al., 2020). Hang time for administration should be limited to 2 h or less to prevent bacterial contamination (Boullata et al., 2017).

### Modular formulas

Modular formulas are used for supplemental use and are designed to provide additional calories, protein, or fiber to meet individual nutrient needs. Modulators used to provide additional kCal contain both fat and protein (typically from vegetable oils and calcium caseinate respectively) and can provide upward of 300 kCal per serving. Protein modulators come in both powder and liquid formulations and can provide between 6 and 10 g protein per serving from whey protein isolates or hydrolyzed collagen. Fiber modulators are also available and can be used to enhance GI function by providing 3 g soluble fiber per serving from partially hydrolyzed guar gum.

**Soluble and Insoluble fibers:** Tube feeding formulas can be fiber-free, contain a mix of both insoluble and soluble fiber, or contain soluble fibers alone depending on the medical needs of the patient. Patients may benefit from a mixed fiber formula or soluble fiber additive for management of diarrhea when other sources of diarrhea have been ruled out (McClave et al., 2016). Soluble fiber helps to decrease diarrhea through increased absorption of sodium and water (Rath et al., 2020) and has been shown to maintain healthy microbiota in the bowel (McClave et al., 2016). Insoluble fibers are used to provide bulk to stool and promote intestinal transit (Rath et al., 2020). All types of fiber should be avoided in the critically ill with severe dysmotility or those at increased risk for bowel ischemia (McClave et al., 2016).

### Medication administration and tube occlusions

Enteral access devices can be used to provide medications to patients, but complications may occur because many medications are not formulated for feeding tube administration. The goal of medication administration is to both reduce drug toxicity and ensure therapeutic levels are being delivered to the patient (Boullata et al., 2017). Gastric administration of medication is ideal as post-pyloric administration can alter a drug's bioavailability (Boullata et al., 2017). The safest method of medication delivery is by mixing crushed compatible solid tablets with 30–60 mL of water and diluting liquid medications to reduce its viscosity (Boullata et al., 2017).

Enteral tube occlusion is a common problem that can sometimes be resolved but may require replacement of the tube. Medications are a common cause. Water flushes should be provided before and after medications are given, every 4 h during continuous feedings, and before and after each bolus feeding (Rath et al., 2020). A single-center survey in the UK found that there were significant practice variations among nurses when administering medications via enteral access devices. Theoretically, this may have contributed to blocked tubes and excessive fluid administration to some patients (Tillott et al., 2020). An interdisciplinary team of licensed independent practitioners, nurses and pharmacists are important in preventing errors and developing protocols for medication administration via enteral access devices (Boullata et al., 2017).

**Table 3** Disease-specific formulas.

<i>Type of formula</i>	<i>Description of use</i>
Diabetic	Lower carbohydrate, higher fat formula with fiber to help with glycemic control Can use standard formula as there is limited evidence to support its use in adult patients (McMahon et al., 2013) Avoid overfeeding to prevent hyperglycemia
Renal	Fluid restricted, energy dense formula that contains less potassium, sodium, phosphorus and magnesium for patients not on dialysis. Protein content varies depending on need. If patient on frequent hemodialysis or CRRT, recommend increased protein up to 2.5 g/kg/day
Pulmonary/ARDS	High fat, low carbohydrate formula in order to reduce CO <sub>2</sub> production and respiratory quotient, however there is limited data to support use. Fluid restriction, energy dense formulas are recommended for patients with acute respiratory failure Avoid overfeeding kCal especially when weaning from ventilator
Hepatic	Hepatic formulas no longer available. Standard formulas are recommended as there is no evidence for use of branched-chain amino acids in this population. Fluid restricted, lower protein, energy dense formula with high ratio of branched-chain amino acids to aromatic amino acids. High MCT to LCT ratio. Protein restriction has not been shown to reduce hepatic encephalopathy and may lead to malnutrition and decreased muscle mass
Immune enhancing	These formulas contain specialized nutrients to improve immune function, such as arginine, glutamine, nucleic acids and omega-3 fatty acids. There appears to be a synergistic effect with arginine and omega-3 fatty acids Recommended in pre- and post-operative phase for patients with malnutrition; or pre-operatively in well-nourished patients undergoing elective surgeries. May also be used with traumatic brain injury as it may mitigate infections and improve recovery (McClave et al., 2016). Limited studies have shown efficacy with its use in trauma.
Plant/food based	Not used in severe sepsis Contains whole foods for patients who prefer real food sources, vegan options, and Non-GMO ingredients. Can meet 100% nutritional needs with specific volume. Caution with food allergies, as some products contain allergenic foods (i.e., milk, fish, gluten, egg, soy, tree nuts, wheat)

kCal—Calorie CRRT—Continuous renal replacement therapy.

Adopted from: McClave, S.A., Taylor, B.E., Martindale, R.G., et al., 2016. Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.). J. Parenter. Enteral Nutr. 40(2), 159–211.; McMahon, M., Nystrom, E., Braunschweig, C., Miles, J., Comper, C., 2013. American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) clinical guidelines: nutrition support of adult patients with hyperglycemia. J. Parenter. Enteral Nutr. 37, 23–26.

## Methods of infusion

Enteral feedings can be administered via pump assist, which includes a continuous drip, bolus feedings or intermittent infusions; or can be provided using gravity drip or manual bolus (syringe). The method selected depends on the stability of the patient, EN access route, GI anatomy and other medical factors.

- Pump assisted:
  - Continuous drip: EN is administered at a designed rate over a 24 h period. This method is used in hospitals when initiating tube feeding and is well tolerated. Initiation of tube feeds typically start at 10–15 mL/h and increases every 4–8 h depending on EN tolerance until patient's goal rate is met. This method is used with both gastric and small bowel tube feedings.
  - Bolus infusion: Deliver a higher volume of nutrients provided multiple times daily to mimic normal eating patterns. Bolus infusions should be used for gastric tube feeding only.
  - Intermittent infusions: Larger volumes of EN are infused over a designated time period. This type of feeding may result in more adequate volumes being administered and will also provide time off infusion. This method is used with cyclic and nocturnal feeding regimens.
- Gravity feed: Method of administration using a feeding bag with a roller clamp attached to the tubing to adjust the flow to allow more intermittent delivery of nutrients. It is often used in gastric tube feeding patients. This mode of infusion is less expensive than pump-assisted delivery and is also easier to administer (Rath et al., 2020).
- Manual bolus (syringe): Larger volume of EN is delivered multiple times daily via syringe bolus. This method allows the patient more freedom, is easy to use, and is the cheapest route of administration as it does not require a pump. This is a common method to administer tube feeding at home and long-term care facilities. Rapid installation of feeding into the stomach is given by syringe and most patients tolerate this method. Bolus feeding must be provided when the patient is in an upright position to avoid aspiration.

Rate based infusion is the method of providing an EN infusion over a constant hourly rate. Historically, this was a common approach to EN delivery, however volume-based infusion has shown efficacy in providing more nutrient delivery as a prescribed amount of EN is delivered over a 24 h period to help ensure the patient will receive adequate nutrition (Boulatta et al., 2017). This method helps to make up for any missed feedings that may occur during the day in a hospitalized patient undergoing various test or procedures. Studies have shown its safety and improvement in nutrient delivery when compared to rate-based infusion techniques (McClave et al., 2015).

## Complications and monitoring

EN is generally safer than Parenteral Nutrition (PN) but it still has the potential to induce GI, metabolic and mechanical complications. Diarrhea is the most common adverse event associated with tube feedings, but it is rarely due to the formula of the tube feeding itself. Etiologies such as underlying disease, enteric pathogens or sorbitol-containing medications contribute to diarrhea symptoms (Rath et al., 2020).

An adverse event to monitor for while patients are on EN is aspiration. Traditionally, measurements of Gastric Residual Volumes (GRV) were used as an indicator for aspiration risk (Boullata et al., 2017). Elevated and increasing residual volumes may be a symptom of another underlying problem manifesting itself as delayed gastric emptying (Boullata et al., 2017). Alternative methods for monitoring for aspiration include careful daily physical examinations, review of abdominal radiologic studies, and evaluation of clinical risk factors for aspiration. Current ASPEN guidelines recommend against stopping EN for GRVs <500 mL in the absence of other signs of intolerance (Boullata et al., 2017).

## Home enteral nutrition

Transitioning patients to home with EN is a common practice in the United States. To date, there is an estimated >400,000 patients receiving home enteral nutrition (Mundi et al., 2017). A multidisciplinary approach to patient management is key in setting up the patient for success. The team needs to ensure the patient is tolerating the EN formula and that adequate education to either the patient and/or other caregivers who will be providing support for the patient at home. Social work or Case management is involved in assessing the safety of the home environment prior to hospital discharge (Boulatta et al., 2017). Coverage for EN depends on individual insurance coverage, however Medicare and Medicaid combined make up the largest insurers to cover the cost of EN (Bonnes et al., 2017). Documentation for payment coverage must include specific parameters a patient must meet, starting with a permanent condition expecting to last >3 months, limiting the patient's ability to meet their estimated nutritional needs.

## Conclusion

EN is viewed as the safest and most efficacious method to support nutritional status in patients who are unable to eat orally. If managed properly, enteral feeding is associated with improved clinical outcomes and reduced infectious complications and is the preferred form of nutritional support.

## Part II: Parenteral nutrition

### Indications for parenteral nutrition

The use of parenteral nutrition (PN) can be considered in those situations where the GI tract is inaccessible or unsafe for enteral nutrition, a non-functional GI tract or during a period of required bowel rest (ASPEN, 2009). PN is also appropriate when it is anticipated that enteral feedings cannot begin for at least 7 days. However, PN should not be initiated if it is expected to last less than 5–7 days because risk may outweigh potential benefit of this therapy. Enteral nutrition has many advantages over parenteral nutrition and should be considered whenever possible. **Table 4** lists indications for parenteral nutrition. In general, the gastrointestinal tract should not be used in these conditions until the underlying problem is treated.

### Perioperative support in severe malnutrition

Malnutrition has been found to be associated with an increased risk of morbidity and mortality in the postoperative period. The Veteran's Affairs Parenteral Nutrition Cooperative Trial evaluated the benefits of preoperative parenteral nutrition in patients with varying degrees of malnutrition (Veterans Affairs Total Parenteral Nutrition Cooperative Study Group, 1991). Of note, an increased rate of infectious complications was seen in mildly-to-moderately malnourished patients receiving parenteral nutrition. If enteral feeding is feasible and tolerated, preoperative enteral nutrition has been found to be equally effective when used for 7–14 days or longer in malnourished surgical patients. In those postoperative patients who have developed a paralytic ileus from various causes, parenteral nutrition may be attempted if there is no return of gastrointestinal function for 7–10 days.

### Contraindications to parenteral nutrition

The main contraindication to PN includes a functional gastrointestinal tract. Other possible instances where PN would not be recommended would be when a patient is do not resuscitate (DNR) status, or in those cases where patients have unstable fluid, electrolyte, or cardiopulmonary status.

### Vascular access

PN can be infused either into the venous system centrally or peripherally. Central or peripheral access is determined by the position of the distal catheter tip. When the tip is located outside a large-caliber central vein such as the superior vena cava (SVC) or the inferior vena cava (IVC), it is considered a peripheral access device. Lower concentration of dextrose and amino acids may be given through peripheral veins (peripheral parenteral nutrition or PPN) for a short duration of therapy (less than 10–14 days). Such formulas usually do not provide the patient's full nutritional needs and may require large volumes of fluid and therefore should not be used in patients where fluid restriction is necessary (i.e., cardiac patients and renal patients). Osmolality of peripheral

**Table 4** Indications for parenteral nutrition.

#### GI tract is unsafe for enteral nutrition

- Preoperative nutrition optimization for severely malnourished patients unable to meet needs through enteral nutrition
- Severe persistent GI bleeding
- Inability to maintain or obtain enteral access

#### GI tract is non-functional

- Short bowel syndrome or severe malabsorption
- Bowel obstruction or prolonged ileus
- High output enterocutaneous fistula (>500 mL/d)
- Intestinal dysmotility
- Intestinal ischemia
- Intractable vomiting or diarrhea
- Radiation enteritis

#### Bowel rest needed

- Acute exacerbations of inflammatory bowel disease
- Graft-versus-host disease of the gut
- Severe acute pancreatitis (>7–10 days)
- Severe persistent enteritis
- Persistent chyle leak despite very low fat enteral nutrition
- Acute exacerbations of inflammatory bowel disease

Adopted from Ratliff, A., Jaroch, L., Nishnick, A., 2020. Parenteral nutrition. In: DeChicco, R.S., et al., Nutrition Support Handbook, fourth ed. The Cleveland Clinic Foundation, 88–100.

solutions needs to be less than 900 mOsm  $\text{l}^{-1}$ . Potential complications of PPN include phlebitis, infiltration, or fluid-overload issues. Frequent peripheral IV site rotations are required (usually every 48–72 h). Formulas that have higher concentrations of nutrients, thereby making them hyperosmolar, must be administered directly into the SVC or IVC to allow for rapid dilution. Some of the central catheters commonly used to deliver PN include subclavian vein catheters, peripherally inserted central catheters, subcutaneously tunneled percutaneous catheters, or implanted subcutaneous infusion ports. These delivery systems are preferred to peripheral options because they allow for maximal amounts of calories and protein per volume to be provided.

### Nutrition components of parenteral nutrition

PN is a compounded formulation, which includes protein as amino acids, energy in the form of dextrose and fats, as well as electrolytes, vitamins, minerals, and trace elements. Sterile water is added to provide necessary volume to the formula. Parenteral solutions are divided into two main categories: 3-in-1 or 2-in-1 solutions. A 3-in-1 solution, referred to as Total Nutrient Admixture, is composed of amino acids, dextrose, and lipids all combined in one bag. A 2-in-1 solution contains the mixture of amino acids and dextrose in one bag and a separate intravenous fat emulsion infusion.

### Amino acids

Amino acids yield 4 kcal  $\text{g}^{-1}$  when oxidized for energy. Amino acid solutions range from 3 to 20% concentrations. Standard amino acid solutions are a combination of essential and nonessential amino acids. Some standard amino acid solutions also contain an appreciable amount of phosphorus which should be considered when dosing electrolytes. Disease specific amino acid solutions for renal or hepatic failure are available commercially, however, evidence does not support improved outcomes with these products compared to standard solutions. Ascertaining goal protein requirements is vital in terms of maintaining lean body mass and promoting positive nitrogen balance. Degree of suspected catabolism, renal function, and hepatic function all play an important role in determining this. [Table 5](#) provides a listing of protein needs estimates based on clinical condition. Reductions in protein doses may be required in cases of hepatic encephalopathy complicating hepatic failure. Likewise, renal insufficiency may also be a situation where lower amounts of protein can be used depending on the severity of renal failure and whether dialysis is indicated. IBW should be utilized in morbidly obese individuals to estimate protein needs.

### Dextrose

Carbohydrate is the primary energy source for the human body, especially the brain. Carbohydrate calories come in the form of dextrose, which provides 3.4 kcal  $\text{g}^{-1}$  of energy when metabolized. Excessive carbohydrate administration is associated with increased infections, hepatic steatosis, hyperglycemia and increased carbon dioxide production. To minimize these complications, the maximum parenteral carbohydrate infusion rate should be 7 mg/kg/minute in hospitalized patients and 4–5 mg/kg/minute in the critically ill patient ([McClave et al., 2016](#)) ([Table 6](#)).

### Lipid emulsions

Parenteral nutrition formulas contain lipid emulsions as a source of fat calories that prevents essential fatty acid deficiency (EFAD). In US, the lipid formulations are mostly composed of n-6 long-chain fatty acids derived from vegetable oils. Intravenous fat emulsion provides 10 kcal  $\text{g}^{-1}$  of energy due to the addition of the glycerol molecule. Lipids are contraindicated in patients with significant hypertriglyceridemia. It is recommended that intravenous fat emulsion be held or limited from the parenteral nutrition regimen if serum triglyceride concentration exceeds 400 mg/dL. Withholding lipid emulsions greater than 2 weeks is not advised due to increased risk of essential fatty acid deficiency ([Hamilton et al., 2006](#)). Since ILE contains egg yolk phospholipids, it is contraindicated in the rare instance of documented egg allergy. In this case, safflower or sunflower oil can be administered topically or enterally ([Miller et al., 1987](#)). Two polyunsaturated fatty acids, linoleic and  $\alpha$ -linolenic, cannot be synthesized by the body and are therefore considered essential in that they have to be brought into the body via diet. Thus, to prevent essential fatty acid deficiency, 1–2% of daily energy requirements should be derived from linoleic acid and approximately 0.5% of energy from linolenic

**Table 5** Estimation of protein needs.

BMI	g protein/kg ABW
<25	1.5–2
25–29.9	1.3–1.7
30–34.9	1.2–1.6
≥35	1.1–1.5

Adopted from Nutrition requirements. In: Coughlin, K. (Ed.), Cleveland Clinic Nutrition Support Handbook. 35–38.

**Table 6** Determination of energy needs.

<i>Condition</i>	<i>Need (kcal kg<sup>-1</sup>)</i>

Maintenance	25
Undernourished	30
Stressed/critically ill	25

acid. Clinical manifestations of essential fatty acid deficiency are important to recognize and include scaly dermatitis, dermatitis, alopecia, hepatomegaly, thrombocytopenia, fatty liver, and anemia.

### Electrolytes

Electrolytes are added as salts to PN solutions depending on the patient's requirements for daily maintenance and to replace losses (Table 7). Sodium and potassium can be added as chloride or acetate salts, depending on acid-base needs. In general, acetate and chloride content of the solution should be adjusted carefully because they help to maintain the acid-base balance. Also, calcium and phosphorus concentrations must be watched closely to prevent precipitation. Many factors may influence the solubility of these electrolytes in the PN solution, including the concentration of electrolytes, the pH of the final formula, temperature, and the presence of other components. Fluid and electrolyte status can be maintained utilizing standard intravenous (IV) fluids along with additional oral or IV replacements.

### Vitamins

Multivitamin preparations, including both water- and fat-soluble vitamins, are available for inclusion in the PN formulation. Available parenteral multivitamin products for adults contain 12 or 13 known vitamins (with or without vitamin K). Table 8 lists the composition of standard adult multivitamin products. Iron is not usually added to PN solutions because it can result in destabilization of the lipid emulsion. However, addition of iron in the form of iron dextran can be administered with 2-in-1 solution. A test dose of the iron should be given separately initially to ensure that there is no adverse reaction before it is incorporated routinely into a 2-in-1 bag.

### Trace elements

Commonly used trace elements in PN formulas include zinc, selenium, manganese, copper, and chromium. Intravenous trace element preparations are available as single component products as well as a variety of combination products. Table 9 provides a list of the doses of trace elements in a common combination product. The commercially available multiple trace element combinations in the US contain three-to five-times the recommended doses for manganese, and this is important to keep in mind in those patients on long-term PN.

### Titration of volume

Final volume can be titrated by the addition of sterile water for injection. Concentrated substrates may be used to minimize volume in those situations where patients need to be volume restricted. Typical PN volumes range from 800 to 2500 mL daily.

**Table 7** Daily electrolyte requirements for patients receiving nutrition support.

<i>Electrolyte</i>	<i>Parenteral</i>
Sodium	1–2 mEq/kg
Potassium	1–2 mEq/kg
Chloride	As needed to maintain acid-base balance
Acetate	As needed to maintain acid-base balance
Calcium	10–15 mEq
Magnesium	8–20 mEq
Phosphorus	20–40 mmol

Note: General ranges for safe administration in healthy people with normal losses.

Adopted from Krishnan, K., Meyer, S., Wolford, M., 2020. Parenteral nutrition. In: DeChicco, R.S., et al., Nutrition Support Handbook, fourth ed. The Cleveland Clinic Foundation, 88–100.

**Table 8** Contents of parenteral multivitamin preparations.

<i>Vitamin component</i>	<i>Current FDA requirement (2020)</i>
Vitamin A	900 mcg RAE
Vitamin D	20 mcg
Vitamin E	15 mg alpha- tocopherol
Vitamin K	120 mcg
Vitamin C	90 mg
Folate	400 mcg DFE
Niacin	16 mg NE
Vitamin B <sub>2</sub>	1.3 mg
Vitamin B <sub>1</sub>	1.2 mg
Vitamin B <sub>6</sub>	1.7 mg
Vitamin B <sub>12</sub>	2.4 mcg
Pantothenic acid	5 mg
Biotin	30 mcg

Note- General ranges for safe administration in healthy people with normal losses. Needs for pregnant or lactating women may be higher.

**Table 9** Contents of a common parenteral trace element preparation (Tralement®).

<i>Component</i>	<i>Dose</i>
Zinc	3 mg
Copper	0.3 mg
Manganese	55 mcg
Chromium	0 mcg
Selenium	60 mcg

### Parenteral nutrition monitoring

Careful evaluation and monitoring of patients is essential to provide optimal nutritional therapy while avoiding complications. Changes in patient clinical condition necessitate frequent reassessment. The possibility of enteral feeding should continue to be readdressed. Moreover, as parenteral nutrition is transitioned to enteral intake, tolerance should be closely monitored, allowing for weaning and eventual discontinuation. Initial laboratory measurements should include liver chemistries, electrolyte levels, as well as renal profile. Electrolytes including calcium, magnesium, and phosphorus should be monitored daily (Misra and Kirby, 2000). Volume status is also an important parameter and intake and output should be continuously assessed. Physical exam signs looking for evidence of volume overload include weight gain, increasing swelling of the extremities, ascites, and pulmonary congestion. Likewise, tachycardia, low blood pressure, poor skin turgor, and dry mucous membranes may indicate hypovolemia. Increased losses such as urine, diarrhea, nasogastric output, emesis, fistula, and drains should also be considered. Blood glucose levels should be monitored to follow any hyper or hypoglycemia. Coverage with subcutaneous sliding-scale insulin is frequently utilized to manage hyperglycemia; however, separate intravenous insulin infusion or the addition of insulin as a component of the total parenteral nutrition (TPN) could also be done.

### Cyclic parenteral nutrition

When initiating PN in an acutely ill patient, continuous infusion over 24 h is started. Once the patient has demonstrated stability on a given formula by way of physical exam, clinical parameters such as weight, volume status, and ins/outs as well as labs such as electrolyte balance and nutritional parameters, the patient can then be cycled to have the same volume of solution run over a shorter time frame (for example 12 h at night). Infusion pumps can aid in programming desired volumes and administration times. Although cycling does allow the patient to have more flexibility and therefore lead to a more active lifestyle, limitations include fluid or glucose intolerance. Abrupt cessation of the infusion may be associated with rebound hypoglycemia due to circulating insulin; therefore, the rate of administration is often tapered down at the end of the cycle to allow for downregulation of pancreatic release of insulin.

## Complications of parenteral nutrition

### Catheter occlusion/thrombosis

Catheter occlusion is the most common noninfectious complication associated with long-term venous access. Symptoms of a catheter-related venous thrombosis include vein distension, edema, tingling, or pain over the ipsilateral arm and neck, and a prominent venous pattern over the anterior chest. It may require thrombolytic treatment or line replacement. Parenteral formulas with inappropriate calcium/phosphate ratios favoring precipitation as well as lipid residue collecting within the catheter lumen can also create occlusion. Catheter flushing protocols should be followed closely to prevent the risk of occlusion. Kinking of the catheter tubing or angulation of the catheter can also contribute. Pinch-Off Syndrome refers to the compression of a subclavian vein central venous catheter (CVC) between the clavicle and the first rib resulting in an intermittent or permanent catheter obstruction. Findings are confirmed by venogram and/or chest radiograph and requires catheter replacement.

### Infection

Catheter-related bloodstream infections (CRBSI) are another serious, and common complication of PN. The CDC recently estimated 250,000 cases of CRBSI annually in the US. Moreover, there was an average of 5 cases per 1000 catheter days and mortality ranged between 12% and 25% for these infections. Infection with fungal pathogens has an extremely high rate of mortality, ranging from 30% to 60%. Fever and unexplained hyperglycemia can herald the presence of a catheter-related infection. When a CRBSI is suspected, blood cultures should be obtained from each lumen of the catheter as well as the peripheral blood before antibiotics are started. The most common infective micro-organisms are coagulase negative staphylococci, *Staphylococcus aureus*, *Klebsiella*, *Candida*, and *Enterobacter* (Mermel et al., 2009). Treatment of CRBSI typically include the removal of the catheter as well as antibiotic or antifungal therapy. In those patients on long-term home PN with limited venous access, catheter salvage is certainly important and can be considered with the help from an infectious disease specialist. PN should be held if an infection is suspected to prevent worsening bacteremia due to infusion of hypertonic dextrose and other nutrients. A 5% dextrose solution can be given instead through a peripheral line until the infection has been adequately treated.

### Metabolic

Metabolic complications are seen in 5–10% of patients on PN. Hyperglycemia is the most common complication and is typically related to the proportion of dextrose in the formulation, but other contributing factors include stress due to acute illness or sepsis, steroid use, postoperative period, diabetes, and pancreatitis. Excess sugar through PN can lead to hepatic steatosis, increased carbon dioxide production, and adverse outcomes. Blood glucose levels should be monitored very closely and a sliding-scale coverage of regular insulin can be used for elevated levels. Two-thirds of the total amount of sliding-scale insulin required over 24 h can be added to the next day's parenteral nutrition formulation. However, hypoglycemia can result from the abrupt cessation of parenteral nutrition. To decrease the risk of rebound hypoglycemia, a 1–2 h taper down of the rate of parenteral nutrition may be required. Alternatively, if the infusion is abruptly stopped, a 5% or 10% dextrose infusion should be utilized for at least an hour once the parenteral nutrition infusion is discontinued to avoid a possible rebound hypoglycemia. To avert hypertriglyceridemia, intravenous fatty emulsion intake should be limited to less than 30% of total calories or 1 g/kg/d. Hypertriglyceridemia may increase the risk of pancreatitis, particularly in those with triglyceride levels greater than 1000 mg dL<sup>-1</sup>. It is generally recommended that lipid infusion be discontinued when serum triglyceride concentration exceeds 400 mg dL<sup>-1</sup>. Electrolyte disturbances also commonly occur and warrant close clinical evaluation. Lower concentrations or even elimination of selected electrolytes from parenteral nutrition are indicated in patients with renal failure. Refeeding syndrome is another metabolic complication seen in malnourished patients (Solomon and Kirby, 1990). The rapid delivery of calories in the form of carbohydrates stimulate insulin secretion, which causes an intracellular shift of phosphorus, magnesium, and potassium. Clinically, the patient develops symptoms of generalized fatigue, lethargy, muscle weakness, edema, cardiac arrhythmia, and hemolysis. Prevention of this phenomenon is achieved by identifying individuals at risk, repleting electrolytes before PN initiation, and slow caloric advancement of PN with daily monitoring of electrolytes.

### Hepatic injury

There are three types of hepatobiliary conditions that are associated with PN. Steatosis is a benign disorder that is seen in the setting of overfeeding and characterized by fat accumulation in the liver. Most patients are asymptomatic and usually transaminases are mildly elevated. Progression to fibrosis and subsequently cirrhosis may rarely occur in long-term PN. Parenteral-associated cholestasis is characterized by impaired bile secretion or biliary obstruction and presents as an elevation of alkaline phosphatase,  $\gamma$ -glutamyl transpeptidase, and conjugated (direct) hyperbilirubinemia (Guglielmi et al., 2008). Lastly, lack of enteral feeding that results in decreased cholecystokinin release, which leads to impaired bile flow and gallbladder contractility, causes the development of gallstones and gallbladder sludge with subsequent cholecystitis. The duration of PN therapy appears to correlate with the development of biliary sludge. When a patient on PN develops hepatic complications, a trial of decreasing calories to avoid overfeeding should be considered. A balanced carbohydrate:fat ratio needs to be obtained with approximately 70–85% of non-protein calories supplied as carbohydrates and 15–30% as fat. In addition, carbohydrate content should not exceed 7 g/kg/day in adults. Infusing cyclic PN rather than as a 24 h infusion may also reduce the risk of liver injury. Early transition to enteral or oral feedings should be optimized, as small amounts of intake would promote enterohepatic circulation of bile acids.

### Metabolic bone disease

There is a high prevalence of metabolic bone disease in patients on long-term PN which contributes to an increase in morbidity due to fracture risk. Metabolic bone disease may develop due to underlying disease, inadequate intake of calcium particularly because the amount that can be included into the parenteral nutrition formulation is physically limited due to risk of precipitation and hypercalciuria. Higher protein levels in parenteral formula further enhance hypercalciuria, therefore reducing protein intake to maintenance doses (0.8–1 g/kg/d) is recommended (Seidner, 2002). Both vitamin D deficiency and excess can be contributing factors. Calcium balance and phosphorus levels also play a critical role in the development of metabolic bone disease. For selected long-term PN patients, treatment with bisphosphonates along with calcium and vitamin D supplementation should be considered to prevent complications. An increase in weight-bearing activity and avoiding corticosteroids may also be useful. Careful attention to magnesium, phosphorus, and calcium concentrations in the PN solution and establishing a good acid–base balance is also critical to prevent metabolic bone disease.

### Home parenteral nutrition

Home PN is a viable option when it has been determined that a hospitalized patient on PN is not able to advance to enteral or oral feedings and is otherwise stable. The patient and/or caregiver should be taught to administer PN safely utilizing sterile technique, in addition to actively watching for signs of infection, fluid imbalances, or other complications. Cycling PN to 12 h/day provides increased mobility and flexibility and helps minimize hepatobiliary complications.

### Conclusions

Parenteral nutrition can be a lifesaving therapy for individuals who are unable to utilize their gastrointestinal tract for a prolonged time. Patients and caregivers should be appropriately evaluated and educated to help prevent complications associated with PN. Management of PN is most effective when done through a multidisciplinary approach, utilizing the expertise of physicians, pharmacists, dietitians, nurses, case managers, and social workers.

### Documenting Possible Food Allergies

The diagnosis of food allergy is made from the history, supported by investigations and by responses to avoidance of specific food triggers. Because the value of investigations is limited, it is especially important to obtain a clear history. There are a number of practical points to be made:

- *Speed of onset*: In general, the quicker the onset of the allergic reaction, the more reliable is the history. If a child develops a violent allergic reaction within a minute or two after ingesting a food, it is much easier to link the reaction to a specific food than if a reaction only occurs hours or days after eating a food.
- *Coincidences need to be excluded*: If a child becomes unwell (e.g., starts wheezing) an hour after eating a specific food, the wheezing could be caused by the food, or it could just be a coincidence. The more times that such a sequence has been observed, the more likely it is that there is a cause and effect relationship.
- *Observations need to be tested for internal consistency*: Someone may believe that he or she is allergic to a food if a symptom (e.g., urticaria) occurs on (say) three occasions after eating a specific food. It is important to find out the following:
  1. Whether the subject has had the same symptoms on other occasions when the suspect food trigger was not taken.
  2. Whether the subject has taken the suspect food on one or more other occasions without any adverse effects.

Failure to seek inconsistencies such as these is one factor that is responsible for the overdiagnosis of food allergy.

## Documenting a Diagnosis of Food Allergy

If it is reported that someone is allergic to an item, it is important to probe further and find out on what basis the person has been deemed allergic. It is common to find children and adults who are believed to be allergic to a food solely on the basis of tests such as skin tests or blood tests, which are in fact almost wholly unreliable (see below). It is also common for people to believe that they are allergic to something because a health professional said so one day, which on further enquiry turns out to be on flimsy or non-existent grounds.

Another common problem is the misinterpretation of a sequence of events. For example, a child with an ear infection is given an antibiotic, and 3 days later gets diarrhea, so the parents come to believe the child is allergic to the antibiotic. In fact the cause of the diarrhea is far more likely to be either an underlying viral infection, or a disturbance of the gut flora. Another example is the report of a child who is believed to be allergic to sesame seeds because of the reactions occurring after eating buns coated with sesame seeds; many such children are in fact not allergic to sesame seeds but are reacting to the egg glaze that has been used as an adhesive for the seed coating. Another common example is the child with asthma who coughs and wheezes after drinking a diluted orange squash drink, with the result that it is believed that the child is reacting to the yellow-orange coloring agent tartrazine. In fact such reactions are more likely to be due to sulfite preservatives in the squash; sulfites trigger symptoms in 60% or more of children with asthma.

## Practical Diagnostic Difficulties

### Multiple Mechanisms

Reactions to foods are a heterogeneous group of disorders caused by a variety of different immunological and pharmacological mechanisms. In any individual case, the precise mechanism is often not known. No single type of laboratory test could possibly cover all the different types of possible mechanisms of reactions to foods. Even if one focuses on food allergy, there are a number of different possible immunological mechanisms, including IgE antibody mediated, cell mediated, and circulating immune complexes.

### Inability to Predict Outcome

In many situations (e.g., atopic disease), the subject wants to know whether there will be any benefit from food avoidance (e.g., not drinking cows' milk or not eating apples). Even if there were valid tests for the diagnosis of food intolerance, the outcome of avoidance measures depends on a number of other variables. Allergen avoidance may succeed for the following reasons:

- (1) the patient was intolerant to the item; (2) coincidental improvement; (3) placebo response.

The reasons why a trial of food avoidance may fail to help can be summarized as follows:

(1) The subject is not allergic to the food. (2) The period of elimination was too short. For example, where a child has an enteropathy (damage to the small intestine) due to food allergy, it may take a week or more for improvement in symptoms to occur. (3) The food has been incompletely avoided. This may happen in a subject supposedly on a cows' milk protein-free diet who still continues to receive food that contains cows' milk proteins such as casein or whey. (4) The subject is allergic to other items, which have not been avoided. For example, a child with an allergy to cows' milk protein who fails to improve when given a soy-based milk to which they also have an allergy. (5) Coexisting or intercurrent disease, for example, gastroenteritis in a child with loose stools who is trying a cows' milk-free diet. (6) The patient's symptoms are trivial and have been exaggerated or do not exist at all and have either been imagined or made up by the parents. It is unrealistic to expect there to be a simple test that can overcome all these problems.

## Diagnostic Tests

### Skin Prick Tests

The principle of skin prick tests is that the skin weal and flare reaction to an allergen demonstrates the presence of mast-cell-fixed antibody, which is mainly IgE antibody. IgE antibody is produced in plasma cells, and is distributed in the circulation to all parts of the body, so that sensitization is generalized and therefore can be demonstrated by skin testing. In the presence of specific IgE antibody, mast cells in the skin release histamine, which in turn causes a visible weal and flare reaction in the skin.

The procedure involves a drop of allergen solution being placed on the skin, which is then pricked with a hypodermic needle. Two control solutions should also be used: the diluent, in order to detect false-positive reactions; a positive control (e.g., a histamine solution), to enable comparison with a positive result of an allergen solution. The skin prick test induces a response that reaches a peak in 8–9 min for histamine and 12–15 min for allergens. The size of the weal reaction (and not the larger red flare) is measured.

There are numerous problems with skin prick tests, including the following:

1. There is no agreed definition about what constitutes a positive reaction.
2. The size of the weal depends to some extent on the potency of the extract.

3. Antihistamines and tricyclic antidepressants suppress the histamine-induced weal and flare response of a skin test. The suppressive effect of antihistamines may last from a week up to several months for some of the more recently introduced non-sedating antihistamines.
4. *False-positive tests:* Skin prick test reactivity may be present in subjects with no clinical evidence of allergy or intolerance. This is sometimes described as 'asymptomatic hypersensitivity' or 'subclinical sensitization.' Whilst many with positive skin prick tests will never develop the allergy, some subjects with positive skin prick tests do develop symptoms later. However, since the test cannot identify those who are going to develop symptoms, the skin test information is of no practical value.
5. *False-positive results:* Skin prick test reactivity may persist after clinical evidence of intolerance has subsided. For example, in a study of children with egg allergy, it was noted that five out of 11 who grew out of egg allergy had persistently positive skin prick tests after the allergy had disappeared.
6. *False-negative tests:* Skin prick tests are negative in some subjects with genuine food allergies.
7. Skin prick tests mainly detect IgE antibody. However, many adverse reactions to food are not IgE mediated, in which case skin prick tests can be expected to be negative. Taking cows' milk protein intolerance as an example, patients with quick reactions often have positive skin prick tests to cows' milk protein, but those with delayed reactions usually have negative skin prick tests.
8. False-negative results are a problem in infants and toddlers, when the weal size is much smaller than later in life.
9. There is a poor correlation between the results of provocation tests (e.g., double-blind food challenges) and skin prick tests. For example, in one study of 31 children with a strongly positive (weal >3 mm in diameter) skin prick test to peanut, only 16 (56%) had symptoms when peanuts were administered.
10. Commercial food extracts (sometimes heat treated) and fresh or frozen raw extracts may give different results (more positives with raw foods), reflecting the fact that some patients are allergic to certain foods only when taken in a raw state. In others the reverse is the case.

Skin prick tests are mainly used in research studies. The results of skin tests cannot be taken alone, and standard textbooks on allergy acknowledge that "the proper interpretation of results requires a thorough knowledge of the history and physical findings." The problems in clinical practice are, for example, whether or not a subject with atopic disease (eczema, asthma, or hay fever) or symptoms suggestive of food intolerance will benefit from attempts to avoid certain foods or food additives. However, skin prick test results are unreliable predictors of response to such measures.

Skin test results are known to be misleading in cases of inhalant allergy (e.g., allergy to dust mites or grass pollen) but skin prick tests for food allergy are especially unreliable because of the large number of false-positive and false-negative reactions.

### Intradermal Testing

Intradermal testing comprises the intradermal injection of 0.01–0.05 ml of an allergen extract. It can cause fatal generalized allergic reaction (anaphylaxis), and is only performed if a preliminary skin prick test is negative. Intradermal tests are more sensitive than skin prick testing, and hence also produce even more false-positive reactions, making the interpretation of the results of intradermal testing even more difficult than that for skin prick testing. The difficulty in interpretation of the results, the pain of intradermal injections, and the risk of anaphylaxis mean that intradermal testing has no place in the routine investigation of food allergy.

### Skin Application of Food before Food Challenges

There is one situation where direct application of food to the skin may be of practical value, and that is before a food challenge in a child in whom one fears an anaphylactic reaction. An example might be a 6-month-old infant with a history of a severe allergic reaction to egg. If the parents wish to see if the child has outgrown the allergy without directly administering egg and risking a violent reaction, a simple approach is to rub some raw egg white into the skin and observe the skin for a few minutes. If the skin application of egg in this way causes an urticarial reaction, then a gradual diminution and disappearance of this response during the succeeding months and years can probably be taken to indicate the development of tolerance, and a continuing brisk response to skin contact would constitute a deterrent to an oral challenge. However, this is only an approximate guide, and there are a number of possible reasons why such testing may give false-positive (e.g., using a raw food when the food is usually eaten cooked, such as egg or potato) or false-negative (e.g., the child is receiving antihistamine drug) results.

### Tests for Circulating IgE Antibodies: The Radioallergosorbent (RAST) Test

The RAST test is the best known of a number of laboratory procedures for the detection and measurement of circulating IgE antibody. Unfortunately, the clinical interpretation of RAST test results is subject to most of the same pitfalls as that for skin prick testing. Additional problems with RAST tests are the cost, and the fact that a very high level of total circulating IgE (e.g., in children with severe atopic eczema) may cause a false-positive result. Depending on the criteria used for positivity, there is a fair degree of correlation between the RAST test and skin prick test results.

## Provocation Tests

A provocation test may be useful to confirm a history of allergy. An example might be a child who developed wheezing and urticaria minutes after eating a rusk that contained, as its main ingredients, wheat and cows' milk protein. To determine which component, if any, caused the reaction, oral challenges with individual components can be conducted.

However, the results of provocation tests cannot prove that improvement in a disease has been caused by food avoidance. For example, a child with atopic eczema is put on a diet avoiding many foods, and the eczema improves. This improvement could be a coincidence, a placebo effect, or due to the diet. Just because the child is shown to react to a single food does not prove that avoidance of that food was the cause of the improvement.

### Open and Blind Challenges

Where the subject and the observer knows the identity of the administered material at the time of the challenge, the procedure is said to be an 'open' challenge. In a 'single-blind challenge' the observer but not the patient or family know the identity of the test material. To avoid bias on the part of the observer, a double-blind challenge is required. A 'double blind' challenge involves exposing the subject to a challenge substance, which is either the item under investigation or an indistinguishable inactive (placebo) substance. Neither the subject nor the observer knows the identity of the administered material at the time of the challenge or during the subsequent period of observation.

### The Purpose of Provocation Tests

The aim of a food challenge is to study the consequences of food or food additive ingestion. Provocation tests are helpful in the following ways:

(1) to confirm a history (parents' observations of alleged food allergy are notoriously unreliable, as are adults' beliefs about their own allergies); (2) to confirm the diagnosis, for example, of cows' milk protein allergy in infancy, where the diagnostic criteria include improvement on elimination diet and relapse on reintroduction; (3) to see if a subject has grown out of a food intolerance; (4) as a research procedure. The food challenge should replicate normal food consumption in terms of dose, route, and state of food. It should also be performed in such a way that the history can be verified. Thus, for example, there is no point solely looking for an immediate reaction if the parents report a delayed reaction.

Open food challenges are the simplest approach, but open food challenges run the risk of bias influencing the parents' (or doctors') observations. Often this is unimportant. But in some cases belief in food intolerance may be disproportionate, and where this is suspected there is no substitute for a double-blind placebo-controlled challenge. An open challenge may be an open invitation to the overdiagnosis of food intolerance. For example, in the UK parents widely believe that there is an association between food additives and bad behavior, but in one series, double-blind challenges with tartrazine and benzoic acid were negative in all cases in a study of 24 children with a clear parental description of adverse reaction.

The double-blind placebo-controlled challenge is regarded as the state-of-the-art technique to confirm or refute histories of adverse reactions to foods. The ability to unravel food-related problems is said to be limited only by the imagination of the physician and a clever dietitian. In fact, the technique is subject to a number of potential limitations, not all of which can be overcome.

### Effect of Dose

In some cases of food intolerance, minute quantities of food (e.g., traces of cows' milk protein) are sufficient to provoke florid and immediate symptoms. In other cases, much larger quantities of food are required to provoke a response. Hill *et al.* demonstrated that whereas 8–10 g of cows' milk powder (corresponding to 60–70 ml of milk) was adequate to provoke an adverse reaction in some patients with cows' milk protein allergy, others (with late onset symptoms and particularly atopic eczema) required up to 10 times this volume of milk daily for more than 48 h before symptoms developed.

### Concealing Large Doses is Difficult

Standard capsules that contain up to 500 mg of food are suitable for validation of immediate reactions to tiny quantities of food, but concealing much larger quantities of certain foods (especially those with a strong smell, flavor, or color) can be very difficult.

### Route of Administration

Reactions to food occurring within the mouth are likely to be missed if the challenge by-passes the oral route, e.g., administration of foods in a capsule or via a nasogastric tube. In practice, patients whose symptoms are exclusively confined to the mouth are unusual, and where there is a history of purely oral reactions an alternative challenge procedure can be employed. In subjects who are intolerant to sulfites, it is well recognized that the administration of sulfites in capsules or directly into the stomach via a nasogastric tube usually fails to provoke an adverse reaction, whereas the oral administration of solution will succeed in doing so.

### Problems with Capsules

Capsules are unsuitable for use in children who cannot swallow large capsules, and this is a major limitation as most cases of suspected food allergy are in infants and toddlers. Furthermore, it is unsatisfactory to allow patients or parents to break open capsules and mix the contents with food or drink, as the color (e.g., tartrazine) or smell (e.g., fish) will be difficult or impossible to conceal and the challenge will no longer be blind.

### Anaphylactic Shock Danger

There is a danger of producing anaphylactic shock, even if it had not occurred on previous exposure to the food. For example, in Goldman's classic study of cows' milk protein intolerance, anaphylactic shock had been noted before cows' milk challenge in five out of 89 children, but another three developed anaphylactic shock as a new symptom after cows' milk challenge. In a study of 80 children with atopic eczema treated with elimination diets, anaphylactic shock occurred in four out of 1862 food challenges. The risk appears to be greatest for those who have received elemental diets.

### Effect of Disease Activity

A food challenge performed during a quiescent phase of the disease (e.g., urticaria, eczema, or asthma) may fail to provoke an adverse reaction.

### Additive Effect of Triggers

Although some patients react repeatedly to challenges with single foods, it is possible (but unproven) that some patients only react adversely when multiple allergens are given together. There certainly are some subjects who only react in the presence of a nonfood trigger, such as exercise or taking aspirin.

### Special Types of Provocation Testing

Other than giving a suspect food by mouth, and asking the subject to swallow it, there are some alternative approaches, which are outlined below.

#### Oral Mucosal Challenge

A small portion of food is applied to the mucosa inside the mouth, and one looks for reactions such as swelling of the lips, and tingling or irritation of the mouth or tongue, possibly followed by other more generalized symptoms such as urticaria, asthma, vomiting, abdominal pain, or anaphylactic shock. Patients with food intolerance commonly make use of these oral symptoms, spitting out and avoiding further consumption of a food that provokes the symptom.

#### Gastric Mucosal Challenge

In this procedure, an allergen is applied directly to the gastric mucosa via an endoscope, and the mucosa is then observed for signs of a reaction. In addition, it is possible to take biopsies of the gastric mucosa to study the histological changes and measure the tissue concentration of mediators of inflammation such as histamine.

#### Rectal Challenges

The standard test to confirm a diagnosis of celiac disease is the jejunal biopsy, in which a small portion of jejunal mucosa is obtained with the aid of a special capsule that is swallowed, and which passes into the small intestine. When in the correct location, the capsule is triggered and withdrawn; it contains a portion of intestinal mucosa, which can then be examined under the microscope. Alternatively, gluten can be instilled into the rectum, in order to look for a reaction that would signify celiac disease. This procedure requires multiple biopsies from the rectum, and it is uncertain whether the results are reliable.

## Management

### Dietary Elimination

The management of food allergy consists largely of elimination from the diet of the trigger food or foods. Elimination diets are used either for the diagnosis or the treatment of food intolerance, or for both. A diet may be associated with an improvement in symptoms because of intolerance to the food, a placebo effect, or the improvement may have been a coincidence. The degree of avoidance that is necessary to prevent symptoms is highly variable. Some patients are intolerant to minute traces of food, but others may be able to tolerate varying amounts. Strict avoidance and prevention of symptoms are the aims in certain instances, but in many cases it is unknown whether allowing small amounts of a food trigger could lead to either enhanced sensitivity or to the reverse, increasing tolerance. The duration required for dietary avoidance varies. For example, intolerance to food additives may last only a few years, whereas intolerance to peanuts is usually lifelong. Although food allergy is common in children, most have grown out of the problem by the age of 5 years; an important exception is those with nut allergy.

### Malnutrition

Malnutrition is a major risk of unsupervised diets.

### Calcium

Cows' milk is an important source of calcium, and avoidance of cows' milk and its products carries the risk of an inadequate intake of calcium. Unfortunately, it is far from clear what constitutes an adequate intake for various different age groups.

### **Protein and Energy**

Milk, eggs, fish, meat, wheat, and their respective manufactured food products are important sources of protein and energy. Avoidance of these without the provision of alternative sources of protein and energy runs the risk of an inadequate intake, and growth failure, serious malnutrition, and weight loss are well documented sequelae of unsupervised and inappropriate dietary elimination.

### **Iodine**

Cows' milk and dairy products are important sources of dietary iodine. Exclusion of cows' milk products and a number of other items from the diet, coupled with the consumption of large amounts of soy milk, which has been reported to cause hypothyroidism by increasing fecal loss of thyroxine, have resulted in hypothyroidism and growth failure due to dietary iodine deficiency.

### **High-Risk Factors**

The risk of malnutrition from an elimination diet is particularly high in the following situations:

(1) The diet is not supervised by a dietitian. (2) There is chronic disease before diagnosis, or concurrent chronic disease such as severe atopic eczema. The subject's nutrient requirements may be increased. (3) Malabsorption or enteropathy increases the risk of malabsorption of nutrients. (4) The subject is avoiding sunlight. The risk of vitamin D deficiency may compound the effects of a low calcium intake. (5) The subject is already on a diet that excludes multiple foods, e.g., vegan or macrobiotic diet.

## **The Role of the Dietitian**

The dietitian has three roles in the management of elimination diets. One is to ensure that the resulting diet is nutritionally adequate, and to prevent potential deficiency states by recommending (in an infant) appropriate amounts of infant milk formula, and (in older children or adults) supplements of calcium, vitamins, and so on. Another role is to advise how to avoid specific foods, particularly those contained in manufactured foods. Third, the dietitian makes suggestions as to how to make the diet practical and palatable, and suggests recipes for use with a limited range of foods (e.g., how to make biscuits with potato flour).

### **Cows' Milk Protein Avoidance**

Any form of cows' milk, whether fresh, skimmed, condensed, or evaporated, needs to be avoided. Also forbidden are milk products that contain casein, whey, and nonfat milk solids. Where milk substitutes are required, the choice lies between formulas based on soy protein, casein hydrolysate, or whey hydrolysate. Soya formulas are cheaper, but unsuitable for those who are also intolerant to soya.

Butter, margarine, cream, cheese, ice cream, and yogurt all need to be avoided. Fats that can be used instead include margarines made from pure vegetable fat (e.g., Tomor) and lard. Caution is required with baby foods, as a large number of manufactured products, e.g., rusks, contain milk protein. A common trap is the so-called 'vegetarian' cheese, often wrongly believed to be safe for subjects with cows' milk allergy. In fact, it differs from ordinary cheese only in the use of nonanimal rennet and is unsuitable for people with cows' milk allergy. Meat, game, and poultry are all allowed, but sausages and pies should be avoided unless it is known that they are milk free. Intolerance to cows' milk protein is not a reason to avoid beef. Eggs are allowed, but not custard or scrambled egg, which may contain milk. Fish is permitted, unless it is cooked in batter (which unless otherwise stated should be assumed to contain milk) or milk. Lemon curd, chocolate spread, chocolate (unless stated to be milk-free), toffee, fudge, caramels, and butterscotch are all unsuitable. All ordinary cereals (e.g., oats) are allowed, but caution is required with manufactured breakfast cereals, some of which contain milk powder.

It is essential to check the list of ingredients on the label of any manufactured foods. There is a special problem with unwrapped foods, because there is no label of ingredients. Examples include bread, sausages, or confectionery.

### **Egg Avoidance**

Eggs (both the white and the yolk) and all products that contain egg or albumen must be avoided. As well as hen's eggs, eggs of other birds such as geese, turkeys, and quails must be avoided. Eggs are widely used to make cakes and are sometimes used in the manufacture of bread. Egg wash or glaze is commonly brushed on to the surface of rolls, buns, or baps, and also bread, cakes, and pastry used in puddings (e.g., apple pie). Sweets can be a hazard because they are usually sold without information about ingredients, and egg is included in several products.

Mayonnaise normally contains egg; custard usually does not, with the exception of egg custard and egg custard tarts. Eggs are an essential ingredient of souffles and certain sauces, such as Bearnaise or Hollandaise sauce.

Egg allergy is not a reason to avoid eating chicken.

### Soy Avoidance

The major difficulty is mass-produced bread, because in the UK soy is often included as an ingredient in flour. Soy is also found in manufactured products that contain hydrolyzed or textured vegetable protein, and minced beef, which unless described as 'pure beef' has been known to include quantities of soy protein.

### Wheat-Free and Gluten-Free

These terms cause confusion; they are not interchangeable. Subjects who are allergic to wheat cannot tolerate foods that contain any type of wheat. Subjects with celiac disease can tolerate all wheat proteins other than the gluten fraction.

### Peanut Avoidance

Peanut is also known as groundnut or arachis, so these three names need to be sought on labels of manufactured foods as well as some pharmaceutical products. The difficulty comes with 'vegetable oil,' which may include peanut oil; only by writing to the manufacturer of individual products can the composition of the vegetable oil be determined. It is not known to what extent subjects with peanut allergy should avoid peanut oil. Most peanut oil used in food manufacture is highly refined, and contains only very minute quantities of peanut protein. In a number of small-scale studies, subjects with peanut allergy were found not to react when given highly refined peanut oil. However, it remains possible that such oil contains traces of protein sufficient to result in enhanced reactivity, such that when the subject does ingest peanut accidentally the reaction is worse than previously. On this basis, subjects with peanut allergy should really be advised to avoid peanut oil.

### Drug Treatment in the Management of Food Allergy

At present, drug treatment has little part to play in the management of food allergies. There are two exceptions. First, there are a very small number of cases in which the reaction to a food is exclusively gastrointestinal, and in whom the reaction can be blocked by taking the drug sodium cromoglycate by mouth 20 min before the trigger food is swallowed. Second, there are a small number of individuals who develop the life-threatening reaction, of anaphylactic shock when exposed to a trigger food. There are three ways in which anaphylactic shock may prove fatal. First, rapid swelling of the soft tissues in the pharynx may completely obstruct the airway; the treatment is to bypass the obstruction, either by passing an endotracheal tube, or by performing a tracheostomy. Another mechanism is severe shock, with a profound drop in blood pressure; the life-saving treatment is to restore the circulating volume with intravenous fluids and to give oxygen. The third mechanism is severe bronchoconstriction (asthma); here, the life-saving treatment is with bronchodilator drugs and artificial ventilation. If patients with life-threatening anaphylactic shock are to be saved, they must be given urgent (within minutes) medical attention. For individuals who have already experienced a life-threatening allergic reaction to a food, it is a common practice to provide them with a syringe preloaded with adrenaline (epinephrine), with the aim that this should be administered while waiting for medical help. Unfortunately, self-administered adrenaline is not without its hazards (e.g., inadvertent intravenous administration causing fatal cardiac arrest), and there is no proof that it is life saving; indeed, there are many cases in which the subject died despite the use of epinephrine. Nevertheless, it is the best one can do when faced with someone who is experiencing a life-threatening allergic reaction to a food. The need for urgent medical help cannot be overemphasized.

There is little evidence that antihistamine drugs are of any value. It would be reasonable to take a nonsedating fast-acting antihistamine such as terfenadine if experiencing an allergic reaction to a food, but it is questionable whether it will have much effect.

A number of new approaches to the treatment of IgE-mediated food allergy are being examined. In a double-blind placebo-controlled study of monthly injections of a preparation of anti-IgE antibodies, treated patients with peanut allergy required significantly greater amounts of peanut protein to elicit allergic symptoms compared with control subjects. Another anti-IgE preparation has been used in the treatment of asthma but has not been evaluated in peanut allergy. Theoretically, anti-IgE antibody treatment should be protective against multiple food allergens, although it would have to be administered indefinitely. Other experimental approaches include a concoction of traditional Chinese herbs, injection of heat-killed *Escherichia coli* containing mutated recombinant peanut proteins Ara h 1 to Ara h 3, the use of immunostimulatory sequences, and the use of chimeric protein that could form complexes with allergen-specific IgE bound to mast cells and basophils.

### Desensitization

In theory it ought to be possible to desensitize subjects with food allergy by giving injections of gradually increasing quantities of an appropriate extract of the food trigger. In practice, such treatment is not available. One at present insurmountable difficulty is that desensitization (also known as hyposensitization) treatment carries a small risk of death from the treatment itself. A subject has a series of injections without any major problem, but then without warning drops dead from anaphylaxis after the next injection. There is some data to show that desensitization performed in this way can work, but such subjects would probably require

maintenance injections on a permanent basis, and the very subjects most at risk of fatal anaphylaxis from accidental injection are quite probably also the ones most at risk from fatal anaphylaxis resulting from desensitization treatment.

## Definition of Food Intolerance

Food intolerance can be defined as a reproducible adverse reaction to a specific food or food ingredient, and it is not psychologically based. Although this appears straightforward, a key limitation of this definition is the lack of consistent definition on what constitutes an ‘adverse reaction.’ The phrase has a strong subjective component, from the part of both the patient as well as the physician. The problem is compounded by the wide variation in tolerance to the different ‘reactions’ associated with eating in the general population.

### Any Food taken in Excess may be Harmful

The definition above does not take into account the dosage. Large quantities of certain foods may result in disease in certain individuals, although such disorders are not usually included in the category of food intolerance. Any food, however harmless, can be harmful if taken in excess. Notable examples of this are:

1. Apples, pears, and honey are rich sources of fructose – a sugar which in early childhood is not well absorbed if taken in large quantities. Thus, if a child takes a quantity of fructose in excess of that which can be absorbed in the gastrointestinal tract, the result will be loose stools (diarrhea) due to the osmotic effect of unabsorbed fructose. It should be noted that whereas this

- applies to normal children, there are, in addition, a few children who are especially poor at handling ingested fructose, and in these children even small quantities of fructose-containing foods will cause florid diarrhea.
2. Chicken liver is a rich source of vitamin A. There are reported cases of infants who were fed large quantities of chicken liver, and who developed raised intracranial pressure as a consequence of vitamin A toxicity.
  3. In those who are genetically predisposed, ingestion of an excess of purine-rich foods contributes to hyperuricemia, leading to gout, a disorder which is not usually regarded as a form of food intolerance.

## **Principal Mechanisms and Pathophysiology of Food Intolerance**

### **Food Allergy**

The term 'allergy' implies a definite immunological mechanism. This could be antibody mediated, cell mediated, or due to circulating immune complexes. The clinical features of an allergic reaction include urticaria (nettle rash), angioedema, rhinitis (sneezing, nasal discharge, blocked nose), worsening of preexisting atopic eczema, asthma (wheezing, coughing, tightness of the chest, shortness of breath), vomiting, abdominal pain, diarrhea, and anaphylactic shock.

### **Enzyme Defects**

Inborn errors of metabolism may affect the digestion and absorption of carbohydrate, fat, or protein. In some subjects the enzyme defect is primarily gastrointestinal, causing defects in digestion or absorption. An example is lactase deficiency (see below). In other subjects, the enzyme defect is systemic. An example is the rare disorder of hereditary fructose intolerance, described below.

#### **Lactase Deficiency**

An example of an enzyme defect causing food intolerance is lactase deficiency. In this condition, which is primarily a disorder that affects infants and young children, there is a reduced or absent concentration of the enzyme lactase in the small intestinal mucosa. Affected individuals are unable to break down ingested lactose, the main sugar found in milk, and which if unabsorbed passes into the large intestine, where there are two consequences. One is an osmotic diarrhea. The other is that some of the unabsorbed lactose is broken down by intestinal bacteria, accompanied by the production of gas (hydrogen) leading to abdominal distension and flatus and the production of organic acids that cause perianal soreness or excoriation. The elimination in exhaled air of hydrogen produced in the colon from unabsorbed carbohydrate can be used as a simple yet reliable test for malabsorption (breath hydrogen test). Most commonly used to assess lactose malabsorption, the test provides quantitative estimates of the amount of carbohydrate that was not absorbed in the small intestine and reached the colon. Because hydrogen is produced by colonic bacteria, the test requires a normal gut flora and is therefore affected by antibiotic use, diarrhea, or other large intestine disorders.

The management of lactose intolerance is to avoid foods that contain lactose (mainly cows' milk and its products). For infants it is worth noting that the soya-based infant formulas are lactose free. In theory, an alternative is to add microbial  $\beta$ -galactosidase to cows' milk, which can produce a lactose-free milk, with the inconvenience that it has a sweeter flavor and requires a 24-h incubation period at 4 °C.

In infants and young children, lactase deficiency is usually a transient problem occurring after an episode of gastroenteritis, but it is commonly a feature of any disease that causes damage to the intestinal mucosa (e.g., celiac disease). Levels of lactase tend to fall during mid- to later childhood, and in a number of populations (e.g., African, Mexican, and Greenland Eskimo) a high proportion of adults have very little lactase activity. This adult deficiency is believed to have a genetic basis. Man is the only animal apart from the domestic cat that drinks milk after weaning, and deficiency of lactase in adults could in certain populations be considered the normal state.

#### **Hereditary Fructose Intolerance**

In this condition, which has autosomal recessive inheritance, there is deficiency of the liver enzyme fructose 1,6-bisphosphate aldolase. As a result, fructose-1-phosphate accumulates in liver cells, and acts as a competitive inhibitor for phosphorylase. The resulting transient inhibition of the conversion of glycogen to glucose leads to severe hypoglycemia (low blood glucose concentration). Affected infants are symptom free as long as their diet is limited to human milk. If they receive milk formulas or any food that contains fructose they develop attacks of hypoglycemia, shock, coma, and convulsions. There may be jaundice, an enlarged liver, and sometimes progressive liver disease. The treatment requires the complete elimination of fructose from the diet, which may be difficult as fructose is a widely used food additive and a sweetener. A trivial but interesting feature of the condition in survivors is a notable reduction in dental caries, a beneficial result from the need to avoid many types of confectionery.

## **Pharmacological Mechanisms**

### **Caffeine**

A good example of a pharmacological agent found in food with the ability to cause adverse reactions is caffeine. The stimulant effect, which may be welcome at times but unwelcome at others, of 60 mg caffeine in a cup of tea or 100 mg caffeine in a cup of coffee are

well recognized. What is less well recognized is that heavy coffee or tea drinkers can suffer a number of other side effects of caffeine, which stimulates gastric secretion and can cause heartburn, nausea, vomiting, diarrhea, and intestinal colic. Also common are irregular heartbeats, episodes of rapid pulse, sweating, tremor, anxiety, and sleeplessness. Caffeine also has a diuretic effect.

### Sodium Nitrite

Another pharmacological effect occurs when unusually large quantities of sodium nitrite are ingested. Sodium nitrite is an antioxidant used as an antibacterial agent, and in quantities of 20 mg or more it can cause dilatation of blood vessels causing flushing and headache, and urticaria.

### Tyramine, Histamine, and Other Vasoactive Amines

A further example of a pharmacological mechanism is the adverse effect of various vasoactive amines such as tyramine, serotonin, tryptamine, phenylethylamine, and histamine, which are found in a range of foods such as tuna, pickled herring, sardines, anchovy fillets, bananas, cheese, yeast extracts (such as Marmite), chocolate, wine, spinach, tomato, and sausages. There appear to be three main mechanisms in operation:

1. An abnormally high intake of vasoactive amines, such as histamine or tyramine, either because of a high content in food or because of synthesis of these chemicals in the gut by bacteria.
2. An abnormal effect whereby drugs or chemicals in food interfere with the enzymes that break down vasoactive amines.
3. An abnormal release from mast cells of histamine and other mediators of inflammation, triggered by eating certain foods such as strawberries, shellfish, and alcohol.

Vasoactive amines are the normal constituents of many foods. They arise mainly from the decarboxylation of amino acids, but they may also develop during normal food cooking and during the storage of food. **Table 1** shows the histamine level of various sausages. The term 'semidry' when applied to sausages (**Table 1**) means sausages that are fermented for varying periods. During this sausage-ripening process, the histamine concentration increases, depending on the length of the ripening process. It is estimated that 70–1000 mg of histamine ingested in a single meal is necessary for the onset of toxicity, depending on individual sensitivity. Thus, 130 g of the pepperoni sample that contained 55.0 mg histamine per 100 g (see **Table 1**) would be necessary to cause symptoms in the most sensitive individuals.

The largest amounts of histamine and tyramine are found in fermented foods such as cheese, alcoholic drinks, sausage, sauerkraut, and tinned fish. Badly stored food (see below) such as mackerel and tuna can also contain large amounts of histamine.

The effects of large doses of tyramine, histamine, and other vasoactive amines are extremely variable. Histamine causes flushing (by dilatation of blood vessels), constriction of smooth muscle in the intestine and the bronchi, increased heart rate, headache, fall in blood pressure, and asthma. Tyramine causes constriction of blood vessels, and it stimulates the release of noradrenaline from nerve endings. It can also cause the release of histamine and prostaglandins from mast cells. Dietary tyramine is known to induce hypertension and headache in patients who are taking monoamine oxidase inhibitor drugs. This effect has been shown to be due to inhibition, by these drugs, of intestinal and hepatic metabolism of tyramine, so that the amine accumulates.

The variable effect of histamine taken by mouth is in part due to the varying degree of inactivation in the gastrointestinal tract. Histamine is inactivated by mucoproteins that are produced in the gastrointestinal tract mucosa, but this inactivation can be

**Table 1** Histamine levels in sausages

Type of sausage	Histamine level (mg/100 g)	
	Mean	Range
<i>Cooked sausages<sup>a</sup></i>		
Bologna	0.55	0.19–0.84
Cooked salami	0.83	0.47–5.86
Kosher salami	0.50	0.33–0.97
<i>Semidry sausages<sup>a</sup></i>		
Thuringer cervelat	2.35	1.03–3.63
Thuringer	1.19	0.31–2.56
<i>Dry sausages<sup>a</sup></i>		
Italian dry salami	2.14–24.5 <sup>b</sup>	0.42–36.4 <sup>b</sup>
Pepperoni	1.03–38.1 <sup>b</sup>	0.72–55.0 <sup>b</sup>
Chorizo	2.29	0.60–8.08

Source: Reproduced from Taylor SL, Leatherwood M, and Lieber ER (1978) A survey of histamine levels in sausages. *Journal of Food Protection* 41: 634–637, with permission from International Association For Food Protection

<sup>a</sup>The sausages were obtained from retail markets in the San Francisco Bay area.

<sup>b</sup>Depending on the brand tested.

blocked by other amines such as cadaverine and putresceine, which also bind strongly to mucoproteins. Thus, when food that contains cadaverine and putresceine is ingested, more histamine can be absorbed. In fact, most of the histamine that is absorbed is degraded as it is transported across the mucosa by the intestinal enzyme diamine oxidase. Cadaverine and putresceine also have a high affinity for diamine oxidase and can also interfere with the inactivation of histamine by this enzyme. Another barrier to the absorption of histamine is provided by the liver enzyme methyl transferase.

Thus, the effect of histamine and other vasoactive amines on an individual will depend on a number of factors, which include:

1. The amount of vasoactive amine that is present in food.
2. The amount of histamine released (as a result of an allergic process).
3. The permeability of the gastrointestinal tract, including inactivation by mucus and by mechanisms in the gut mucosa.
4. Interference with the synthesis or release of enzymes involved in amine breakdown (e.g., liver damage causing reduced activity of methyl transferase).

### **Tyramine and Migraine**

There has been interest in a possible relationship between dietary tyramine and migraine. One hypothesis is that some patients with migraine have defective metabolism of ingested tyramine in the intestinal wall, which leads to increased absorption, apparently explaining why foods that contain tyramine can provoke attacks in susceptible individuals. However, there is no evidence that the activity of monoamine oxidase, the main tyramine-metabolizing enzyme, is lower in patients with food-induced migraine than in other individuals prone to migraine, although levels of monoamine oxidase in platelets are generally lower in patients with migraine.

Set against these theoretical arguments, in fact, most attempts to induce migraine by tyramine challenge in children and adults have been unsuccessful. Furthermore, a controlled study of exclusion of dietary vasoactive amines in children with migraine failed to demonstrate benefit. In the latter study, patients were randomly allocated to either a high-fiber diet low in dietary amines or a high-fiber diet alone. Although there was no significant difference in the results for the two groups, both groups showed a highly significant decrease in the number of headaches, emphasizing the need for a control diet in studies designed to show that dietary manipulation improves disease.

Of the foods reported to be common triggers of attacks of migraine, only cheese is rich in tyramine. Chocolate is low in this and other vasoactive amines, and red wine usually contains no more tyramine than white wine. Alcoholic drinks, particularly red wine, are commonly reported to provoke attacks of migraine. Whether these attacks are due to the alcohol itself or some other compound is a matter of debate. The major chemical difference between red and white wines is the former's high concentration of phenolic flavonoids such as anthocyanins and catechins, which as well as having direct effects on blood vessels may also inhibit the enzyme phenolsulfotransferase. Patients with food-induced migraine were shown to have significantly lower levels of platelet phenolsulfotransferase activity, and it has been hypothesized (but not proven) that low activity of this enzyme could lead to an accumulation of phenolic or monoamine substrates, which in turn might directly or indirectly provoke attacks of migraine.

Regardless of the possible mechanism, there are a number of subjects with migraine who are made worse by specific dietary triggers such as cheese or wine, for whatever reason, and avoidance of specific food triggers in susceptible subjects may prove helpful in reducing the frequency of attacks.

### **11 $\beta$ -Hydroxysteroid Dehydrogenase and Liquorice**

Liquorice contains an enzyme that inhibits 11  $\beta$ -hydroxysteroid dehydrogenase, resulting in sodium and water retention, hypertension, hypokalemia, and suppression of the renin-aldosterone system.

### **Irritant Mechanisms**

Certain foods have a direct irritant effect on the mucous membranes of the mouth or gut, such as the irritant effect of coffee or curry. In certain individuals, food intolerance only occurs in the presence of a coexisting medical disorder. For example, the ingestion of spicy food, coffee, or orange juice provoke esophageal pain in some patients with reflux esophagitis. This effect is unconnected to the temperature or acidity of the food, or to any effect on the lower esophageal sphincter. The treatment in susceptible individuals is to avoid the trigger food item.

### **Specific Drug–Food Combinations**

One example of drug-induced food intolerance is potentiation of the pressor effects of tyramine-containing foods (e.g., cheese, yeast extracts, and fermented soya bean products) by monoamine oxidase inhibitor drugs. Another is the effect of taking alcohol in patients with alcohol dependence during treatment with disulfiram (Antabuse). The reaction, which can occur within 10 min of alcohol and may last for several hours, consists of flushing and nausea.

## Toxic Mechanisms

Nature has endowed plants with the capacity to synthesize substances that are toxic, and thus serve to protect them from predators whether they be fungi, insects, animals, or humans. Thus, many plant foods contain naturally occurring toxins. On a worldwide scale, reactions to naturally occurring toxins may outnumber allergic reactions, although it is currently fashionable to pay more attention to the latter.

### Protease Inhibitors

Soya beans were originally introduced into the US as a source of oil, the extracted meal being used as a by-product that could provide animals with a source of protein. However, it was recognized that it was necessary to subject soya beans to heat treatment if they were to support the growth of animals. It was later found that the substance responsible for growth inhibition in raw soya beans was a protease (trypsin) inhibitor, and it is now known that protease inhibitors are widely distributed throughout the plant kingdom, particularly in legumes, and to a lesser extent in cereal grains and tubers. In addition to inhibition of growth, one of the most characteristic responses of most animals to trypsin inhibitor is enlargement of the pancreas. The depression of growth is believed to result from endogenous loss of protein (i.e., loss into the gastrointestinal tract) due to hypersecretion by the pancreas. Soya bean products that have been adequately heat treated to inactivate trypsin inhibitor are safe for consumption.

### Lectins

There is a protein present in most legumes and cereals that has the property of being able to agglutinate the red blood cells of various species of animals: The so-called phytohemagglutinins or lectins. Some of these lectins, such as ricin from the castor bean, are extremely toxic. Others, such as those in the soya bean, are nontoxic. Lectins appear to be responsible for the fact that many other legumes, unless properly cooked, not only fail to support the growth of animals but can lead to death. Lectins are found in many food items commonly consumed in the human diet including tomatoes, bean sprouts, raw vegetables, fruits, spices, dry cereals, and nuts, and it is not known whether these are harmful in any way. However, it is well recognized that inadequate cooking of red kidney beans can cause severe gastrointestinal upset, with vomiting and diarrhea. It is for this reason that it is recommended that raw red kidney beans should be cooked by initially boiling hard for 10 min.

### Lathyrogens

Lathyrism is a paralytic disease that is associated with the consumption of chickling pea or vetch, *Lathyrus sativus*. The causative factor is believed to be an amino acid derivative,  $\beta$ -N-oxalyl-, -diaminopropionic acid; this is a metabolic antagonist of glutamic acid, a substance that is involved in the transmission of nerve impulses in the brain.

### Mimosine

Mimosine is an amino acid that comprises 1–4% of the dry weight of the legume *Leucaena leucocephala*, and consumption of its leaves, pods, and seeds leads to hair loss in animals. Mimosine is also a goitrogen (see below).

### Djenkolic Acid

In parts of Sumatra the djenkol bean is a popular food item. The bean is a seed of the leguminous tree, *Pithecolobium lobatum*, and resembles the horse chestnut in size and color. Consumption of this seed leads to kidney failure that is accompanied by blood and needle-like clusters in the urine, which have been identified as containing the amino acid djenkolic acid.

### Goitrogens

Substances capable of producing goiter are present in plants belonging to the cabbage family, including cabbage, turnip, broccoli, cauliflower, brussel sprouts, kale, rape seed, and mustard seed. Cows' milk is a vector for the transmission of goitrogens from animals fed kale and turnips, and may have been responsible for endemic goiter in countries such as Australia and Finland.

### Cyanogens

A number of plants are potentially toxic because they contain glycosides from which hydrogen cyanide may be released by enzymatic hydrolysis. The most common plants eaten by humans, in order of their potential cyanide content, are: Lima beans (*Phaseolus lunatus*), sorghum, cassava, linseed meal, black-eyed pea (*Vigna sinensis*), garden pea (*Pisum sativum*), kidney bean (*Phaseolus vulgaris*), Bengal gram (*Cicer arietinum*), and red gram (*Cajanus cajan*s).

### Vicine and Convicine

These are  $\beta$ -glucosides that are present in broad beans (*Vicia faba*). When consumed by individuals with deficiency of the enzyme glucose-6-phosphate dehydrogenase, these substances precipitate the condition of favism, which is characterized by anemia caused by hemolysis of red blood cells. The enzyme deficiency is a genetic disorder that is confined largely to inhabitants of countries surrounding the Mediterranean basin (Italy, Sicily, Lebanon, Israel, and North Africa) although individuals of the same ethnic background residing in other countries may also suffer from favism.

### Cycasin

Cycad seeds or nuts are obtained from *Cycad circinalis*, a palm-like tree that grows throughout the tropics and subtropics. The seeds, unless thoroughly washed, are extremely toxic, causing poisoning in humans and tumors in experimental animals. The toxic ingredient methyl-azoxymethanol, the aglycone of cycasin, is released on hydrolysis of cycasin by intestinal bacteria.

### Pyrrolizidine Derivatives

Pyrrolizidine alkaloids are found in a wide variety of plant species. The toxic ingredient belongs to a class of compounds that are derivatives of pyrrolizidine. Large numbers of people have been poisoned through consumption of cereal and grain crops contaminated with pyrrolizidine-containing plants. It is also possible that milk from cows grazing on pastures that contain such plants could act as a vector for the transmission of pyrrolizidine to humans. In one part of western USA one such plant, the tansy ragwort (*Senecio jacobea*) is readily consumed by cows and goats, and the milk from such animals has been shown to contain significant amounts of a pyrrolizidine derivative, jacoline.

### Lupin Alkaloid

Milk from animals that have eaten plants from the lupin family, notably *Lupinus latifolius*, may contain quinolizidine alkaloids such as anagryne. There is strong evidence that these alkaloids are teratogenic in animals, causing severe bony deformities, and there is some evidence that similar defects may occur in the offspring of human mothers who drink alkaloid-containing milk in pregnancy.

### Other Examples

There are numerous other examples of toxic substances present in foodstuffs. These include solanidine in potatoes, cyanide in tapioca, mycotoxins in mushrooms and cereal grains, and phototoxic furocoumarins in angelica, parsley, dill, and celeriac, which in sufficient quantities can give rise to a wide variety of toxic reactions (Tables 2 and 3).

## Food Storage

Chemical changes in food during storage can produce substances that cause food intolerance. An example is intolerance to ripe or stored tomatoes in subjects who can safely eat green tomatoes, where ripening of the fruit produces a new active glycoprotein. Some adverse reactions resulting from food storage come into the category of toxic reactions, such as the rise in levels of histamine and tyramine in certain foods during storage as a result of bacterial decarboxylation. An example of this is the production of histamine in badly stored mackerel and other fish: Scombroid fish poisoning. Contamination of food by antigens such as storage mites or microbial spores may give rise to adverse effects, particularly asthma and eczema. Contamination of food by microorganisms may result in adverse effects. For example, celery, parsnip, and parsley may become infected with the fungus *Sclerotinia sclerotiorum* ('pink rot'), resulting in the production of the photosensitizing chemicals psoralen, 5-methoxypsoralen, and 8-methoxypsoralen.

**Table 2** Examples of toxic constituents of plant foodstuffs and their role in plant physiology

Toxic constituent	Type of food containing toxic constituent	Physiological role of toxic constituent	Role in plant defense: mechanism of toxic constituent
Protease inhibitors	Legumes, cereals, potatoes, pineapple	?Prevents degradation of storage protein during seed maturation	Part of defense against invading microbes following mechanical damage to leaves
Hemagglutinins	Legumes, cereals, potatoes	(a) Attach glycoprotein enzymes (b) Role in embryonic development/differentiation (c) Role in sugar transport or store (d) ?Involved in root nodule nitrogen-fixing bacteria symbiosis	(a) Counteract soil bacteria (b) Antifungal (c) Protect against seed predators
Glucosinolates	Radish, horseradish, turnip, cabbage, rape seed	?Disease & insect resistance role	
Cyanogens	Almonds, cassava, corn, peas, butter beans, bamboo shoots		
Saponins	Alfalfa, French beans, soya beans

**Table 3** Examples of foodborne toxins or toxin-producing organisms, excluding plant foodstuffs

Pathogen or toxin	Principal symptoms	Common food source
<i>Bacillus cereus</i>	(a) Diarrhea	Proteinaceous food, vegetables, sauces, puddings
<i>Bacillus subtilis</i>	(b) Vomiting Vomiting, diarrhea Flushing, sweating	Fried rice Meat and pastry Meat/seafood with rice
<i>Bacillus licheniformis</i>	Diarrhea	Cooked meat and vegetables
<i>Clostridium botulinum</i>	Neuroparalytic disease (botulism)	Meat, fish, vegetables, hazelnut conserve
<i>Clostridium perfringens</i>	Diarrhea, abdominal pain	Meat, poultry
<i>Salmonella enteridis</i>	Diarrhea, abdominal pain, fever, vomiting	Poultry, eggs
<i>Staphylococcus aureus</i>	Vomiting, abdominal pain, diarrhea	Numerous but specially cooked high-protein foods
Verotoxin-producing <i>Escherichia coli</i>	Hemorrhagic colitis	Ground beef
<i>Listeria monocytogenes</i>	Listeriosis	Unpasteurized cheese, undercooked meat
Dioxins and dibenzofurans	Adverse effects uncertain when consumed in quantities found in food	Fish
Cantharidin	Sensitivity to urethra and genitalia; priapism	Frogs that have Meloidae (blister beetles)
Methyl mercury	Brain damage	Fish, bread
Toxic alkaloid (saxitoxin) in dinoflagellates and plankton	Diverse neurological disorders (paralytic shellfish poisoning)	Clams, oysters, scallops, and mussels
Brevetoxins	Paresthesia, abdominal pain, diarrhea, transient blindness, paralysis, death (neurotoxic shellfish poisoning)	Clams, oysters, scallops, and mussels
Ciguatera toxin	Diverse gastrointestinal and neurological disorders	Fish (especially reef predators)
Tetrodotoxin	Diverse gastrointestinal and neurological disorders	Puffer fish, certain newts
Domoic acid	Vomiting, diarrhea, hyperexcitation, seizures, memory loss (amnesic shellfish poisoning)	Mussels
Okadaic acid, dinophys toxins, yessotoxin, pectenotoxins	Diarrhea, vomiting, abdominal pain (diarrhetic shellfish poisoning)	Mussels, scallops
Scombrototoxin (usually histamine)	Headache, palpitations, gastrointestinal disturbance	Mackerel, tuna, and related species
Tetramine (red whelk poisoning)	Diplopia, dizziness, leg pains	Whelks
Grayanotoxins (in honey from areas of Turkey where <i>Rhododendrons</i> are grown)	Hypotension, bradycardia, vomiting, sweating	Honey
Unknown (? in algae) (turtle flesh poisoning)	Cardiorespiratory failure, death	Turtles

## Practical Applications

Food arouses not only the appetite but also the emotions. The passion for food that is natural (i.e., free from extraneous ingredients) is not new; in 1857, a survey of adulterants in food showed that childrens' sweets were commonly colored by red lead (lead oxide), lead chromate, mercuric sulfide, and copper arsenite. By the late 1850s, 'pure and unadulterated' had become the stock advertising slogan of those anxious to cash in on the then newly awakened fears of the public. The current scale of the use of additives in food comes as a surprise to most people, and it is understandable that many should find these substances vaguely menacing. Nonetheless, the current phobia of food additives and food processing, and the obsession for the so-called natural or health food arises largely out of misinformation and ignorance. Obsession with the so-called natural or health food ignores the wide range of naturally occurring toxins in foods. The concept of health food is wholly misleading. For example, a survey of 'crunchy' peanut butter showed that 11 out of 59 samples from health food producers contained over  $100 \mu\text{g kg}^{-1}$  of aflatoxins, over 10 times the proposed maximum permitted level for total aflatoxins. Only one of the 26 samples from other producers contained aflatoxins in excess of  $10 \mu\text{g kg}^{-1}$ , and none contained more than  $50 \mu\text{g kg}^{-1}$ .

### Key points

- The current pharmacological treatment of individuals diagnosed with hyperactivity or attention-deficit hyperactivity disorder (ADHD) is unsatisfactory.
- Alternative treatment options include nutritional interventions, some of which attempt to improve ADHD symptoms either through the avoidance of certain food compounds or the supplementation of specific food elements.
- Deficiencies of nutrients such as vitamins, minerals or polyunsaturated fatty acids have not convincingly been shown to be involved in the etiology of ADHD.
- Evidence of a causative link between ADHD and dietary surpluses of nutritional items such as sucrose or artificial food additives or other foods causing behavioral reactions in sensitive children is lacking.
- At group level, there is no conclusive evidence supporting dietary interventions for the treatment of ADHD.
- The few-foods diet allows the design of individually tailored diets and may offer treatment opportunities in subgroups of children with ADHD.
- Further research is required to show the utility of nutrition-related interventions alone or in combination with other treatment approaches in ADHD.

### Introduction

While nutrition and diet are an established mainstay of physical and metabolic health, their role in mental health and disease is less commonly recognized. However, considerable evidence points to an important role of nutrition in brain development and functioning. Observational studies have consistently shown that the risk for mental disorders is associated with diet quality. A range of macronutrients and micronutrients have been linked to behavioral, affective and cognitive functions as well as to the incidence and prevalence of mental disorders. Nutritional deficiencies and other dietary factors have been suggested to be involved in the etiology, pathophysiology, prevention, management, and modification of common mental disorders, such as depression, schizophrenia, autism spectrum disorder and attention-deficit hyperactivity disorder (ADHD). Research on dietary and nutritional approaches in the therapy of ADHD and other mental disorders has therefore attracted increasing scientific interest.

The concept of ADHD has developed over the past 50 years, from its early description as a hyperkinetic reaction of childhood to one of the most common diagnoses in child and adolescent psychiatry. ADHD is increasingly diagnosed in adults and is regarded as a lifespan condition. The disorder is complex, multifactorial and heterogeneous, with a wide diversity of features in affected

individuals, including behavioral, cognitive, emotional and motivational profiles, as well as environmental exposures, social influences and genetic susceptibilities. The core symptoms of ADHD, which are age-inappropriate levels of hyperactivity, inattention, and impulsivity, are considered to be continuous traits across the general population, and the disorder is frequently comorbid with other psychiatric conditions. An interaction between genetic susceptibility and environmental and social factors is believed to contribute to the etiology of ADHD. Biological or neuropsychological markers underpinning the validity of the concept of ADHD are currently lacking, and no structural or functional brain alterations can be consistently found in those diagnosed with ADHD. As there are no viable biomarkers or biological diagnostic tools, the diagnosis of ADHD relies solely on clinical symptoms and behavioral assessment. ADHD is diagnosed above a certain degree of symptom severity combined with significant problems in daily life, including social, academic, and occupational dysfunctioning.

Pharmacotherapy with stimulant medications, behavior therapy and parent management training have consistently been demonstrated to yield significant short-term symptom reduction in children and adolescents with ADHD. However, the extent of efficacy of these therapeutic approaches is a matter of debate (Lange, 2017). Many studies have found that ADHD medications administered for several weeks produce statistically significant improvement of core symptoms compared to placebo, as assessed using rating scales. However, small though statistically significant effects on symptom scores may not be noticeable by patients or physicians and do not therefore necessarily equate to any clinically relevant improvements in subjective wellbeing or difficulties in daily life. Furthermore, the minimum difference in rating scale scores indicating an ecologically relevant effect remains unknown. In particular, the impact of medications on academic performance and quality of life in children and adolescents with ADHD has been found to be low.

Cochrane reviews of randomized controlled trials investigating benefits and harms of methylphenidate for children and adolescents with ADHD concluded, in view of low quality of outcome measures and possible bias of studies, that the extent of therapeutic efficacy is unclear (Storebø et al., 2018). Randomized controlled trials supporting the long-term administration of psychostimulants for more than a few months are lacking. As the results of studies investigating efficacy and safety of medications over short-time periods cannot be extrapolated to long-term outcomes, conclusive evidence of longer lasting benefits of ADHD medications on social, educational, and vocational outcomes remains elusive. Furthermore, potential effects are compounded by low adherence to pharmacological treatment.

Short-term administration of stimulant medications in ADHD seems to be relatively safe, but little is known about long-term safety. Long-term observations have suggested that children with ADHD who received psychostimulants into adulthood may present with reduced height as adults with no ongoing improvement in symptomatology. Current information may therefore indicate that pharmacological treatment for ADHD should be used with caution when administered for more than a few months. Given the unproven long-term benefits of medications in the treatment of ADHD, their value may be outweighed by their risks. Concerns regarding the quality and interpretation of the available evidence as well as uncertainties as to the benefit-versus-harm profile of methylphenidate have resulted in the rejection by the World Health Organization Model List of Essential Medicines of applications for the inclusion of this drug in the treatment of ADHD.

In summary, while the pharmacotherapy of ADHD using drugs such as methylphenidate almost certainly provides some symptom reduction in children and adolescents with ADHD, the magnitude and relevance of these effects is unknown. Future large-scale, sufficiently powered and methodologically rigorous randomized controlled trials focusing on both beneficial and harmful effects are required to investigate the effectiveness of pharmacological treatment in alleviating the real-life problems faced by those diagnosed with ADHD.

The lack of evidence demonstrating the ability of either stimulant or non-stimulant agents to address the broader clinical needs of many individuals with ADHD has brought the effectiveness of these treatments into question. The unknown long-term efficacy of ADHD medications as well as concerns regarding unwanted side effects of pharmacotherapy have led to a search for improved or alternative therapeutic options (Lange, 2020a). Lifestyle factors, including diet and nutrition, have been suggested to play a role in the pathogenesis and management of ADHD (Lange, 2018a). As early as the 1920s, a possible relationship between food and hyperkinetic behavior was proposed. More recently, children diagnosed with ADHD have been found to have different dietary patterns from normally developing children. Nutritional interventions in ADHD are mainly based on the assumption that dietary compounds may either produce adverse effects on behavior and should therefore be eliminated or are deficient and need to be supplemented. Dietary agents thought to induce hyperactivity and other ADHD symptoms include sugar as well as food dyes and preservatives. Major dietary components suggested to be involved in the pathogenesis of ADHD and to be effective in assisting in the treatment of ADHD include micronutrients, such as vitamins and minerals, amino acids, and polyunsaturated fatty acids (Lange et al., 2022).

## Methodological issues

Various scientific approaches may be employed in establishing the efficacy of therapies and other interventions, including the potential health benefits of foods and nutrients. The primary methods used are observational (epidemiological or population-based) studies and interventional studies (clinical trials).

Observational studies include (1) cross-sectional studies with data collection from an entire population or a representative subgroup at a certain point of time, (2) case-control studies with two existing groups differing in a health outcome and being compared based on a supposed causal factor and (3) longitudinal studies performing correlational analyses of repeated

observations of the same variables over extended periods of time. All types of observational studies can establish associations between the consumption of certain diets or food components and the risk of certain diseases. However, the major limitation of observational studies is their correlational character and their inability to establish causal relationships, since both dietary habits and health risks may be caused by other factors, which were not recorded but were, in fact, the causal influences.

The highest level of evidence capable of establishing a cause-and-effect relationship between an intervention and a health outcome of nutrition can be derived only from the gold standard of randomized controlled trials (RCTs). The design of these studies involves the random assignment of individuals to two different groups. The experimental group receives the dietary intervention, while the placebo control group receives a diet that resembles the intervention diet but does not restrict or add the dietary elements to be studied. It is important that both study participants and individuals implementing the diet and measuring the outcomes are blinded to which group is receiving the experimental diet. This is a major challenge when, for example, parents are involved in the delivery of the diet and the assessment of its outcome.

### Dietary patterns in ADHD

The role of dietary patterns and whole diets in ADHD has been explored in several cross-sectional and case-control studies. For example, low adherence to a Mediterranean diet was associated with elevated prevalence of ADHD diagnosis. Hyperactivity in children correlated positively with the intake of processed meat and salty snacks, while a negative correlation was observed for the consumption of vegetables, coarse cereals, aquatic foods, beef, mutton, and milk. Furthermore, the diagnosis of ADHD in adolescents was found to be associated with a higher score for a Western dietary pattern, containing heavily processed foods rich in total fat, saturated fat, sodium, and refined sugars. In contrast, ADHD diagnosis was not associated with a dietary pattern characterized by the intake of omega-3 fatty acids, fiber and folate and a relatively low content of total fat, saturated fat, and refined sugars. In Korea, a traditional-healthy dietary pattern, high in kimchi, grains, bonefish and minerals and low in fat, fast foods and sugary beverages, was associated with reduced likelihood of childhood ADHD. A snacking dietary pattern, with high intake of snacks and processed meat and low intake of noodles, was positively associated with the risk of ADHD. A dietary pattern with relatively large amounts of high-fat, processed foods, and another with high intake of sweets, chocolate and other high-sugar foods, correlated positively and significantly with ADHD symptoms in preschool children in China; while a vegetarian pattern, with coarse food grain, wheat foods, beans, all kinds of vegetables and fresh fruit or vegetable juice, was negatively correlated with ADHD symptoms. A positive association of sweet and fast-food dietary patterns with the prevalence of ADHD was also found in Iranian children. A fish-white meat dietary pattern and mineral-protein nutrient diet have been suggested to have beneficial effects in children with ADHD in mainland China, where high intakes of deep-water fish, shellfish, white meat, freshwater fish, algae and fungi were associated with less ADHD in children. Furthermore, a pattern rich in protein, zinc, phosphorus, selenium, calcium and riboflavin also showed an inverse association with ADHD.

While the findings of observational studies emphasize a potential role of dietary patterns in ADHD, a caveat is the observational study designs, which are unable to establish a causal relationship. Reverse causation, with ADHD behaviors leading to a preference for certain diets, may also explain the above associations. Furthermore, various other lifestyle factors, such as physical activity, may correlate with dietary patterns and may be more important factors in ADHD symptomatology. Risk factors for ADHD, including family history, emotional abuse, prenatal problems, and parental education, frequently differed between individuals with ADHD and controls. Even when statistical adjustment for potential confounding variables was performed, residual confounding was still unavoidable. Commonly used food frequency questionnaires are known to contain some degree of measurement error. Moreover, in many studies, dietary patterns derived from food component analysis explained less than 50% of total variance, suggesting the existence of other patterns.

### Elimination of food elements

The elimination of certain elements from the diet is based on the hypothesis that some children may display behavioral changes following the consumption of certain types of food. Elimination diets aim to remove sugar or artificial food colorants and other synthetic food additives. The so-called few-foods diet excludes various foods and additives from children's diets.

### Sucrose restriction

When hyperactive children were reported to show greater hyperactivity following the consumption of large amounts of sucrose, several observational studies examined this issue and found that sucrose intake was associated with ADHD symptoms in children and adolescents. However, whether hyperactive behavior was caused by sucrose or by the circumstances associated with high sucrose consumption remained unclear. Several subsequent studies provided convincing evidence that sucrose consumption is not related to ADHD symptoms (Wolraich et al., 1995). For example, the administration of sucrose versus aspartame resulted in similar behavior in hyperactive boys. Furthermore, no differences in signs of ADHD in children believed to be sensitive to sucrose were found between those receiving sucrose for three weeks and those receiving aspartame or saccharine. A meta-analysis of relevant trials, which were mainly challenge studies using sucrose, glucose, or fructose, concluded that sucrose appeared to have no effect on

the behavior or cognitive performance of children (Wolraich et al., 1995). Definitive conclusions could not be drawn due to the limited number of available studies. Insufficient statistical power did not allow the detection of small effects and a small effect on a subgroup of children cannot be ruled out. The absence of effects of added sugars on hyperactivity have largely discredited the sucrose hypothesis of ADHD.

In summary, sucrose does not appear to be the cause of hyperactivity or ADHD, even though children with ADHD may tend to consume sugar-rich foods and beverages. Current evidence is insufficient to recommend a restriction of sucrose consumption to improve behavior or cognitive functioning.

### Food additives

In the 1970s, Feingold proposed that food additives, such as artificial food colorants and flavors, can cause adverse behavioral effects, with increased sensitivity to these additives underlying hyperactive behavior in some children. A diet free of dyes, colorings, additives and naturally occurring salicylates (Feingold diet), hypothesized to improve symptoms in children with hyperactivity, became a popular approach. While the findings of initial studies suggested that symptoms of hyperactivity could be reduced through a diet free of artificial food colors and other additives, these early studies lacked control groups. More rigorous, controlled research was less conclusive, with only a small fraction of children with ADHD responding to this kind of intervention. More recent evidence, based on a large, well-designed randomized controlled study, has rekindled interest in the theory that food additives may trigger hyperactivity, especially in younger children. Artificial colors and/or a sodium benzoate preservative were shown to cause increased hyperactivity in three-year-old children, as well as children aged eight and nine, in the general population. The findings of this research led public policy groups to petition food manufacturers and governments in several countries to ban the use of artificial food colors. In response to these demands, the British government mandated the removal of most synthetic dyes from food products, and the European Food Safety Authority introduced regulations requiring that foods containing synthetic colors carry warnings stating that their intake may be associated with adverse effects on activity and attention in children. However, the elimination of food colors appears to be unable to provide a general solution to the multifaceted behavioral problems of hyperactivity and ADHD.

The available studies on the effects of artificial food colors assessed the questions of whether hyperactivity or other symptoms of ADHD improved following a diet excluding artificial colorants and whether the symptoms worsened after exposure to these compounds. Several meta-analyses of these studies concluded that artificial food colors have small, but statistically significant, adverse effects on ADHD symptoms in some children (Nigg et al., 2012; Sonuga-Barke et al., 2013). However, the exclusion of artificial food colorants may be limited to children selected for food sensitivities.

In short, although food additives are not the primary cause of ADHD, they have been considered in recent years to be a minor causative factor in hyperactive behavior in at least some children (Nigg et al., 2012). The elimination of food colorants from the diet would not seem to offer a general remedy for the varied behavioral problems of hyperactivity and ADHD. However, the available evidence carries sufficient weight to warrant further investigation, which should attempt to identify subgroups of those with ADHD who may benefit from the exclusion of food additives.

### Few-foods or oligoallergenic diet

As well as artificial food additives and sucrose, various other food items have been hypothesized to elicit allergic reactions or sensitivity in some children diagnosed with ADHD. Foods causing reactions in children, such as subtle behavioral effects or symptoms of ADHD, may vary significantly between children. The hypothesis of a link between specific foods and ADHD has led to the development of the few-foods or oligoallergenic diet.

A strict elimination diet excluding many food items has been found to be a valuable tool in assessing whether symptoms of ADHD are induced by individual foods. The general approach of the few-foods, or oligoallergenic, diet in the identification of foods triggering ADHD is the introduction of a restricted diet, eliminating most food items for a limited period, with the subsequent re-introduction of single foods one at a time. Children responding to the few-foods diet show improvements in behavior or cognitive performance following several weeks on this diet. In those showing a response, food items are added consecutively in a controlled way to determine which foods are causative of adverse reactions or specific behavioral signs and symptoms. This process can be complemented by blinded challenges using disguised forms of foods to which the child had reacted. Finally, an individualized diet is created, eliminating only the foods causing adverse effects.

Significant effects of the few-foods diet, as examined using a RCT design, were found in an unselected sample of children with ADHD. Furthermore, several double-blind placebo-controlled studies assessing the effects of the few-foods diet have consistently demonstrated the role of foods in triggering ADHD, suggesting the existence of a food-related subtype of ADHD (Pelsser et al., 2017). The primary objective of the few-foods approach is the identification of food items provoking symptoms in each individual case and the design of an individually tailored diet for future use.

In summary, the few-foods, or oligoallergenic, diet may offer treatment opportunities in subgroups of children with ADHD. In the Netherlands, the few-foods diet is applied in general practice (Pelsser et al., 2020). Available evidence suggests that this personalized dietary treatment approach deserves further systematic investigation.

## Supplementation of food elements

Brain development requires a sufficient supply of nutrients. Diets deficient in essential nutrients may contribute to dysfunction of brain regions thought to be involved in the pathogenesis of ADHD (such as the prefrontal cortex) and to occurrence of symptoms of the disorder. Dietary supplementation of certain macronutrients or micronutrients rests on the assumption that children with ADHD may be deficient in these nutrients, due to low intake or increased requirement. Research in this area has focused mainly on vitamins, minerals, amino acids, and polyunsaturated fatty acids. As various minerals and vitamins serve as cofactors of enzymes required in the synthesis, uptake and metabolism of neurotransmitters in the brain, metabolic dysfunction resulting from a decreased availability of mineral and vitamin cofactors may underlie the symptoms of mental disorders. The potential value of probiotics in the treatment of ADHD has also attracted increasing interest.

### Vitamins

The findings of various cross-sectional and longitudinal studies suggest a role of vitamin D in the pathogenesis of mental disorders in childhood and adolescence. Mean 25-hydroxyvitamin D concentration was found to differ significantly between children and adolescents with ADHD, relative to controls. While a meta-analysis of RCTs using vitamin D as adjunctive treatment to methylphenidate in children with ADHD, showed small, statistically significant improvements in behavior, hyperactivity and inattention scores, these effects were limited by the low to very low quality of evidence provided by the available studies.

As B vitamins (B6, B9 and B12) are involved in the synthesis of monoaminergic neurotransmitters and metabolism of fatty acids, deficiencies may impact cognitive function. The anti-oxidative effects of vitamin C improve iron absorption and may reduce oxidation in the brain. Several studies have examined the potential benefits of multivitamin supplementation, with vitamins B3, B5, B6 and C administered in doses many times above the commonly recommended daily allowance, in children with ADHD. While some of these studies found beneficial effects, severe methodological limitations, such as short intervention periods, lack of randomization, and poor statistical analysis, undermine their scientific value. Other well-designed RCTs found no effects. Taken together, available findings provide no evidence that the administration of vitamin mega-doses can ameliorate ADHD symptoms in children. Furthermore, excessive intakes of vitamins B3, B5, B6 and C carry risk of liver toxicity.

### Minerals

Possible associations between zinc, magnesium, iron, copper and selenium status and the occurrence of ADHD have been suggested, as has the potential value of supplementation of these minerals in the therapy of ADHD (Robberecht et al., 2020). Zinc is involved in the synthesis of monoaminergic neurotransmitters, and deficiencies in zinc and iron may cause cognitive impairment in children. Observational studies have reported trends toward lower blood concentrations of zinc, magnesium and ferritin in children with ADHD. However, available studies have yielded inconsistent results, potentially resulting from different diagnostic parameters, heterogeneity of studies or variation in daily intake of the minerals. The studies also differed significantly in respect of demographic variables. Moreover, whether differences in mineral status are a cause or a consequence of ADHD is unknown.

Several studies have examined the effects of supplementation with zinc, magnesium and iron. Two double-blind RCTs showed statistically significant beneficial effects of zinc supplementation on ADHD symptoms, with children demonstrating the lowest blood concentrations of zinc and essential fatty acids showing the greatest benefit. A significant effect of iron supplementation was found in a small uncontrolled intervention, while another small RCT showed no effect on ADHD symptoms. Magnesium supplementation showed an improvement in ADHD symptoms, but the evidence was undermined by severe methodological flaws, such as lack of randomization and problematic ADHD symptom assessment.

In summary, the evidence for therapeutic supplementation of minerals in ADHD is insufficient. Zinc supplementation may be considered in individuals with zinc deficiency.

### Micronutrient combinations

Several studies have used combinations of various vitamins and minerals in children with ADHD and found improvements in behavioral, cognitive and emotional symptoms (Rucklidge et al., 2019). However, most studies had small sample sizes and were highly heterogeneous in regard to individuals included and treatments.

### Amino acids

Amino acids have attracted interest in the context of ADHD management, as the monoaminergic neurotransmitters dopamine, norepinephrine, and serotonin, which are believed to be involved in the pathogenesis of ADHD, are synthesized from the amino acid precursors, phenylalanine, tyrosine, and tryptophan. Supplementation of these amino acids has therefore been proposed as a potentially useful therapy in children with ADHD. A few randomized controlled trials with small sample sizes have examined the effects of amino acid supplementation. However, results showed only small effects of tryptophan, and no effects of tyrosine or phenylalanine on ADHD symptoms. Thus, there is currently no evidence of beneficial effects of amino acid supplementation in children with ADHD.

### Polyunsaturated fatty acids

Brain structure and function are critically dependent on an adequate intake of polyunsaturated fatty acids (Lange, 2020b). Both omega-3 fatty acid deficiencies and supplementation with fish oil affect monoaminergic neurotransmitter concentrations in the brain. The role of free fatty acids in the etiology and treatment of ADHD is controversial (Lange, 2018a,b). Early studies using omega-6 fatty acid supplements from vegetable oils gave rise to an interest in fatty acids in ADHD. Since then, the focus of interest in this respect has been the long-chain omega-3 fatty acids, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) from fish oil. Maternal fish oil administration during lactation has been associated with better attention and physical activity in the offspring in both animal and human studies. Children with hyperactivity have been found to present with clinical signs of fatty acid deficiency, such as dry skin and hair, as well as polydipsia and polyuria. Furthermore, plasma levels of DHA, EPA and arachidonic acid were found to be significantly decreased in children and adolescents with ADHD. Children with ADHD symptoms have been shown to have increased ratios of omega-6 to omega-3 fatty acids, compared to those without symptoms. This could be due to dietary patterns, alterations in gut microbiota or abnormal fatty acid metabolism. The findings in a population-based birth cohort suggest that maternal diet during pregnancy with a high ratio of omega-6 to omega-3 fatty acids may increase the risk of subclinical ADHD symptoms in the offspring in childhood.

Numerous interventional studies have assessed the effects of omega-3 fatty acid supplementation on ADHD symptoms. Available RCTs using fish oil in children with ADHD have several limitations. Sample sizes were usually small, the dosages of omega-3 fatty acids were low, the intervention periods were short, and multiple testing using many evaluation scales without adequate statistical correction was performed. Meta-analyses of RCTs assessing effects of polyunsaturated fatty acids on ADHD symptoms found statistically significant but small reductions, the clinical significance of which remains to be determined (Sonuga-Barke et al., 2013). A systematic review of meta-analyses of double-blind placebo-controlled trials in children with ADHD found small effect sizes for the supplementation with omega-3 fatty acids, according to ratings of symptoms by parents and teachers (Pelsser et al., 2017). A more recent randomized placebo-controlled trial investigating the effects of omega-3 fatty acids, administered for three months to children and adolescents with ADHD, found that individuals receiving placebo showed significantly greater total reduction in an ADHD rating score than those on omega-3 fatty acids (Cornu et al., 2018). Pooling of these findings with previous results suggested no overall effect of omega-3 fatty acids on ADHD symptoms (Cornu et al., 2018).

In summary, the evidence of efficacy of omega-3 fatty acids in the treatment of the core symptoms of ADHD in children and adolescents is marginal or non-existent. Pre-treatment status regarding polyunsaturated fatty acids may influence supplementation effects, and therapeutically relevant effects may be confined to children with a deficiency of free fatty acids.

### Probiotics

Based on the hypothesis that gut microbiota and probiotics may influence brain activity, behavior and mental health, the search for factors involved in the pathogenesis of ADHD has recently included the intestinal microbiota and the gut-brain axis. The findings of animal studies suggest that the gut microbiota play a role in brain development and function and may be involved in neurotransmission and neuronal plasticity. Neuronal, metabolic, endocrine, and immune pathways have been proposed to be involved in the modulation by intestinal microbiota of brain development and function as well as behavior. Disturbances of the developing gut microbiota in early life have been shown to influence neurodevelopment and to be associated with mental health issues later in life. Furthermore, early probiotic intervention may influence the risk of mental disorders later in childhood. Based on the findings of animal studies, the gut microbiome has also been suggested as a potential therapeutic target in ADHD. Individuals diagnosed with ADHD have been found to have a different composition of intestinal microbiota compared to healthy controls, with certain bacteria being more and others being less abundant (Bull-Larsen and Mohajeri, 2019).

Bifidobacteria have protective effects on the intestinal barrier function in the gut and influence the dopamine system by elevating phenylalanine and dopamine concentrations through increased production of cyclohexadienyl dehydratase. Intestinal Bifidobacterium levels have been suggested to play a role in the pathogenesis of ADHD and are influenced by several factors related to an elevated risk of ADHD. These factors include delivery by caesarean section, preterm delivery, and the administration of antibiotics during the first months of life. Breastfeeding has been found to be associated with increased Bifidobacterium and lower prevalence of ADHD. However, varying results concerning levels of Bifidobacterium in people with ADHD preclude its use as a potential biomarker for ADHD (Bull-Larsen and Mohajeri, 2019). Furthermore, the role of the gut microbiota in ADHD is still ill-defined due to various factors, such as small sample sizes, differences in age, sex, and medication of children with ADHD included, as well as heterogeneous microbiome sequence analyses.

Few intervention studies have examined probiotics in ADHD. The effects of a 6-month supplementation of the probiotic strain *Lactobacillus rhamnosus* GG soon after childbirth were assessed after 13 years. In children diagnosed with ADHD, the quantity of Bifidobacteria in the feces was lower than in healthy children. At age 13 years, of 35 children in the placebo group, three were diagnosed with ADHD and two with both ADHD and Asperger syndrome, while none of 40 children in the probiotic group were found to have ADHD. This preliminary evidence suggests a preventive role of probiotics in ADHD. A randomized placebo-controlled 3-month pilot trial, investigating the effect of *Lactobacillus rhamnosus* GG on ADHD symptoms in children and adolescents, found better health-related quality of life, but no clear effects on psychometric parameters following probiotic treatment, compared to placebo controls. The potential role of the microbiome in the pathophysiology of ADHD and as a biomarker of the disorder, as well as of probiotics in the prevention and treatment of ADHD requires further large-scale studies.

In summary, it remains unclear whether vitamin (e.g. B vitamins, vitamin D) or mineral (e.g. zinc, magnesium, iron) deficiencies are involved in the pathophysiology of ADHD. At present, the evidence regarding micronutrient supplementation in the treatment of ADHD is inconclusive. Modest effects on hyperactive behavior may be yielded by the supplementation of free fatty acids, but these may be confined to subgroups of children with ADHD. Potential effects of probiotics in ADHD require further investigation.

### Problems of research on nutrition in ADHD

Scientists and laypeople interested in nutrients and their effects on hyperactivity and ADHD usually accept the validity of the concept of ADHD and are seldom acquainted with the problems surrounding the diagnosis and treatment of this disorder. The identification of a role of nutrients in ADHD is hindered by the complex, heterogeneous and ill-defined nature of ADHD as well as the lack of biological markers underpinning the validity of the diagnosis. The validity of ADHD as a diagnostic entity in children and adolescents has been disputed based on inconsistent symptom clustering, lack of biomarkers, high prevalence of comorbid childhood-onset mental disorders and differing cultural perceptions. Particularly in older studies, there is uncertainty regarding the diagnostic classification of ADHD and the psychometric qualities of the assessment tools used. Furthermore, it is often unclear whether those rating behavioral changes were truly blinded (e.g. parents involved in delivering the dietary intervention). The assessment of outcomes of therapeutic interventions in ADHD is commonly based on symptom rating and does not account for measures of adaptive skills, daily functioning in the context of social relationships, education and employment or quality of life. However, these aspects need to be considered when outcome measures with ecological validity beyond the ADHD core symptoms are defined.

Evidence supporting the therapeutic efficacy of single nutrients in ADHD is at present unavailable. Multi-nutrient supplementation may be necessary to achieve beneficial effects on ADHD symptoms. Furthermore, in view of the controversy surrounding the concept of ADHD and the heterogeneity of the disorder in terms of etiology, pathophysiology and clinical presentation, potential therapeutic benefits of nutritional elimination and supplementation could be confined to subpopulations of children with ADHD yet unidentified.

A sufficient supply of certain nutrients is essential during critical phases of brain development, especially during gestation, and dietary supplementation of nutrients after these time windows may be of limited benefit. Controlled interventional studies investigating the effects of single nutrients during childhood and adolescence may fail to account for the requirement of the brain for adequate quantities of various nutritional components at critical times. Nutrients needed during late fetal and early neonatal life include protein, choline, various minerals, and polyunsaturated fatty acids. Prenatal exposure to diets deficient in these essential nutrients has been found to be associated with symptoms of ADHD in childhood. Moreover, low maternal serum vitamin D in the first trimester of pregnancy appear to be associated with ADHD-like symptoms at preschool age.

The effects of unhealthy dietary patterns, such as snack or Western patterns, in children with ADHD are not fully understood. The cumulative benefits of the range of ingredients comprising healthy diets, such as the Mediterranean diet, may result in better outcomes compared to a supplementation of individual nutrients. However, establishing and maintaining adherence to longer term changes in whole diets beyond nutrient supplementation is likely to be a major challenge. Furthermore, associations between adherence to healthy diets and low prevalence of ADHD do not necessarily imply protective effects of healthy foods consumed during childhood. The mothers of children consuming a healthy diet may also have adhered to healthy diets during pregnancy and have provided their children with essential nutritional compounds during critical phases of brain development.

Diet and nutrition interact and overlap with other lifestyle factors, such as physical activity. Children with ADHD may benefit from generally improved lifestyle choices, and the interrelationship between nutrition and lifestyle should play a more prominent role in research on treatment approaches to ADHD ([Lange, 2018a](#)).

### Conclusion

The current pharmacological treatment of individuals diagnosed with ADHD is unsatisfactory. Insufficient evidence of the effectiveness of commonly used ADHD medications on clinically and ecologically relevant outcome measures as well as the unproven long-term efficacy and potentially problematic adverse effects of drug treatment have led to a search for alternative treatment options, including dietary interventions, some of which attempt to improve ADHD symptoms either through the avoidance of certain food compounds or the supplementation of specific food elements.

Low plasma concentrations of minerals such as zinc, magnesium and iron have been found in children with ADHD at the group level, and mineral supplementation may reduce ADHD symptoms in children with deficiencies. However, evidence in support of this is lacking. The question of whether vitamin deficiencies contribute to the pathogenesis of ADHD is also unclear, and, consequently, the potential value of therapeutic compensation through multivitamin supplementation is undetermined. The role of polyunsaturated fatty acids in the treatment of ADHD is controversial. Furthermore, potential adverse effects of long-term administration of food supplements should be considered. These may become apparent many years following supplementation and therefore elude detection ([Lange et al., 2019](#)).

In summary, deficiencies of nutrients including vitamins, minerals and polyunsaturated fatty acids and surpluses of food items such as sucrose and artificial food additives have not convincingly been shown to be involved in the etiology of hyperactivity or ADHD. Furthermore, there is currently no conclusive evidence supporting the efficacy of dietary interventions eliminating or

supplementing single nutrients in reducing hyperactivity or other symptoms of ADHD. However, the few-foods diet provides a diagnostic tool in the identification of children with sensitivity to certain foods. This diet also appears to hold some promise in improving symptoms of ADHD and providing a novel individualized dietary treatment approach. Further large-scale, well-designed studies are needed to demonstrate the utility of dietary interventions alone or in combination with other treatment approaches in ADHD.

### Key points

- Lipid and lipoprotein metabolism are exquisitely regulated and there many metabolic pathways that are subject to dysregulation resulting in hypercholesterolemia and hypertriglyceridemia
- Dyslipidemia can be caused by genetics or unhealthy lifestyle practices
- There is a long-established classification system for the familial dyslipidemic phenotypes
- Hyperlipidemia is a major risk factor for CAD
- A healthy lifestyle including a healthy dietary pattern is recommended for the treatment of hypercholesterolemia and hypertriglyceridemia

### Overview

Hyperlipidemia is a disorder of lipid metabolism that results in an elevated level of circulating cholesterol and/or triglycerides, also known as triacylglycerols (TG). Because of their insolubility in water, these lipids are transported in the circulation packaged in lipoproteins. Lipoprotein particles are comprised of a hydrophobic lipid core (primarily cholesteryl esters and triacylglycerol) and a hydrophilic surface membrane of polar lipids (unesterified cholesterol and phospholipids) and apolipoproteins (**Fig. 1**). There seven major lipoprotein classes are differentiated on the basis of size, lipid, and apolipoprotein (Apo) composition:

- Chylomicrons
- Chylomicron remnants
- Very low-density lipoproteins (VLDL)
- Intermediate-density lipoproteins (IDL)
- Low-density lipoproteins (LDL)
- High-density lipoproteins (HDL)
- Lipoprotein (a) [Lp(a)]

**Fig. 1** Lipoprotein particle. Apolipoprotein (Apo).

Lipoproteins are synthesized in the intestine, liver and modified in the plasma, the latter by enzyme modification and removed from the plasma by a receptor-mediated process that is largely regulated by apolipoproteins. The physicochemical characteristics of the main lipoprotein classes are shown in **Table 1**. The different lipoprotein classes have important and distinct physiological functions. Disruptions in their normal metabolic fates result in disorders of lipid and lipoprotein metabolism.

These disorders cause hyperlipidemia that play a central role in the development of atherosclerosis, particularly coronary heart disease (CHD), stroke, peripheral vascular disease, which are the major cardiovascular diseases (CVD). This has been reviewed recently by [Feingold \(2021\)](#).

## Cholesterol

Cholesterol is a sterol that is present in all animal tissues. It emanates from diet and endogenous synthesis. Cholesterol is found in the body in two metabolically active pools, free and esterified to fatty acids, largely as free cholesterol in membranes, but in the plasma, it is two-thirds esterified, mainly as cholesteryl linoleate and cholesteryl oleate. Body cholesterol homeostasis is tightly regulated by the interplay between absorption, synthesis, and excretion or conversion of cholesterol into bile acids ([Alphonse and Jones, 2016](#)). The rate-limiting step in synthesis is sensitive to cellular levels of cholesterol, which, in turn, are sensitive to plasma cholesterol levels. The feedback regulation occurs through changes in the amount and activity of the enzyme, 3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase), which catalyzes the formation of mevalonate, the rate-limiting step in cholesterol biosynthesis. The rate of synthesis of HMG-CoA reductase mRNA is controlled by the sterol regulatory element binding protein (SREBP). SREBP in its inactive state is attached to the endoplasmic reticulum or nuclear membrane, but when cholesterol levels decline the amino-terminal domain is released from its association with the membrane by proteolytic cleavage, it migrates to the nucleus and binds to the sterol regulatory element of the reductase gene to enhance transcription. As cholesterol levels increase, the proteolytic release of SREBP is blocked, SREBP in the nucleus is rapidly degraded, and cholesterol synthesis is switched off. Hepatic cholesterol homeostasis is important for the regulation of plasma LDL-cholesterol (LDL-C).

The Niemann–Pick C1-like 1 (NPC1L1) transporter that facilitates the uptake of cholesterol is located in the brush border membrane of enterocytes in the proximal jejunum of the small intestine. Two other transporters, adenosine triphosphate protein binding cassette transporters G5/G8 (ABCG5 and ABCG8), are found in the proximal small intestine. These transporters promote the efflux of unesterified cholesterol from the enterocyte back into the intestinal lumen. The non-effluxed intracellular cholesterol translocates to the endoplasmic reticulum and subsequently gets esterified by acetyl-coA cholesterol acyltransferase-2 (ACAT2) and then is incorporated into chylomicrons along with TGs, phospholipids, and Apolipoprotein (Apo) B-48 and delivered to the lymph.

## Triacylglycerol

Triacylglycerols are glycerol molecules esterified with three fatty acid molecules (**Fig. 1**). Diacylglycerols and monoacylglycerols have two and one fatty acid molecules, respectively. Triacylglycerols constitute the main energy storage form in mammals and are the primary storage form of fatty acids.

Dietary TGs are hydrolyzed by pancreatic lipases in the intestinal lumen to monoglycerides and free fatty acids, which are taken up by enterocytes where they are re-synthesized into TGs and packaged into chylomicrons for secretion into the lymph. The chylomicron surface is covered with a phospholipid monolayer, contains free cholesterol and is enveloped by Apo B-48. In addition to Apo B-48, which is synthesized in the small intestine, there are several other apolipoproteins on the surface of the chylomicron, including Apo AI, Apo AIV, and Apo Cs. Chylomicron fatty acid composition is correlated with dietary fatty acids.

**Table 1** Physiochemical characteristics of lipoprotein classes.

Lipoprotein	Density (g/mL)	Size (nm)	Major lipids	Lipid composition	Major apolipoproteins
Chylomicrons	<0.930	75–1200	TG	98–99	Apo B-48, Apo C, Apo E, Apo A-I, Apo A-II, Apo A-IV
Chylomicron remnants	0.930–1.006	30–80	TG and Cholesterol	92–94	Apo B-48, Apo E
VLDL	0.930–1.006	30–80	TG	90–93 <sup>a</sup>	Apo B-100, Apo E, Apo C
IDL	1.006–1.019	25–35	TG and Cholesterol	89	Apo B-100, Apo E, Apo C
LDL	1.019–1.063	18–25	Cholesterol	79	Apo B-100
Lp(a)	1.055–1.100 <sup>b</sup>	30	Cholesterol	65	Apo B-100, Apo (a)
HDL	1.063–1.210	5–20	Cholesterol and Phospholipids	43–68	Apo A-I, Apo A-II, Apo C, Apo E

<sup>a</sup>Ratio of TG to cholesterol is 5:1.

<sup>b</sup>Also found in small amounts between 1.100 and 1.21 g/mL.

## Fatty acids

Fatty acids are present in TGs, as part of lipoprotein particles, and also as free fatty acids (bound to albumin) in the circulation. Common dietary fatty acids and major food sources are listed in [Table 2](#). Fatty acids are straight-chain compounds of differing lengths connecting a hydrocarbon group to a hydroxyl group. Saturated fatty acids (SFA, the most common saturated fatty acid is palmitic acid, C16:0) do not have double bonds; with one or more additional double bonds, the fatty acid is unsaturated. Mono-unsaturated fatty acids (MUFA) have one double bond (e.g., oleic acid, C18:1, is the major MUFA in the diet). Polyunsaturated fatty acids (PUFA) have two or more double bonds and are classified as either an omega-6 or omega-3 fatty acid based on the position of the first double bond from the methyl terminus. For an omega-6 PUFA the first double bond is on the sixth carbon atom (e.g., linoleic acid, C18:2, is the major PUFA in the diet) whereas for omega-3 PUFA, the first double bond occurs on the third carbon atom from the methyl end (e.g., linolenic acid, C18:3). The presence of a double bond allows for two isomers, depending on whether the hydrogen atoms attached to the carbon atoms on either side of the double bond lie on the same side (cis) or opposing sides (trans). In liquid food oils, the unsaturated fatty acids are cis isomers. Trans isomers are produced by microbial biohydrogenation of unsaturated fatty acids in ruminant animals and also by partial hydrogenation of liquid oils, during food processing. Naturally occurring trans fatty acids are found in foods that come from ruminant animals (e.g., milk, cheese, beef, lamb). Industrially produced trans fatty acids have largely been removed from the food supply since they lost GRAS (Generally Recognized as Safe) status by FDA.

Dietary unsaturated fatty acids decrease risk of CVD whereas SFA increase risk. The biological effects of dietary fatty acids are due to changes in membrane lipid composition, cellular metabolism, intracellular signal transduction, and the regulation of gene expression. Recent evidence has emerged that suggests that some fatty acids may act at the level of the microbiome, which could have important health implications.

## Phospholipids

The common phospholipids in plasma are derived from glycerol and consist of TG containing phosphate and a nitrogenous base (glycerophospholipids). The phosphate group is usually attached at position 3 of the glycerol molecule, and the nitrogenous base is usually an amino acid or an alcohol. The phosphatidyl cholines (lecithins) are the most common phospholipid and are found in plasma and in cell membranes. Lecithin-cholesterol acyl transferase (LCAT) catalyzes the transfer of a fatty acyl group at position 2 on glycerol to cholesterol to produce cholesteryl ester and leaves monoacyl glycerophosphate (lysolecithin). Another class of phospholipids, the cephalins, includes phosphatidyl ethanolamine, phosphatidyl serine, and phosphatidyl inositol.

Phospholipids are essential for the structural integrity of the membrane that surrounds lipoprotein particles. Phospholipids form a bridge between nonpolar lipids and water and act to allow the particle to be transported in an aqueous environment (i.e., the plasma). In lipoproteins, the hydrophobic core of TG and cholesteryl esters is surrounded by phospholipids and free cholesterol. The nonpolar hydrocarbon end of the phospholipid is attracted to lipid, whereas the polar phosphate group is attracted to water.

## Apolipoproteins

There is a diverse array of apolipoproteins located on the surfaces of the lipoprotein particles, which play crucial roles in the formation, transport and metabolism of lipoproteins. Their major functions are to: (1) play a structural role—they interact with phospholipids to solubilize cholesterol esters and TG; (2) act as ligands for lipoprotein receptors; (3) help with the assembly of lipoproteins; and (4) serve as activators or inhibitors of enzymes involved in lipoprotein metabolism. For example, they are involved in the regulation of enzymes (e.g., lecithin cholesterol acyltransferase (LCAT), lipoprotein lipase (LPL), and hepatic lipase (HL)), and bind with cell surface receptors to initiate the cellular metabolism of lipoproteins or their constituents. Of note, levels of some are associated with CVD risk (e.g., Apo B and Apo C-III).

## Apolipoprotein A-I

This is the main structural protein of HDL and accounts for 70% of HDL protein. It is synthesized in both the liver and intestine. Apo A-I has two important roles: (1) it is involved in the regulation of the interaction of HDL with ATP-binding cassette protein A1 (ABCA1), ABCG1, and class B, type I scavenger receptor (SR-B1); and (2) activates LCAT, which is responsible for esterification of free cholesterol in plasma and allows the binding of HDL to many cell surfaces. The production and catabolism of ApoA-I determine the plasma concentration of HDL cholesterol. Elevated levels of Apo A-I are associated with lower CVD risk.

**Table 2** Average triacylglycerol fatty acid composition of common foods, fats and oils.

		Saturated (% TG)				Monounsaturated (% TG)		Polyunsaturated (% TG)

### **Apolipoprotein A-II**

Apolipoprotein A-II, which is synthesized in the liver, accounts for approximately 20% of HDL protein. In contrast to Apo A-I, the biological and physiological functions of Apo A-II remain unclear. Clinical and epidemiological studies report conflicting results about the role of Apo A-II and CVD risk.

### **Apolipoprotein A-IV**

Apo A-IV, which is synthesized in the intestine during the absorption of fat, is associated with both chylomicrons and high-density lipoproteins. Many questions remain about the role of Apo A-IV in lipoprotein metabolism.

### **Apolipoprotein A-V**

Apo A-V is synthesized in the liver and is located on triglyceride rich lipoprotein particles (chylomicrons and VLDL), and also on HDL. Apo A-V activates LPL mediated lipolysis and, consequently, affects the metabolism of triglyceride rich lipoproteins, which modulates plasma triglyceride concentrations.

### **Apolipoprotein B-48**

There are two circulating forms of apolipoprotein B, Apo B-48 (which is synthesized in the small intestine) and Apo B-100 (which is produced in the liver). Apo B-48 is the amino-terminus of Apo B-100 and has a molecular mass of 48% of the parent protein, which was the basis for its name. It is the predominant structural protein on chylomicrons and chylomicron remnants. There is a single molecule of Apo B-48 on each chylomicron particle. Importantly, the LDL receptor (LDL-R) does not recognize Apo B-48.

### **Apolipoprotein B-100**

Apo B-100 is the main protein component of VLDL, IDL and LDL, and is synthesized in the liver. Each of these lipoproteins has one molecule of Apo B-100. Apo B-100 is the primary ligand for the LDL-R and is involved in the clearance cholesterol-rich lipoproteins. Elevated Apo B-100 levels increase risk of atherosclerosis.

### **Apolipoproteins C-I, C-II and C-III**

These Apo C particles are synthesized in the liver and all are found in chylomicrons, VLDL and HDL. These C apolipoprotein exchange freely between lipoprotein particles. Notably, they have different biological functions. Apo C-I activates LCAT, which catalyzes the transfer of cholesterol from the surface of HDL to the core of HDL. Apo C-II is a co-factor for lipoprotein lipase (LPL), which hydrolyzes TG in TG-rich lipoproteins to fatty acids that are taken up by cells and the conversion of chylomicrons to chylomicron remnants and VLDL into IDL. Apo C-III is the most abundant form of Apo C and is mainly produced in the liver and to a lesser extent in the intestine. Importantly, plasma Apo C-III levels are positively correlated with plasma TG levels and CVD risk. Clinical and preclinical studies have shown that Apo C-III raises plasma TG levels by inhibiting hepatic TRL clearance, which occurs primarily as a result of its effect to reduce the rate of TG hydrolysis in plasma by both LPL and HL. In addition, Apo C-III inhibits the binding of TG-rich lipoproteins with their receptors. In the Framingham Heart Study Apo C-III was an independent CVD risk factor.

### **Apolipoprotein E**

Apo E is a glycoprotein with three common isoforms Apo E-2, E-3, and E-4. Apo E-3 is the most common isoform. The Apo E isoforms are synthesized in many tissues, but liver and intestine are the major sources. Apo E exchanges between lipoprotein particles and is associated with chylomicrons, chylomicron remnants, VLDL, IDL, and a subgroup of HDL particles. Apo E-3 and E-4 are ligands for the LDL-R, whereas Apo E-2 is poorly bound. Patients who are homozygous for Apo E-2 can develop dysbetalipoproteinemia (type III hyperlipoproteinemia) in which chylomicron remnants and IDL are cleared slowly, which increases risk of CVD. Apo E-4 is a risk factor for the development of CVD and Alzheimer's disease.

## Apolipoprotein (a)

Apo(a), when bound to Apo B-100 on an LDL particle results in the creation of a unique lipoprotein referred to as Lp(a). Apo(a) is synthesized in the liver, shares close sequence homology with plasminogen and has been shown to inhibit fibrinolysis. In addition, it also increases the uptake of lipoproteins by macrophages, which initiates and promotes atherosclerosis.

## Lipoproteins

Lipoprotein transport and metabolism are highly complex and exquisitely regulated. Each of the seven lipoprotein classes has unique biological functions. An important function is to transport lipids from one organ to another. In addition, there is a transfer of lipids and apolipoproteins, as well as between lipoproteins and lipoprotein classes which affects their functionality (Feingold, 2021). Lipoproteins also function in transporting toxic foreign hydrophobic and amphipathic compounds so that they are cleared from the body.

## Chylomicrons

These are the largest lipoproteins, consisting mainly of TG derived principally from the diet via lipid digestion and absorption. These particles contain apolipoproteins A-I, A-II, A-IV, A-V, B-48, C-II, C-III, and E. Apo B-48 is the core structural protein and each chylomicron particle contains one Apo B-48 molecule. Their major role is transport of dietary TG and cholesterol to peripheral tissues and the liver. Chylomicron size varies depending on the amount of fat consumed. Higher fat intake results in both the formation of larger chylomicron particles and higher postprandial TG levels. Peak chylomicronemia occurs 3–6 h after a meal, with a half-life of less than 1 h, and is cleared from the circulation after a 12 h fast. The lipolytic processes result in smaller particles known as chylomicron remnants (reviewed by Ginsberg et al., 2021).

## Chylomicron remnants

Lipolysis of chylomicrons results in the formation of chylomicron remnants that are enriched in cholesterol, have an altered apolipoprotein composition, as well as physicochemical properties. The resulting remnants have retained virtually all the cholesterol contained in their precursors and acquire several molecules of apo E via exchange with HDL. Because of these changes, remnant lipoproteins are rendered highly atherogenic (reviewed by Ginsberg et al., 2021).

Because of their size, chylomicrons and large VLDLs are not taken up by the artery wall. In contrast, smaller chylomicron and VLDL remnants can and do penetrate the artery wall. Unlike chylomicrons and large VLDL, remnant particles have a 2-fold increased affinity for crossing the endothelium and accumulating into the subendothelial space, where they become trapped by subendothelial proteoglycans and may ultimately be engulfed by vascular macrophages. This fuels the atherogenic process.

## Very low-density lipoproteins

These TG-rich lipoproteins are produced and secreted mainly by the liver (and the intestine to a limited extent) and contain apolipoprotein B-100, C-I, C-II, C-III, and E. VLDL size varies as a function of the amount of TG that is packaged in the particle during hepatic synthesis. Once released in the circulation, the nascent VLDL are transformed into mature VLDL by accumulating cholesterol ester, apo C, and apo E from HDL. Subsequently they undergo delipidation by the actions of lipoprotein lipase and are converted to IDL. Small VLDL is converted into LDL, via IDL, to a greater extent than large VLDL, which is converted to a form of IDL that appears to be removed from the plasma before conversion to LDL (Ginsberg et al., 2021).

**Table 3** Classification of HDL.

<i>Method of classification</i>	<i>Types of HDL</i>
Density gradient ultracentrifugation	HDL2, HDL3, very high-density HDL
Nuclear magnetic resonance	Large, medium, and small
Gradient gel electrophoresis	HDL 2a, 2b, 3a, 3b, 3c
2-dimensional gel electrophoresis	Pre-beta 1 and 2, alpha 1, 2, 3, 4
Apolipoprotein composition	A-I particles, A-I: A-II particles, A-I: E particles

Source: Feingold (2021).

### Intermediate-density lipoproteins

IDLs are intermediate particles formed from the conversion of VLDL to LDL. Also known as VLDL remnants, some are removed directly from plasma, whereas some are converted to LDL.

### Low-density lipoproteins

LDL is the major cholesterol-carrying particle in the plasma with apo B-100 being the predominant apolipoprotein. LDLs are derived from VLDL and IDL due to the delipidation process and are further enriched in cholesterol. LDLs consist of a spectrum of particles that range in size. All LDL particles are atherogenic (Ferenec et al., 2017). Small dense LDL particles are particularly pro-atherogenic because of prolonged retention time in the circulation, which reflects a decreased affinity for the LDL receptor-mediated uptake and removal. In addition, they more easily enter the arterial wall and readily bind to intra-arterial proteoglycans, which trap them in the arterial wall thereby promoting the atherogenic process. Finally, small dense LDLs are very susceptible to oxidation, which is thought to enhance uptake by macrophages followed by foam cell formation, which accelerates atherogenesis. Oxidized LDL in the cell wall stimulates inflammation and the production of cytokines and growth factors, which promote monocyte recruitment and smooth muscle cell proliferation. Moreover, the modified LDL particle is also a ligand for certain receptors (the scavenger receptor and perhaps a specific receptor for oxidized LDL), which contributes to the formation of cholesterol-laden foam cells.

### High-density lipoproteins

Nascent HDL is secreted by the liver and gut. There is a family of HDL particles that vary in size and density (see Table 3). HDL particles are heterogeneous due to differences in size, lipid, and protein content. Based on ultracentrifugation, there are two main subfractions, HDL2 and HDL3. These can be further sub-fractionated into at least five subpopulations (HDL2b, HDL2a, HDL3a, HDL3b, and HDL3c).

The long-held view that HDL-C is inversely associated with the risk of cardiovascular events stems from several epidemiological studies. There is evidence that HDL particles have an important role in reverse cholesterol transport (RCT) from peripheral tissues to the liver, which may explain its anti-atherogenic property, along with having antioxidant, anti-inflammatory, anti-thrombotic, and anti-apoptotic properties. However, recent epidemiologic studies found that individuals not only with the lowest HDL-C but also those with the highest HDL-C levels have an increased risk of CVD mortality. This “U-shaped” association raises the question of whether a “sweet spot” exists for the HDL-C–CVD relationship, and whether the reasons for the increased association with CVD (and mortality) at both ends of the distribution are based on different characteristics of the HDL particle profile. The idea is evolving that the diversity of HDL subclasses, each perhaps endowed with some specific biological effects, rather than being based solely on their cholesterol content. Also, involvement in cholesterol efflux capacity may account, at least in part, for the U-shaped risk profile. Thus, estimating CVD risk on the basis of HDL-C concentration is limited by the complexity of the HDL family (Casula et al., 2021).

### Lipoprotein(a)

Lp(a) is an LDL-like particle containing apolipoprotein (a) linked to Apo B-100 via a disulfide bond. High concentrations of Lp(a) are associated with increased risk of CVD-related events, including myocardial infarction, stroke, and heart failure, as well as valvular aortic stenosis. Lp(a) also has atherothrombotic traits and thrombo-inflammatory traits (Wilson et al., 2019).

### Enzymes and transfer proteins

The enzymes presented below all play important roles in lipid and lipoprotein metabolism. Related to dyslipidemia, HMG-CoA reductase and LPL are essential for modulating plasma cholesterol and TG levels, respectively. Many of the perturbations in plasma cholesterol and triglyceride levels occur because of a complex genetic etiology with gene variants that occur in key regulatory steps in the pathways that modulate cholesterol and TG levels. These genetic variants can occur in enzymes, apoproteins and other factors (binding proteins, receptors) that affect cholesterol and TG metabolism.

### Acyl-coenzyme A:cholesterol O-acyltransferase (ACAT)

Acyl-coenzyme A:cholesterol O-acyltransferase is an intracellular enzyme that catalyzes the acylation of cholesterol with long-chain fatty acids to form cholesteryl esters (CE). The CE in nascent VLDL are generated by ACAT. There are two isoforms of ACAT. ACAT-1 is expressed predominantly in liver (Kupffer cells), macrophage, adrenal gland and the brain. ACAT-2 is synthesized in the

hepatocytes and enterocytes. ACAT-1 has been associated with adverse effects on the arterial wall and macrophage-derived foam cell formation. An important role of ACAT-2 is for the synthesis of CE used for chylomicron and VLDL production.

### **ATP binding cassette transporter A1 and G1 (ABCA1, ABCG1)**

Both ABC transporters function as a lipid transporter and are essential for RCT. ABCA1 and ABCG1 are critical receptors for the initial step of RCT in atherosclerotic plaques, i.e., cholesterol efflux out of foam cells. The activity ABCA1 in hepatocytes and enterocytes plays a central in plasma HDL production. The transporter mediates the release of phospholipid and free cholesterol from the plasma membrane of these cells to apo A-I in the extracellular medium, thereby producing nascent HDL particles. Thus, ABCA1 is important in the efflux of cholesterol to lipid poor pre-beta Apo A-1 particles. ABCG1 also mediates the efflux of cholesterol from the cell to mature HDL particles and is present in a diverse array of cells.

### **Cholesterol ester transfer protein (CETP)**

CETP facilitates the transfer of esterified cholesterol from anti-atherogenic HDL to pro-atherogenic LDL and VLDL in exchange for triglycerides. The hypothesis that inhibition of CETP activity might prevent CHD was based on the evidence that it both reduces plasma LDL-C concentration, and raises HDL-C. Several large trials evaluating different CETP inhibitors have failed to prevent cardiovascular events even though there was a marked increase in HDL-C. Subsequent studies showed that HDL functionality and reverse cholesterol transport were compromised in response to these inhibitors ([Yamashita and Matsuzawa, 2016](#)).

### **Fatty acid binding protein (FABP)**

Fatty acid binding proteins (FABPs) are a family of lipid chaperones that are involved in several lipid signal transduction pathways that regulate lipid trafficking and metabolic and inflammatory pathways. At least nine different FABP isoforms have been identified. FABP4 is primarily expressed in adipocytes and macrophages and plays an important role in insulin resistance and atherosclerosis. FABPs are involved in the solubilization of long-chain fatty acids and their CoA-esters to various intracellular organelles. FABPs serve as intracellular receptors of LCFAs and are involved in ligand-dependent transactivation of peroxisome proliferator-activated receptors in trafficking LCFAs to the nucleus.

### **Hepatic lipase (HL)**

Hepatic lipase (HL) is an endothelial-bound enzyme synthesized and secreted from hepatocytes that catalyzes the hydrolysis of TG and phospholipids in several lipoproteins. HL is involved in the remodeling of apo B-containing lipoproteins and HDL, and in the production of small, dense LDL, as well as small HDL remnants. HL hydrolyzes HDL triacylglycerol and phospholipids to form HDL3 from HDL2, contributing to the process of HDL regeneration in the reverse cholesterol transfer process. Thus, HL plays a role in determining the size, density, and consequent metabolic fate of these lipoprotein particles.

### **HMG CoA reductase**

HMG-CoA reductase is the key (and rate limiting) enzyme in the synthesis of cholesterol. It catalyzes the NADPH-dependent reduction of HMG-CoA to mevalonic acid in the cholesterol synthetic pathway. Statin drugs are HMG-CoA reductase inhibitors, the first line drugs for treating hypercholesterolemia. Clinical studies have shown that they effectively reduce CVD morbidity and mortality in primary and secondary prevention. Maximal reduction of LDL-C is approximately 60% with high dose statin therapy.

### **Lecithin:cholesterol acyltransferase (LCAT)**

Lecithin:cholesterol acyltransferase (LCAT), the only enzyme capable of esterifying cholesterol in plasma, mediates the esterification of cholesterol by transferring a fatty acid from lecithin to cholesterol to form cholesteryl ester. Thus, LCAT is centrally involved the maturation of HDL. Because it maintains an unesterified cholesterol gradient between peripheral cells and extracellular acceptors, LCAT is considered to be a key enzyme in reverse cholesterol transport. The preferred lipoprotein substrate is pre  $\beta$ -HDL, a newly assembled small discoidal HDL. Following interaction with LCAT, pre  $\beta$ -HDL is converted to mature, spherical and  $\alpha$ -migrating HDL, which comprises most of plasma HDL.

### **Lipoprotein lipase (LPL)**

Lipoprotein lipase (LPL) is an endothelial-bound enzyme that has long been known to be the rate-limiting step in the removal of TG from TG-rich lipoproteins. Lipoprotein lipase is activated by apoC-II and catalyzes the hydrolysis of TG in chylomicrons and VLDL. It is a biomarker for diagnosing Type I hyperlipidemia.

### **Microsomal triglyceride transfer protein (MTP)**

Microsomal triglyceride transfer protein (MTP) is an endoplasmic reticulum (ER) resident protein in enterocytes and hepatocytes that facilitates the transfer of neutral lipids to nascent apo B. It plays a key role in the assembly and secretion of apo B-containing lipoproteins.

Inhibition of MTP reduces apo B synthesis and, hence, lipoprotein assembly and secretion, and decreases plasma cholesterol levels (LDL-C), apo B and TG by over 50% ([Hussain, 2014](#)).

### **Phospholipid transfer protein (PLTP)**

Plasma PLTP catalyzes the transfer of phospholipids from apoB-containing TG-rich lipoproteins to HDL, and also exchanges phospholipids between lipoproteins. In addition, PLTP has been shown to act like a fusion factor to enlarge HDL particles. PLTP is required for efficient PLTP-mediated HDL enlargement ([Jiang, 2018](#)).

### **Sterol regulatory element binding proteins (SREBPs)**

Sterol regulatory-element binding proteins (SREBPs) are transcription factors that regulate the promoters of genes involved in cholesterol biosynthesis and the LDL receptor pathway that regulates sterol balance. SREB is activated when cellular cholesterol levels are decreased and LDL receptor gene expression is increased, thereby increasing LDL-C uptake from the plasma. When cellular cholesterol levels are high, SREBP remains inactive.

### **Lipoprotein receptors and transporters**

Lipoprotein metabolism is importantly regulated by different lipoprotein receptors and transporters that, consequently, affect atherogenesis and CVD risk ([Mineo, 2020](#)).

### **LDL receptor (LDLR)**

The LDLR is a transmembrane glycoprotein present on the plasma membrane of most cell surfaces. The LDLR binds to Apo B-100 and Apo E, which is the first step in receptor-mediated uptake of LDL, chylomicron remnant and IDL. Following internalization, the particle is degraded in lysosomes and the free cholesterol is released. The accumulation of free cholesterol reduces both cell synthesis of cholesterol and cell uptake of more LDL-C via regulatory steps involving HMG CoA reductase and the SREBPs. LDLR gene expression is regulated by changes in intracellular cholesterol.

### **LDLR-related protein (LRP)**

In addition to LDLR, there are many other structurally and functionally related receptors that have been identified, which include low-density lipoprotein receptor-related protein (LRP)1, LRP5, LRP6, very low-density lipoprotein receptor, and apolipoprotein E receptor 2. In the liver, LRP1 partners with the LDLR in the endocytosis and clearance of cholesterol-rich chylomicron remnants from the circulation. The LRP family is a large and complex array of different proteins that bind to dozens of different ligands that not only affect lipoprotein metabolism but other cellular processes.

### **Scavenger receptor (SR) family**

The scavenger receptors belong to a large family of pattern recognition receptors, which can interact with a wide range of ligands. Interacting with the circulating native or modified lipoproteins, such as oxLDL, these receptors modulate vascular inflammation, lipid accumulation, and plaque formation. Two important SR, CD36 and SR-BI, play a role in atherogenesis in different ways.

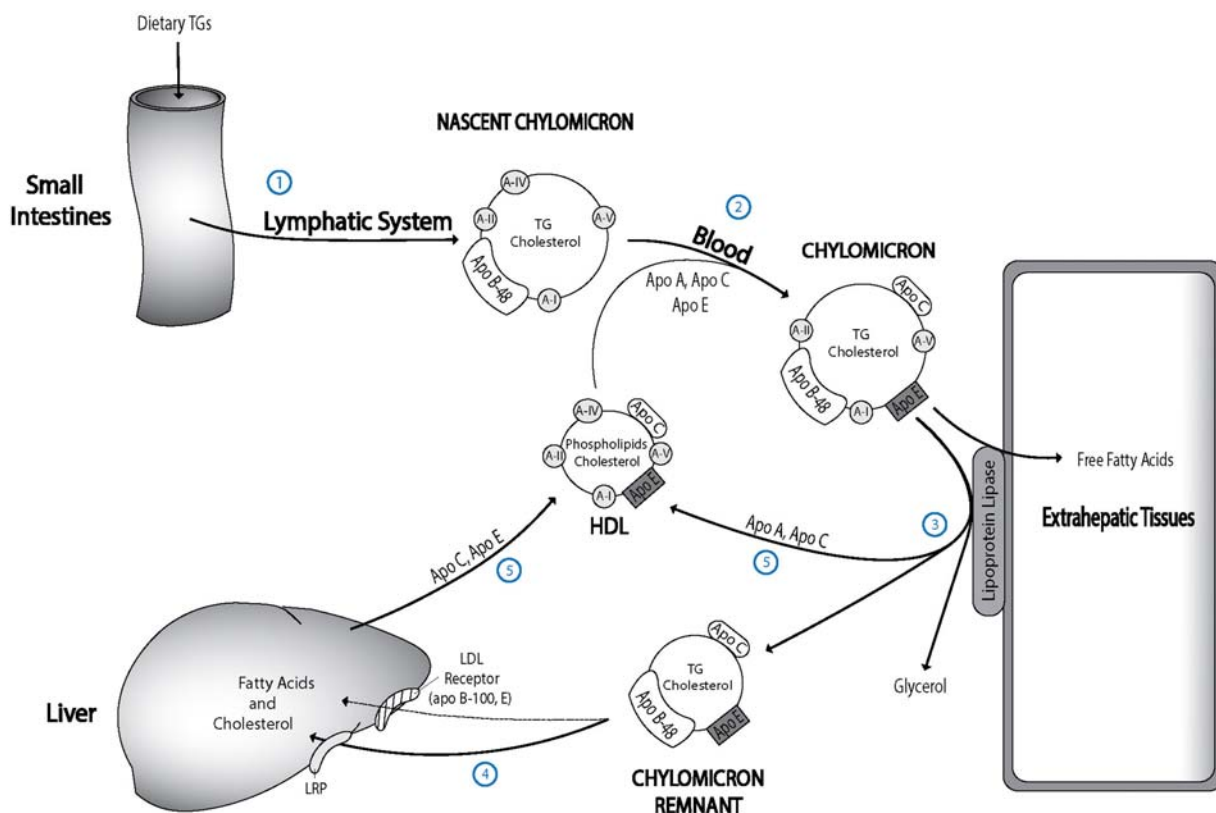

CD36 promotes endothelial dysfunction, macrophage foam cell formation, vascular inflammation, and thrombosis. In contrast, SR-B1, a high-affinity HDL receptor mediates the uptake of HDL cholesterol ester into the liver. SR-B1 also facilitates the bidirectional flux of free cholesterol (FC) between cells and HDL. Also, hepatic SR-B1 has been linked to clearance of proatherogenic lipoproteins VLDL and Lp(a). Thus, hepatic SR-B1 is thought to protect against atherosclerosis by promoting RCT and maintaining anti-atherogenic characteristics of HDL and decreasing atherogenic lipoproteins. Lastly, there is compelling evidence in support of atheroprotective functions of macrophage SR-B1.

### Exogenous (dietary) lipid pathways

In the small intestine, dietary lipids undergo pancreatic lipase-mediated lipolysis and are emulsified by bile acids. Lipolysis of TG produces 2-monoacylglycerol (2-MG) and fatty acids that are taken up by intestinal enterocytes. Cholesterol ester is hydrolyzed by carboxyl ester hydrolase (cholesterol esterase) to free cholesterol and fatty acids. The free cholesterol is incorporated into micelles, which are primarily comprised of bile acids and lesser amounts of phospholipids, fatty acids and 2-MG. These micelles are transported across the intestinal unstirred water layer to the brush border of the enterocyte where cholesterol, fatty acids and 2-MG are taken up.

In the enterocyte, re-esterification of fatty acids into TG and cholesterol into cholesteryl ester occurs to form chylomicrons, to which is added a surface layer of A-I, A-II, A-IV, A-V, B-48, C-II, C-III, and E, phospholipid, and free cholesterol. This allows secretion of the chylomicron into the intestinal lymphatics. Apo B-48 is required for secretion of the chylomicron.

Chylomicrons in the circulation take up Apo C from HDL (releasing it back to HDL later) and acquire Apo E. Apo C-II allows the chylomicron to activate lipoprotein lipase on capillary endothelial cells of muscle and fat. This promotes hydrolysis of TG, releasing glycerol and fatty acids to be taken up by local tissue. Surface phospholipids, free cholesterol, and Apo C transfer to HDL as the

**Fig. 2** Exogenous (dietary) lipid pathway. Chylomicrons transport triglycerides from the intestines to peripheral tissues. ① Lipids are digested and absorbed in the small intestines where chylomicron synthesis occurs on the template of apo B-48. Nascent chylomicrons are released into the lymphatic system before entering circulation. ② Mature chylomicrons are formed after receiving the full complement of apolipoproteins from HDL. ③ Lipids are made available to peripheral tissues by lipoprotein lipase mediated lipolysis ultimately forming a chylomicron remnant. ④ Removal of chylomicron remnants occurs by LRP and LDL receptor in the liver. ⑤ Apolipoproteins are recycled through chylomicron remnant—HDL interaction and by the liver. Triacylglycerol (TG). Apolipoprotein (Apo). LDL Receptor-related protein (LRP). Low-density lipoprotein (LDL). High-density lipoprotein (HDL).

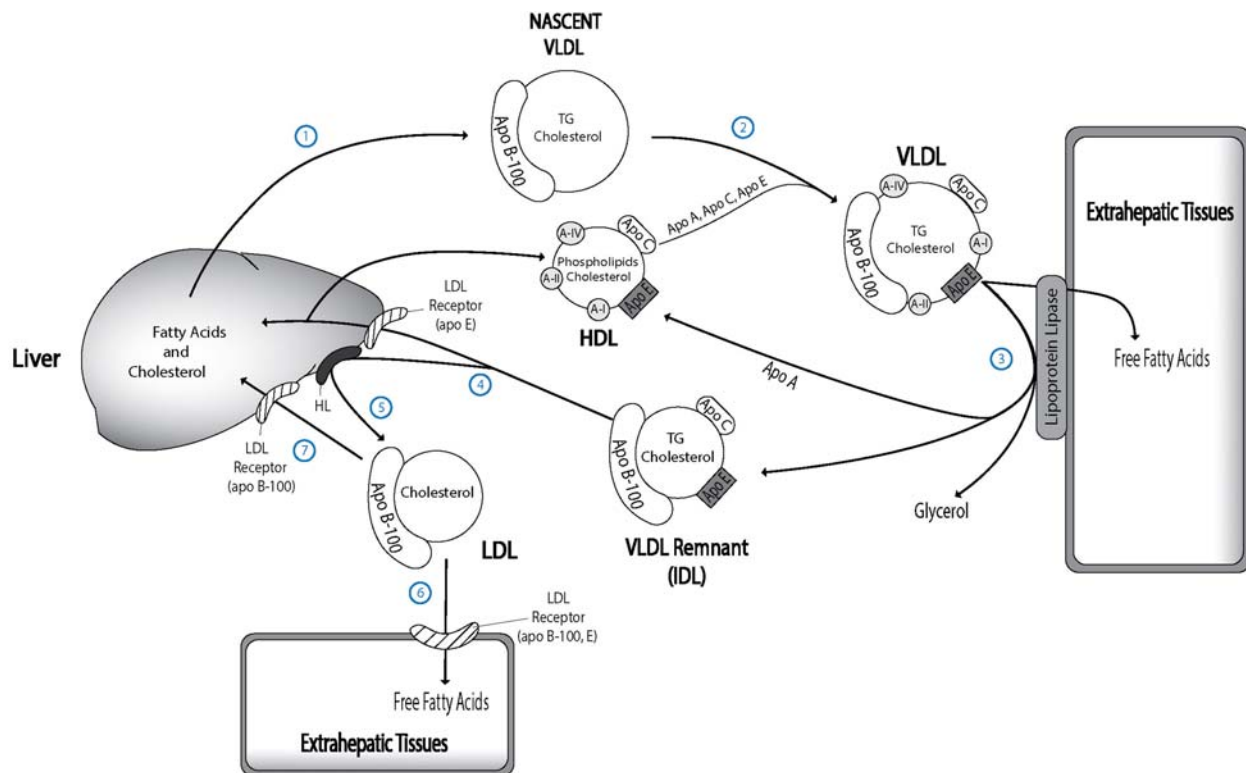

particle shrinks thereby becoming a chylomicron remnant. Thereafter the apo E on the chylomicron remnant binds to the hepatic LDLR which catalyzes remnant uptake. This transport of dietary lipid from the intestinal to the peripheral tissues is shown in Fig. 2.

### Endogenous lipid pathways

The endogenous lipoprotein pathway is dynamic and complex and involves the synthesis and transport of TG and cholesterol from sites of origin to tissues/organs (Ko et al., 2020). The liver is the main source of endogenous lipid (Fig. 3). In particular, the liver secretes the TG-rich VLDL. Triacylglycerol, which is formed from fatty acids either newly synthesized or taken up from plasma, together with free cholesterol, which is delivered to the liver in chylomicron remnants, join with Apo B and phospholipids to form VLDL. Apo C and Apo E are added in the circulation. Triacylglycerol is progressively hydrolyzed in VLDL (same way as chylomicrons) resulting in the formation of VLDL remnants (IDL). The IDL particles are either removed from the circulation by the liver (via the LDLR) or converted to LDL in the plasma. IDL is then modified through interaction with HL leading to a further decrease in TG which occurs in conjunction with transferring apoproteins to other lipoproteins that results in the formation of LDL (see Fig. 3). The production rate of LDL is inversely related to hepatic LDLR activity (i.e., high receptor activity decreases LDL production and low receptor activity increases production). Circulating LDL is cleared by LDLR-mediated uptake in the liver.

HDL synthesis begins with the synthesis of Apo A-1 by the liver and intestine (Fig. 4). Once Apo A-1 is secreted, it is the nascent HDL and matures by accumulation of cholesterol and phospholipids that come from the liver and intestine and also from chylomicrons and VLDL (during lipolysis which also promotes of transfer of other apolipoproteins to HDL).

Free cholesterol transfers to HDL and is esterified by LCAT (which is activated by Apo A-1). Cholesteryl ester in the core of HDL can be transferred to Apo B-containing particles, via CETP, in exchange for TG transfer to HDL. In this way, VLDL becomes smaller and transforms to become IDL, although some small VLDLs may be removed directly. HL catabolizes TG in HDL resulting in the formation of small HDL particles with the release and degradation of Apo A-1. HDL delivers cholesterol to the liver. Thereafter a small HDL particle is released into the circulation.

**Fig. 3** Endogenous lipid pathway. Transport of TGs and cholesterol from sites of origin (liver) to peripheral tissues/organs. ① The liver secretes TG-rich, apo B-100 containing, nascent VLDL. ② Apolipoproteins from HDL are transferred to nascent VLDL to form VLDL. ③ TGs and cholesterol are delivered to peripheral tissues by VLDL decreasing the size which forms VLDL remnants. ④ Further lipolysis of VLDL remnants forms IDL. IDL is either taken up by the liver or ⑤ is converted to LDL after removal of apo E and apo C. ⑥ LDL delivers TGs to peripheral tissues or ⑦ is removed from circulation by LDL receptor in the liver. Triacylglycerol (TG). Apolipoprotein (Apo). Very Low-density lipoprotein (VLDL). High-density lipoprotein (HDL). Intermediate-density lipoprotein (IDL). Hepatic lipase (HL).

## Reverse cholesterol transport

RCT is defined as the process by which cholesterol moves out of cells in peripheral tissues (including foam cells in atherosclerotic plaques), enters the circulation, and is excreted in the feces. The CV protective effect of HDL has been attributed to its ability to function as an acceptor of cholesterol from cells and as the cholesterol carrier in the RCT pathway, including delivery to the liver (Fig. 4).

ABCA1 preferentially lipidates small HDL particles, specifically apo A-I to form nascent HDL, ABCG1 stimulates net cholesterol efflux to larger HDL, but not to lipid-poor apo A-I. Efflux of cholesterol to HDL involves both passive diffusion and also active cholesterol transfer; ABCA1, ABCG1 as well as unrelated scavenger receptor class B type 1 (SR-B1) mediate lipid transfer to HDL. After cholesterol transfer to HDL particles, LCAT esterifies the acquired cholesterol to form cholesteryl esters (CE), and, hence, mature HDL. Remodeling of HDL particles occurs via hydrolysis of HDL triglycerides and phospholipids, mediated by hepatic lipase and endothelial lipase, respectively. CE in the HDL core can be transferred to TG-rich lipoproteins by CETP for elimination via hepatic clearance by the LDLR, or taken up by SR-B1, which acts as a hepatic receptor for CE on HDL. Therefore, RCT to the liver of cholesterol derived from peripheral cells involves two routes: (1) direct (HDL-SR-B1); and (2) indirect (HDL-LDL/VLDL-liver LDLR). In the liver, the CE is hydrolyzed and the free cholesterol is either converted to bile acids or transported into the bile for excretion into the feces (Ouimet et al., 2019).

## Risks associated with hypercholesterolemia and hypertriglyceridemia

Hyperlipidemia can have multiple clinical manifestations, including atherosclerosis, xanthomas, xanthelasmas, corneal arcus, and pancreatitis. Visible manifestations, such as xanthomas and corneal arcus, are due to lipid buildup in the skin, tendons, and the eye. Acute pancreatitis is a serious risk for individuals with elevated cholesterol and triglycerides carried in chylomicrons and/or VLDL. This is a particular concern for individuals with genetic conditions that impair chylomicron clearance, such as familial chylomicronemia syndrome (FCS).

For most individuals with hyperlipidemia characterized by elevations in LDL-C alone or in combination with hypertriglyceridemia, the primary concern is increased risk of atherosclerotic cardiovascular disease (ASCVD). Atherosclerosis begins when lipoproteins, such as LDL and VLDL remnants, infiltrate artery walls and are modified (e.g., oxidized), triggering an inflammatory response. Macrophages internalize the lipoproteins leading to foam cell formation and fatty lesions. Continued inflammatory signaling promotes a greater immune response and smooth muscle cells are recruited to proliferate and create a barrier between prothrombotic factors in the lesion and procoagulant factors in the blood. This leads to plaque formation and partial occlusion of the artery lumen. If inflammation within the plaque remains unresolved, the plaque may rupture, leading to thrombus formation and possible ischemic events, such as myocardial infarction or stroke. Individual risk for ASCVD events must also consider other major risk factors beyond hyperlipidemia, including age, family history of CHD, smoking, hypertension, and low HDL-C (Jacobson et al., 2015).

Evidence demonstrates that LDL-C and TG (which is highly correlated with VLDL-C) independently and additively increase the risk of CHD and cardiovascular events. A recent study of individuals on statins for cholesterol-lowering reported participants with elevated TG ( $\geq 3.9$  mmol/L or 150 mg/dL) had a 26% increased risk of cardiovascular events compared to individuals with TG  $< 3.96$  mmol/L (150 mg/dL) (Toth et al., 2021). The relative risk was further increased for individuals with TG 5.2–12.9 mmol/L (200–499 mg/dL). For this reason, measures including both LDL-C and TG-rich VLDL-C, such as Apo B and non-HDL-C, are considered better indicators of ASCVD risk than LDL-C alone, particularly in individuals with elevated TG. In fact, individuals with desirable LDL-C  $< 2.6$  mmol/L (100 mg/dL) but elevated non-HDL-C ( $> 3.4$  mmol/L or 130 mg/dL) are at increased risk for cardiovascular events compared to individuals with desirable LDL-C and desirable non-HDL-C (Boekholdt et al., 2012).

## Benefits of lipid-lowering on ASCVD risk

There is considerable evidence of reductions in ASCVD risk with reductions in LDL-C; thus, the consensus of experts is that lower is better for LDL-C (Grundey et al., 2019). Further, there is a strong indication that lower LDL-C for a longer period is better for risk reduction of ASCVD. LDL-C-lowering therapies in studies where subjects were followed for  $\sim 5$  years, resulted in a 22% reduction in CHD risk for every 1 mmol/L (38.7 mg/dL) reduction in LDL-C. In observational studies with longer follow up, from approximately a decade to  $> 50$  years, the reduction in CHD risk for every 1 mmol/L (38.7 mg/dL) reduction LDL-C increased to 32% (mean follow-up of  $\sim 12$  years) and 52% (mean follow-up of multiple decades) (Ference et al., 2017).

Lowering of VLDL-C, which can be approximated by TG/5 in those without marked hypertriglyceridemia, can also reduce the risk of ASCVD events. Ference et al. (2019) demonstrated a 0.56 mmol/L (50 mg/dL) reduction in TG, equivalent to a 0.26 mmol/L (10 mg/dL) reduction in VLDL-C, was associated with a similar reduction in CHD risk as a 0.26 mmol/L (10 mg/dL) reduction in LDL-C. These results suggest that Apo B concentration, or non-HDL-C concentration (cholesterol carried by all Apo B particles) is likely to be a better predictor of ASCVD risk than LDL-C or TG levels individually. In fact, after adjustment for Apo B concentration, both LDL-C and TG concentration lose statistical significance as predictors of CHD risk (Ference et al.,

**Fig. 4** Reverse cholesterol transport. Removal of peripheral cholesterol from peripheral tissues to the liver and transfer of cholesteryl ester to TG-rich lipoproteins. ① Nascent HDL formed on Apo A-I derived from the liver and small intestines develop by aggregating cholesterol and phospholipids released by ABCA1 in the intestines, liver, and peripheral tissues. ② Peripheral SR-B1 and ABCG1 facilitate cholesterol transfer from cells into nascent HDL. ③ LCAT esterifies cholesterol in nascent HDL to cholesteryl ester to prevent cholesterol release. ④ The nascent HDL matures to HDL<sub>3</sub> with the accumulation of cholesteryl esters and eventually to HDL<sub>2</sub>. ⑤ Mature HDL<sub>2</sub> is converted back to HDL<sub>3</sub> by depositing cholesteryl esters, phospholipids, and TG in the liver for excretion or lipoprotein synthesis. ⑥ CETP facilitates exchange of cholesteryl esters in HDL<sub>2</sub> for TG in TG-rich lipoproteins (VLDL, LDL) which is then removed from circulation by the liver. ATP binding cassette transporter A1/G1 (ABCA1/G1). Scavenger receptor B-1 (SR-B1). Lecithin:Cholesterol acyltransferase (LCAT). Cholesteryl ester transport protein (CETP). Triacylglycerol (TG).

2019). Over periods of ~5 year, each mmol/L reduction in non-HDL-C (LDL-C + VLDL-C) is associated with a reduction in major ASCVD event risk of ~20–25%.

### Categories and classifications of hyperlipidemia

The different phenotypes of dyslipidemia were first classified in 1965 by Fredrickson, Levy and Lees (Fredrickson et al., 1965) and are still commonly used today (Table 4). This classification was also adopted by the World Health Organization in 1970 (Beaumont et al., 1970). Classifications for LDL-C, triglycerides, non-HDL-C and HDL-C for healthy adults without known ASCVD or other high-risk conditions are included in Table 5 (Miller et al., 2011; Jacobson et al., 2015).

## Causes of hyperlipidemia

### Genetics

Primary hyperlipidemia can result from monogenic (one gene) or polygenic (multiple genes) causes. Monogenic causes of hypertriglyceridemia are rare but include FCS or Type I hyperlipoproteinemia, which most often results from loss-of-function mutations in both alleles of the lipoprotein lipase gene, responsible for chylomicron clearance, although defects in apolipoprotein CII and CIII can also manifest as FCS. FCS is usually diagnosed in childhood and risk of acute pancreatitis is of primary concern for these individuals. Acute pancreatitis can lead to systemic inflammation and multiple organ failure; thus, strict dietary fat restriction, which reduces chylomicron formation, is necessary to treat FCS. Interestingly, individuals with FCS do not typically have markedly increased risk for ASCVD, perhaps due to the large size of chylomicron particles which prevent translocation into the arterial wall and subsequent accumulation of atherosclerotic plaques. Type IIa hyperlipoproteinemia, most commonly results from multiple genetic polymorphisms that predispose individuals to elevated LDL-C. More than 50 genetic loci have been identified as possible contributors to polygenic hypercholesterolemia (Warden et al., 2018). However, environmental factors, such as obesity or a high saturated fat diet, are often necessary for hypercholesterolemia to manifest in these individuals.

There are also monogenic causes for inherited or familial hypercholesterolemia (FH) (Warden et al., 2018). These dominantly inherited conditions involve genetic mutations that result in defects in the LDL receptor, apolipoprotein B (apo B), or proprotein convertase subtilisin/kexin type 9 (PCSK9) which is involved in the degradation of LDL receptors. Individuals with heterozygous familial hypercholesterolemia experience high levels of LDL-C, typically from a young age, and are at risk of early ASCVD. Homozygous FH results when two copies of a defective gene are inherited for the LDL receptor, apo B or PCSK9 are inherited, resulting in a severe elevation of LDL-C. Early diagnosis is critical to prevent clinical ASCVD events as well as tendon xanthomas that are often observed in patients with FH.

Type IIb hyperlipoproteinemia, sometimes referred to as familial combined hyperlipidemia (FCH) or mixed dyslipidemia, is characterized by elevated LDL-C and TG (as well as VLDL). The prevalence is estimated to be around 1 in 40 individuals (Brahm et al., 2013). However, the genetics are not completely understood, and it is likely that multiple genetic polymorphisms combined with environmental factors, such as obesity, sedentary lifestyle, and a diet high in saturated fats and added sugars, contribute to the development of FCH. Individuals with FCH have an elevated Apo B level, which is the primary protein in LDL and VLDL. Since each LDL and VLDL particle contains a single Apo B molecule, the circulating Apo B concentration is a direct measure of the concentration of potentially atherogenic lipoprotein particles. It should be noted that chylomicron remnants make a quantitatively small contribution to the circulating Apo B concentration. Each chylomicron particle contains a single molecule of a truncated form of Apo B that contains 48 amino acids, whereas there are 100 amino acids in the Apo B contained in LDL and VLDL particles. Individuals with FCH are at increased risk of ASCVD, thus early diagnosis and management is important.

Familial dysbetalipoproteinemia, or Type III dyslipidemia, is a rare form of hyperlipidemia occurring in individuals homozygous for the Apo E2 genotype. The prevalence is estimated at 1 in 5000 to 1 in 10,000 people, although the prevalence of homozygosity for Apo E2 is roughly 1%. In Type III dyslipidemia, there is a decrease in clearance of VLDL and chylomicron remnant lipoprotein particles because the Apo E2 variant does not interact efficiently with hepatic receptors. The result is elevated cholesterol and TG because TG-rich particles are not efficiently converted to smaller LDL particles. Most individuals with the Apo E2/E2 genotype do not develop marked dyslipidemia in the absence of a secondary condition, such as diabetes, obesity, or hypothyroidism. Palmar xanthomas, identified as orange lipid deposits in the plantar creases of the hands, may occur as a clinical manifestation of this condition. Tuberoeruptive xanthomas may also be found in joint areas, such as elbows and knees. These individuals are also at high risk of ASCVD.

Type IV dyslipidemia is the most common hypertriglyceridemia and is most often polygenic (Cruz-Bautista et al., 2021). Typically, there is a defect in the catabolism of VLDL particles leading to elevated blood TG. Unlike FCH, individuals with Type IV dyslipidemia do not have elevations in LDL-C. When individuals with Type IV dyslipidemia experience other environmental factors, such as obesity or poorly controlled type 2 diabetes, TG levels can exceed 5.6 mmol/L (500 mg/dL) and increase the risk of acute pancreatitis, particularly when above 8.5 mmol/L (750 mg/dL), which is the TG concentration above which fasting chylomicronemia generally manifests.

Type V hyperlipoproteinemia seems to result from a similar genetic predisposition as individuals with Type IV, but with additional polygenic and environmental factors that contribute to an elevation in chylomicron particles in addition to VLDL elevation. Unlike FCS, Type V hyperlipoproteinemia does not typically manifest until adulthood and often in response to secondary conditions, such as poorly controlled diabetes or excess weight gain. Extremely high TG levels increase the risk of pancreatitis in these individuals. In both Type IV and Type V dyslipidemia, ASCVD risk may be elevated, but this is generally true for the subset of such individuals who have elevated levels of Apo B.

### Lifestyle

Lifestyle factors, particularly an unhealthy diet, elevated body weight, physical inactivity and smoking/tobacco use, as well as poor sleep are contributors to hyperlipidemia and numerous randomized controlled trials have shown the benefit of lifestyle therapies in reducing hyperlipidemia and risk of ASCVD (Jacobson et al., 2015; Lloyd-Jones, 2022).

Dietary components, particularly fats and carbohydrates have been implicated in hyperlipidemia. Saturated and *trans* fatty acids, are contributors to elevations in LDL-C and dietary cholesterol can also raise LDL-C. Unsaturated fats and viscous dietary fibers

lower LDL-C. Excess body weight can also contribute to dyslipidemia (higher LDL-C and TG, lower HDL-C) and weight loss improves the lipid profile ([Jensen et al., 2014](#)).

Physical activity also has important effects on the lipid profile, generally lowering the TG level and raising the HDL-C concentration, particularly if accompanied by weight loss ([Kraus et al., 2002](#)). Smoking is associated with elevations in TG and reductions in HDL-C ([Maeda et al., 2003](#)). Smoking is a strong risk factor for ASCVD, in part because of its association with other risk factors associated such as endothelial dysfunction and arterial stiffness, as well as its effects on the lipid profile. It has been estimated that 40% of all smoking-related deaths are due to CVD ([Athiros et al., 2013](#)).

### Secondary causes

Hyperlipidemia can result from various conditions, such as metabolic diseases, excess alcohol consumption, or from certain medications. In these situations, often treating the primary condition or altering medications can restore normal lipid levels. For example, individuals with hypothyroidism often have an elevated LDL-C due to a reduction in LDL catabolism. Treating the hypothyroidism may reduce LDL-C. Similarly, individuals with uncontrolled diabetes mellitus or obesity can experience hypertriglyceridemia which may resolve when glycemia and body weight are controlled. Excessive alcohol consumption can also increase TG which can be decreased by reducing or abstaining from alcohol intake.

Several medications can alter lipoprotein lipid levels. For example, postmenopausal women on estrogen therapy may experience hypertriglyceridemia that improves when estrogen is stopped. Medications used to treat hypertension, such as diuretics and beta-blockers, may also increase LDL-C and/or TG in some individuals. Anti-viral therapies, immunosuppressants, and retinoid medications used to treat skin disorders have all been reported to increase blood lipids in some individuals. For individuals with these

**Table 4** Fredrickson, Levy and Lees classification of hyperlipoproteinemias.

Type	Elevated blood lipids	Elevated lipoproteins	Clinical manifestations
I	Triglycerides	Chylomicrons	Eruptive xanthomas, pancreatitis
II-a	Cholesterol	LDL	Tuberous and/or tendon xanthomas, coronary atherosclerosis
II-b	Cholesterol and possibly triglycerides	LDL and VLDL	Coronary atherosclerosis, xanthelasmas, corneal arcus
III	Cholesterol and triglycerides	Chylomicron remnants and VLDL	Palmar, tuberoeruptive xanthomas, coronary atherosclerosis
IV	Triglycerides	VLDL	Coronary atherosclerosis (if also elevated Apo B)
V	Cholesterol and triglycerides	Chylomicrons, VLDL	Eruptive xanthomas, pancreatitis

**Table 5** Classifications for normal and hyperlipidemia.

LDL-C	mmol/L	mg/dL
Desirable	<2.6	<100
Above desirable	2.6–3.3	100–129
Borderline high	3.4–4.1	130–159
High	4.2–4.9	160–189
Very high (severe)	≥5.0	≥190
<b>Triglycerides</b>		
Optimal	<1.1	<100
Normal	<1.7	<150
Borderline high	1.7–2.2	150–199
High	2.3–5.5	200–499
Very high (severe)	≥5.6	≥500
<b>Non-HDL-C</b>		
Desirable	<3.4	<130
Above desirable	3.4–4.1	130–159
Borderline high	4.2–4.9	160–189
High	5.0–5.6	190–219
Very high (severe)	≥5.7	≥220
<b>HDL-C</b>		
Low	<1.3 (women) <1.0 (men)	<50 (women) <40 (men)

Data sources: [Miller et al. \(2011\)](#), [Jacobson et al. \(2015\)](#).

situations, a risk-benefit analysis should be undertaken to determine if medication use should continue or if there may be alternative medications that could treat the condition without adversely altering blood lipids.

## Dietary management of hyperlipidemia

### Healthy dietary patterns

Clinical guidelines consistently recommend a healthy dietary pattern for the management of hyperlipidemia and prevention of CVD (Eckel et al., 2014; Jacobson et al., 2015; Arnett et al., 2019; Visseren et al., 2021; Lichtenstein et al., 2021). A healthy dietary pattern emphasizes consumption of fruits, vegetables, whole grains, nuts, seeds, legumes and non-tropical oils, and minimizes intake of saturated fat, *trans* fat, sodium, and added sugars, consistent with the Dietary Guidelines for Americans (US Department of Agriculture and US Department of Health and Human Services, 2020). The recommendations also emphasize incorporating more plant foods and lean sources of protein in the diet and reducing intake of processed or high-fat animal products. Consumption of fatty fish (containing omega-3 fatty acids) at least once or twice a week is often recommended. It is important to ensure the diet meets caloric needs, but in individuals with overweight or obesity, caloric restriction may be necessary to achieve weight loss and maintenance. These recommendations are reflective of dietary patterns such as Dietary Approaches to Stop Hypertension (DASH) and Mediterranean diet, which are associated with reduced risk of CVD (Eckel et al., 2014; Jacobson et al., 2015; Arnett et al., 2019; Visseren et al., 2021; Lichtenstein et al., 2021).

### Dietary recommendations for reduction of atherogenic cholesterol

In addition to a healthy dietary pattern, there are additional dietary modifications that have been shown to improve LDL-C and non-HDL-C levels. While healthy dietary patterns recommended by the Dietary Guidelines for Americans suggest <10% of calories from saturated fat, for individuals with elevated LDL-C it is recommended to target <7% of calories from saturated fat (Eckel et al., 2014; Jacobson et al., 2015). Replacing calories from saturated fat with carbohydrate, protein, monounsaturated fatty acids, or polyunsaturated fatty acids all contribute to a reduction in LDL-C. However, the effect on overall blood lipids is more favorable when saturated fat is replaced with polyunsaturated fatty acids (Sacks et al., 2017).

Dietary cholesterol has been shown to raise LDL-C, but the effect is modest with every 100 mg of dietary cholesterol raising LDL-C by approximately 0.05 mmol/L (2 mg/dL) (Jacobson et al., 2015). For this reason, some recommendations do not include specific dietary restrictions of cholesterol since following a healthy dietary pattern low in saturated fat should also achieve a reduction in dietary cholesterol (Eckel et al., 2014; Visseren et al., 2021; Lichtenstein et al., 2021).

For individuals who have overweight or obesity, caloric restriction combined with physical activity to achieve weight loss is recommended to reduce LDL-C. A loss of 5% of body weight can reduce LDL-C by 3%–5% (Jacobson et al., 2015).

Dietary adjuncts may be useful when a healthy dietary pattern low in saturated fat, *trans* fat and cholesterol and weight loss, if indicated, are insufficient. These include 5–10 g/day of viscous dietary fibers and 2 g/day plant sterols/stanols. Randomized controlled trials have shown these dietary components can each lower LDL-C by 4%–10%.

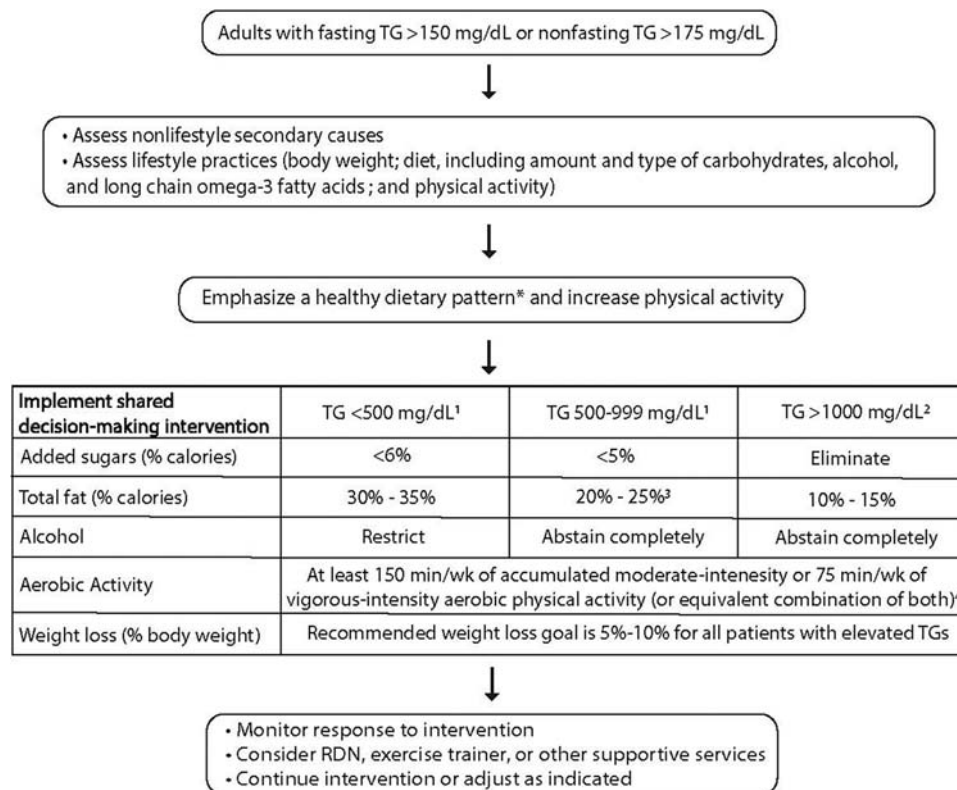

A combination of dietary approaches can achieve substantial reductions in LDL-C possibly eliminating the need for pharmacological interventions. For example, achieving a diet low in saturated fat in combination with 5% weight loss could lower LDL-C by 8%–15%. The portfolio diet approach which combines a diet low in saturated fat with viscous fiber, plant sterols/stanols, soy protein and nuts has been shown to reduce LDL-C up ~30% in controlled settings and by 15% in free-living subjects (Jacobson et al., 2015).

### Dietary management of hypertriglyceridemia

There are 4 main categories of hypertriglyceridemia (HTG), Borderline: between 150 and 199 mg/dL, High: 200–499 mg/dL, Very High: 500–999 mg/dL and Severe: >1000 mg/dL with chylomicronemia (Virani et al., 2021). Diet is the first line of treatment for elevated triglycerides. Recommendations are based on the TG level (Virani et al., 2021). For all individuals with elevated triglycerides, a weight loss of 5–10% is recommended, if indicated. This reduction in weight can lead to a 10–20% decrease in triglyceride levels in most patients, with some patients experiencing a reduction in triglycerides up to 70% (Virani et al., 2021).

Fig. 5 describes dietary recommendations for individuals with elevated triglycerides. If triglyceride levels are <500 mg/dL added sugars (jams, jellies, and desserts) should be less than 6% of total calories, total fat is ideally between 30 and 35% of calories, and alcohol intake should be restricted. An emphasis on vegetables, legumes, fatty fish at least twice a week, and whole grains is encouraged. For individuals with triglyceride levels between 500 and 999 mg/dL added sugars should be less than 5% of energy, total fat should be between 20 and 25%, and alcohol should be eliminated. Vegetables, legumes, fatty or lean fish twice a week, and whole grains are emphasized. For individuals with triglyceride levels >1000 mg/dL added sugars and alcohol should be eliminated, and total fat should comprise only 10–15% of calories. Vegetables, legumes, lean fish, and whole grains are encouraged (Virani et al., 2021). Dietary modifications (that include alcohol restriction or abstinence) can lower triglycerides by over 70%, although, responses may vary depending on the initial triglyceride level, as well as dietary adherence. Physical activity is important for all patients HTG. Exercise can lower triglycerides by up to 30%, however, the response depends on the type, duration, and intensity of the activity (Virani et al., 2021).

**Fig. 5** Recommendations for lifestyle interventions in patients with increasing levels of weight loss and effects on triglycerides. Registered Dietitian Nutritionist (RDN). Triglyceride (TG).

\*Recommendations for a healthy dietary pattern: vegetables; fruits; legumes; nuts; whole grains; and fish/seafood (other healthy proteins such as low-fat dairy, low-fat poultry); liquid plant-based oils; and replacing saturated fatty acids with monounsaturated fatty acids and polyunsaturated fatty acids. Recommendations also emphasize limiting: red and processed meats; refined carbohydrates; added sugars (sweets and sugar-sweetened beverages); sodium and dietary cholesterol; and avoiding trans fats.

<sup>1</sup>RDN referral advised.

<sup>2</sup>RDN referral necessary.

<sup>3</sup>Clinicians may opt to reduce total fat as percent of calories in some of these patients to 10%–15% (examples include those with a history of pancreatitis or those at the higher end of this range).

<sup>4</sup>Although clinicians should aim for their patients to meet the guideline-recommended goals for physical activity, any amount of physical activity is likely beneficial in sedentary individuals and should therefore be encouraged to reduce cardiometabolic risk. Source: Virani et al. (2021).

## Summary

Dyslipidemia is a major risk factor for CAD. Metabolism of lipoproteins is a complex biological system that can be disrupted at many regulatory steps by genetics or lifestyle leading to hypercholesterolemia and/or hypertriglyceridemia, thereby increasing CAD risk. The resulting dyslipidemias present in a variety of clinical phenotypes that have been classified by Frederickson, Levy and Lees. A healthy lifestyle, including a recommended dietary pattern, is the primary therapy for managing dyslipidemia and CAD risk.

## Key points

- Summarize key issues related to the relation between the amount and type of dietary fat and CVD.
- Discuss the differences between the major classes of fatty acids and CVD prevention and treatment.
- Review the controversies related to dietary cholesterol, and plasma lipids concentrations and lipoprotein profiles.
- Discuss the importance of adequate dietary fiber for CVD prevention and treatment.
- Discuss the role of plant sterols (phytosterols) for CVD prevention and treatment.
- Summarize the available data related to nutrient supplements and CVD prevention and treatment.

## Introduction

A wide range of diet related factors alter risk of developing cardiovascular disease (CVD). Some were identified early in the 20th century and have stood the test of time. Others have emerged more recently. In some cases, they too have stood the test of time (e.g., moderate rather than low fat diets, unmodified plant oils rather than hydrogenated plant oils), yet, others have not (e.g., vitamin E and vitamin D supplements). Although emerging data have resulted in shifts in certain dietary guidance over time, none of the changes are without controversy, due to inconsistent results. Some inconsistencies are likely attributable to differences across study cohorts in biological factors (e.g., genetics, sex), physiological characteristics (e.g., body weight, body composition), and long-term lifestyle practices (e.g., physical activity, exposure to tobacco products). Also, the approach used for data analyses may contribute to differences in reported responses to similar dietary interventions; for example, expression of the data in relative (e.g., energy percent) or absolute (e.g., grams, servings) terms. This article will present evidence-based current trends in dietary approaches for the prevention and management of CVD.

## Assessing the impact of diet on CVD risk

It is logistically difficult, if not impossible, to directly assess the effect of dietary interventions on hard CVD outcomes, given that the natural course of the disease is measured in years or decades rather than days or months (Virani et al., 2021). Hence, most dietary interventions aimed at reducing CVD risk are evaluated based on intermediate biomarkers. As the number of dietary variables potentially associated with CVD risk has increased (and occasionally decreased) over the past few decades, so have the number of potential biomarkers of CVD used to assess the efficacy of dietary interventions. The independent and relative importance of each biomarker has yet to be fully adjudicated. With the widespread advent of 'omics technology the field is expected to continue to evolve.

Historically, total cholesterol, individual lipoproteins (low density lipoprotein-cholesterol [LDL-C] and high-density lipoprotein-cholesterol [HDL-C]) and triacylglycerol (triglyceride) concentrations were used to evaluate the efficacy of a dietary intervention for CVD risk. Total cholesterol, HDL-C and triglyceride concentrations were measured directly, whereas LDL-C concentration was calculated using the Friedewald formula ( $\text{LDL-C} = \text{total cholesterol} - \text{HDL-C} - [\text{triglyceride}/5]$ ) unless triglyceride concentrations exceeded 400 mg/dL. Reliable automated direct assays for LDL-C are now available and obviate the need for this calculation. Circulating factors, such as lipoprotein(a) [Lp(a)], C-reactive protein (CRP) and other markers of inflammation, LDL particle size, hematologic factors, apoprotein concentrations and genotypes, measures of glucose homeostasis, plant sterol and intermediates of cholesterol biosynthesis, HDL subspecies, cholesterol efflux capacity, trimethylamine N-oxide concentration, and remnant-like particle (triglyceride-rich lipoprotein particles) concentration are also considered potentially informative in estimating CVD risk and the effect of dietary interventions on CVD risk. As new data emerge, the relative importance of each is elucidated and additional factors are identified. Currently, much dietary guidance aimed at decreasing CVD risk is made on the basis of plasma lipid and lipoprotein concentrations. In some cases, additional factors, such as CRP and Lp(a), are taken into consideration for individuals classified as at intermediate risk to inform risk management.

## Dietary lipids: approaches for the prevention and management of CVD

### Amount of dietary fat

For most individuals consuming Western-type diets, dietary fat serves as a major energy source. One gram of fat contributes 9 kcal, a little more than twice that contributed by protein or carbohydrate (4 kcal/g), and somewhat more than that contributed by alcohol (7 kcal/g). Focusing on the importance of total dietary fat on CVD prevention and management, there are two independent factors for consideration; plasma lipoprotein profiles and body weight. The former is used to determine diet and pharmacotherapy treatment. The latter is of importance due to secondary effects of excess body weight on plasma lipid profiles and factors associated with the metabolic syndrome (elevated blood pressure, waist circumference and blood glucose concentration, and dyslipidemia [low HDL cholesterol and high triglyceride concentrations]).

The effects of total dietary fat (as a percent of total energy intake) on plasma lipoprotein profiles, are measured by triglyceride and HDL-C concentrations, and the total cholesterol to HDL-C ratio. Relatively consistent evidence indicates that, when body weight is maintained at a constant level, a decrease in the percent of energy contributed by dietary fat, accompanied by a concomitant increase in dietary carbohydrate, results in increased triglyceride and decreased HDL-C concentrations, and less favorable (higher) total cholesterol to HDL-C ratio. The underlying mechanism is carbohydrate induced hypertriglyceridemia. The influx of glucose exceeds the capacity of peripheral tissues to oxidize it or store as glycogen, forcing the liver to use the excess glucose to synthesize fatty acids, which are released into circulation as triglyceride-rich particles termed very low density lipoprotein (VLDL). This situation can be exacerbated when the source of carbohydrate is refined, such as added sugar, which results in a rapid raise in blood glucose contractions. Both low HDL-C and high triglyceride concentrations are associated with increased risk for CVD, and frequently coexist. Very low fat diets are not recommended, and should be particularly avoided by individuals with insulin resistance, because such a dietary pattern is more likely to result in dyslipidemia (low HDL-C and high triglycerides) than higher fat diets.

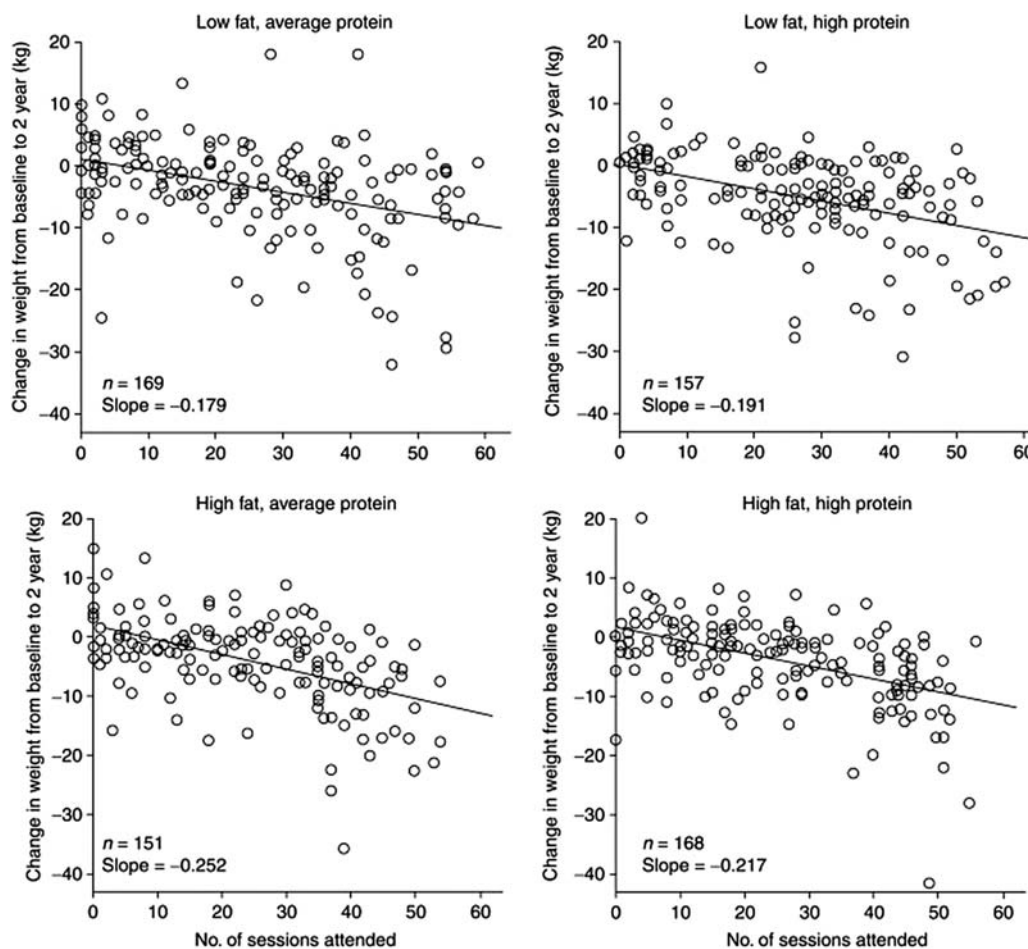

Available historical data suggest a null or weak association between the amount of dietary fat and body weight. Data from two relatively long-term weight loss intervention trials confirm this finding, indicating that the percent of energy from dietary fat is not a major determinant of weight loss (Figs. 1 and 2) (Gardner et al., 2018; Sacks et al., 2009). In one study, a major determinate of weight loss was adherence to the diet intervention, as assessed by number of group sessions attended during the study period, rather than the proportions of dietary fat, carbohydrate or protein. Hence, despite the theoretical logic of the assertion that high fat diets lead to weight gain, the data do not support the premise.

### Type of dietary fat

The relation between dietary fat and atherosclerosis, the major form of CVD, was first identified at the turn of the 20th century. Subsequently, a series of meticulously conducted studies in humans during the 1960s demonstrated that changes in individual dietary fatty acids altered plasma total cholesterol concentration. As knowledge expanded and analytical techniques became more sophisticated, the focus on biomarkers for CVD risk shifted from total cholesterol to lipoprotein concentrations; LDL-C and HDL-C. Although many studies have confirmed early observations, inconsistencies among more recent work are not rare. These

**Fig. 1** Mean change in body weight and waist circumference from baseline to 2 years according to dietary macronutrient content. Low protein, fat or carbohydrate. High protein, fat or carbohydrate. From Sacks FM, Bray GA, Carey VJ, Smith SR, Ryan DH, Anton SD, McManus K, Champagne CM, Bishop LM, et al. Comparison of weight-loss diets with different compositions of fat, protein, and carbohydrates. *NEJM*. 2009;360:859-873.

**Fig. 2** Waterfall plot of weight loss by diet group (A) healthy low fat diet; (B) healthy low carbohydrate (carb) diet. From Sacks FM, Bray GA, Carey VJ, Smith SR, Ryan DH, Anton SD, McManus K, Champagne CM, Bishop LM, et al. Comparison of weight-loss diets with different compositions of fat, protein, and carbohydrates. *NEJM*. 2009;360:859-73.

inconsistencies are likely due to differences across diet interventions, such as absolute vs relative amounts of dietary fat, length of intervention period, and diet prior to the start of the study period (background diet), onto which the dietary variable(s) was superimposed. Additional differences among studies may include characteristics of participants such as age, sex, genetics, efficiency of cholesterol absorption and baseline plasma lipid concentrations.

## Saturated fatty acids

Early evidence showed that diets relatively high in total saturated fatty acids (SFA) increased plasma total cholesterol concentration, compared to diets relatively high in a comparable amount of unsaturated fatty acids. It was also noted that not all SFA had identical effects. Subsequent work confirmed the hypercholesterolaemic effect of SFA, demonstrating that increasing SFA intake results in an increase in both LDL-C and HDL-C concentrations, although LDL-C more so than HDL-C, and reaffirmed that individual SFA had different effects on plasma lipoprotein particles. Short-chain fatty acids (6:0 to 10:0) and stearic acid (18:0) appear to have little or no effect on LDL-C or HDL-C concentrations, whereas intermediate chain SFA (lauric [12:0], myristic [14:0] and palmitic [16:0] acids) appear to be the most potent in increasing LDL-C concentration (Table 1). Subsequent work indicated that a high proportion of stearic acid (18:0) is converted to the monounsaturated fatty acid oleic acid (18:1) and, therefore, has a relatively neutral effect on plasma cholesterol concentration. The underlying mechanism by which fatty acids with 10 or fewer carbon atoms have different effects from those with 12–16 carbons on plasma cholesterol may be related to the mode of absorption (portal vein rather than lymphatic system) and preferential hepatic oxidation. An analysis that pooled data from multiple studies demonstrated that when dietary SFA was replaced by polyunsaturated fatty acids (PUFA), CVD risk was lowered (Fig. 3) (Jakobsen et al., 2009). When dietary SFA was replaced by carbohydrate (resulting in lower fat diets), this advantage was lost.

The major contributor to dietary SFA are fats from animal origin, meat and dairy fat. Approaches to reduce SFA intake from meat include replacing fatty cuts with leaner cuts, trimming visible fat prior to cooking, and reducing portion size. Reducing dietary SFA from dairy products can be achieved by substituting non-fat and low-fat (1%) for full-fat and reduced-fat (2%) versions and reducing portions of full fat dairy foods such as cheese. Foods high in SFAs tend to be solid at room temperature. Notable exceptions include the tropical oils, palm, palm kernel and coconut. Tropic oils are liquid at room temperature because they have a relatively high concentration of short chain SFA. Reducing dietary SFA from tropical oils can be achieved by using the information in the ingredient list to identify sources and replace them with similar foods formulated with unsaturated fats, such as soybean and canola oils.

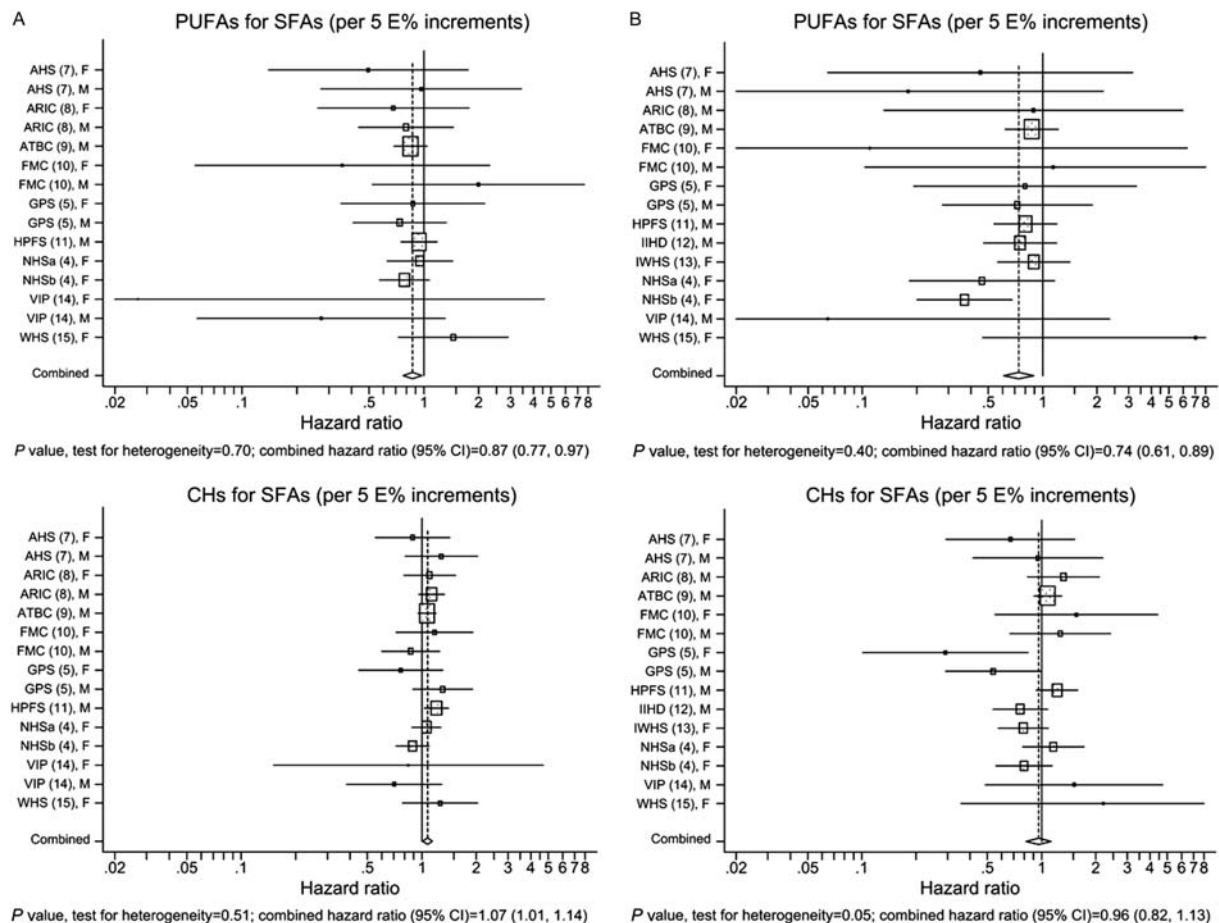

## Unsaturated fatty acids

Unsaturated fatty acids are those that contain one or more double bonds in the acyl chain. As their name implies, monounsaturated fatty acids (MUFA) have one double bond and PUFA have multiple double bonds (two or more). Most fatty acids containing

**Table 1** Major dietary fatty acids.

Dietary fatty acids		
Code	Common name	Formula
<b>Saturated</b>		
12: 0	Lauric acid	$\text{CH}_3(\text{CH}_2)_{10}\text{COOH}$
14: 0	Myristic acid	$\text{CH}_3(\text{CH}_2)_{12}\text{COOH}$
16: 0	Palmitic acid	$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$
18: 0	Stearic acid	$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$
<b>Monounsaturated</b>		
16: 1n-7 <i>cis</i>	Palmitoleic acid	$\text{CH}_3(\text{CH}_2)_6\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_7\text{COOH}$
18: 1n-9 <i>cis</i>	Oleic acid	$\text{CH}_3(\text{CH}_2)_7\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_7\text{COOH}$
18: 1n-9 <i>trans</i>	Elaidic acid	$\text{CH}_3(\text{CH}_2)_7\text{CH} = (\text{t})\text{CH}(\text{CH}_2)_7\text{COOH}$
<b>Polyunsaturated</b>		
18: 2n-6, 9 all <i>cis</i>	Linoleic acid	$\text{CH}_3(\text{CH}_2)_4\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_7\text{COOH}$
18: 3n-3, 6, 9 all <i>cis</i>	$\alpha$ -Linoleic acid	$\text{CH}_3\text{CH}_2\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_7\text{COOH}$
18: 3n-6, 9,12 all <i>cis</i>	$\gamma$ -linoleic acid	$\text{CH}_3(\text{CH}_2)_4\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_4\text{COOH}$
20: 4n-6, 9,12,15 all <i>cis</i>	Ara chidoleic acid	$\text{CH}_3(\text{CH}_2)_4\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CHCH}_2\text{CH} = (\text{c})\text{CH}(\text{CH}_2)_3\text{COOH}$
20: 5n-3, 6, 9,12,15 all <i>cis</i>	Eicosapentaenoic acid	$\text{CH}_3(\text{CH}_2\text{CH} = (\text{c})\text{CH})_5(\text{CH}_2)_3\text{COOH}$
20: 6n-3, 6, 9,12,15,18 all <i>cis</i>	Docosahexaenoic acid	$\text{CH}_3(\text{CH}_2\text{CH} = (\text{c})\text{CH})_6(\text{CH}_2)_2\text{COOH}$

**Fig. 3** Study-specific and combined hazard ratios and 95% CIs for coronary events (A) and coronary deaths (B) in the pooling project of cohort studies on diet and coronary disease. The squares and horizontal lines represent the study-specific hazard ratios and 95% CIs, respectively. The area of the squares reflects the study-specific weight (inverse of the variance). Major types of dietary fat and risk of coronary heart disease: a pooled analysis of 11 cohort studies. *Am J Clin Nutr*. 2009;89:1425-32.

double bonds in food are in the *cis* configuration, that is, the hydrogen atoms associated with the carbons forming the double bond are oriented on the same side of the acyl chain. Alternatively, some double bonds occur in the *trans* configuration, and the hydrogen atoms associated with the carbons forming the double bond are on the opposite side of the acyl chain. This difference in double bond conformation has implications for bond angle (see section on **Trans fatty acids**). This part of the discussion of unsaturated fatty acids will be restricted to those containing *cis* double bonds.

Relative to SFA, both MUFA and PUFA lower both LDL-C and HDL-C concentrations. The absolute magnitude of the change is greater for LDL-C than HDL-C, resulting in an improvement in the total cholesterol/HDL-C ratio. Most data suggest that MUFA has a somewhat smaller effect than PUFA in lowering both LDL-C and HDL-C concentrations (**Fig. 4**). Regardless, a shift from food sources rich in SFA to those rich in MUFA and PUFA should be encouraged for the prevention and management of CVD.

## MUFA

The major MUFA in the diet is oleic acid (18:1) (**Table 1**). Plant oils high in MUFA include canola (rapeseed) and olive. Fats from meats are relatively high in MUFA, but unlike plant oils, they also contain relatively high levels of SFA, and therefore are not recommended as good source of dietary MUFA.

**Fig. 4** Predicted changes based on replacement of 5% of energy as carbohydrates with specific fatty acids under isocaloric conditions. From Hu FB, Willett WC. Optimal diets for prevention of coronary heart disease. JAMA. 2002;288:2569-78.

## PUFA

There is a wider range of PUFA than MUFA in the diet. Dietary PUFA vary based on chain length, degree of unsaturation (number of double bonds) and position of the double bond(s) (positional isomers). Two positional isomers of interest with respect to diet and CVD risk are omega (n)-6 and n-3 fatty acids (Table 1). The distinction is made based on the location of the first double bond from the methyl end of the fatty acyl chain (as opposed to the carboxyl end). If the first double bond is six carbons from the methyl end, the fatty acid is classified as n-6 fatty acid. If the first double bond is three carbons from the methyl end, the fatty acid is classified as n-3 fatty acid.

## N-6 fatty acids

Diets rich in n-6 PUFA, relative to SFA, are associated with optimal cardiovascular outcomes (see prior section for SFA). Plant oils high in PUFA include soybean, corn, and unmodified sunflower and safflower. The major n-6 PUFA in the diet is linoleic acid (18:2n-6). Other n-6 PUFA, such as  $\gamma$ -linolenic acid (18:3n-6) and arachidonic acid (20:4n-6), occur in smaller amounts. These fatty acids are important for a wide range of metabolic functions.

## N-3 fatty acids

Quantitatively, the major n-3 PUFA in the diet is  $\alpha$ -linolenic acid (18:3n-3). Major dietary sources include soybean and canola oils. Two metabolically important n-3 PUFA that occur in smaller amounts are eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). These are very long chain n-3 fatty acids (Table 1). Although humans have the capacity to convert  $\alpha$ -linolenic acid to EPA and DHA, efficiency is low, estimated at about 3%–5%. The major dietary sources are fish and seafood. Dietary patterns rich in fish (very long chain n-3 fatty acids) have been associated with lower risk of coronary heart disease (Fig. 5). The beneficial effects of fish and seafood have been attributed, in part, to their EPA and DHA content (Wang et al., 2006). A variety of factors may contribute to the beneficial effect of dietary EPA and DHA, including lower likelihood of ventricular fibrillation, resulting in lower risk of sudden death, as well as lower triglyceride concentration, platelet aggregation and blood pressure. An additional benefit of dietary patterns that routinely include fish and seafood is their use as a substitute for other protein sources such as meat and cheese, rich in SFA. For plant-based diets, EPA and DHA rich algae is now available.

## Trans fatty acids

*Trans* fatty acids, by definition, contain at least one double bond in the *trans* configuration (Fig. 6) (Mensink and Katan, 1990). In contrast to the more common *cis* double bonds, *trans* double bonds have a larger bond angle, resulting in a fatty acid with a straighter acyl chain, resulting in a conformation similar to saturated fatty acids. Fatty acids with *trans* double bond(s) can either be MUFA or PUFA. The intake of *trans* fatty acid containing foods has been positively linked to CVD risk (Lichtenstein et al., 1999). Concern about the use of partially-hydrogenated fat emerged in the early 1990s when it was reported that fatty acids with a *trans* double bond resulted in unfavorable lipoprotein profiles (Fig. 7) and later, with increased CVD risk (Ascherio et al., 1999).

Dietary *trans* fatty acids occur naturally in meat and dairy products because of anaerobic bacterial fermentation in ruminant animals and subsequent absorption and deposition in milk and muscle. *Trans* fatty acids are also introduced into foods when they are prepared with oils that have been partially hydrogenated. Partial hydrogenation results in changes in the fatty acyl chains;
