conversion of *cis* to *trans* double bonds, saturation of double bonds and migration of double bonds along the acyl chain. Plant oils are partially hydrogenated to increase viscosity (change a liquid oil into a semi-liquid or solid) and extend shelf life (decrease susceptibility to oxidation). It has been suggested that there is a difference in response to *trans* fatty acids of ruminant fat compared to partially hydrogenated fat origin. However, most of the evidence suggests that, if present, differences are small and all sources of *trans* fatty acids should be limited.

The major source of dietary *trans* fatty acids worldwide is from partially hydrogenated fat, primarily in commercially fried foods and baked goods. However, over the past decades there has been a shift away from the use of partially hydrogenated fats in some countries. In some cases, this change was spurred by consumer demand, and in some cases, by legislation. In the US, changes in legislation include mandatory inclusion of *trans* fat on the Nutrient Facts panel and removal of partially hydrogenated fat from the FDA's Generally Recognized as Safe (GRAS) list. It is expected that this trend will continue globally.

## Dietary cholesterol

The observation that dietary cholesterol increased plasma total cholesterol concentration leading to an acceleration of arteriosclerotic lesion progression was originally made early in the 20th century, in rabbits. In humans, positive associations have been observed between dietary cholesterol and plasma LDL-C concentration when dietary cholesterol was provided at high intake levels (800–900 mg/d; ~4–5 eggs/d) (Carson et al., 2020). Within the context of amounts habitually consumed, the effect was modest and not significant. Hence, the most recent editions of the Dietary Guidelines for Americans and the American Heart Association do not include a numerical target for dietary cholesterol. Dietary cholesterol is present only in foods of animal origin. Major sources

**Fig. 7** Change in LDL:HDL cholesterol ratio in response to *trans* fatty acids (solid line) and saturated fatty acids (dashed line). From Ascherio, A., Katan, M. B., Zock, P. L., Stampfer, M. J., Willett, W. C. *Trans* fatty acids and coronary heart disease. *N Engl J Med* 1999;340: 1994-1998.

include eggs, fatty cuts of meat and full fat dairy products. Current dietary patterns recommended to lower chronic disease risk, particularly, cardiometabolic risk, are relatively low in dietary cholesterol.

## Other dietary considerations for the prevention and management of CVD

### Fiber

Dietary soluble fiber, primarily  $\beta$ -glucan, has a modest independent effect of lowering LDL-C concentration (Armet et al., 2020; Hui et al., 2019). Approximately 50% of human controlled intervention trials report a significant benefit (Pereira et al., 2003; Doucette et al., 2019). Potential LDL-C lowering mechanisms of fiber include binding bile acids and cholesterol in the intestine, leading to increased fecal loss, and providing substrate for the production of short-chain fatty acids by the gut microbiota. In addition to whole grains, other fiber rich foods include fruit and vegetables, nuts and seeds, and legumes. Dietary patterns abundant in fiber rich foods, usually those that are predominately plant based, are associated with lower CVD risk (Fig. 8).

**Fig. 8** Relative risk of death from coronary heart disease (CHD) by category of total dietary fiber intake. Pereira MA, O'Reilly E, Augustsson K, Fraser GE, Goldbourt U, Heitmann BL, Hallmans G, Knekt P, Liu S, Pietinen P, Spiegelman D, Stevens J, Virtamo J, Willett WC, Ascherio A. Dietary fiber and risk of coronary heart disease: a pooled analysis of cohort studies. *Arch Intern Med*. 2004;164:370-6.

### Plant sterols (phytosterols)

The term sterol represents a group of compounds that are essential constituents of cell membranes in animals and plants (Katan et al., 2003). Cholesterol is the major sterol of mammals. Phytosterols, such as beta-sitosterol, campesterol, and stigmasterol, are the major sterols of plants (Fig. 9). Humans cannot synthesize plant sterols and they are poorly absorbed. When consumed they replace cholesterol in intestinal micelles, thereby interfering with cholesterol absorption. Maximal LDL-C lowering attributable to plant sterols occurs at a dose of about 2 g/d (Grundy et al., 2003). Although a relatively wide range of responses has been reported, most work suggests an expected LDL-C lowering of 5%–10% in individuals with high cholesterol. Given that the mechanism is at the point of absorption, this response can be additive to other LDL-C lowering approaches, such as statin therapy. In addition to plant sterol supplements, foods enriched with plant sterols, referred to as functional foods, are available. In some cases, the saturated form of the plant sterol, stanols, are added to these products. With respect to LDL-C lowering, the efficacy of plant sterols and stanols is similar. It is important to note that if an individual with hypercholesterolemia is encouraged to use plant sterols or stanols to lower their LDL-C and they choose food forms, such as margarine, orange juice or yogurts, these foods should replace, rather than be added to their habitual diet. No benefit will be derived from exceeding the maximal recommended dose or using plant sterols as a prophylactic measure to prevent the development of hypercholesterolemia.

### Nutrient supplements

In the past, considerable interest had been generated for the potential benefit of supplementation with vitamin C, beta-carotene, vitamin E, folate, or vitamin D for reducing CVD risk. Support came from observational studies, and in some cases biological plausibility was derived from experimental animal models and *in vitro* work. Despite these links, randomized controlled intervention trials have failed to demonstrate a benefit of nutrient supplementation (Manson et al., 2019) and, in some cases, have identified risks at high intake levels (Miller et al., 2005; Banach and Penson, 2021). Currently, the data do not support a use of nutrient supplements for the prevention or management of CVD.

### Dietary patterns

Because multiple components of a typical day's food and beverage intake, such as type of fat and carbohydrate and amount of fiber or added sugar, affect blood lipid levels and CVD risk, to facilitate adoption, current prevention recommendations have shifted from individual foods and nutrients to dietary patterns. This includes the most recent guidance from the American Heart Association (Lichtenstein et al., 2021). The advantages include adaptability to personal preferences, ethnic and religious practices and life stages, uniformity with guidance across multiple chronic risk reduction strategies (e.g., diabetes, cancer), and consistency with best practices for sustainability and environmental health. The guidance is summarized into 10 features (Table 2) and pictorially (Fig. 10). The features include adjusting energy intake and expenditure to achieve and maintain a healthy body weight; eating plenty and a variety of fruits and vegetables; choosing whole grain foods and products; choosing healthy sources of protein (mostly from plants, regularly from fish and seafood, primarily low-fat or fat-free dairy products, and if meat or poultry is desired, mostly lean cuts and unprocessed forms); using liquid plant oils rather than tropical oils and partially hydrogenated fats; choosing minimally processed foods instead of ultra-processed foods; minimizing the intake of beverages and foods with added sugars; choosing and preparing foods with little or no salt; if not consuming alcohol, do not start, if you choosing to consume drink alcohol, limiting intake; and adhering to this guidance regardless of where food is procured prepared or consumed.

**Fig. 9** Structures of cholesterol, and the phytosterols campesterol,  $\beta$ -sitosterol and sitostanol

**Table 2** Evidence-based dietary guidance to promote cardiometabolic health.

1. Adjust energy intake and expenditure to achieve and maintain a healthy body weight
2. Eat plenty of fruits and vegetables, choose a wide variety
3. Choose whole grain foods and products made mostly with whole grains rather than refined grains
4. Choose healthy sources of protein a. Mostly protein from plants (legumes and nuts)
  - b. Regular intake of fish and seafood
  - c. Low-fat or fat-free dairy products instead of full-fat dairy products
  - d. If meat or poultry are desired, choose lean cuts and avoid processed forms
5. Use liquid plant oils rather than tropical oils (coconut, palm and palm kernel), animal fats (e.g., butter and lard) and partially-hydrogenated fats
6. Choose minimally processed foods instead of ultra-processed foods<sup>a</sup>
7. Minimize intake of beverages and foods with added sugars
8. Choose and prepare foods with little or no salt
9. If you don't drink alcohol, do not start; if you choose to drink alcohol, limit intake.
10. Adhere to this guidance regardless of where food is prepared or consumed

<sup>a</sup>There is no commonly accepted definition for ultra-processed foods, and some healthy foods may exist within the ultra-processed food category.

## Conclusions

Relationships between diet and CVD risk have been clearly established, particularly with lipid and lipoprotein profiles, in addition to other risk factors. The current recommendation is to focus on the whole dietary pattern rather than not individuals foods or nutrients. Specific focus is on type rather than amount of dietary fat, and to replace SFA and *trans* fatty acids with unsaturated fatty acids, particularly PUFA, consuming at least two fish meals per week and fiber rich diets. Daily intake of plant sterols can result in LDL-C concentration lowering, in addition to that achieved with statins (Han et al., 2016). Currently, data do not support the use of nutrient supplements for the prevention or treatment of CVD. Attainment or maintenance of a healthy body weight should be emphasized along with engagement in regular physical activity. These recommendations are the culmination of more than a century of work. They have evolved slowly and continue to be fine-tuned as new findings emerge, leading to subsequent modifications.

## Key points

- High blood pressure, also termed hypertension, affects over 1.4 billion individuals worldwide and is the leading preventable cause of mortality.
- High blood pressure results from dietary factors, other environmental factors, genetic factors, and their interactions; of these factors, diet likely has a predominant role.
- Dietary factors that effectively lower blood pressure are weight loss, reduced dietary sodium intake, increased dietary potassium intake, moderation of alcohol intake (among those who drink), and adoption of a DASH-style or vegetarian dietary pattern.
- The current challenge is to develop and implement clinical and public health strategies that lower blood pressure through sustained dietary changes among individuals and more broadly among populations.

## Introduction

Worldwide, high blood pressure (BP) is the leading cause of preventable death, not just in high income countries, but also in low- and middle-income countries (GBD Collaborators, 2018). The high global burden from high BP reflects its causal relationship with multiple diseases and its enormous prevalence—an estimated 1.4 billion people have hypertension (Mills et al., 2016). High BP is causally related to cardiovascular (CV) and kidney diseases, including stroke, myocardial infarction, heart failure, kidney failure, and likely cognitive decline. As blood pressure (BP) rises, so does the risk of these diseases (Fig. 1) (Lewington et al., 2002). The relationship is strong, consistent, continuous, independent, and etiologically relevant. Accordingly, the adverse consequences of high BP are not just restricted to individuals with hypertension (classically defined as a systolic BP  $\geq 140$  mm Hg and/or a diastolic BP  $\geq 90$  mm Hg, or more recently revised to a systolic BP  $\geq 130$  mm Hg and/or a diastolic BP  $\geq 80$  mm Hg) (Whelton et al., 2018). A normal BP is considered a systolic BP  $< 120$  mm Hg and diastolic BP  $< 80$  mm Hg. Those with intermediate levels

**Fig. 1** Stroke mortality rate by decade of age versus systolic BP (A) and diastolic BP (B): meta-analysis of 61 prospective studies with 2.7 million person-years. Reproduced from Lewington, S., Clarke, R., Qizilbash, N., Peto, R., Collins, R., 2002. Age-specific relevance of usual blood pressure to vascular mortality: a meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet* 360, 1903–1913.

between normal BP and hypertensive BP have a high probability of developing hypertension and carry an excess risk of cardiovascular disease (Vasan et al., 2001). It has been estimated that approximately 20% of all deaths and >50% of deaths from ischemic heart disease and stroke can be attributed to high BP (Forouzanfar et al., 2017).

In Western countries and most economically developing countries, systolic BP rises with age in both children and adults. As a consequence, the lifetime risk of developing hypertension is extremely high, approximately 90% among US adults older than the age of 50 years (Vasan et al., 2002). However, the rise in BP with age is not inevitable. There are numerous isolated populations in which the rise in BP is blunted or even flat (Rose et al., 1988). These populations are typically characterized by extremely low intakes of salt, relatively high intakes of potassium, and a lean body habitus.

Lifestyle modification, which includes dietary changes and increased physical activity, has important roles in both non-hypertensive and hypertensive individuals (Appel et al., 2006b). In non-hypertensive individuals, lifestyle modifications have the potential to prevent hypertension, reduce BP, and thereby lower the risk of BP-related cardiovascular disease. Even an apparently small reduction in BP, if applied to an entire population, could have an enormous beneficial impact (Stamler, 1991). Specifically, it

**Fig. 2** Estimated effects of population-wide shifts in systolic BP on mortality. Reproduced from Stamler, R., 1991. Implication of the intersalt study. *Hypertension* 17, 1-16-1-20, with permission from LWW.

has been estimated that a 3 mm Hg reduction in systolic BP could lead to an 8% reduction in stroke mortality and a 5% reduction in mortality from coronary heart disease (Fig. 2). In hypertensive individuals, lifestyle modifications can serve as initial treatment before the start of drug therapy and as an adjunct to medication in people already on antihypertensive drug therapy. In hypertensive individuals with medication-controlled BP, lifestyle therapies can facilitate drug step-down and potentially drug withdrawal in individuals who sustain lifestyle changes (Whelton et al., 1998).

High BP results from dietary factors, other environmental factors, genetic factors, and their interactions (Appel et al., 2006a; Levy et al., 2009). Of these factors, diet likely has a predominant role in BP homeostasis. Dietary factors that effectively lower BP are weight loss, reduced dietary sodium intake, increased dietary potassium intake, moderation of alcohol intake (among those who drink), and adoption of a DASH-style or vegetarian dietary pattern. Other aspects of diet might also affect BP, but the effects are small and/or the evidence uncertain.

## Dietary factors that lower BP

### Weight loss

On average, as weight increases, so does BP. The importance of this relationship is reinforced by the high and increasing prevalence of overweight and obesity throughout the world. With rare exception, clinical trials have documented that weight loss lowers BP. Importantly, reductions in BP occur before and without attainment of a desirable body weight. In one meta-analysis that aggregated results across 25 trials, mean systolic and diastolic BP reductions from an average weight loss of 5.1 kg were 4.4 and 3.6 mm Hg, respectively (Neter et al., 2003). Greater weight loss leads to greater BP reduction. Still, the long-term effects of weight loss on BP are unclear, with some studies suggesting that BP reductions attenuate over time (Stevens et al., 2001).

Additional trials have documented that modest weight loss can prevent hypertension by approximately 20% among overweight, individuals without hypertension, and can facilitate medication step-down and drug withdrawal (1997). Lifestyle intervention trials have uniformly achieved short-term weight loss, primarily through a reduction in total calorie intake. In some instances, substantial weight loss has also been sustained over 3 or more years (TOHP Collaborative Research Group, 1997; Svetkey et al., 2008).

In aggregate, available evidence strongly supports weight reduction, ideally attainment of a body mass index less than  $25 \text{ kg m}^{-2}$ , as an effective approach to prevent and treat hypertension. Weight reduction can also prevent diabetes and control lipids. Hence, the beneficial effects of weight reduction in preventing cardiovascular–renal disease should be substantial. Finally, in view of the well-recognized challenges of maintaining weight loss, efforts to prevent weight gain among those with a normal body weight are critical.

### Reduced salt intake

On average, as dietary salt (sodium chloride) intake rises, so does BP. (In view of the format of published data and of most dietary recommendations, data are presented as g/day (mmol/day) of sodium rather than g/day of salt.) To date, over 100 randomized trials have tested the effects of salt on BP, including dose–response trials; several meta-analyses have aggregated data across trials. In a recent meta-analysis (Mozaffarian et al., 2014), a reduction in sodium intake of 2.3 g/d lowered systolic BP by 3.8 in adults; larger BP reductions occurred in older than younger persons, blacks compared to whites, and hypertensive individuals compared to normotensive individuals.

One of the most important dose–response trials is the Dietary Approaches to Stop Hypertension (DASH)-Sodium trial, which tested the effects of three different salt intakes separately in two distinct diets—the DASH diet and a control diet more typical of what Americans eat (Sacks et al., 2001). As displayed in Fig. 3, the rise in BP with higher salt intake was evident in both diets. The BP response to salt intake was nonlinear. Specifically, decreasing salt intake caused a greater lowering of BP when the starting sodium intake was less than  $2.3 \text{ g day}^{-1}$  ( $100 \text{ mmol day}^{-1}$ ) than when it was above this level.

The BP response to changes in salt intake is heterogeneous. Despite the use of the terms “salt sensitive” and “salt resistant” to classify individuals in research studies, the change in BP in response to a change in salt intake is not binary. Rather, the change in BP from a reduced salt intake has a continuous distribution, with individuals having greater or lesser degrees of BP reduction. Genetic factors influence the response to salt reduction. Concomitant diet also modifies the effects of salt on BP. The rise in BP for a given increase in salt intake is blunted in the setting of either the DASH diet or a high potassium intake (Fig. 3). In general, the effects of salt on BP tend to be greater in blacks, middle-aged and older people, and individuals with hypertension, or chronic kidney disease (McMahon et al., 2015). Importantly, although it is possible to identify groups that tend to be salt sensitive, it is impossible, given currently available diagnostic tools, to identify individuals who are salt sensitive.

In addition to lowering BP, clinical trials have documented that a reduced salt intake can prevent hypertension by approximately 20% (with or without concomitant weight loss) (1997) and can lower BP in the setting of antihypertensive medication (Appel et al., 2001). Evidence from observational studies suggests that a reduced salt intake can blunt the age-related rise in systolic BP (Fig. 4) (Rose et al., 1988). A reduced salt intake may also reduce the risk of left ventricular hypertrophy, osteoporosis, and gastric cancer (Institute of Medicine, 2005). Still, the evidence base does have limitations, largely because of the difficulty in measuring sodium intake and the potential for reverse causality. For these reasons, results from observational studies have been inconsistent and occasionally paradoxical with some studies suggesting that a low sodium intake might be harmful. However, such analyses are fraught

**Fig. 3** Mean systolic BP change in the DASH-Sodium Trial from salt reduction in two diets and from the DASH diet at three salt levels. **Fig. 4** Slope of systolic BP increase with age plotted by median sodium excretion in 52 communities worldwide: results from intersalt. Reproduced with permission from Rose, G., Stamler, J., Stamler, R., et al., 1988. Intersalt: an International Study of electrolyte excretion and BP. Results for 24 h urinary sodium and potassium excretion. *Br. Med. J.* 297, 319–328.

with methodologic issues (Cobb et al., 2014) and have been largely dismissed in policy-making (National Academies of Sciences, 2019).

Recently, two major studies have provided strong evidence in support of population-wide sodium reduction. First, a major trial documented that replacement of regular salt with a potassium-enriched salt substitute significantly reduced the risk of stroke (14%) and total mortality (12%) in rural China (Neal et al., 2021). Second, a meta-analysis of observational studies in generally healthy adults documented that higher sodium and lower potassium intakes, as measured in multiple 24 h urine samples, were associated in a dose-response manner with a higher cardiovascular risk, without evidence of harm at lower levels of sodium excretion (Ma et al., 2021).

Still, the effects of salt on health have been debated. Some have argued that the increases in plasma renin activity, uric acid and perhaps insulin resistance that occur as a result of a reduced salt intake mitigate the beneficial effects of salt reduction on BP (Grau-dal et al., 2012). However, in contrast to BP, the clinical relevance of increased plasma renin activity and uric acid is uncertain, especially because antihypertensive medications that raise plasma renin levels and uric acid actually lower cardiovascular disease risk. It has also been argued that a reduced salt intake has little or no effect on BP in many individuals.

Available evidence strongly supports population-wide sodium reduction, as recommended by the World Health Organization (WHO), most governments, and numerous organizations. The WHO has recommended that adults consume less than 5 g of salt per

day, corresponding to less than 2000 g of sodium per day. A National Academy of Medicine (NAM) committee recommended an upper limit of 2300 g of sodium per day (National Academies of Sciences, 2019). In view of the high burden of BP-related disease in middle and older-aged persons, and individuals with hypertension and chronic kidney disease, several authoritative bodies have recommended an even lower intake of sodium (Lloyd-Jones et al., 2010). The NAM committee set a lower limit, termed Adequate Intake (AI) of 1500 g of sodium per day. This level of salt intake allows for excess sweat salt loss among unacclimatized individuals who become physically active or who become exposed to high temperatures.

In most Western countries, average intake of sodium is high, greatly exceeding  $2.3 \text{ g day}^{-1}$  ( $100 \text{ mmol day}^{-1}$ ). In the United States, the mean intake of sodium from foods, not including salt added at the table, is  $\sim 4200 \text{ g/day}$  in adult men and  $\sim 3000$  in adult women (Bailey et al., 2015). In addition to gender, sodium intake varies considerably by age. Worldwide, there is substantial variation in sodium intake, ranging from an estimated mean intake of  $0.02 \text{ g day}^{-1}$  ( $1.0 \text{ mmol day}^{-1}$ ) in Yanomamo Indians to more than  $10.3 \text{ g day}^{-1}$  ( $450 \text{ mmol day}^{-1}$ ) in northern Japanese (Rose et al., 1988).

In aggregate, available data strongly support current population-wide recommendations to lower salt intake. In some regions of the world, e.g., rural China, most dietary sodium comes from the addition of salt during cooking (Anderson et al., 2010). In this context, counseling and replacement of regular salt with potassium-enriched, reduced-sodium salt are the preferred, sodium reduction strategies. However, in the vast majority of countries, the primary source of sodium is processed and restaurant foods, which account for more than 70% of sodium intake (Fig. 5) (Harnack et al., 2017). Hence, any meaningful strategy to reduce sodium intake must involve the efforts of food manufacturers, who should reduce the amount of salt added during food processing.

### Increased potassium intake

High levels of potassium intake are associated with reduced BP. Observational data have been reasonably consistent in documenting this inverse relationship, whereas data from individual trials, which typically achieve a higher potassium intake through pill supplements, have been less consistent. Meta-analyses of these trials have documented a significant inverse relationship between potassium intake and BP in studies of hypertensive individuals, and non-significant effects in studies of non-hypertensive persons. In one meta-analysis, average net systolic/diastolic BP reductions from increased potassium intake were 3.5/2.0 mm Hg (Aburto et al., 2013). Available studies have documented greater BP reductions from potassium in blacks compared to non-blacks and in hypertensive compared to non-hypertensive individuals. A high potassium intake appears to blunt the rise in BP in response to increased salt intake (Morris et al., 1999). Potassium appears to have greater BP lowering in the context of a higher salt intake and lesser BP reduction in the setting of a lower salt intake. Conversely, the BP reduction from a reduced salt intake is greatest when potassium intake is low. These data are consistent with subadditive effects of reduced salt intake and increased potassium intake on BP.

Most trials that tested the effects of potassium on BP used pill supplements, typically potassium chloride. However, in foods, the conjugate anions associated with potassium are mainly citrate and other bicarbonate precursors. The latter is important because other potential benefits of foods rich in potassium (i.e., reduced risk of kidney stones and reduced bone turnover) likely result from effects of the conjugate anion. Because a high dietary intake of potassium can be achieved through diet rather than pills and because potassium derived from foods also comes with a variety of other nutrients, the preferred strategy to increase potassium intake is to consume foods, such as fruits and vegetables, rather than potassium supplements.

On the basis of available data, a National Academy of Medicine committee set an Adequate Intake for potassium of 3400 mg per day for healthy men and 2600 mg per day for healthy women (National Academies of Sciences, 2019). This level of dietary intake should lower BP levels and have the potential benefits of reducing the adverse effects of salt on BP, reducing the risk of kidney stones, and possibly decreasing bone loss (Institute of Medicine (U.S.) Panel on Dietary Reference Intakes for Electrolytes and Water, 2005). Currently, dietary intake of potassium is lower than these levels. In recent surveys, the mean intake of potassium in the United States was  $\sim 3200 \text{ mg/day}$  in adult men and  $\sim 2400 \text{ mg/day}$  in adult women (Bailey et al., 2015). Because African Americans have a relatively low intake of potassium and a high prevalence of high BP and salt sensitivity, this subgroup of the population would especially benefit from an increased potassium intake.

In the generally healthy population with normal kidney function, a potassium intake from foods higher than 3400 mg/day poses no potential for increased risk because excess potassium is readily excreted in the urine. However, in individuals whose

**Fig. 5** Sources of dietary sodium. Data from Harnack, L.J., et al., 2017. Sources of sodium in US adults from 3 Geographic Regions. *Circulation* 135, 1775–83.

urinary potassium excretion is impaired, a potassium intake of less than 3400 mg/day might be appropriate because of the potential for adverse cardiac effects (arrhythmias) from hyperkalemia. Common drugs that impair potassium excretion are angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics. Medical conditions associated with impaired potassium excretion include diabetes, chronic kidney disease, end stage kidney disease, severe heart failure, and adrenal insufficiency. Elderly individuals are at increased risk of hyperkalemia because they often have one or more of these conditions or take one or more of the medications that impair potassium excretion.

### **Moderation of alcohol intake**

Alcohol intake raises BP, particularly at an alcohol intake above approximately two drinks per day (~1 oz. or ~28 g of ethanol per day). In a meta-analysis of 32 trials with 767 participants, the effects of alcohol differed by dose and time after ingestion. Low-dose alcohol (<14 g/d) had no effect on BP. Medium-dose alcohol (14–28 g/d) lowered BP soon after ingestion, within 6 h, but did not affect BP after 6 h. However, high-dose alcohol (>30 g/d) lowered BP within 6 h and up to 12 h later. However, after 12 h, high-dose alcohol increased systolic BP by a mean of 3.7 mmHg and diastolic BP by a mean of 2.4 mmHg (Tasnim et al., 2020). In non-hypertensives and hypertensives, BP reductions did not differ, potentially because of small sample sizes. In aggregate, evidence supports recommendations to lower alcohol intake (among those who drink) as an approach to lower BP. Alcohol consumption be limited to no more than 1 oz. (30 mL) of ethanol (e.g., 24 oz. (720 mL) beer, 10 oz. (300 mL) wine, or 2 oz. (60 mL) 100-proof whiskey) per day in most men and to no more than 0.5 oz. (15 mL) ethanol per day in women and lighter weight people.

### **Whole dietary patterns**

#### **Vegetarian diets**

Vegetarian diets have been associated with low BP. In observational studies, vegetarians also experience a markedly lower, age-related rise in BP (Yokoyama et al., 2014). Aspects of a vegetarian lifestyle that might affect BP include nondietary factors (e.g., physical activity), established dietary risk factors (e.g., salt, potassium, weight, and alcohol), and other aspects of a vegetarian diet (e.g., high fiber and no meat). To a very limited extent, observational studies have controlled for the well-established determinants of BP. In a meta-analysis of trials of dietary patterns, consumption of a vegan dietary pattern had no significant effect on BP, while a lacto-ovo vegetarian patterns significantly reduced systolic and diastolic BP by 5.5 and 2.5 mmHg, respectively (Gibbs et al., 2021).

#### **DASH-style dietary patterns**

The DASH trial tested whether modification of whole dietary patterns affect BP (Appel et al., 1997). In this trial, participants were randomized to eat one of three diets: (1) a control diet; (2) a diet rich in “fruits and vegetables” but otherwise similar to control; or (3) the DASH diet. The DASH diet emphasizes fruits, vegetables, and low-fat dairy products; includes whole grains, poultry, fish, and nuts; and is reduced in fats, red meat, sweets, and sugar-containing beverages. Accordingly, it is rich in potassium, magnesium, calcium, and fiber and reduced in total fat, fat, and cholesterol; it is also slightly increased in protein.

Among all participants, the DASH diet significantly lowered mean systolic BP by 5.5 mm Hg and mean diastolic BP by 3.0 mm Hg. The fruits and vegetables diet also reduced BP but to a lesser extent—approximately half of the effect of the DASH diet. The effect was relatively rapid; the full effect was apparent after 2 weeks (Fig. 6). In subgroup analyses, the DASH diet significantly lowered BP in all major subgroups (men, women, Blacks, non-Blacks, hypertensives, and non-hypertensives) (Svetkey et al., 1999). However, the effects of the DASH diet were especially prominent in Blacks, who experienced net systolic/diastolic BP reductions of 6.9/3.7 mm Hg, and hypertensive individuals, who experienced net BP reductions of 11.6/5.3 mm Hg.

Subsequently, the OmniHeart trial compared three variants of the DASH diet (a diet rich in carbohydrate (58% of calories), a second version rich in protein (approximately half from plant sources), and a third diet rich in unsaturated fat (predominantly monounsaturated fat)) (Appel et al., 2005). In several respects, each diet was similar to the DASH diet—each was reduced in saturated fat, cholesterol, and sodium, and rich in fruit, vegetables, fiber, and potassium at recommended levels. Although each diet lowered systolic BP, substituting some of the carbohydrate (approximately 10% of total kcal) with either protein (approximately half from plant sources) or with unsaturated fat (mostly monounsaturated fat) further lowered BP.

Results from the DASH and OmniHeart trials have important clinical and public health implications. The effect of the DASH diet in hypertensive individuals was similar in magnitude to that of drug monotherapy. From a public health perspective, the DASH diet could potentially shift the population distribution of BP downward, thereby reducing the risk of BP-related cardiovascular disease (Fig. 2). In a meta-analysis of 11 trials ( $n = 1400$  participants) that tested the effects of the DASH diet on BP, adoption of the DASH diet lowered mean systolic and diastolic BP by 5.5 and 3.8 mmHg, respectively (Gibbs et al., 2021). In the same meta-analysis, adoption of a Mediterranean style diet lowered mean systolic BP by ~1 mmHg and had no significant effect on diastolic BP.

### **Protein intake**

A large and generally consistent body of evidence from observational studies and clinical trials has documented that higher protein intake, particularly protein from plant-based sources, is associated with lower BP (Rebholz et al., 2012; Elliott et al., 2006). Several trials have tested the effects of soy-based interventions on BP. In several but not all of these trials, soy supplementation reduced BP; however, it is unclear whether the BP reductions are due to soy protein or isoflavones (He et al., 2011). As previously discussed, the

**Fig. 6** BP by week during the DASH feeding study in three diets (control diet, fruits and vegetables diet, and DASH diet). Reproduced with permission from Appel, L.J., Moore, T.J., Obarzanek, E., et al., 1997. The effect of dietary patterns on BP: results from the Dietary Approaches to Stop Hypertension (DASH) clinical trial. *N. Engl. J. Med.* 336, 1117–1124.

OmniHeart trial documented that a dietary pattern with increased protein intake from mixed sources, predominantly plants, lowered BP (Appel et al., 2005).

## Dietary factors with limited or uncertain effect on BP

### Fiber

Evidence from observational studies and several clinical trials suggests that increased fiber intake may reduce BP. A meta-analysis documented that supplemental fiber (average net increase of 11 g day<sup>-1</sup>) was associated with net systolic/diastolic reductions of 1.2/1.7 mm Hg, respectively (Whelton et al., 2005). Still, high-quality epidemiological studies and clinical trials are needed before one can recommend increased fiber intake as a means to lower BP.

### Calcium and magnesium

Evidence that increased calcium intake might lower BP comes from a variety of sources, including animal studies, observational studies, clinical trials, and meta-analyses. Meta-analyses of trials documented small reductions in systolic and diastolic BP with calcium supplementation (400–2000 mg/day) (Allender et al., 1996). There is also evidence that calcium intake may affect the BP response to salt. Overall, data are insufficient to recommend supplemental calcium alone as a means to lower BP.

The body of evidence implicating magnesium as a major determinant of BP is likewise inconsistent. In observational studies, often cross-sectional in design, a common finding is an inverse association of dietary magnesium with BP (Jee et al., 2002). However, in pooled analyses of clinical trials, there was no clear effect of magnesium intake on BP. Hence, data are insufficient to recommend increased magnesium intake alone as a means to lower BP.

### Fish oil supplementation

High-dose,  $\omega$ -3 polyunsaturated fatty acid (commonly termed “fish oil”) supplements can lower BP in hypertensive individuals. In a meta-analysis of 17 trials with a total of 1524 participants, high dose fish oil reduced systolic and diastolic BP by a mean of 2.6 and 1.5 mmHg, respectively, in persons with hypertension, but had no significant effect in non-hypertensive persons. It is noteworthy that the dose of fish oil was relatively high in many trials, i.e., 3 g or more per day (Campbell et al., 2013). Side effects from fish oil supplements, particularly belching and a fishy taste, are common. In view of the side effect profile and the high dose required to lower BP, fish oil supplements are not routinely recommended as a means to lower BP.

### Fats (other than fish oil) and cholesterol

Numerous studies, including both observational studies and clinical trials, have examined the effects of fat intake on BP. Overall, there is no apparent effect of saturated fat and *n*-6 polyunsaturated fat intake on BP. Although a few trials suggest that an increased intake of monounsaturated fat may lower BP, evidence is insufficient to make recommendations. Likewise, few studies have examined the effect of dietary cholesterol intake on BP. Hence, although modification of dietary fat and cholesterol intake can be recommended as a means to prevent and treat hyperlipidemia and dyslipidemia, evidence is insufficient to recommend these changes alone as a means to lower BP.

### Vitamin C

Laboratory studies, depletion–repletion studies, and epidemiological studies suggest that increased vitamin C intake or status is associated with lower BP. Several trials, many with methodological limitations, have also addressed this issue ([Juraschek et al., 2012](#)). Overall, it remains unclear whether an increased intake of vitamin C lowers BP.

### Gene–diet interactions

A rapidly increasing body of evidence indicates that genetic factors affect BP levels and the BP response to dietary changes. Most of the evidence relates to genetic factors that affect the BP response to salt ([Elijovich et al., 2016](#)). Several genotypes that influence BP have been identified. Most of these genotypes influence the renin–angiotensin–aldosterone axis or renal salt handling.

### Special populations

#### Children

High BP begins well before adulthood, during the first two decades of life and likely during gestation. In addition to the age-related rise in BP observed in children, numerous studies have documented that BP tracks with age from childhood into the adult years ([Dekkers et al., 2002](#)). Hence, efforts to reduce BP and to prevent the age-related rise in BP in childhood are prudent.

With the exception of sodium, few trials have tested the effects of dietary factors as a means to lower BP in children and adolescents. In a meta-analysis of 10 trials conducted in children, sodium reduction significantly lowered BP ([He and MacGregor, 2006](#)). Because few trials have tested dietary interventions in children, the effect of diet on BP in children and adolescents is, in large part, extrapolated from trials conducted in adults. Such extrapolations are reasonable because high BP is a chronic condition resulting from the insidious rise in BP throughout childhood and adulthood.

#### Pregnant women

Hypertension during pregnancy is a constellation of diverse clinical conditions, some of which can be extremely serious. Of substantial concern are preeclampsia and eclampsia. Both are multisystem disorders that are manifest by the onset of hypertension and proteinuria during the second half of pregnancy. Convulsions occur in the setting of eclampsia but not preeclampsia. Many studies have explored the possibility that dietary factors cause hypertensive disorders in pregnancy. In clinical trials, several dietary interventions, including sodium reduction, fish oil supplementation, and calcium supplementation, have been tested as a means to prevent preeclampsia, but none were effective. Currently, the focus of research on the pathogenesis of pre-eclampsia is abnormal placental development and subsequent placental ischemia.

#### Older people

Because of the age-related rise in systolic BP and because of the high prevalence of BP-related cardiovascular disease in middle-aged and older people, dietary strategies should be especially beneficial as adults age. It is well documented that older people can make and sustain dietary changes, specifically weight loss and dietary salt reduction ([Whelton et al., 1998](#)). Furthermore, salt sensitivity increases as individuals age. Lastly, because of the high attributable risk associated with high BP in older people, the beneficial effects of dietary changes on BP should translate into substantial reductions in cardiovascular risk in this age group.

### Populations defined by race/ethnicity or geography

The worldwide prevalence of hypertension is enormous—an estimated 1.4 billion have hypertension, of whom over 1 billion live in low- and middle-income countries ([Mills et al., 2016](#)). Yet, such staggering estimates mask the fact that there is substantial variation in BP among populations. In certain primitive societies, such as the Yanomamo Indians in Brazil, BP does not rise with age, and hypertension is absent ([Mueller and Appel, 2019](#)). Until recently, rural populations tended to have a lower population than corresponding urban populations. However, this pattern is now less apparent with rural populations having a similar, or even higher,

prevalence of hypertension. Among urbanized populations, the prevalence of hypertension is high, especially among African Americans, a population in which the prevalence of hypertension approaches 40%. Other groups, such as Australian Aborigines, Eastern Europeans, and Russians, also have a high prevalence of hypertension.

Understanding the causes of geographic variation is difficult. However, migration studies provide strong evidence that modifiable environmental factors (e.g., diet and physical activity) rather than genetic factors or geographic factors account for this variation (He et al., 1991; Poulter et al., 1990). Furthermore, as noted previously, trials have documented that compared to non-blacks, blacks achieve greater BP reduction from several nonpharmacological therapies, specifically a reduced salt intake, increased potassium intake, and the DASH diet. The potential benefits of these dietary therapies is amplified because US survey data indicate that Blacks consume less potassium than non-Blacks, while salt intake is high and similar in Blacks and non-Blacks. In this context, changes in diet should provide a means to reduce racial and perhaps geographic disparities in BP.

## Conclusion

In view of the continuing epidemic of BP-related cardiovascular disease, efforts to reduce BP in both non-hypertensive and hypertensive individuals are warranted. Such efforts will require individuals to change behavior and society to make substantial environmental changes. The current challenge to the general public, health care providers, researchers, and policy makers is to develop and implement effective clinical and public health strategies that lead to sustained dietary changes among individuals and more broadly among populations.

## Key points

- Spontaneous hypoglycemia is not a diagnosis but a manifestation of an underlying disorder.
- Hypoglycemic symptoms may be non-specific. Acute and subacute neuroglycopenia may only be confidently confirmed when Whipple's triad is fulfilled; namely neuroglycopenic symptoms, a low blood glucose and symptoms relieved by raising blood glucose to or above normal.
- Although uncommon, it is important to recognize spontaneous hypoglycemia and its etiology because preventative or curative therapy is often available.

- Appropriate laboratory tests in hypoglycaemic samples and subsequent radiological investigations identify most of the causes of hypoglycemia.

## Introduction

Hypoglycemia is defined as a blood glucose concentration of  $2.5 \text{ mmol L}^{-1}$  (plasma glucose concentration of  $3.0 \text{ mmol L}^{-1}$ ) or less. Its definition is necessarily arbitrary and owes its importance to the fact that hypoglycemia (low blood glucose) of this severity produces brain dysfunction by depriving its neurons of glucose.

Hypoglycemia is not a disease but a manifestation of it. It has, however, come to have a totally different meaning, among certain sections of the population, that has nothing to do with blood glucose concentration but much to do with feelings of well-being, discomfort, attitudes to life and, above all, with the role of diet in the achievement and maintenance of good health. No discussion of the dietary treatment of hypoglycemia can be meaningful without reference to this concept—referred to, for want of a better term, as non-hypoglycemia. Hypoglycemia will, throughout this article, be used only to describe a condition associated with a measured low blood glucose concentration.

## Brain function and hypoglycemia

The brain malfunction and symptoms to which hypoglycemia gives rise will be referred to as neuroglycopenia to distinguish them from a low measured blood glucose concentration.

Although glucose is the major source of energy for brain, the brain is able, under certain circumstances including prolonged fasting, to utilize the “ketone bodies” ( $\beta$ -hydroxybutyrate and acetoacetate) produced exclusively in the liver from partial oxidation of fatty acids. Under these circumstances the need for glucose and its supply through gluconeogenesis is drastically reduced. The survival value of this adaptation is immense as it permits fat stores rather than structural muscle and other tissue proteins to be utilized for maintenance of vital processes under stressful conditions. Only when fat stores have become completely exhausted and plasma ketone levels fail to rise does the brain’s demand for glucose exceed the ability of gluconeogenesis to provide it. At this point hypoglycemia intervenes and portends death from starvation or inanition (see [Starvation](#)).

## The blood glucose concentration

Failure to appreciate the differences between arterial and venous blood glucose is a major cause of the confusion that has surrounded the recognition and diagnosis of hypoglycemia and been responsible for non-hypoglycemia becoming a common diagnosis among those whom Singer and coworkers refer to as the folk sector, which includes many health writers.

In the fasting subject the concentration of glucose in arterial and venous blood is virtually identical but following ingestion of a carbohydrate rich meal it may differ by as much as  $2.5 \text{ mmol L}^{-1}$ . It is arterial blood glucose that determines glucose supply to the brain, regulates the secretion of insulin and other hormones, and is itself homeostatically controlled and therefore, it is necessary to define hypoglycemia in terms of glucose in arterial (or more practically free flowing capillary) than in venous blood.

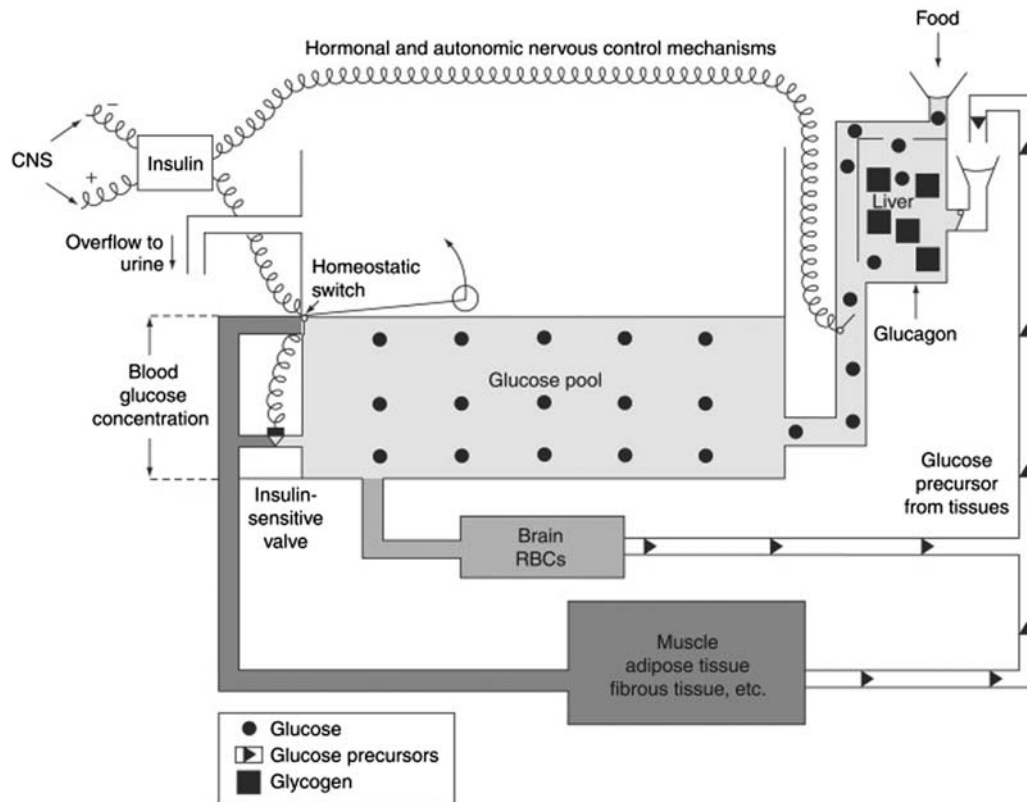

## Mechanism of hypoglycemia

### The glucose pool in fasting subjects

Glucose is confined within the body to the extracellular or interstitial fluid where it is referred to as the glucose pool; detailed discussion of its regulation is outside the scope of this article except to stress that its size is reflected by the concentration of glucose in the blood. This remains remarkably constant despite huge changes in the rates of delivery and utilization of glucose, by meals and exercise (and fasting), respectively, and is described as glucose homeostasis ([Fig. 1](#)). The main but far from sole regulator is insulin.

### Insulin release in response to eating and fasting

After a carbohydrate-containing meal, glucose derived from food enters the portal vein and transported to the liver where about one-third of it is extracted and converted to glycogen. The un-extracted glucose passes into the systemic circulation, producing small and variable rises in arterial, capillary, and, initially, venous blood glucose concentrations. The modest rise in arterial blood glucose concentration perfusing the pancreas, augmented by nervous stimuli and insulinotrophic hormones stimulate insulin secretion. The most notable insulinotrophic hormones are glucagon-like polypeptide 1 (GLP-1) and gastric inhibitory hormone, sometimes called glucose dependent insulinotrophic peptide but best referred to simply as GIP ([Marks, 2020](#)) and collectively called incretins ([Marks, 2018](#)). These are released from the gut in response to meals containing carbohydrate and fat and lead to the secretion of insulin in greater amounts than simply due to the rise in blood glucose concentration, a phenomenon known as the “incretin effect.” The

**Fig. 1** Schematic representation of homeostatic control of blood glucose level and mechanism of hypoglycemia. Hypoglycemia results whenever inflow of glucose from the gut or liver fails to meet the outflow of glucose from the glucose pool, which consists of glucose dissolved in the extracellular water only. Imbalance arises from: (1) excessive outflow into the tissues owing to insulin (or very rarely IGF-II) overproduction or activity; or (2) in the fasting state, an inability of the liver to liberate or produce glucose at a rate sufficient to meet the noninsulin-dependent, and obligatory, requirements of the brain and red blood cells for glucose.

incretin effect minimizes blood glucose excursions very efficiently following a meal and plays an important role in maintaining postprandial glucose homeostasis.

Evidence for a "cephalic phase" of insulin secretion in humans is scanty and conflicting. Most observers have found a minimal, if any, response to the prospect of eating, or the reality of drinking, a non-calorigenic sweet drink. Others have reported insulin secretion especially in the 10 min or so after eating an appetizing meal and before the blood glucose concentration has risen. They attribute it to vagal activation.

In the postprandial period, as the blood glucose concentration falls toward its homeostatically controlled level, insulin secretion declines to a level that is just sufficient to suppress unbridled lipolysis. Absence of this constitutive insulin secretion in patients with type 1 diabetes is the cause of diabetic ketoacidosis.

### The role of the liver in glucose homeostasis

The liver, under the influence of insulin reaching it in high concentration in the portal vein after ingestion of a meal, switches from being a net exporter to net importer of glucose from the glucose pool. Any insulin not extracted and degraded by the liver passes through the heart and lungs to reach peripheral tissues, notably muscle, adipose tissue, and skin, where, providing the concentration of insulin in blood is sufficiently high, it promotes glucose uptake.

Except in disease, the glucose pool, amounting to just 5–15 g, rarely expands by more than 100% even after ingestion of a meal providing up to 300 g of carbohydrate as starch or glucose; nor does it shrink to less than 4 g, corresponding to a blood glucose concentration of about  $3.5 \text{ mmol L}^{-1}$ , even after many days of fasting.

Entry of glucose into the glucose pool is limited by the rate at which it can be absorbed from the intestine. This is normally in the region of  $25\text{--}50 \text{ g h}^{-1}$ . In people with normal glucose tolerance, venous blood glucose levels generally return to overnight fasting values within 2–3 h of eating a meal regardless of how much carbohydrate it contains. Arterial blood glucose levels take longer to return to pre-ingestion levels but they too are always within the normal fasting range by 3–4 h, even though the evidence provided by measurement of the gut hormone GIP, indicates that absorption of large meals continues for much longer. Absorption of a 200 g liquid glucose meal by normal healthy subjects, for example, is still incomplete 5 h later even though both their venous and arterial blood glucose levels have long since returned to normal.

The outflow of glucose into the tissues depends upon many factors; the two most important are the plasma insulin and blood glucose concentrations. Under maximum insulin stimulation—and at “normal” blood glucose levels—glucose disappears from the glucose pool at a rate of up to  $40\text{--}50\text{ g h}^{-1}$  but these conditions are rarely encountered except experimentally or in cases of gross insulin overdose.

Onset of insulin action is almost instantaneous and persists for as long as insulin remains bound to insulin receptors. Glucose continues to enter insulin dependent cells for up to 30 min after plasma insulin levels have returned to “fasting” levels. During this time the glucose pool may shrink sufficiently to produce hypoglycemia unless replenished by glucose continuing to enter from the intestine (or experimentally/therapeutically by intravenous infusion) or from the liver, once it has switched from the glycogenic to glycogenolytic mode.

Small, and always temporary, imbalances between the rate at which insulin action declines and glucose enters the glucose pool can occur in healthy subjects after ingestion of a large dose of glucose in solution on an empty stomach, but is rare following the ingestion of an ordinary mixed meal.

A slight delay in stimulating insulin release in response to a meal is the earliest and most characteristic abnormality observed in patients with typical type 2 diabetes mellitus who may secrete more insulin in total than people of comparable age and body mass index. They are, however, generally insulin resistant, which explains why, despite the larger amounts of insulin secreted in response to meals in the early stages of glucose intolerance, they do not suffer from meal-induced hypoglycemia.

## **Hypoglycemic syndromes**

### **Brain malfunction from hypoglycemia**

The brain ordinarily receives a regular and plentiful supply of glucose from the blood by active transport across the blood brain barrier utilizing the glucose transporter protein GLUT1. Reduction of glucose supply to below critical limits causes the brain to malfunction and this manifests itself clinically as activation of the autonomic nervous system and cognitive neural deficit. The blood glucose level at which autonomic activation and cognitive impairment occurs varies. Symptoms are unusual at blood glucose levels above  $3.0\text{ mmol L}^{-1}$  except in diabetic and elderly subjects in whom they may occur at higher levels. Objective evidence of cerebral impairment can however often be discerned by an investigator at blood glucose levels around  $3.5\text{--}4\text{ mmol L}^{-1}$  especially in people with diabetes.

Causes of neuroglycopenia other than hypoglycemia, i.e., normoglycemic neuroglycopenia, are rare but include reduced GLUT1 activity and poorly controlled diabetes. GLUT1 deficiency, due to a *SLC2A1* gene mutation, results in reduced blood glucose delivery to the brain in the presence of normal blood glucose levels (Klepper and Voit, 2002). Patients present with epilepsy, movement disorders and impaired neurological growth. The possibility that less severe forms are more common than currently supposed and may be responsible for some cases of “non-hypoglycemia” cannot be completely dismissed. It also explains why, under research conditions, some people diagnosed with this condition develop symptoms at higher blood glucose levels than control subjects.

## **Neuroglycopenic syndromes**

### **Acute neuroglycopenia (adrenergic symptoms)**

This syndrome comprises a collection of vague symptoms such as feelings of alternating hot and cold, feeling unwell, anxiety, panic, inner trembling, unnatural feelings, blurring of vision, and palpitations, any or all of which may be accompanied by objective signs of facial flushing, sweating, tachycardia, and unsteadiness of gait. There is no particular order in which these features occur, nor are they constant. Nevertheless, patients on insulin or sulfonylurea therapy for diabetes, in whom they are common, rely upon them to warn of more severe neuroglycopenic impairment culminating in loss of consciousness. These patients can be taught to abort progression of symptoms by eating carbohydrate hence they are often referred to as warning symptoms.

Many of the features of acute neuroglycopenia resemble those produced by adrenaline which is released in large amounts and consequently are often referred to as adrenergic.

### **Sub-acute neuroglycopenia or hypoglycemic unawareness**

This syndrome is more insidious and may go completely unrecognized unless or until the patient loses consciousness. Often, however, there is loss of spontaneous activity, impairment of cognitive function, and the onset of somnolence that is more discernible to the bystander than to the patient and which, when it occurs *de novo* in an insulin-treated diabetic, is often referred to as hypoglycemia unawareness. Although suffering from sub-acute neuroglycopenia patients may perform quite complicated actions, such as driving a motorcar, of which they are total unaware when restored to consciousness. In other words they may behave as an automaton.

Acute can proceed to sub-acute neuroglycopenia and both can progress to stupor or coma unless relieved by food or injection of glucagon. Even if this is not done, full recovery under the influence of endogenous counter-regulatory mechanisms, is almost invariable and is the reason why treatment with insulin is relatively safe despite the dangers of hypoglycemia.

## Chronic neuroglycopenia

This neuroglycopenic syndrome is exceedingly rare. It occurs only when the blood glucose concentration remains low, either owing to the presence of an insulin-secreting tumor of the pancreas or overzealous treatment of diabetes with insulin for weeks or months. It is characterized by mental dysfunction resembling clinical depression, schizophrenia, or dementia, the symptoms of which are not relieved by restoring the blood glucose level to normal. Partial recovery may, however, take place over the ensuing months or years if the cause of the hypoglycemia is remedied.

This condition might be confused with “non-hypoglycemia” were it not for the fact that the blood glucose concentration is invariably low ( $<3.0 \text{ mmol L}^{-1}$ ) while the patient is fasting, does not rise normally in response to food, and evidence of underlying disease can always be found.

## Diagnosis

### Whipple's triad

Whipple's triad of occurrence of symptoms, a simultaneous measured low blood glucose concentration, and rapid symptomatic relief with correction of hypoglycemia following glucose administration is a *sine qua non* for ascertaining neuroglycopenia due to hypoglycemia (Whipple, 1938).

### Causes of hypoglycemia

There are in the region of 100 causes of hypoglycemia but all, apart from exogenous (or iatrogenic) insulin overdose, are uncommon. The most important causes of recurrent hypoglycemia are listed and briefly described in Table 1. Differentiation is seldom simple and always rests heavily upon the results of laboratory data of which measurements of plasma insulin, proinsulin, C-peptide and beta-hydroxybutyrate (BHB) are the most important.

Endocrinological, anatomico-pathological, iatrogenic and toxic causes of hypoglycemia will not be considered further. Instead, attention will be given to those conditions (including “nonhypoglycemia”) that have a mainly or exclusively dietary etiology and which respond partially or completely to dietary measures.

### Postprandial (reactive) hypoglycemia

Within a year of the discovery of insulin, and the symptoms to which hypoglycemia can give rise, Seale Harris, an American physician, had proposed that spontaneous overproduction of endogenous insulin might produce a similar condition. Confirmation of this hypothesis soon followed. The seminal work of Whipple on the diagnosis of insulinoma and of Conn on diet-induced postprandial reactive hypoglycemia, both in 1936, distinguished between fast-induced (fasting) hypoglycemia and that which occurred only in response to feeding. The latter, reactive or postprandial hypoglycemia, could be reproduced by oral administration of large doses of glucose in solution and this became the standard criterion for its diagnosis—the 5 h glucose tolerance or load test.

### Prolonged glucose load test

The observation that in a substantial percentage of normal healthy people glucose taken in solution on an empty stomach produces a rebound fall in venous blood glucose levels to below fasting levels was made very soon after blood glucose measurements became possible and before the discovery of insulin. It attracted little attention at the time being considered to have only curiosity value and little pathological significance.

The situation changed dramatically during the early 1950s and, subsequently, particularly in the US, with the appearance of books written for lay consumption attributing a vast array of common symptoms to hypoglycemia, whether the blood glucose concentration was low at the time or not. Belief in the importance and prevalence of hypoglycemia grew among fashionable medical practitioners and the general public alike to such an extent that, by the early 1970s, alarm bells began to ring among consumer action groups and the scientific medical community.

With the passage of time the original, well-defined syndrome of postprandial reactive hypoglycemia had become so distorted and the criteria for its diagnosis so blurred, that anyone with vague symptoms could be, and often was, described as suffering from hypoglycemia, without bothering to measure their blood glucose concentration.

Not until a consensus Statement on Postprandial or Reactive Hypoglycemia was issued by the Third International Symposium on Hypoglycemia and generally recognized by medical practitioners throughout the world did scientific criteria for the diagnosis of reactive hypoglycemia gain universal acceptance and its purported incidence declined dramatically. This has been emphasized by endocrine society clinical practice guidelines which define hypoglycemic symptoms without Whipple's triad as a functional disorder.

**Table 1** Diagnostic criteria and treatment of the main types of hypoglycemia.

<i>Description</i>	<i>Mechanism</i>	<i>Diagnostic criteria</i>	<i>Management</i>
Insulin-secreting tumor: insulinoma	Abnormal $\beta$ -cells with failure to suppress insulin secretion in response to hypoglycemia	Fasting hypoglycaemia. Inappropriate high plasma insulin ( $>18$ pmol L <sup>-1</sup> ) and C-peptide ( $>200$ pmol L <sup>-1</sup> ) concentrations in presence of hypoglycemia (BG $< 2.5$ mmol L <sup>-1</sup> ). Suppressed $\beta$ -hydroxybutyrate levels ( $<0.6$ mmol L <sup>-1</sup> )	High carbohydrate intake until curative surgical ablation, or effective hyperglycemic therapy with diazoxide plus chlorothiazide or with octreotide, can be instituted.
Non insulinoma pancreatogenous hypoglycemia (NIPHS)	Exact cause unknown; no h/o surgery; excessive insulin secretion after meals	Postprandial hypoglycemia 3–5 h after eating. High insulin, C-peptide. Negative imaging, diffusely positive intra-arterial calcium stimulation test	Frequent small mixed meals low in absorbed carbohydrates, rich in soluble dietary fiber. May benefit from treatment with acarbose or miglitol ( $\alpha$ -glucosidase inhibitors)
Post bariatric surgery and idiopathic rapid gastric emptying	Accelerated deposition of nutrients in duodenum and increased release of insulinotropic hormones, for example, GIP, GLP-1.	Postprandial hypoglycemia only follows 1–3 h after eating. History of gastrectomy or objective evidence of rapid gastric emptying. Exaggerated insulinaemic response to food.	Frequent small mixed meals, low in rapidly absorbed carbohydrate; rich in dietary fiber. May benefit from treatment with acarbose ( $\alpha$ -glucosidase-inhibitors), diazoxide or octreotide
Autoimmune insulin syndrome	Delayed release of insulin from antibody binding after all of meal has been absorbed	Postprandial hypoglycemia 3–12 h after last eating: total plasma insulin high; C-peptide high, normal or low; proinsulin normal or high. Antibodies to insulin present. Common in Japan, infrequent elsewhere	Frequent small mixed meals, low in rapidly absorbed carbohydrate; rich in dietary fiber
Non-islet cell tumor hypoglycemia (NICTH) Mesenchymal, epithelial and hematopoietic tumors	Tumor cells secrete big IGF-II which binds to insulin receptors and IGF receptors, reducing hepatic glucose production, increasing glucose uptake by peripheral tissues	Fasting hypoglycemia. Low plasma insulin and C-peptide levels: low plasma IGF-I, normal or raised IGF-II levels; high IGF-II: IGF1 ratio. Suppressed $\beta$ -hydroxybutyrate levels ( $<0.6$ mmol L <sup>-1</sup> )	High carbohydrate intake orally or intravenously until curative treatment of tumor or debulking is instituted. Glucagon and somatostatin analogs may be helpful
Fasting alcohol-induced hypoglycemia	Alcohol impaired hepatic gluconeogenesis	Low blood glucose, raised blood alcohol, lactate and usually $\beta$ -hydroxybutyrate: low plasma insulin and C-peptide	Avoid drinking alcohol while fasting or on a low energy diet.
Endocrine disease for example, hypopituitarism, addison's disease	Reduced availability of diabetogenic or hypoglycemia counter-regulatory hormones	Clinical features of primary disease with subnormal levels of appropriate counter-regulatory hormones, for example, cortisol, growth hormone. Appropriately raised $\beta$ -hydroxybutyrate levels ( $>500$ $\mu$ mol L <sup>-1</sup> ) during hypoglycemia. low plasma insulin and C-peptide	High carbohydrate intake orally or intravenously until effective hormone replacement therapy has been established
Drugs Insulin, sulfonylurea Others-quinine, beta blocker, etc.	Drugs other than insulin and SU may cause hypoglycemia mostly in patients with restricted food intake, age, liver or kidney disease	High insulin, low C-peptide in insulin overdose High insulin, high C-peptide with SU and quinines Low insulin, low C-peptide with others	Treat hypoglycemia, adjust insulin or SU dose. Remove other potential offenders
Critical illness Sepsis, renal failure hepatic failure <b>Inherited metabolic disorders</b> a. Glycogen storage diseases (GSDs)	Excess glucose utilization and impaired glucose formation  Inability to release glucose from liver during fasting	Clinical features of primary disease Low insulin, low C-peptide  Usually present in childhood: low blood glucose, high $\beta$ -hydroxybutyrate levels, low insulin and C-peptide: high lactate: impaired or absent glucose response to glucagon	Treat hypoglycemia and primary disease  Avoid fasting: a constant intake of slowly absorbed carbohydrate (uncooked corn starch) may be required day and night in infants

**Table 1** Diagnostic criteria and treatment of the main types of hypoglycemia.—cont'd

Description	Mechanism	Diagnostic criteria	Management
b. Disorders of mitochondrial $\beta$ -oxidation of fatty acid	Defective utilization of fat as fuel in tissues: compensatory increase in glucose utilization	Presents mostly in infancy: low glucose, low insulin and C-peptide, high FFA, low $\beta$ -hydroxybutyrate, increased urinary organic acids. Low carnitine in some cases	Avoid fasting: frequent high carbohydrate low fat feeding.
c. Gluconeogenesis disorders—fructose 1,6 biphosphatase deficiency	Fructose biphosphatase enzyme deficiency	Hypoglycemia, lactic acidosis following fasting and ingestion of fructose	Avoid prolonged fasting and fructose containing food
d. Hereditary fructose intolerance	Aldolase B enzyme deficiency causing impaired release of glucose from liver in response to ingestion of fructose or sucrose.	Hypoglycemia evoked by food containing fructose or sucrose	Avoid fruit and fructose/sucrose containing food.
e. Congenital endogenous hyperinsulinemia due to genetic mutations	Dysregulated insulin secretion	Mostly seen in infants and children, low glucose, high insulin and C-peptide, low free fatty acids, low $\beta$ -hydroxybutyrate levels	Frequent feeding of low carbohydrate (avoiding short-acting carbohydrates), high-protein diet, and addition of fiber and fat.

## Definition

It is now accepted that a few people exhibit, in the course of their everyday life, symptoms similar to those caused by acute neuroglycopenia and may, if accompanied by a capillary or arterialized venous blood glucose concentration of 2.5–3.0 mmol L<sup>-1</sup> or less, justify description as being of postprandial reactive hypoglycemic origin. Reactive hypoglycemia may itself be a consequence of anyone of a large number of well-recognized but generally uncommon organic conditions, such as an islet cell tumor, that also produce fast-induced hypoglycemia. It is, therefore, only after all of these have been excluded by appropriate laboratory investigations that a diagnosis of functional or dietary reactive hypoglycemia is justified.

Specifically, the prolonged oral glucose load (tolerance) test is now deemed inappropriate for the diagnosis of postprandial or reactive hypoglycemia because the high incidence of false-positive results with this test makes it meaningless, especially if, as is so often the case, venous rather than arterial blood is sampled. A mixed meal test *containing protein, carbohydrates, and fat, however, may be used to identify postprandial hypoglycemia.*

## The postprandial syndrome

Typically, the patient is a woman of 20–50 years whose main complaint is of vague feelings of distress occurring predominantly mid-morning, but occasionally mid-afternoon or evening and never before breakfast. In between attacks, characterized by feeling of faintness, anxiety, nervousness, irritability, inner trembling, rapid heartbeat, headache, and sweatiness, either alone or in combination, they may be completely well. Often they describe themselves as suffering from increased tiredness, lacking in zest for life, and apathetic: symptoms often associated with depression or chronic alcohol abuse.

Patients often have diagnosed themselves, on the basis of articles they may have read, as suffering from hypoglycemia. Almost without exception they reject the possibility that their symptoms might have a contributory, or even large, psychogenic element.

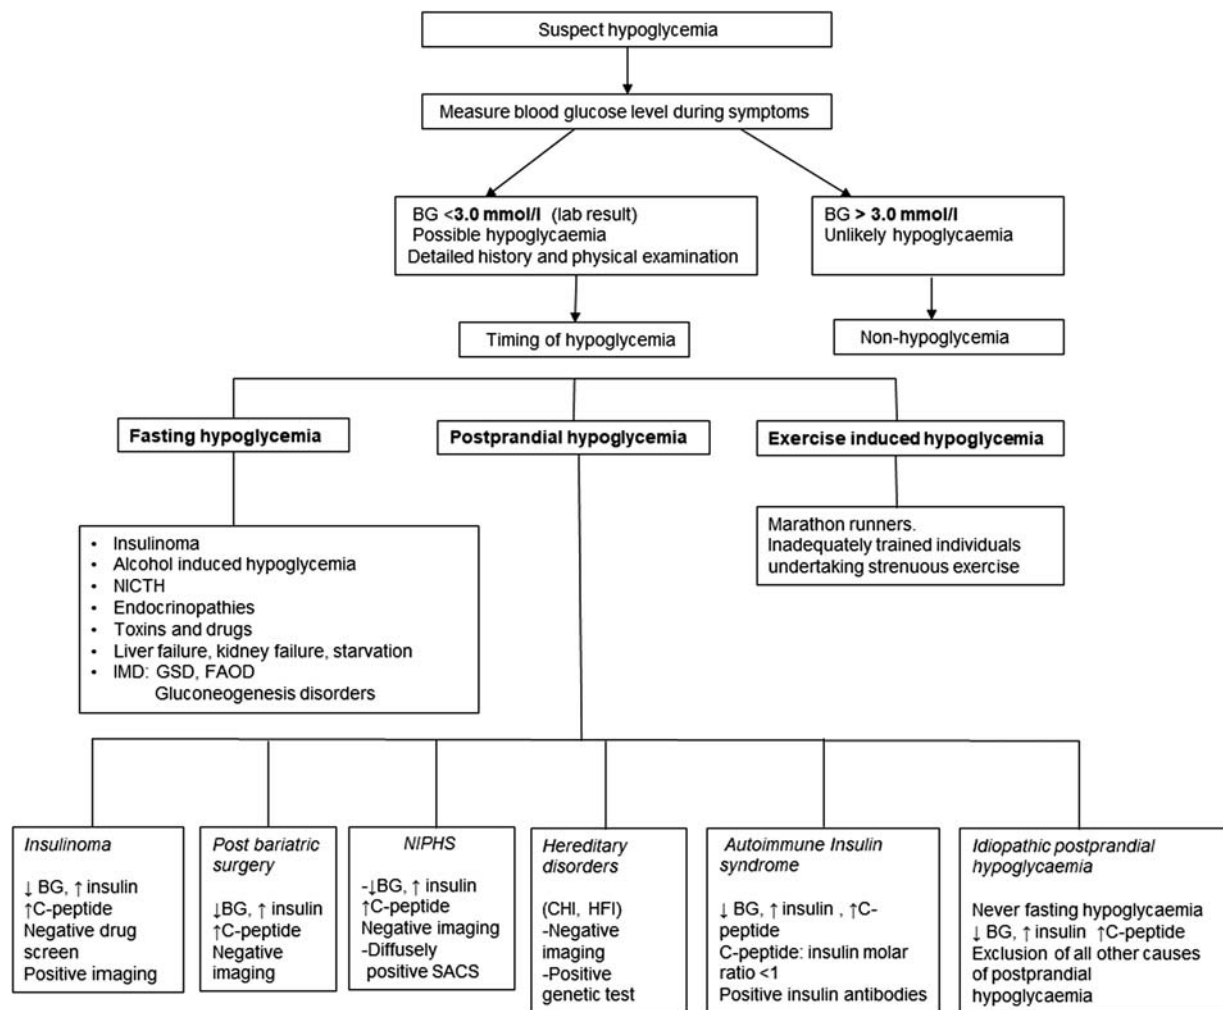

Symptoms wax and wane during middle life but often remit completely for years or may never recur. They are not progressive and never cause severe neurological dysfunction such as coma, psychosis, or dementia. Hypoglycemia cannot be demonstrated during spontaneous symptomatic episodes in people with the postprandial syndrome and some other explanation should be sought for them. Psychotherapy is often helpful.

## Differential diagnosis

Studies using continuous interstitial glucose monitoring confirm that only a very small proportion of those with postprandial syndrome have symptomatic hypoglycemia. Of those who do, a substantial proportion have an identifiable cause for it. The commonest, in the West, is partial gastrectomy, pyloroplasty and bariatric surgery (gastric sleeve or gastric bypass) for the treatment of obesity (Lee et al., 2015); in the Far East, for example, Japan, it is the autoimmune insulin syndrome (AIS) which also occurs in Europe and the US but is rare (Lupsa et al., 2009). Other rare causes include insulinoma and noninsulinoma pancreatogenic hypoglycemia.

In some people postprandial hypoglycemia occurs only in response to a specific dietary indiscretion, for example, ingestion of moderate amounts of alcohol (eg gin) and glucose (eg tonic) on an empty stomach or fructose in people with a rare inborn errors of

**Fig. 2** Investigation of hypoglycemia. NICTH: Non islet cell tumor hypoglycemia, IMD: inherited metabolic disorders; GSD: glycogen storage disease; FAOD: fatty acid oxidation defect; NIPHS: non insulinoma pancreatogenous hypoglycemia; CHI: congenital hyperinsulinism; HFI: hereditary fructose intolerance; SACS: selective intra arterial calcium stimulation test.

metabolism-hereditary fructose intolerance (Douillard et al., 2012). In a small number of subjects for whom no satisfactory pathogenic mechanism can be identified (Fig. 2), it is justified to describe them as suffering from idiopathic reactive (postprandial) hypoglycemia.

## Management of reactive (postprandial) hypoglycemia

### Treatment of attacks

Because of their short duration and modest severity, acute spontaneous neuroglycopenic episodes due to reactive hypoglycemia require no specific treatment beyond ingestion of a rapidly assimilable form of carbohydrate (e.g., a lump of sugar). There is no evidence that this ever produces rebound hypoglycemia and should it do so the grounds for making the diagnosis should be reviewed.

Postprandial hypoglycemia secondary to disease is similarly treated with oral carbohydrate but if severe may require parenteral glucagon followed by carbohydrate ingestion.

### Prevention

Dietary prevention of postprandial hypoglycemia is based on the premise that it is caused by imbalance between the timing and amount of insulin secreted in response to the ingestion of a meal and disposal of the glucose derived from it. Frequent small meals containing only modest amounts of sugars (glucose and sucrose) and refined starches but rich in poorly absorbed complex carbohydrates and containing dietary fiber have replaced the diets rich in proteins (and fats) previously advocated, but evidence of their unique efficacy is lacking. Avoidance of drinks rich in sucrose or glucose, especially with alcohol, may be helpful in subjects who are

highly susceptible to this combination. There is no evidence that confectionery eaten in moderation e.g., 25–50 g, is uniquely detrimental, though excessive use should be discouraged, if only, on general health grounds.

Dietary modification alone may be insufficient and supplementary pharmacological intervention may be required to achieve a satisfactory therapeutic outcome. Guar, acarbose and miglitol, which slow glucose absorption and decrease the insulinemic response to food, may be effective. When these medications fail to improve the symptoms, somatostatin analogs which reduce synthesis and secretion of insulin may also be effective. Interestingly, diazoxide which inhibits insulin secretion has not been found effective except in patients with proven endogenous hyperinsulinism due to insulinoma or pancreatic islet hyperplasia.

### **Non-hypoglycemia**

No account of dietetic treatment of hypoglycemia would be complete without a brief description of non-hypoglycemia, which has been described as a controversial illness and epidemic in the US. Clinically, the illness is indistinguishable from (idiopathic) postprandial hypoglycemia, except that the blood glucose level is never pathologically low during symptomatic episodes. Moreover, although transient turns are often a major feature of the illness, only rarely if ever, does the patient consider their health, between turns, as normal.

The attribution of these patients' illness to hypoglycemia had its origins in the early 1950s with the appearance, in the US, of a book by Drs. Abrahams and Pezet entitled "Body, Mind and Sugar." Other American practitioners, notably John Tintera, founder of the Hypoglycemia Foundation Inc., Stephen Gyland, Harry Saltzer and, others, including the medical writer Carlton Fredericks, publicized the concept. This led to hypoglycemia being held, by a large section of the public, responsible for such diverse diseases as coronary artery disease, allergy, asthma, rheumatic fever, susceptibility to viral infections, epilepsy, gastric ulcer, alcoholism, suicide, and even homicide, as well as for a whole galaxy of symptoms in their own right. Hypoglycemia was treated as though it was a disease entity and asserted by its advocates to be "one of the most common illnesses in the United States" and that because of it "thousands of Americans have forgotten, or perhaps never known, what it is like to feel completely healthy." Diagnosis of non-hypoglycemia generally depended upon the results of the now discredited 6 h oral glucose tolerance test, using venous blood, although some have dispensed even with this discredited formality in favor of just purely clinical criteria.

The appearance in the *New England Journal of Medicine* of an article in 1974 entitled "Non-hypoglycemia is an epidemic condition" first drew international attention to its existence (Yager and Young, 1974). Many patients with non-hypoglycemia undoubtedly derive some benefit, probably through a powerful placebo effect, from severely restrictive dietary regimes. Although differing in details most of the diets emphasize the purported specifically detrimental effects of sugar (sucrose), salt, alcohol, and caffeine.

Although the cause of illness in people with non-hypoglycemia remains unknown, it is unlikely to be the same in all cases. In some it is chronic alcoholism and in a tiny number of others it is owing to caffeine intoxication, which can be confirmed by a dietary history and measurement of plasma caffeine levels. Such patients benefit specifically from reducing their intake of caffeinated beverages, though not necessarily from avoiding them completely. Ironically, and probably significantly, caffeine restores hypoglycemia awareness to diabetic patients on insulin who have become insensitive to it. The possibility exists, therefore, that a combination of reasonable or normal caffeine intake occurring in combination with the normal rebound in arterial blood glucose to just below fasting levels that sometimes occurs 3–5 h after a meal in someone with an unusually low threshold for neuroglycopenia, might precipitate symptoms. This explanation must, however, be considered no more than speculative (Kerr et al., 1993).

On the other hand such diverse illnesses as hyperventilation, panic attacks, drug abuse, and genuine food intolerances are all established as capable of producing the non-hypoglycemia syndrome and should always be considered in the differential diagnosis.

### **Exercise-induced hypoglycemia**

Previously only associated with marathon running, hypoglycemia is now recognized to be comparatively common in inadequately trained individuals undertaking strenuous exercise (Brun et al., 2001). Consumption of rapidly absorbed carbohydrate before taking exercise may encourage its appearance although consumption of slowly absorbed, low glycemic index foods may prevent it as does appropriate training.

Exercise, however, may provoke hypoglycemia in those who are fasting with an underlying organic cause for hypoglycemia, such as insulinoma.

### **Drug induced hypoglycemia**

In addition to insulin or insulin secretagogues, a number of medications which are not used to treat hyperglycemia, have been implicated in causing hypoglycemia such as quinine, disopyramide, beta blockers, salicylates and pentamidine, quinolones, angiotensin-converting enzyme agents and IGF. Liver or kidney disease, old age and polypharmacy are the predisposing factors for drug induced hypoglycemia.

### **Hepatic and renal failure**

Considering the importance of the liver and kidneys in the maintenance of blood glucose levels, hypoglycemia is rare in both hepatic and renal disease. In liver disease hypoglycemia is virtually confined to patients with acute toxic hepatic necrosis, whether owing to overwhelming viral infection or specific hepatotoxins such as poisonous mushrooms, unripe akee fruit, or paracetamol in excess. Its appearance always portends an extremely poor prognosis as it does in all critically ill patients regardless of their pathology.

The association of hypoglycemia with primary cancer of the liver is comparatively common and owing to over-expression and secretion of big IGF-II, and is not due to nonspecific destruction of hepatic tissue as previously supposed.

Renal failure is one of the most common causes of hypoglycemia in nondiabetic hospital inpatients but does not carry quite as grave a prognostic significance as in patients with liver disease. It generally responds to appropriate dietary and other supportive treatments for end-stage kidney disease (Arem, 1989).

### Sepsis

Infections, usually bacterial, not necessarily severe enough to produce a full blown Systemic Inflammatory Response Syndrome (SIRS) may cause hypoglycemia. The hypoglycemia is usually uncovered serendipitously by a blood glucose measurement, and generally portends a fatal outcome (wang et al., 2021). It results from increased glucose utilization by the peripheral tissues, reduced glycogen reserves and impaired gluconeogenesis in liver. Treatment is that of the primary condition as well as of the hypoglycemia.

### Inborn errors of metabolism

Hypoglycemia is a manifestation and often a presenting feature of many inborn errors of metabolism (see Table 1) usually in children but occasionally in adults (Douillard et al., 2012).

In glycogen storage diseases (GSD), various enzymes deficiencies prevent breakdown of glycogen into glucose, resulting in severe hypoglycemia. GSDs usually present in childhood with fasting hypoglycemia, hyperketonemia and lactic acidosis which may persist in adulthood particularly in GSD type I and type III. These are managed with slowly absorbed uncooked cornstarch, which is broken down slowly to provide a continuous supply of glucose, and avoidance of prolonged periods of fasting. In infants and children continuous feeding through a nasal or gastrostomy tube may be necessary to prevent hypoglycemia, especially at night when glycogenolysis normally maintains normoglycemia.

Abnormalities of fatty acid metabolism, on the other hand, are characterized by hypoglycemia, increased non-esterified fatty acids and hypoketonemia. As with children with liver GSD, treatment is to ensure that they are constantly supplied with carbohydrates and are never fasting for more than a very short period. The fasting tolerance, however, increases with age. Milder forms of fatty acid oxidation defects may remain undiagnosed till adulthood.

Hereditary fructose intolerance (HFI) results from a deficiency of the enzyme aldolase-B which breaks down fructose. Ingestion of fructose (fruit sugar) or sucrose (cane or beet sugar) leads to the accumulation of fructose-1-phosphate in the liver, inhibiting glycogenolysis and gluconeogenesis. This results in hypoglycemia and lactic acidosis. The diagnosis may be delayed till adult life. Similarly, deficiency of the enzyme fructose 1,6 biphosphatase prevents gluconeogenesis resulting in hypoglycemia, lactic acidosis and ketosis triggered during prolonged fasting, inter-current illness or ingestion of large amount of fructose containing food. The mainstay of treatment in these conditions is a fructose-free diet.

Endogenous hyperinsulinemic hypoglycemia, a genetically heterogeneous condition, is emerging as a common cause of severe persistent hypoglycemia in neonates and children. Hypoglycemia may occur fasting, postprandial or related to exercise. Normoglycemia is maintained with oral and intravenous glucose. Some resolve spontaneously or require treatment with diazoxide or if severe partial pancreatectomy.

### Starvation

Although average fasting blood glucose levels are lower in victims of famine than in well-fed populations, hypoglycemia is rare. Even in patients suffering from Kwashiorkor, hypoglycemia is uncommon and is usually associated with infection, hypothermia, and coma. Patients with anorexia nervosa develop hypoglycemia only as an agonal phenomenon and its appearance generally portends imminent death. The characteristic clinical biochemistry findings are of low plasma insulin, proinsulin, C-peptide, IGF-1, nonesterified fatty acids (NEFA) and  $\beta$ -hydroxybutyrate levels and elevated growth hormone and cortisol levels. Relief of hypoglycemia by re-feeding is the only measure carrying any chance of preventing death, but it is rarely successful.

### Hypoglycemia in the elderly sick

The high incidence of hypoglycemia in sick elderly patients—especially those with infections—has become apparent from the use of routine blood glucose measurements. The cause is seldom attributable to any of the well-recognized causes of hypoglycemia found in younger fitter people. It is probably owing to chronic malnutrition that is so common in the elderly sick, compounded by coincident disease but which is not of itself sufficiently severe to produce hypoglycemia.

### Conclusion

Spontaneous (non-diabetic) hypoglycemia needs laboratory confirmation followed by full evaluation to establish and treat the underlying cause. Prompt treatment of acute hypoglycemia is important to prevent irreversible neurological sequelae.

## Key points

- Understand the basis of inborn errors of metabolism
- The key clinical features of disorders due to an enzyme deficiency in the catabolic pathways of:
  - carbohydrates
  - proteins
  - fatty acids
  - essential vitamins and cofactors
- Understand the pathology of disorders
  - accumulation of toxic intermediates
  - depletion of end products/energy

## Introduction

Garrod described the first inborn error of metabolism in his Croonian Lectures ([Garrod, 1908](#)) when he associated the symptoms that had been observed in patients with Alkaptonuria as being due to an inherited enzyme deficiency. Since that time more than 400 disorders have been described that are due to an enzyme deficiency in the catabolic pathways of protein, fatty acids, and carbohydrates. The resulting accumulation of the toxic intermediates, and in some cases, the depletion of a necessary end product, causes a variety of metabolic derangements, often with significant neurological sequelae. The severity and the age of onset of symptoms usually, although not always, depend on the amount of residual enzyme activity.

Genetic disorders are inherited by various modes. The most common pattern is autosomal recessive, where each parent carries a recessive in a specific gene in one of the autosomal chromosomes, i.e., not one of the sex-determining chromosomes, X or Y. As there are four possible combinations for the chromosomes carrying the abnormal gene, the offspring has 25% chance of inheriting two mutations (one from each parent) and therefore being affected (also referred to as being homozygous for the disorder) with the disorder, a 50% chance of inheriting one mutation from one or other parent, thus being an unaffected carrier (heterozygous) and a 25% chance of inheriting two normal genes.

In autosomal dominant inheritance, a dominant mutation in one of the autosomal chromosomes is inherited in 50% of the offspring, irrespective of sex. The affected parent is usually symptomatic, although the onset of symptoms may not be apparent until later in life (such as in Huntington's disease), or the spectrum of severity may be variable in different generations, so the disease may not always be recognized. Approximately 30% of dominant mutations arise spontaneously and are not inherited.

In X-linked inheritance, the mutation occurs on the X chromosome. Females have two X chromosomes (one of which is always inactivated, usually randomly), and males an X and a Y. At fertilization, the mother contributes one X and the father either an X or a Y chromosome. If there is a mutation on the inherited X chromosome and the offspring receives a Y chromosome from the father, the mutation will be expressed. If the offspring receives a normal X chromosome from the mother, and an X from the father, the offspring will be a normal female. If the abnormal X is received with a Y from the father, the son will be affected. There is thus a 50% chance of sons from a carrier mother being affected and a 50% chance of daughters being carriers. In rare circumstances, X inactivation is nonrandom or skewed, so that the female carrying the abnormal gene can be symptomatic. X inactivation is also often referred to as lyonization, named after Dr. Mary Lyon who first described the phenomenon. In X-linked disorders, approximately 30% of mutations arise spontaneously, so not inherited from the mother.

The vast majority of genetic disorders are inherited in an autosomal recessive fashion.

While the individual inborn errors of metabolism are rare, based on recent results of expanded newborn screening programs (in which more than 30 disorders can be detected), the overall incidence is approximately 1/5000 live births worldwide ([Waters et al., 2018](#)). The incidence of disorders may vary in different populations because of the "founder effect," where a specific mutation arises and is maintained in subsequent generations, or where there is a higher incidence of consanguinity.

With a few exceptions, infants are normal at birth because the placenta efficiently eliminates the toxic metabolites, but symptoms can become apparent in some cases, within days.

## Newborn screening

Mass population screening of newborns was introduced in the 1960s, initially for phenylketonuria (PKU), after the development of the bacterial inhibition assay (BIA) for phenylalanine by [Guthrie \(1961\)](#). This simple method, popularly referred to as the Guthrie Test, is still the mainstay of screening for PKU in much of the world. Essentially, the method entails the addition of a solution of *B. subtilis* into an agar well, into which is added a standardized punched sample from the newborn screening filter paper from which the blood is then eluted. High levels of phenylalanine inhibit growth of the bacteria, and the laboratory technician can easily

visually identify this “no-growth” zone as abnormal. Quantification is necessary, using a follow-up method such as high performance liquid chromatography (HPLC). BIA has been adapted for screening for elevated levels of leucine (for maple syrup urine disease (MSUD)) and for methionine (for homocystinuria).

The most significant advance in newborn screening since its inception has been the adaptation of tandem mass spectrometry (MS/MS), (Millington et al., 1990). With this technology, multiple compounds can be identified (both amino acids and acylcarnitine species) from the same dried blood filter paper sample after a simple preparation. More than 30 different inborn errors of metabolism can now be identified. The major drawback, however, is the relative expense of the equipment and lack of long-term data on the outcome of infants detected and treated presymptomatically. Further modification of MS/MS will enable future screening for many more inborn errors of metabolism, as well as increased efficiency by adding already screened disorders to the same platform. Methods have been developed for screening for several lysosomal storage disorders and introduced in several countries. New screening methods are also under development.

## Disorders of protein metabolism

### Amino acid disorders

Amino acidopathies are due to an enzyme deficiency early in the catabolic pathway of one or more amino acids that results in the accumulation of the amino acid(s), detected by plasma amino acid analysis of serum or plasma. Symptoms may be due to the chronic accumulation of toxic amino acid(s) or due to acute metabolic decompensation, for which aggressive intervention is necessary to prevent death or severe morbidity. Treatment is dietary restriction of the toxic amino acid by limiting the intake of whole protein and supplementing with special modular amino acid formulas to provide the appropriate nutrients for normal growth and development. All disorders are inherited in an autosomal recessive fashion.

The classic example is PKU. In PKU, a deficiency of the phenylalanine hydroxylase (PAH) enzyme (Fig. 1) results in a high level of phenylalanine, which, if not treated with dietary restriction of phenylalanine in the early newborn period, causes severe, irreversible mental retardation. The diagnosis is confirmed by finding a phenylalanine level  $1200 \text{ mmol/L}^{-1}$  in an infant on unrestricted protein intake. The incidence of PKU is approximately 1/20,000 in caucasians (Hillert et al., 2020). Although PKU is pan ethnic, the incidence varies in certain populations. The level of phenylalanine can vary in individual patients because of the amount of residual enzyme activity, which in turn depends on the specific variants. There are currently more than 400 known variants. Most have biallelic variants previously described as compound heterozygote) i.e., have one copy each of two different variants). Before the introduction of newborn screening, PKU was the commonest cause for inherited mental retardation. Early recognition of the presymptomatic infant allows for initiation of dietary treatment with a phenylalanine-restricted diet, with the best outcomes when recommended phenylalanine levels are attained by 2 weeks of age.

Untreated patients develop progressive severe mental retardation, often with seizures and Parkinson disease-like neurological symptoms. The primary pathogenesis is due to the toxic effect of phenylalanine on the central nervous system; secondary symptoms

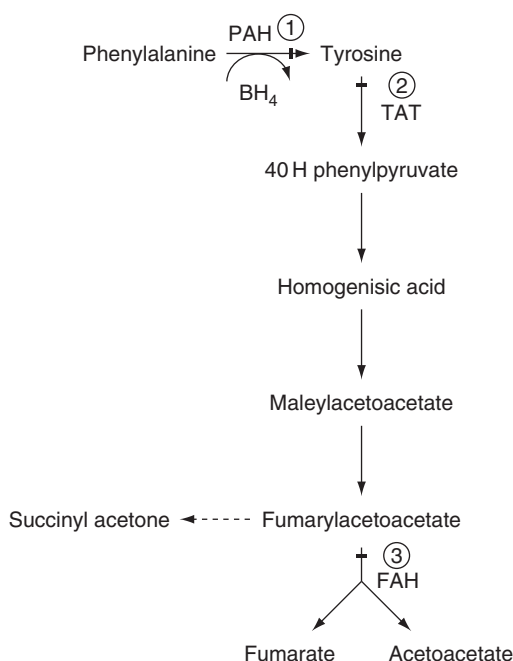

Fig. 1

may be due to a deficiency of tyrosine, which is an important precursor for the synthesis of some neurotransmitters. These symptoms include anxiety and depression.

Treatment is discussed in detail in the following article.

Benign or mild hyperphenylalaninemia is due to allelic variants of PAH, which result in greater residual enzyme activity. On an unrestricted diet, levels are typically in the range 120–360 mmol/L<sup>-1</sup>, and no dietary treatment is necessary.

Moderate elevation of phenylalanine is also present with defects of tetrahydrobiopterin (BH4), the cofactor for PAH. BH4 is also the cofactor for other enzymes, tryptophan hydroxylase and tyrosine hydroxylase. These amino acids are important precursors for the neurotransmitters 5-hydroxytryptophan and dopamine. A deficiency causes a neurological syndrome characterized by hypotonia, seizures, and movement disorder (dystonia).

### Maple syrup urine disease (MSUD)

MSUD has an incidence approximately 1/185,000 births. It is due to a deficiency of the branched chain ketoacid dehydrogenase enzyme, resulting in the accumulation of the branched chain amino acids (BCAAs), leucine, isoleucine, and valine, which are detected on plasma amino acid analysis (Chuang, 1998). Elevation of alloisoleucine (a derivative of isoleucine) is pathognomonic. In classic MSUD, symptoms typically occur in the first week of life and, if untreated, rapidly progress to cerebral edema, coma, and death. Toxicity is due primarily to high levels of leucine. The characteristic maple syrup (or burnt sugar) odor is due to presence of sotolone, a metabolite of isoleucine or alloisoleucine. It is only detectable when the BCAAs are significantly elevated; the ester is concentrated in the urine and in the earwax of affected patients. Ingestion of the spice, fenugreek, produces a similar odor, but the branched chain amino acids are normal.

Variant forms of MSUD occur. Intermediate MSUD typically presents later in infancy with developmental delay; seizures may occur. Moderate levels of the BCAAs (including alloisoleucine) are present.

Intermittent MSUD is associated with intermittent symptoms during acute infections or periods of prolonged fasting. Typical symptoms include ataxia, vomiting, and seizures. Acute severe decompensation may occur, similar to the classic form of MSUD. The BCAAs are only elevated during the episode of acute symptoms. Other disorders are listed in Table 1.

### Urea cycle disorders

Urea cycle defects are due to enzyme deficiencies associated with the elimination of waste nitrogen produced by the normal catabolism of protein (AhMew et al., 2003). There are six enzymatic steps involved in this process (Fig. 2): a deficiency in any of the first five enzymes causes accumulation of nitrogen, in the form of ammonia (NH<sub>3</sub>) and increased levels of the amino acids glutamine, alanine and glycine. Glutamine and alanine are the major carriers of nitrogen.

Another very rare disorder has recently been characterized, due to a defect of N-acetylglutamate synthase (NAGS). N-acetylglutamate is the essential cofactor for the first enzyme in the urea cycle, carbamoylphosphate synthase (CPS).

Symptoms occur typically in the newborn period, except for arginase deficiency, but milder late-onset variants have been well described. Symptoms include lethargy, poor feeding, vomiting, tachypnea, and progressive encephalopathy. Routine biochemical testing shows respiratory alkalosis and hyperammonemia. The liver transaminases are usually elevated. Hypoglycemia is not typical.

Plasma amino acid and urine organic acid analysis is necessary to make a presumptive diagnosis. In ASS, citrulline is elevated, in ASL argininosuccinic acid and citrulline are elevated and in arginase deficiency, arginine is elevated, and ornithine low.

**Table 1**

Disorder (deficient enzyme)	Elevated analyte	Clinical features	Treatment
Tyrosinemia type I (fumarylacetoacetase)	Tyrosine SA	Cirrhosis Liver failure Failure to thrive Renal tubular acidosis Rickets Hepatocellular carcinoma (late)	NTBC (inhibits SA production) Tyrosine restriction
Tyrosinemia type II (tyrosine aminotransferase)	Tyrosine (↑↑)	Keratoconjunctivitis Palmar keratosis Mental retardation	Tyrosine restriction
Homocystinuria (cystathionine β synthase)	Methionine Total homocysteine Free homocystine+ Mixed disulfides	Mental retardation Thromboembolism Lens dislocation Osteoporosis	Vitamin B <sub>6</sub> (50% respond) Methionine restriction
Nonketotic hyperglycinemia (glycine cleavage enzyme deficiency)	Glycine (↑↑) (plasma and CSF)	Seizures developmental delay	Sodium benzoate (decreases glycine)

CSF, cerebrospinal fluid; SA, succinylacetone; NTBC, 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione.

Fig. 2

In OTC, however, the citrulline is very low or absent. In each of these disorders, orotic acid is also present (found on urine organic acid analysis), produced via the pyrimidine cycle from excessive carbamoylphosphate that accumulates due to the deficiency of enzymes distal to CPS. In CPS and NAGS, however, the amino acids and orotic acid levels are normal, so the diagnosis is essentially one of exclusion in a patient who presents with the typical symptoms and severe hyperammonemia in which no other cause is determined. Confirmation of the diagnosis has previously required liver biopsy for enzyme analysis for CPS, NAGS, and OTC, however molecular genetic detection of pathogenic variants is more available, and necessary for confirmation of an OTC carrier mother. Skin fibroblasts can be assayed for ASS and ASL and red blood cells for arginase deficiency.

OTC is the most common urea cycle defect. It is inherited in an X-linked disorder (all other disorders are autosomal recessive). Male infants usually present in the first few days of life with severe life-threatening hyperammonemia. Newborn screening may be abnormal because of very low or absent citrulline, although severe symptoms and irreversible brain damage may occur before results are available. Females carrying the X-chromosome variant may be asymptomatic, but can present with variable symptoms ranging from acute hyperammonemia to recurrent episodes of nausea, vomiting, and headache. The severity of these symptoms depends on the degree of lyonization (the inactivation of one of the X chromosomes) and the resultant residual enzyme activity. Some women may remain asymptomatic and a diagnosis is made after the birth of a symptomatic son.

Patients with ASL deficiency also have progressive liver cirrhosis, possibly due to the direct toxic effect of the argininosuccinic acid. In arginase deficiency, hyperammonemia is rare (most of the urea has already been eliminated) but arginine itself is toxic to the central nervous system causing progressive spastic quadriplegia and developmental delay; seizures are common.

The toxicity of these disorders is primarily due to the accumulation of ammonia ( $\text{NH}_3$ ) and glutamine, which is increased because of the transfer of excess ammonium ions (transamination). Acute, severe hyperammonemia in the newborn period is catastrophic and often fatal. Survivors have variable neurological deficits. Increased awareness and prompt diagnosis and treatment can improve outcomes.

Acute treatment of hyperammonemia due to a urea cycle defect is elimination of dietary protein, elimination of ammonia (by hemodialysis or peritoneal dialysis), high concentration of intravenous dextrose to reverse catabolism, arginine (except in arginase deficiency) to regenerate the cycle, and the nitrogen scavenging drugs, sodium benzoate (which conjugates with glycine to form hippurate) and sodium phenylacetate (which conjugates with glutamine to form sodium phenylbutyrate), glycerol phenylbutyrate is a recently developed drug that is more tolerable for oral administration. An intravenous solution of sodium phenylbutyrate and sodium phenylacetate is used acutely, until the patient can transition to an oral scavenger medication.

Early reintroduction of limited dietary protein is necessary to provide substrate for anabolism and to prevent further catabolism. This should consist of whole protein and a special formula to provide enough essential amino acids to ensure normal weight gain, without producing excessive amounts of nitrogen for ammonia production. Chronic treatment includes similar dietary protein restriction, citrulline and an oral form of nitrogen scavenging medication.

A derivative of the amino acid, L-glutamic acid, N-carbamylglutamate (NCG), has recently been approved for treatment of NAGS, by providing an alternate activator of CPS. For arginase deficiency, dietary protein restriction and formula are usually adequate.

Liver transplant can be an option for treatments. It has been most widely used for infants with OTC, or in patients with argininosuccinic aciduria (ASL), which also often has liver disease.

Gene therapy, where the abnormal gene may be replaced by functional gene, is currently being evaluated in clinical trials for OTC; an enzyme replacement therapy is also in clinical trial for arginase deficiency.

### Organic acidemias

Organic acidemia are due to enzyme deficiencies further along the catabolic pathway, resulting in the accumulation of the toxic products of intermediary metabolism (organic acids). In some cases, there is a functional defect of the enzyme due to a deficiency of the enzyme cofactor, rather than of the enzyme itself. Examples of this are biotinidase deficiency and defects of cobalamin (vitamin B<sub>12</sub>) metabolism.

Accumulation of large amounts of organic acids causes severe metabolic acidosis and ketosis. Hyperammonemia is often present, due to secondary inhibition of the urea cycle. Hypoglycemia may be variably present, due to secondary inhibition of fatty acid oxidation. Symptoms are often present in the newborn period; recurrent episodes of metabolic decompensation can occur because of excessive protein intake or because of catabolism (and therefore an increased load of amino acids endogenously released from muscle) associated with acute infections or prolonged periods of fasting. Morbidity and mortality are due to acute acidosis and the associated neurologic sequelae.

The diagnosis is made by finding high levels of the characteristic organic acids in urine. Newer analytic methods, such as MS/MS can detect even small elevations of characteristic plasma acylcarnitine and urine acylglycine conjugates of the intermediary metabolites. Confirmation is by enzyme analysis, usually in skin fibroblasts. Molecular genetic analysis is available for many disorders. Treatment typically entails limitation of dietary protein and supplementation with a specific metabolic formula that is depleted in the amino acid precursors in the specific catabolic pathway.

Propionic acidemia is a typical organic acidemia. It is due to an isolated defect of the enzyme, propionyl CoA carboxylase in the catabolic pathways of the amino acids isoleucine, valine, methionine, and threonine as well as cholesterol and odd chain fatty acids (Fig. 3). The resulting accumulation of the intermediary metabolites, 3-hydroxypropionic acid, methylcitric acid, propionylglycines, and tiglylglycine, can cause severe metabolic acidosis, ketosis, coma, and death. Other associated symptoms can be hyperammonemia, hypoglycemia, and pancytopenia, due to bone marrow suppression by the accumulated toxic organic acids, cardiomyopathy and renal dysfunction, can occur, usually later in life.

Symptoms can occur within days of birth in the classic disease or later in infancy or childhood in the milder variant forms. The later-onset form may be associated with persistent vomiting, failure-to-thrive, and developmental delay, but often without severe episodes of metabolic acidosis. Dystonia may occur due to infarction of the basal ganglia.

Liver and/or kidney transplant may improve outcomes in some patients.

The potential for gene therapy is being evaluated in animal studies.

### Cofactor deficiencies

Biotin is an essential cofactor for the four carboxylase enzymes, propionyl CoA carboxylase, methylcrotonyl CoA carboxylase, pyruvate CoA carboxylase, and acetyl CoA carboxylase. It is endogenously derived from lysine and also present in its protein-bound form in small amounts in many foods. Holocarboxylase synthetase (HCS), which forms the inactive parent apoenzyme, is also biotin dependent. Enzyme activation requires free biotin, which is released by the action of biotinidase; this enzyme also plays an essential role in the recycling of biotin for further use. A deficiency of biotinidase, therefore, results in depletion of biotin and a functional defect of the carboxylases. Symptoms include hypotonia, lethargy, vomiting, and ataxia. Recurrent metabolic acidosis may occur. Alopecia and a generalized erythematous rash are common. The symptoms are more severe in HCS deficiency. The characteristic pattern of organic acids is present in both disorders. The diagnosis is made by measuring biotinidase activity in plasma or carboxylase enzyme activity in leukocytes or fibroblasts. Treatment with pharmacologic doses of biotin is effective.

Multiple defects of cobalamin (vitamin B<sub>12</sub>) metabolism can occur, starting with the transport of vitamin B<sub>12</sub> into the cell (defects of the transporter proteins, Transcobalamin I and II) or subsequent intracellular utilization of the different biologically active forms. These disorders are classified as complementation groups, depending on whether the defect is in adenosylcobalamin (Cbl A and B), methylcobalamin (Cbl G and E), or both (Cbl C and D).

Adenosylcobalamin is the cofactor for methylmalonyl CoA mutase; a defect results in a milder form of methylmalonic acidemia than found with a defect of the enzyme itself. Methylcobalamin is the cofactor for methionine synthase, which results in low methionine and homocystinuria (distinct from classic homocystinuria due to a defect of cystathionine  $\beta$  synthase). A defect of both adenosyl and methylcobalamin causes both methylmalonic acidemia and homocystinuria (Table 2).

Symptoms vary with the complementation group, but can include metabolic acidosis, hypotonia, developmental delay, macular degeneration, and megaloblastic anemia.

Treatment with hydroxocobalamin corrects some of the biochemical derangements, especially in Cbl A and B. Addition of betaine, a remethylating agent, may decrease homo-cysteine levels in CblC. Treatment is less successful in the other groups.

Fig. 3

**Table 2**

<i>Disorder (deficient enzyme)</i>	<i>Elevated analyte(s)</i>	<i>Clinical features</i>	<i>Treatment</i>
Methylmalonic acidemia (methylmalonyl CoA mutase)	Methylmalonic acid	Metabolic acidosis Hyperammonemia Failure to thrive Vomiting	Protein restriction Carnitine
Isovaleric acidemia (isovaleryl CoA dehydrogenase)	Isovalerylglycine	Metabolic acidosis Vomiting	Protein restriction Glycine
Glutaric aciduria type I (glutaryl CoA dehydrogenase)	3-Hydroxyglutaric acid Glutaric acid	Metabolic acidosis Vomiting Macrocephaly Developmental delay	Protein restriction Carnitine
3-Methylcrotonyl glycinuria (3-methylcrotonyl CoA carboxylase)	3-Hydroxyisovaleric acid 3-Methylcrotonylglycine	Metabolic acidosis Hypoglycemia Hyperammonemia Seizures (Some patients asymptomatic)	Protein restriction Carnitine
Mitochondrial acetoacetyl CoA thiolase deficiency	2-Methyl-3-hydroxybutyrate acid 2-Methylacetoacetic acid Tiglylglycine	Metabolic acidosis Vomiting	Protein restriction Carnitine

A syndrome similar to Cbl C has been described in the breastfeeding infants of strict vegetarian (vegan) mothers and in mothers with pernicious anemia, who are vitamin B12 deficient.

## Disorders of fatty acid oxidation

These disorders have only been recognized since the early 1980s, but as a group are the most common inborn errors of metabolism. Fat provides a source of energy as ATP and ketone bodies during times of metabolic stress (such as febrile illness) or with prolonged fasting. Free fatty acids, released from the adipose tissue, are transported into the mitochondria via the carnitine shuttle system, where they then undergo beta-oxidation (Fig. 4), the progressive cleavage from an 18-carbon length very long-chain fatty acid to the 2-carbon acetoacetyl CoA, the substrate for the TCA cycle, ketones and ATP through the mitochondrial respiratory chain. A deficiency of any of the enzymes in this pathway can cause symptoms, primarily hypoketotic hypoglycemia and hepatic encephalopathy, with hyperammonemia (due to secondary inhibition of the urea cycle) and sudden death. Many cases of what would previously have been diagnosed as Reye syndrome are now known to be due to fatty acid oxidation defects. Symptoms can occur at any time, from the newborn period to adulthood.

Carnitine has a dual role: as well as its critical role in the transport of free fatty acids into mitochondria, it also conjugates with the fatty acyl CoA intermediates that accumulate proximal to an enzyme block, forming acylcarnitine species that can be excreted by the kidneys. They can also be measured in plasma for diagnostic purposes and in the newborn screening dried blood spot. Increased utilization of carnitine due to an enzyme defect causes a secondary depletion, further impairing fatty acid oxidation.

Defects of the carnitine shuttle (CPTI, CACT, CPT II) and beta-oxidation (VLCAD, TFP, and LCHAD) may present in the newborn period or later in infancy with severe hypoketotic hypoglycemia, cardiomyopathy and hepatic encephalopathy, due to deposition of fat in the heart and liver. Rhabdomyolysis (lysis of muscle cells) is common. Pigmentary degeneration of the retina is almost universal in patients with LCHAD, thought to be due to impaired endogenous production of DHA, which is necessary for normal retinal function. Peripheral neuropathy is common in TFP and retinopathy has been found in older patients. Variant forms of CPT II and VLCAD may present in adolescence or adulthood with exercise intolerance, muscle cramping and rhabdomyolysis, which may be severe enough to cause acute renal failure due to the deposition of the muscle pigment, myoglobin, in the renal tubules, causing acute necrosis.

Treatment for these disorders includes frequent feeding and avoidance of fasting and limitation of long-chain fat, which is the most abundant fat in human diets. Supplementation with medium-chain triglycerides, which bypass the long-chain enzyme deficiencies due to independent diffusion into the mitochondria, provide an alternate substrate for energy metabolism. MCT refers even chain triglycerides, of 6, 8 and 10 carbon length.

Special formulas (medical foods) can provide the medium chain triglycerides, but some are deficient in essential fatty acids, such as linoleic and linolenic acids and DHA. Addition of oil, such as canola, provides most of the essential fatty acids. DHA can be added to the formula as walnut oil. Uncooked cornstarch has been used to provide an alternate source of complex carbohydrate (especially for overnight fasting) after the age of about 9 months. Normal pancreatic amylase activity is necessary, and may not be active e

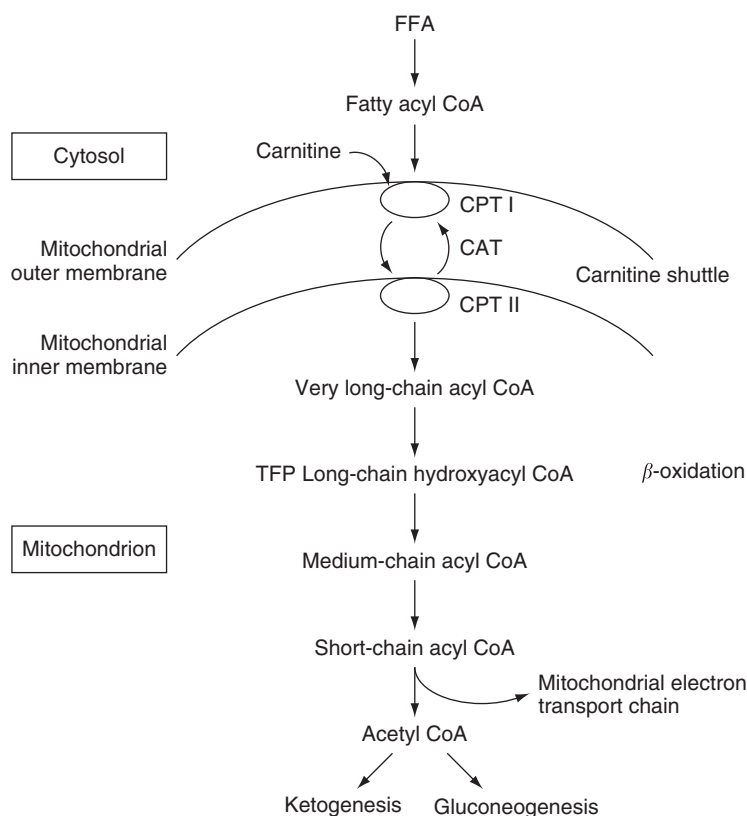

Fig. 4

before this age. A dietary guideline for VLCAD has recently been published (Van Calcar et al., 2020). Nutrition management guideline for very-long chain acyl-CoA dehydrogenase deficiency (VLCAD): an evidence-and-consensus-based approach).

In 2020, FDA (Food and Drug Administration) approved triheptanoin (Dojolvi), a 7 carbon chain triglyceride, in the US, as a source of calories in children and adults with long-chain fatty acid oxidation disorders. FDA based its approval on a 4-month double-blind randomized controlled study in which triheptanoin and trioctanoin (8-carbon demonstrated similar efficacy) (Gillingham et al., 2017).

Treatment for the medium- and short-chain defects (MCAD and SCAD) is simpler, involving avoidance of fasting and early intervention during acute illness to prevent hypoglycemia. Carnitine supplementation is frequently used to prevent secondary depletion. Dietary fat recommendations are approximately 30% of total calories, or a "heart healthy" diet for MCAD. Most cases of SCAD (detected on newborn screening) are due to two common variants in the general population, and considered to be non-pathogenic (Pedersen et al., 2008).

Newborn screening, where available, may detect the fatty acid oxidation disorders and allow early confirmation and intervention. This has resulted in significant improvement in morbidity and mortality.

## Disorders of carbohydrate metabolism

### Galactosemia

Galactose is derived primarily from dietary lactose, which is the major disaccharide in dairy products, human breast milk and many fruits and vegetables. There is also a small contribution from endogenous production. There are three known enzyme deficiencies in the pathway that oxidizes galactose to glucose (Fig. 5); all are autosomal recessive genetic disorders.

Fig. 5

Classic galactosemia is due to almost complete absence of galactose-1-phosphate uridyl transferase enzyme (GALT) activity. Symptoms generally occur in the first few weeks of life, with poor weight gain, lethargy, hypotonia, and liver disease (hyperbilirubinemia, coagulopathy, and hepatomegaly) and renal tubular acidosis. Hypoglycemia can occur, but is rare. *E. coli* sepsis may also be a complication; elevated galactose is thought to impair leukocyte bactericidal activity, allowing the bacteria to more easily invade the red blood cells with subsequent dissemination. Cognitive impairment may be a long-term complication.

The underlying pathogenesis of galactosemia is not fully understood; despite compliance with the lactose-restricted diet, speech delay is almost universal in children; some patients have learning disorders; many female patients develop ovarian failure, though successful pregnancies have been reported. Early recognition and hormone replacement therapy may be used.

Treatment is restriction of lactose in the diet, primarily by elimination of dairy products and other foods known to be high in galactose (Welling et al., 2017).

Variant forms of galactosemia occur due to mutations in the GALT gene that result in greater residual enzyme activity. The commonest variant is the Duarte Variant, in which there is usually one copy of a classic galactosemia mutation (e.g., Q188R) and one copy of the variant N314D. This combination results in approximately 25% residual enzyme activity. There is varying opinion on whether or not dietary treatment is necessary; some programs consider that the residual enzyme activity is adequate to prevent the pathologic sequelae, others elect to treat with lactose restriction for the first year of life. There are no long-term outcome data to support either approach (Fridovich-Keil et al., 2020).

Galactokinase (GALK) deficiency causes excessive accumulation of galactitol, which is oxidized from galactose by an alternative pathway. High levels of galactitol cause cataract formation, which is the only symptom of this disorder. Lactose restriction is necessary.

Epimerase deficiency (GALE) is very rare. There are two isoforms of the enzyme, one in red blood cells, and one in the liver. The most common disorder is due to an isolated deficiency of the RBC isoform, which will be detected incidentally by newborn screening programs that measure total galactose. There are no clinical symptoms and no treatment is necessary. A defect of both isoforms will cause symptoms similar to classic galactosemia and should be treated similarly.

### Glycogen storage disorders

Glycogen is a complex carbohydrate stored primarily in liver and muscle. Liver glycogen provides glucose to maintain blood sugar levels in between normal feedings; defects of the liver enzymes for glycogen degradation lead to hypoglycemia and/or liver disease because of excessive accumulation of glycogen. Muscle glycogen is an important substrate for energy production and normal muscle function; symptoms are typically exercise induced muscle pain or rhabdomyolysis (Ellingwood and Cheng, 2018).

Glycogen Storage Disease Type I (GSD Ia, (von Gierke disease) (Fig. 6), the most common disorder, is due to a deficiency of glucose-1-phosphatase in liver, kidney, and intestinal mucosa. Symptoms typically occur in infancy when frequency of feeding decreases. Profound hypoglycemia can occur; progressive hepatomegaly and liver dysfunction is due to storage of glycogen. Other metabolic derangements include hypertriglyceridemia and hyper-cholesterolemia (causing xanthomas); hyperuricemia (causing gout and renal calculi) is due to decreased renal excretion) as well as increased uric acid production due to phosphate depletion. Other long-term complications include progressive renal disease (proteinuria) and hepatocellular carcinoma. Treatment is frequent meals and continuous nocturnal feeding (in infants) and supplemental uncooked cornstarch to provide exogenous glucose from the age of about 9 months when pancreatic amylase is mature and can metabolize the corn starch (Kishnani et al., 2014).

Gene therapy is being evaluated in clinical trials for GSD 1a and III ([www.Clinicaltrials.gov](http://www.Clinicaltrials.gov)) (gene therapy, GSD1a, GSD 111).

Other disorders are summarized in Table 3.

### Disorders of fructose metabolism

There are three disorders of fructose metabolism, all inherited in an autosomal recessive fashion. Fructose is widely distributed in the diet as the primary sugar in fruits, vegetables, and honey. It is also derived from sucrose and sorbitol, which are also found in a large variety of products, including infant formulas and intravenous fluids. The toxic effect of fructose is due to inhibition of gluconeogenesis by high levels of fructose-1-phosphate and subsequent depletion of inorganic phosphate and thus, ATP.

Essential fructosuria is a benign disorder due to a defect of the enzyme, fructose kinase. Patients have increased urinary excretion of fructose, which is usually an incidental finding on routine testing for reducing substances.

**Fig. 6**

**Table 3**

<i>Disorder</i>	<i>Deficient enzyme</i>	<i>Primary affected tissue</i>	<i>Symptoms</i>	<i>Treatment</i>
GSD 0	Glycogen synthase	Liver	Hypoglycemia	Uncooked cornstarch, frequent feeds
GSD I	Glucose-6-phosphatase	Liver, muscle	Hypoglycemia, hepatomegaly, growth retardation, proteinuria, lactic acidemia, hyperlipidemia, hyperuricemia (gout), hepatocellular carcinoma	Uncooked cornstarch, frequent feeds
GSD II (Pompe disease)	Acid maltase ( $\alpha$ glucosidase)	Lysosomes of muscle (skeletal and cardiac)	Cardiomyopathy, skeletal myopathy, cardiorespiratory failure	Enzyme replacement (in clinical trial)
GSD III	Debranching enzyme (amylo-1, 6-glucosidase)	Liver, muscle	Hypoglycemia (mild), hepatomegaly, myopathy, hyperlipidemia	Uncooked cornstarch, frequent feeds
GSD IV (amylopectinosis)	Branching enzyme	Liver	Hepatomegaly, cirrhosis, liver failure, myopathy	Liver transplant, uncooked cornstarch
GSD V (McArdle disease)	Myophosphorylase	Muscle	Muscle cramping (with exercise)	Oral glucose, high-protein diet
GSD VI (Hers disease)	Liver phosphorylase	Liver	Hepatomegaly, hypoglycemia, myopathy	Frequent feeds
GSD VII (Tarui disease)	Phosphofructokinase	Muscle	Fatigue exercise intolerance, cramping	Avoidance of strenuous exercise
GSD IX	Phosphorylase kinase	Liver, muscle	Hepatomegaly, growth retardation	Frequent feeds

GSD, glycogen storage disorder.

Hereditary fructose intolerance (HFI) is due to a deficiency in aldolase B, which splits fructose-1-phosphate into glycer-aldehyde and dihydroxyacetone. Symptoms only occur after exposure to fructose, usually from dietary ingestion, although they are more severe after intravenous infusion. These symptoms include gastrointestinal discomfort, vomiting, and hypoglycemia. Chronic exposure causes failure to thrive, liver disease, and renal tubular acidosis. Affected patients are often misdiagnosed as having behavioral problems or an eating disorder. Treatment is elimination of fructose from the diet.

Fructose-1,6-bisphosphatase is a defect of gluconeogenesis and is not dependent on exposure to fructose. Symptoms of recurrent episodes of vomiting, lactic acidosis, tachypnea, seizures and apnea, occur when dietary glucose and glycogen stores are depleted, such as during periods of fasting or with febrile illnesses. Approximately 50% of patients are symptomatic in the newborn period. Treatment is prevention of fasting and supplementation with uncooked cornstarch to provide a source of complex carbohydrate. Acute episodes respond to intravenous infusions of dextrose.

## Disorders of micronutrient metabolism

### Disorders of copper metabolism

Copper plays an essential role in normal cell metabolism as a cofactor for several critical enzyme pathways. Normal homeostasis is regulated through a balance of gut absorption and biliary excretion (Hasan and Lutsenko, 2021). There are two major inherited disorders of copper metabolism: Wilson disease and Menkes disease.

Wilson disease (Mulligan and Bronstein, 2020) is an autosomal recessive disorder with an incidence of approximately 1/30,000 (higher in China, Japan, and Sardinia), due to a deficiency of hepatic ATPase(ATP 7B gene). Symptoms usually start in childhood, but there is a wide range of clinical features. Copper that cannot be excreted in the bile is initially deposited in the liver, with reduced incorporation into the carrier protein ceruloplasmin, causing chronic liver dysfunction (cirrhosis), and in some cases, acute liver failure. Increasing levels of copper are also deposited in other tissues, especially the cornea (Kayser-Fleischer rings) and the central nervous system, which is usually later in life, manifesting as a movement disorder and poor coordination. Difficulties with speech and swallowing can also occur. Psychiatric symptoms are also common, often beginning in adolescence.

The diagnosis is made by finding decreased serum ceruloplasmin with increased urine excretion of copper; copper deposition may also be seen on liver biopsy. Confirmation is by mutation analysis.

Treatment is aimed at increasing the excretion of the stored copper with chelating agents, such as D-penicillamine, and a copper-depleted diet. Liver transplantation may be an option. Clinical trials for gene therapy are underway ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)) Wilson Disease, gene therapy.

Menkes disease is an X-linked disorder due to a deficiency of the membrane transporter, ATP 7A, resulting in intracellular copper accumulation and lack of transport to critical tissues, such as the CNS, kidneys, and also to connective tissue. It usually presents in the first few months of life with typical facial features and unusual kinky hair (pili torti), seizures, poor weight gain, and loss of developmental milestones. Death usually occurs by approximately 3 years of age. Diagnosis is made by finding decreased serum

copper and ceruloplasmin and mutation analysis. Treatment with copper chloride injections before 10 days of age may slow the progression of the disease in some patients (Vairo et al., 2018).

A milder form of the disease (due to higher residual enzyme activity) is Occipital Horn Syndrome. Patients have characteristic occipital calcifications (occipital horns), borderline cognitive delay, a distinctive facial appearance, and connective tissue abnormalities (e.g., joint laxity). Treatment with copper-histidine may be beneficial if started in the neonatal period.

## Disorders of iron metabolism

### Hemochromatosis

There are four different subtypes of hereditary hemochromatosis, due to excessive absorption of iron from the gastrointestinal system, leading to toxic accumulation of iron in various tissues.

Hereditary hemochromatosis is the most common disorder, inherited in autosomal recessive fashion, due to pathogenic variants in the HFE gene (Gan et al., 2011). The carrier frequency is approximately 1:10 in Caucasians with a disease frequency of approximately 1/400. The typical presentation is in adults by age 40–60 years, with increased skin pigmentation, chronic liver disease (cirrhosis), portal hypertension, and diabetes mellitus (also called 'bronzed diabetes'), due to excessive iron deposition in skin, liver, and pancreas, respectively. Deposition also occurs in the heart and other endocrine tissues, including the pituitary gland, leading to hypogonadism in men. Hepatocellular carcinoma is a complication in approximately 30% of patients. There appears to be a male preponderance for end-stage organ failure. Homozygosity for the common mutation, C282Y appears to be associated with greater iron overload, but there is no clear correlation with disease severity. The diagnosis is suggested by increased serum iron and ferritin studies, with confirmation by mutation analysis. Current treatment is removal of excess iron by regular phlebotomy.

Other rare forms of inherited hemochromatosis are juvenile hemochromatosis (Piperno et al., 2020). Which is due to bi-allelic pathogenic variants in the HJV or HAMP genes. It presents in the first to third decades, with hypogonadotropic hypogonadism, cardiomyopathy, liver fibrosis, cirrhosis. Hemochromatosis type 3, due to a defect in the transferring receptor-2 gene, is similar to HFE-related hemochromatosis.

Type 4 is an autosomal dominant disorder (only one copy of the pathogenic variant is required. It transports iron from the diet.

Neonatal hemochromatosis (Feldman and Whittington, 2013) also known as Gestational Alloimmune Liver Disease (GALD) is very severe and presents as neonatal liver failure or cirrhosis. Fetal demise and/or still-birth can occur. When a mother is exposed to a fetal antigen that is not recognized as "self", IgG antibodies, which activates a complement cascade, causing liver injury. Mortality is high. Early intervention with IVIG may be beneficial.

## Conclusions

Inborn errors of metabolism, while individually rare, are the cause of a significant number of inherited disorders. With the development and continued evolution of newborn screening, many more disorders are detected early and may benefit from early treatment.

The classic management with dietary treatment will likely continue to be the mainstay for many disorders, however new approaches, such as gene therapy, and newer medications, may provide much greater tools for managing many disorders and improving outcomes and quality of life.

## Key points

- Phenylketonuria was the first inherited metabolic disorder to be identified by newborn screening and managed by nutrition to prevent adverse intellectual outcomes.
- A phenylalanine-restricted diet requires the use of medical food to provide protein without phenylalanine; the semi-synthetic nature of the diet and restriction of whole protein result in increased risk for inadequate growth, reduced bone mineral density, as well as essential fatty acid and vitamin and mineral deficiencies.
- While the phenylalanine-restricted diet prevents developmental delay, it is a difficult diet to sustain chronically, and blood phenylalanine concentrations often increase as children reach adolescence and adulthood resulting in suboptimal control and associated neurocognitive deficits.
- Strict control of blood phenylalanine is necessary in pregnant women with PKU to prevent the teratogenic effects of high blood phenylalanine.
- Pharmacological therapies for PKU include sapropterin, a tetrahydrobiopterin supplement that can increase phenylalanine hydroxylase activity in some individuals with PKU and pegvaliase, an injectable enzyme substitution therapy.

## Introduction

Phenylketonuria (PKU) is a disorder of amino acid metabolism caused by a deficiency in the enzyme phenylalanine hydroxylase, which converts the essential amino acid phenylalanine to tyrosine. High concentrations of phenylalanine are toxic to the central nervous system (CNS), resulting in severe irreversible developmental delay. Details of the biochemistry are discussed elsewhere in the encyclopedia.

PKU is often considered a paradigm for the nutritional therapy for metabolic disorders. It was the first inborn error of metabolism identified by newborn screening, thus allowing for early dietary treatment. Early treatment was successful in preventing the

developmental delay associated with untreated PKU. Since the advent of successful nutrition management of PKU over 5 decades ago, the field has expanded greatly, but the principle of treating PKU with diet remains the same—to control the intake of the amino acid that is not metabolized normally. This principle applies to all amino acidopathies, but PKU is used here as an example.

Dietary treatment is started as soon as the diagnosis is confirmed in a newborn. Outcomes are best when the diet is implemented and the phenylalanine concentrations are within the recommended range by 2 weeks of age (Camp et al., 2014). Lifelong treatment is recommended as individuals with PKU who have resumed an unrestricted diet, although intellectually normal, have been shown to have an increased incidence of neuropsychiatric deficits as well as increased anxiety and depression (Bilder et al., 2016).

The pathophysiology of PKU is not well understood, and may be related to the disturbance of normal amino acid concentrations in the brain. Phenylalanine competes with other large neutral amino acids for transport across the blood–brain barrier, and it is theorized that high levels of brain phenylalanine and low levels of other amino acids, specifically tyrosine and tryptophan, may impede neurotransmitter synthesis in the brain and be responsible for the symptoms associated with untreated PKU (Schuck et al., 2015). Although the ideal brain concentration of phenylalanine has not been established, treatment guidelines have been established for blood phenylalanine at various ages, as these guidelines differ slightly in different countries. In the United States, the American College of Medical Genetics (ACMG) recommends that blood phenylalanine be maintained between 120 and 360  $\mu\text{mol/L}$  throughout the lifespan (Vockley et al., 2014).

The goal of nutritional therapy is to keep blood phenylalanine controlled while providing a nutritionally sound diet. This necessitates the use of a special medical food that provides amino acids other than phenylalanine because the phenylalanine restriction required to maintain blood concentration within the desired range is so severe that the amount of natural protein allowed in the diet would not support normal growth and development.

Medical foods vary in amino acid content and most also provide carbohydrates, fats, vitamins, and minerals, but others do not. The amount of medical food prescribed is intended to meet protein needs at various ages in the life cycle, which is shown in Table 1.

## Introduction to nutrition management

The phenylalanine-restricted diet is introduced after the diagnosis is confirmed. Typically, a phenylalanine-free medical food is given for a few days so that blood phenylalanine will quickly decrease to an acceptable concentration. Then, a limited amount of breast milk or standard infant formula is added to the diet to provide 130–430 mg/d of phenylalanine (Singh et al., 2014), depending on the severity of the PAH mutation. This prescribed amount of intact or natural protein is needed to meet the infant's phenylalanine requirements and prevent phenylalanine deficiency, which leads to muscle protein catabolism and inadequate weight gain.

If parents prefer to formula-feed their infant, both standard infant formula and the PKU medical food are mixed in prescribed amounts and are bottle-fed. Breast milk as the protein source is encouraged. Mature breast milk contains approximately 46 mg per 100 cc of phenylalanine compared to approximately 57 mg per 100 cc in cow's milk protein-based formula and approximately 90 mg per 100 cc in soy-based formulas (USDA, 2022). Breast-fed infants, therefore, may initially have slightly lower blood phenylalanine concentrations. If the parents wish to continue breast-feeding, they are taught the proper ratio of breast milk to PKU medical food to feed the infant. The infant can feed the breast for some feedings and is given the PKU medical food from a bottle at others. The key to success with either feeding method is frequent monitoring of blood phenylalanine and adjusting the diet based on phenylalanine intake, weight gain, and blood phenylalanine. In the newborn period, weekly or twice weekly monitoring is recommended (Singh et al., 2014). The method used for monitoring varies depending on the resources available at individual PKU clinics—either frequent visits to the clinic for blood drawing or collecting filter paper specimens at home and mailing them to the lab for analysis. Because of the time delay in the latter method, it is more suitable for use after blood phenylalanine concentrations have stabilized.

When an infant with PKU is 4–6 months old, solid food is introduced. Because the total amount of phenylalanine tolerated remains relatively constant, as phenylalanine from solid food is added to the diet, the amount of regular infant formula or breast milk decreases. Since nearly all foods contain some phenylalanine, it must be counted with the goal of reaching the prescribed

**Table 1** Recommended daily intakes of PHE, TYR and protein for individuals with PKU (Singh et al., 2014).

Age	PHE (mg)	TYR (mg)	Protein (g/kg)
0 to <3 months	130–430	1000–1300	2.5–3.0
3 to <6 months	135–400	1400–2100	2.0–3.0
6 to <12 months	145–370	2500–3000	2.0–2.5
1 to <2 years	135–330	2500–3000	2.0–2.5
2–4 years	200–320	2800–3500	1.5–2.1
>4 years	200–1100	4000–6000	120–140% DRI for age

PHE, phenylalanine; TYR, tyrosine.

amount of phenylalanine each day. Several methods of counting are used. Historically, all food was measured or weighed, and every milligram of phenylalanine was counted. Caregivers were given lists of the phenylalanine content of foods and the daily phenylalanine intake goal. Now, most clinics teach parents the “simplified diet” in which foods that are relatively low in phenylalanine (less than 75 mg phe/100 g of food) are not counted, and instead parents only count the foods that have higher phenylalanine content. Since the uncounted foods are fruits and some vegetables, the simplified diet is intended to encourage healthy eating and reduce parental stress associated with weighing measuring and recording (Hansen et al., 2020). While not counted by the caregiver, dietitian accounts for the amount of for the phenylalanine content of the uncounted foods, usually about 30% of the total phe intake (Hansen et al., 2020). Typically, pureed fruits and vegetables are offered first, and then as the infant’s appetite increases, “counted” foods, such as vegetables with >75 mg/100 g, for example corn, peas and potatoes, as well as bread and cereal products. For most individuals with PKU, intake regular grain products is either not allowed or severely limited. Instead, specialty low-protein foods are available, often through mail order. A whole array of low-protein breads, cereals, crackers, bagels, pasta, cakes, cookies, and low-protein cheeses, “meats” and “peanut butter” are helpful to include in the diet. These foods provide much-needed variety and calories to the diet. High-protein foods such as meat, fish, poultry, dairy, nuts, eggs, and legumes are not allowed on a PKU diet. Thus, the medical food continues to be the main source of protein for life. A variety of medical foods are available for older children and adults with PKU in order to meet different tastes and energy needs. Many of the medical foods for children, teens, and adults are packaged in ready to drink containers for convenience and come in several flavors. Nevertheless, many individuals with PKU struggle with taking the full amount of the prescribed medical food, perhaps because off the taste of amino-acid based formulas, taste fatigue, or inconvenience. If the full amount of medical food is not taken, nutritional intake is inadequate and may lead to catabolism of lean body mass, which, in turn, leads to poor control of blood phenylalanine.

Many medical foods contain L-amino acids as the nitrogen source, but others contain glycomacropeptide (GMP), a derivative of whey protein that is naturally low in phenylalanine, although not phenylalanine-free. There is some evidence that GMP-based medical foods improve satiety and are better-tasting than amino acid-based medical foods (Ney et al., 2016).

Other medical foods contain primarily the large neutral amino acids (LNAAs), phenylalanine, tyrosine, tryptophan, and branched-chain amino acids which share the same L-amino acid transport system across the blood–brain barrier. High concentrations of phenylalanine in the blood, therefore, impede the transport of these other amino acids into the CNS. Tyrosine and tryptophan are important neurotransmitter precursors; relative deficiency or imbalance of which may contribute to the neuropsychiatric symptoms seen in some adult PKU patients who have resumed an unrestricted diet. Treatment with supplemental LNAAs theoretically will increase the competition with phenylalanine for transport into the CNS. A net reduction in phenylalanine and an increase in CNS tyrosine and tryptophan may result in improvement in symptoms. This treatment is not suitable for children or women in the childbearing years that might be contemplating pregnancy (Vockley et al., 2014).

Once established, the amount of dietary phenylalanine an individual is allowed remains the same, except for periods of rapid growth, when more phenylalanine may be necessary. A typical phenylalanine intake for a child with severe PKU is approximately 250 mg day<sup>−1</sup> and that for a child with moderate PKU is 400 mg day<sup>−1</sup>. Thus, in addition to getting the proper amount of medical food, the crux of the diet is to provide the prescribed amount of phenylalanine while making the diet taste and appear as appetizing and socially acceptable as possible. Families require a good deal of support in doing this. Parent/patient organizations such as the National PKU Alliance, family events, and camps for children with PKU provide a connection for families and a forum for exchange of practical information and emotional support. PKU clinic personnel are another source of support and reliable information on medical advances in treating PKU.

All patients with PKU should have blood phenylalanine and other amino acids monitored regularly as long as they remain on diet; they should also be seen on a regular basis for a physical examination, especially for assessment of growth parameters in children and adolescents, and review of the dietary intake since the previous visit. Extensive nutrition counseling is an ongoing process. It is also recommended that adult patients, who are not following phenylalanine-restricted diets with prescribed medical foods, should be seen at least yearly for nutritional assessment, as they often tend to self-limit their protein intake and may have inadequate diets (Singh et al., 2014).

Nutritional therapy is the mainstay of treatment for individuals living with PKU (van Wegberg et al., 2017) (Vockley et al., 2014). Although nutritional therapy has been shown to prevent the severe neurological manifestations of the disease (Jameson and Remington, 2020; Acosta and Matalon, 2010), a profoundly modified nutritional intake creates risk to growth, development, and nutritional adequacy in the PKU population.

Restriction of whole protein sources can create deficiencies in essential fatty acids, vitamin B<sub>6</sub>, vitamin B<sub>12</sub>, selenium, zinc, calcium, and iron (Blau et al., 2010). The use of medical foods for supplementation of the required macro and micronutrients mitigates the risk of deficiency, however, adherence to the consumption of medical foods varies between age groups and decreases throughout adolescence (Strisciuglio and Concolino, 2014). Additionally, individuals that are non-adherent to the consumption of medical food tend to consume high-carbohydrate diets that lead to obesity, vitamin and mineral deficiencies, and secondary disease sequela (McBurnie et al., 1991).

Nutritional therapy, including nutritional assessments, nutritional interventions, and nutritional prescriptions, followed by monitoring and evaluation are essential for maintaining the health of individuals with PKU.

## Growth

Adequate growth in individuals with PKU is both a historical and current consideration in the manifestation of the disease. Studies examining the growth of individuals with PKU have demonstrated concern for growth retardation, even in the presence of nutritional therapy providing adequate micronutrient and macronutrient needs (Dobbelaere et al., 2003). There is, however, evidence of improved linear growth in the presence of increased intakes above the Recommended Daily Allowance (RDI) (ranging from 113% to 129% RDI) for protein (Singh et al., 2014) suggesting that the protein needs of individuals with PKU may be higher than the standard population. Growth must be carefully monitored and evaluated at, a minimum, of every clinic visit (Singh et al., 2014).

Some evidence suggests the rate of overweight and obesity within the PKU population is higher than in the general population (Acosta et al., 2003; Walkowiak et al., 2019) however, data is inconsistent (Shakiba et al., 2020). An analysis from the Collaborative Study of Children Treated for Phenylketonuria (PKU) was compared to growth data from the National Center for Health Statistics (NCHS) to determine if growth patterns were affected in the PKU population. This investigation found that growth in children treated for PKU differs from national standards for weight by age and weight by height, but not for height by age, with poor diet adherence being a consideration for an increased risk of obesity (McBurnie et al., 1991). A positive correlation between phenylalanine with body weight and age has been indicated in other investigations (de Almeida et al., 2020) demonstrating the importance of metabolic control on overweight and obesity.

The first multi-center European and Turkish cross-sectional study of 947 patients with PKU found a higher risk for obesity and overweight in the female cohort than the male cohort (Ozel et al., 2014). An observational study of 30 pediatric (ages 5–18 years) with PKU, however, demonstrated no difference in lean body mass (LBM) or fat free mass (FM) percentage in female subjects compared to control, but did see less LBM and higher FM percentage in males compared to controls. Additionally, 30% of the subjects with PKU and 6.67% of the controls were overweight (BMI 85–95th percentile,  $n = 9$  vs.  $n = 2$ ); and 10% of the subjects with PKU and 13.33% of the controls were obese (Sailer et al., 2020). Additionally, male subjects with PKU demonstrated significantly lower height z-scores compared to controls, however, pubertal maturation and/or genetic potential were not included in the analysis (Sailer et al., 2020).

Further investigation into the risk of overweight and obesity in the PKU population is warranted, however, metabolic control of the disease and gender may play a role in the risk of overweight and obesity (Walkowiak et al., 2019). Weight must be carefully monitored and evaluated at, a minimum, of every clinic visit (Singh et al., 2014).

## Fatty acids

Individuals with PKU following a protein restriction consume limited to no animal products, including eggs and dairy, or nuts. These products are primary sources of long-chain polyunsaturated fatty acids (LC-PUFAs). Main n-3 LC-PUFA in food sources are  $\alpha$ -linolenic acid (ALA), docosahexaenoic acid (DHA), and eicosapentaenoic acid (EPA). Main n-6 LC-PUFA in food sources include linoleic acid (LA) and arachidonic acid (AA or ARA) (Abedi and Sahari, 2014). These LC-PUFAs are essential fatty acids that cannot be produced in adequate amounts endogenously and must be consumed from foods to prevent essential fatty acid deficiency. As natural sources of essential fatty acids are restricted in the nutritional treatment of PKU and there is evidence of changes in concentrations of plasma/serum lipoprotein lipids, as well as in the fatty acid profile of plasma and red blood cells in the PKU population (Guerra et al., 2020), essential fatty acid deficiency is of concern.

Evidence demonstrates aberrations in lipoprotein components in individuals with PKU, even with metabolic stability (Guerra et al., 2020). The majority of individuals receiving adequate amounts of the essential fatty acid precursors, linoleic acid and alpha linolenic acid, are able to synthesize LC-PUFAs via elongation and desaturation reactions. When LC-PUFAs are not supplemented in treated infants with PKU, however, plasma and erythrocyte levels contain lower concentrations of ARA and DHA than controls (Giovannini et al., 1995). Additionally, the essential fatty acid profiles of individuals with PKU vary from their peers and essential fatty acid concentrations in the blood appear to be dependent on the consumption of essential fatty acids in this population (van Gool et al., 2000). A systematic review of literature of 65 publications from 1990 to July 2016 demonstrated significantly lower levels of DHA, EPA and cholesterol in individuals with PKU compared to healthy controls (Parra et al., 2018). Supplementation with EFA precursors, or with preformed docosahexaenoic acid (DHA) and/or ARA, may be necessary in individuals with PKU at any age and may be conditionally essential nutrients in this population (Giovannini et al., 1995).

Several studies suggest improved clinical outcomes in individuals with PKU when supplemented with DHA and/or AHA. A study of 36 children supplemented with 15 mg DHA per kilogram body weight showed improvement in visual processing, motor function, and coordination though they had been receiving adequate alpha linolenic acid (Giovannini et al., 1995) and had adequate metabolic control, however, further investigation is needed on the effect of DHA supplementation on neurocognitive function. Additionally, supplementation with DHA has been shown to correct and prevent essential fatty acid deficiency (Agostoni et al., 2001) and has been shown to decrease visual evoked potential P100 wave latency in children (Couce Pico et al., 2019). Further research is necessary into the full benefits of supplementation of LC-PUFAs in the PKU population.

In infancy, including breast milk or standard formulas containing DHA and arachidonic acid, as well as medical foods that contain DHA/arachidonic acid, can help ensure adequacy (Singh et al., 2014). Medical foods, however, are not consistently supplemented and, therefore, may not provide adequate sources of essential fatty acids. Essential fatty acid supplementation should be

considered for individuals with PKU of all ages and yearly monitoring, or sooner if deficiency is suspected, of essential fatty acid profiles is recommended (Singh et al., 2014).

### Vitamins and minerals for consideration

The standard of care for PKU is restriction of dietary protein. This restricted intake leads to deficient vitamins B<sub>2</sub>, Niacin (B<sub>3</sub>), B<sub>12</sub>, D, iron, zinc, and selenium (Bakaloudi et al., 2021). B-group vitamins, niacin, vitamin D, iron, zinc, and selenium all play a critical role in inflammatory responses and may affect cognition (Godos et al., 2020), possibly by decreasing reactive intermediates in the brain.

Several studies within the PKU population reveal micronutrient deficiencies in vitamins B<sub>2</sub>, Niacin (B<sub>3</sub>), B<sub>12</sub>, D, zinc, and selenium, among others. Current data suggests that supplementation with micronutrients, both individually and within medical foods, has improved the nutritional status in those living with PKU, however, supplementation from medical foods may be insufficient (Lammardo et al., 2013) and concentrations in the blood may remain low (Nazari et al., 2016). The mechanisms for utilization of micronutrients in the PKU population and the bioavailability of the micronutrients added to medical foods are not sufficiently researched (Nazari et al., 2016).

Individuals living with PKU may be at significantly higher risk of deficiency of vitamins B<sub>2</sub>, Niacin (B<sub>3</sub>), B<sub>12</sub> due to the lack of vitamin B rich foods in the diet and other theorized mechanisms (Brantley et al., 2018). The risk of B vitamin deficiencies is greater in those individuals with PKU not under medical supervision (Schoen et al., 2019). Vitamin B supplementation is warranted in the PKU population when not obtaining adequate amounts of these vitamins from medical food (Kose and Arslan, 2019) or when serum concentrations are low. Careful monitoring of vitamin B status is recommended (Schoen et al., 2019).

A higher rate of vitamin D deficiency exists in the PKU population (Kose and Arslan, 2019), however, the risk of deficiency is lowered in those individuals consuming medical foods (Geiger et al., 2016). The rate of vitamin D deficiency in the PKU population is as high as 30–53.6% depending on age and access to sunlight. Zinc and iron status in individuals with phenylketonuria has long been researched due to potential deficiency in the protein restricted diet. Low concentrations of zinc and iron in individuals with PKU have been evidenced in multiple studies (Acosta et al., 2004), even despite intake above the recommended daily allowances (Evans et al., 2014). A systematic review of literature from 1990 to July 2016 exhibited lowered zinc concentrations in those living with PKU compared to controls (Parra et al., 2018). Although the meta-analysis did not show statistical significance, the observation of lowered zinc concentrations in the PKU cohort may be of clinical consideration (Parra et al., 2018). Selenium deficiency has been demonstrated in the PKU population (Evans et al., 2014), even in the presence of supplementation, however, the rate of deficiency is lower with selenium supplementation (Darling et al., 1992). Until recently, selenium was not routinely added to PKU formulas, and reliance on the selenium content of soil may not be sufficient.

Active monitoring of B vitamins, zinc, and selenium concentrations is recommended. Monitoring may be necessary with inadequate consumption or supplementation of these micronutrients in medical foods, clinical signs/symptoms of nutritional inadequacy including poor growth, or serious intercurrent illness (van Wegberg et al., 2017). Vitamin D and iron statuses should be assessed yearly (Singh et al., 2014). Monitoring the impact of supplementation or nutrition intervention after one month is recommended to ensure improvement (Singh et al., 2014).

### Bone mineral density

Abnormal bone mineral density (BMD) has long been observed (Feinberg and Fisch, 1962) in the PKU population. An elevation in the prevalence of low BMD-for-age in PKU, defined as a Z-score  $\leq -2.0$ , has been demonstrated in numerous studies and has been shown to affect approximately 20% of individuals with PKU compared to 2% in the general population (de Castro et al., 2020). Although the exact mechanisms for decreased BMD in this population are unknown, there are numerous factors that may be of influence. It has been theorized that calcium and vitamin D status, the quality of bone proteins, physical activity, endocrine status, and genetic and environmental factors impact BMD in individuals with PKU (van Wegberg et al., 2017). Gender and intake of medical foods may also play a role in the risk for decreased bone mineral density, although the data is confounding (Stroup et al., 2018). A systematic review of cross-sectional and cohort studies on bone status in phenylketonuria demonstrated that mean BMD is reduced in PKU patients compared with healthy controls, however, they did not observe an increased prevalence of bone mass below the expected range for age as defined by Z-scores of  $-2.0$  SD (de Castro et al., 2020). The authors also observed lower significant differences in bone mineral content (BMC) between PKU patients and healthy controls, however, the concentration of minerals was heterogeneous (de Castro et al., 2020). Additionally, the authors found a trend toward an imbalance between bone formation and bone resorption, favoring bone removal in the PKU population (de Castro et al., 2020). An alternative systematic review and meta-analysis further demonstrated individual study findings of low BMD in the PKU population, however, available data suggested the reduction in BMD is not clinically relevant when compared to the standard definitions of low BMD (Demirdas et al., 2015). Additionally, they concluded that phenylalanine concentrations, vitamin D, PTH, and nutrient intake do not correlate with BMD or BTM (Demirdas et al., 2015).

Numerous methods of evaluation have been implemented in the PKU population to study bone mineral density. These methods have included dual-energy X-ray absorptiometry (DEXA), peripheral quantitative computed tomography (pQCT), and single-photon absorptiometry (SPA). The various methods used could be leading to conflicting findings within the PKU population on the risk factors for decreased BMD. A European survey study of seventeen centers specialized in treating adults with PKU was unable

to identify any risk factors for low BMD in adults living with PKU and found that low BMD occurred only in a small subset of PKU patients (Lubout et al., 2020).

Further investigation into the prevalence and mechanism of decreased BMD in this population is needed, however, the need for frequent monitoring of BMD in the PKU population is well understood. Measurement of BMD through dual-energy X-ray absorptiometry (DEXA or DXA) is indicated in PKU (Singh et al., 2014; van Wegberg et al., 2017) medical intervention to improve BMD in this population should include all considerations for the healthy population.

## Maternal PKU

For women with PKU who intend to become pregnant, following a strict phenylalanine-restricted diet and controlling blood phenylalanine to 120–360  $\mu\text{mol/L}$  is critical to offspring health. Women with PKU who have high blood phenylalanine levels are at high risk of having children with microcephaly, developmental delay, low birth weight and, congenital heart anomalies. In an International Study of Maternal PKU, women who were in good metabolic control by 10 weeks' gestation had babies with good birth outcomes and development. In women in poor control, the degree of microcephaly and mental retardation was proportional to the concentration of blood phenylalanine (Koch et al., 2003). Congenital heart disease (CHD), however, was not directly related to the degree of metabolic control, suggesting that etiology is multifactorial. In the international study, a significantly higher risk for CHD was found in the women with lower natural protein and medical food intake, regardless of blood Phe levels. In addition, these women had lower red blood cell folate concentrations (Matalon et al., 1991).

The recommendation is for women to maintain blood phenylalanine concentrations in the recommended range before conceiving in order to prevent damage to the fetus (Vockley et al., 2014). Nevertheless, many women come to medical attention during pregnancy, indicating the need for better strategies for keeping women on treatment for life, as well as determining the safety of pegvaliase and other emerging therapies during pregnancy.

## Pharmacological therapies

### Tetrahydrobiopterin

Tetrahydrobiopterin (BH4) is the cofactor for phenylalanine hydroxylase. A synthetic form of BH4, sapropterin dihydrochloride, has been used in conjunction with dietary therapy for over a decade and lowers blood phenylalanine in some individuals with PKU. Responsiveness to BH4 therapy depends on the severity of PKU; patients with mild or moderate degrees of PKU are more likely to respond and those with 2 null mutations do not. Data from a registry of 504 patients continuously treated with sapropterin showed an average 34% decrease in blood phenylalanine  $\mu\text{mol/L}$  ( $p = 0.0009$ ) after 5 years. Dietary phenylalanine tolerance increased an average of 54% above baseline intake after 6 years, however most patients remain on some degree of protein restriction and medical food intake (Longo et al., 2015).

### Pegvaliase

Pegvaliase, an injectable form of phenylalanine ammonia lyase, converts phenylalanine to ammonia and cinnamic acid and is an approved enzyme substitution therapy for adults with PKU who have blood phe  $>600 \mu\text{mol/L}$ . In clinical trials, patients treated with pegvaliase showed a sustained reduction in blood phenylalanine concentrations while phenylalanine intake increased, and medical food was discontinued. By 24 months of therapy, approximately 60% of patients achieved blood phenylalanine concentrations below 360  $\mu\text{mol/L}$  (the recommended upper limit for blood phe by ACMG). Common adverse events include injection site reactions, arthralgia, hypersensitivity reactions, and headaches. Most patients on pegvaliase can ultimately consume an unrestricted diet, but because of the likelihood of side effects, the drug is titrated slowly, and it often takes 6 months or more before blood phenylalanine concentrations decrease. In addition, because of the possible risk of anaphylaxis, patients must carry auto injectable epinephrine (Thomas et al., 2018).

## Conclusion

Phenylketonuria was the first inherited amino acid disorder to be identified by newborn screening and for which nutrition management prevented the serious developmental delay associated with untreated PKU. The diet for PKU became a paradigm for other amino acid disorders and led to the development of medical foods based on L-amino acids without the offending amino acids. While nutrition management has been a huge public health success in preventing a generation of individuals with PKU from developmental delay, the diet has considerable limitations, including the difficulty of maintaining blood phenylalanine in the recommended treatment range due to the severe limitation of protein-containing foods, the neurocognitive deficits that are associated with suboptimal control and the nutritional risks the diet imposes. Pharmacological therapies offer an adjunct to or a substitution for the phenylalanine-restricted diet.

## Introduction

The two ketone bodies acetoacetate ( $\text{CH}_3\text{COCH}_2\text{COO}^-$ ) and D-3-hydroxybutyrate ( $\text{CH}_3\text{CHOHCH}_2\text{COO}^-$ ) are the only freely soluble lipids in the circulation.

The name ketone bodies originates from the German *Ketonkörper* (literally, ketones excreted from the body) and refers to their discovery in the urine of diabetic patients in the latter half of the nineteenth century. In reality, the term is a misnomer because 3-hydroxybutyrate is not a ketone. It arose because the reagent originally used reacted positively with ketones in diabetic urine. Acetone ( $\text{CH}_3\text{COCH}_3$ ), the product of the spontaneous decarboxylation of acetoacetate, is also a ketone and is present in blood and urine when the plasma concentration of acetoacetate is elevated. It is excreted via the kidneys and lungs and is responsible for the sweet smell on the breath in ketotic states.

The association of ketone bodies with the pathology of diabetes resulted in the view that they were toxic waste products. It is only in the past 30 years that this view has been convincingly reversed. Two factors led to this change, namely the development of an enzymatic method for the determination of acetoacetate and 3-hydroxybutyrate, which in turn allowed the dramatic finding of Cahill and colleagues in 1967 that adult human brain removed appreciable amounts of ketone bodies from the circulation in prolonged starvation.

The aim in this contribution is to review (a) the formation of ketone bodies in physiological and pathological situations and (b) the function of ketone bodies as physiological substrates and signals.

## Formation of Ketone Bodies

It is well established that in humans and other mammals the only organ that contributes significant amounts of ketone bodies to the blood is the liver; this organ, unlike peripheral tissues, is unable to utilize ketone bodies to any appreciable extent. More recently it has been found that during the suckling period (high-fat diet) the intestine also has the capacity (approximately 10% of that of the liver) to produce ketone bodies. Whether ketone bodies are used *in situ* or are transported via the portal blood to supplement the existing hyperketonemia is an open question.

The main blood-borne substrates for the synthesis of ketone bodies (ketogenesis) are the nonesterified fatty acids; others of lesser importance are the branched-chain amino acids, leucine and isoleucine. In addition, acetate (sources: intestinal fermentation, in vinegar, or an oxidation product of ethanol) is a ketogenic substrate.

Long-chain fatty acids contained in dietary lipids do not enter the portal blood directly but are esterified in the intestinal cells, packaged with proteins and phospholipids to form chylomicrons (large lipoproteins), and transported via the lymphatic system to

<sup>†</sup>Deceased.

the thoracic duct, where they enter the blood. In contrast, the short- and medium-chain fatty acids (below  $C_{14}$ ) contained in dairy products or in clinical medium-chain triacylglycerol preparations are directly absorbed as the respective fatty acids and are transported to the liver via the portal blood (Figure 1). The long-chain fatty acids in the plasma are bound to albumin and are released from adipose tissue triacylglycerol stores by the process of lipolysis.

### Extrahepatic Regulation

A key factor in the regulation of ketogenesis is the availability of nonesterified long-chain fatty acids to the liver, which in turn is controlled by their release from adipose tissue. The enzyme responsible for the initiation of the hydrolysis of stored triacylglycerols to fatty acids is hormone-sensitive lipase. As its name implies, this enzyme is exquisitely sensitive to hormones: adrenaline (in the plasma) and noradrenaline (released from sympathetic nerve endings) are activators, whereas insulin inhibits the activity. In small mammals glucagon is also an activator of the enzyme, but this does not seem to be the case in the human.

Insulin has an additional effect on the net release of long-chain fatty acids from adipose tissue in that it stimulates their re-esterification to triacylglycerols. Thus after a high-carbohydrate meal, when insulin secretion and its concentration in the plasma is high, the release of fatty acids from adipose tissue is suppressed and their concentration in the plasma is low (Figure 2). In contrast, during stress, when adrenaline and noradrenaline are elevated, the release of fatty acids is increased and their plasma concentration is high.

In experimental animals increased plasma ketone body concentrations (hyperketonemia) can inhibit adipose tissue lipolysis (a) indirectly by increasing the secretion of insulin or (b) by a direct effect on the tissue (Figure 3). This can be viewed as a feedback mechanism for controlling the rate of ketogenesis via fatty acid supply to the liver, but whether this is important in the human is not known. In contrast, the supply of short- and medium-chain fatty acids to the liver is mainly dependent on the dietary intake and on the proportion that escapes further metabolism in the intestinal tract; there is no known involvement of hormones in the process.

### Intrahepatic Regulation

There are situations (e.g., stress) where the supply of fatty acids to the liver may be increased, but there is no necessity to increase the availability of ketone bodies to the peripheral tissues. Consequently, there is a requirement that the rate of hepatic ketogenesis should be controlled independently of the supply of fatty acids. However, it must be stressed that without an increase in the supply of fatty acids the rate of ketogenesis cannot increase.

Much of the current interest is concerned with how the intrahepatic metabolism of fatty acids (Figure 4) is regulated. Long-chain fatty acids entering the liver have three main fates:

1. They can be re-esterified to phospholipids and triacylglycerols and then be secreted as very-low-density lipoproteins (VLDL).
2. They can be oxidized via the mitochondrial  $\beta$ -oxidation complex to acetyl-CoA. The latter can combine with another molecule of acetyl-CoA in the reaction catalyzed by acetoacetyl-CoA thiolase and then enter the hydroxymethylglutaryl-CoA pathway to form acetoacetate.
3. The acetyl-CoA derived from the fatty acids can be completely oxidized in the tricarboxylate cycle.

The short- and medium-chain fatty acids cannot be re-esterified to any appreciable extent in mammalian liver and therefore they are either metabolized to ketone bodies or completely oxidized. In addition, unlike the long-chain fatty acids, they are transported directly into the mitochondrial matrix without the need to be converted first to the corresponding acyl-CoA derivatives.

**Figure 1** Intertissue fluxes of substrates in the suckling neonate. Thickness of line denotes rate of flux.

**Figure 2** Intertissue fluxes of substrates in the fed state. Thickness of line denotes rate of flux.

### Role of Malonyl-CoA

The entry of free long-chain fatty acids into the hepatocyte is via a specific carrier on the plasma membrane. Once inside the cytosol the long-chain fatty acids are bound to binding proteins, converted to the acyl-CoA derivatives, and then can either be esterified or enter the mitochondria via a complex transport system, the carnitine–acyl-CoA transferase (CAT) system. This consists of two proteins: CAT I located on the outer mitochondrial membrane and CAT II on the inner mitochondrial membrane (**Figure 5**). The overall action of the two enzymes results in the transfer of a long-chain fatty acyl-CoA to the mitochondrial matrix and the return of free carnitine to the cytosol via an exchange mechanism. Although carnitine is not consumed in the reaction, the available concentration can be critical. In nutritional carnitine deficiency there is impairment of long-chain fatty acid oxidation and ketogenesis.

The activity of CAT I is the key to the intrahepatic regulation of fatty acid metabolism in most situations. Its activity increases in ketogenic situations. More importantly, CAT I is inhibited by malonyl-CoA and the sensitivity of CAT I to this inhibitor changes in various pathophysiological situations such as fasting or diabetes.

As malonyl-CoA is a key intermediate in the synthesis of fatty acids (lipogenesis) from products (pyruvate and lactate) of glucose metabolism, this interaction provides a regulatory link between lipid and carbohydrate metabolism (**Figure 5**). Thus on high-carbohydrate diets, when the rate of hepatic lipogenesis, and consequently the cytosolic concentration of malonyl-CoA, is high, the activity of CAT I will be inhibited and fatty acids will be diverted to esterified products and secretion as VLDL rather than oxidation and conversion to ketone bodies. Conversely, on high-fat diets or in starvation, when lipogenesis is inhibited, malonyl-CoA concentration is low and CAT I is active. The sensitivity of CAT I to malonyl-CoA generally correlates with the prevailing concentration of the latter.

The short- and medium-chain fatty acids do not utilize the CAT I and II system to enter the mitochondrial matrix and therefore their oxidation is not greatly influenced by the prevailing 'carbohydrate status' (amount of glycogen, direction of carbohydrate flux, glycolysis, or gluconeogenesis) of the liver (**Figure 5**).

**Figure 3** Role of ketone bodies as feedback regulators.

**Figure 4** Pathway of fatty acid catabolism in liver. Enzymes involved: (a) long-chain fatty acyl-CoA synthetase; (b) glycerol-3-phosphate acyl-CoA transferase; (c) CAT I; (d) CAT II; (e) carnitine exchange; (f) short- and medium-chain fatty acyl-CoA synthetase; (g) fatty acid oxidation complex; (h) citrate synthase; (i) acetoacetyl-CoA thiolase; (j) hydroxymethylglutaryl-CoA synthase; (k) hydroxymethylglutaryl-CoA lyase; (l) hydroxybutyrate dehydrogenase; and (m) tricarboxylate cycle.

Insulin can rapidly depress the rate of ketogenesis *in vitro*. This effect is thought to result mainly from its stimulatory action on a key enzyme of lipogenesis, acetyl-CoA carboxylase, which in turn increases the concentration of malonyl-CoA. Glucagon and catecholamines have the opposite effect. Thus hormonal effects can be exerted at both the extrahepatic (lipolysis) and intrahepatic (modulation of lipogenesis) levels.

### Intramitochondrial Regulation

Once the fatty acyl-CoA molecule is attached to the mitochondrial  $\beta$ -oxidation complex there appears to be little regulation exerted until release of the acetyl-CoA fragments. As indicated above, the acetyl-CoA can enter the tricarboxylate cycle and be oxidized to CO<sub>2</sub> or can be converted to ketone bodies via the hydroxymethylglutaryl-CoA pathway.

It appears that in most experimental situations the complete oxidation of fatty acids proceeds at a low, but relatively similar, rate and it is the activity of the hydroxymethylglutaryl-CoA pathway that shows larger changes. This has led to the view that the pathway might be regulated by mechanisms other than substrate supply.

Studies on the expression of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) synthase have shown that both the mRNA coding for the protein and the amount of protein increase during the onset of ketogenic states (fasting, diabetes) and that these changes are rapidly reversed (refeeding, insulin treatment). However, the finding that rates of ketogenesis from medium-chain fatty acids (CAT I and II) do not alter greatly with change in physiological state, if the rate of fatty acid supply is held constant, would seem to rule out appreciable regulation within the hydroxymethylglutaryl-CoA pathway. Indeed, current thinking suggests that the activity of CAT I is

**Figure 5** Inter-relationship between hepatic carbohydrate metabolism, lipogenesis, and ketogenesis. Circled minus signs indicate inhibition by the metabolite.

the primary intrahepatic site for the regulation of fatty acid oxidation and ketogenesis. If there is another important site, particularly during situations associated with the reversal of ketogenesis, it is likely to be proximal to the step catalyzed by this protein (e.g., the supply of fatty acids to the liver). Thus *in vivo* there is little doubt that the primary step that controls ketogenic flux is the rate of long-chain fatty acid release from adipose tissue.

## Function of Ketone Bodies

The major role of ketone bodies is to supply an alternative oxidizable substrate to glucose for the brain in situations where the availability of the latter is impaired (e.g., starvation). In addition, ketone bodies can act as precursors for the acetyl-CoA required in neural lipid synthesis (myelin). Other mammalian tissues, including heart, skeletal muscle, kidney, and lactating mammary gland, can utilize ketone bodies but, in contrast to glucose utilization, no energy can be obtained in the absence of oxygen. In these tissues metabolism of ketone bodies results in the inhibition of glucose utilization and inhibition of the oxidation of pyruvate. The net result is a sparing of carbohydrate for the brain and the strictly glycolytic tissues (erythrocytes, retina).

## Pathways of Ketone Body Utilization

### Mitochondrial Pathway

The major site of ketone body utilization in peripheral tissues is the mitochondria (Figure 6). Although transporters for ketone bodies have been described on the plasma and inner mitochondrial membranes of some tissues, these do not appear to limit the flux. The initiating enzyme for acetoacetate metabolism is 3-oxoacid-CoA transferase:

The resulting acetoacetyl-CoA is cleaved to two molecules of acetyl-CoA by acetoacetyl-CoA thiolase; they are then oxidized in the tricarboxylate cycle.

3-Hydroxybutyrate is converted to acetoacetate by 3-hydroxybutyrate dehydrogenase:

The ready reversibility of the three enzymes of the mitochondrial pathway (Figure 6) means that if the overall system is near equilibrium within the cell *in vivo*, the utilization of the ketone bodies will be dependent on their respective concentrations and on the rate of removal of the products. Thus acetoacetate utilization will be promoted when mitochondrial acetyl-CoA is decreased, whereas an increase in the latter will have the opposite effect. Similarly, oxidation of hydroxybutyrate will increase if the concentrations of NADH<sub>2</sub> and acetoacetate fall. Unlike the hepatic hydroxymethylglutaryl-CoA pathway for ketogenesis, which is essentially irreversible, the free reversibility of this pathway in peripheral tissues can be viewed as means of buffering the

**Figure 6** Pathways of ketone body utilization in peripheral tissues: (1) hydroxybutyrate dehydrogenase; (2) 3-oxoacid-CoA transferase; (3) acetoacetyl-CoA thiolase; and (4) acetoacetyl-CoA synthetase.

mitochondrial acetyl-CoA pool and hence energy production. Some of the acetyl-CoA can be transported to the cytosol in the form of citrate to act as a precursor for lipogenesis (Figure 6).

### Cytosolic Pathway

The cytosol of tissues where active lipogenesis occurs (adipose tissue, developing brain, lactating mammary gland, and liver) contains an enzyme, acetoacetyl-CoA synthetase, which converts acetoacetate to acetoacetyl-CoA (Figure 6):

Its activity is at least an order of magnitude lower than that of the mitochondrial 3-oxoacid-CoA transferase, whereas its affinity for acetoacetate is appreciably higher. The presence of acetoacetyl-CoA thiolase in the cytosol allows the conversion of acetoacetate to acetyl-CoA and then to lipids without the involvement of the mitochondria.

Brain cytosol also contains 3-hydroxy-3-methylglutaryl-CoA synthase, allowing acetoacetate to act as a direct precursor for sterol synthesis. Evidence from *in vivo* experiments with <sup>14</sup>C-labeled acetoacetate has confirmed the existence of this pathway in developing brain and liver. The cytosolic route for acetoacetate utilization can be seen as a mechanism for directing this substrate to lipid or sterol synthesis rather than to oxidation.

## Ketosis

The concentration of ketone bodies in the blood at any time represents a balance between the rate of hepatic ketogenesis and the rate of utilization by peripheral tissues. It is generally assumed that an increase in ketogenesis leads to a rise in blood ketone bodies, which in turn results in their increased utilization. In rare situations, such as congenital absence of key enzymes involved in ketone body utilization (e.g., 3-oxoacid-CoA transferase) or inhibition of these enzymes by pharmacological agents, blood ketone bodies may increase without any concomitant increase in ketogenesis.

The concentration of ketone bodies in the blood is exquisitely sensitive to changes in pathophysiological state. It is therefore useful to define *normoketonemia* in mammals as a concentration of total ketone bodies in blood below 0.2 mmol l<sup>-1</sup>, *hyperketonemia* as above this level, and *ketoacidosis* (ketosis; by analogy to the definition of lactic acidosis) as above 7 mmol l<sup>-1</sup>. In adult mammals there are small but characteristic diurnal variations in ketone body concentrations. Larger increases in concentration occur in humans in response to change in pathophysiological state (Table 1). The concentrations span a 200-fold range and it is this which underlines the important role of ketone bodies as substrates and signals.

### Physiological Ketosis

Physiological hyperketonemia is found in the suckling neonate (high-fat diet of the milk; Figure 1), postexercise (depletion of hepatic glycogen reserves), and after prolonged fasting (more than 24 h; Figure 7). All these situations have in common a low

**Table 1** Range of blood ketone body concentrations in humans

Situation	Ketone body concentration ( $\text{mmol l}^{-1}$ )
Fed normal diet	About 0.1
Fed high-fat diet	Up to 3
Fasted: 12–24 h	Up to 0.3
Fasted: 48–72 h	2.0–3.0
Postexercise	Up to 2
Late pregnancy	Up to 1
Late pregnancy: fasted 48 h	4.0–6.0
Neonate: 0–1 day	0.2–0.5
Neonate: 5–10 days	0.7–1.0
Hypoglycemia	1.0–5.0
Untreated diabetes mellitus	Up to 25

hepatic carbohydrate status (depletion of glycogen or activation of gluconeogenesis) and therefore from a physiological standpoint one would expect an increased rate of ketogenesis. Comparison of the factors that can influence ketogenesis in suckling and fasting (Table 2) shows the expected broad agreement.

More detailed information on the hierarchy of the regulatory factors during onset and reversal of ketogenesis has been obtained for the fasting state by measurements at short time intervals. The first event after withdrawal of food is a lowering of plasma insulin accompanied by an increase in plasma fatty acids (stimulation of lipolysis). However, for an appreciable period (8–10 h) there is no increase in blood ketone bodies or in the *in vitro* rates of hepatic ketogenesis (measured with saturating fatty acid concentrations). The major increment in ketogenic rate occurs at the nadir of the hepatic malonyl-CoA concentrations and when the sensitivity of CAT I to malonyl-CoA starts to increase rapidly. This long time lag before a change in sensitivity of the protein to malonyl-CoA inhibition is thought to be due to the time required to bring about alterations to the lipid environment of the outer mitochondrial membrane.

Confirmation of this view is that on refeeding, when insulin rapidly increases and plasma fatty acids decrease with a parallel decrease in blood ketone bodies, there is again a time lag before malonyl-CoA concentrations rise and a longer one before sensitivity returns. In physiological and nutritional terms this delay of return to the normal feeding settings of intrahepatic regulation makes excellent sense. It is only when the refeeding consists primarily of large amounts of carbohydrate that the starved liver needs to inhibit the activity of CAT I to prevent the oxidation of newly synthesized fatty acids. If the meal consists mainly of lipid with little carbohydrate the activity of CAT I needs to remain high to allow oxidation of the excess fatty acids. Thus the liver must sense a prolonged increase in plasma insulin before the high activity of CAT I is suppressed.

### Pathological Ketosis

The major example of pathological ketosis is of course insulin-dependent or type 1 diabetes. Essentially the changes in this condition are similar to those that occur during fasting, but they are more pronounced. Insulin is absent or very low in the plasma and therefore there is no antagonistic action to restrain the opposing hormones, adrenaline, noradrenaline, and glucagon. Consequently, lipolysis in adipose tissue is greatly stimulated and plasma fatty acids increase to high levels.

**Figure 7** Intertissue fluxes of substrates in the starved state. Thickness of line denotes rate of flux.

**Table 2** Comparison of factors influencing ketogenesis in suckling and fasted states

Factor	Suckling	Fasted
Plasma nonesterified fatty acids	Increased	Increased
Plasma insulin	Decreased	Decreased
Plasma glucagon	Increased	Increased
Hepatic carnitine	Increased	Increased
Hepatic lipogenesis	Decreased	Decreased
Hepatic malonyl-CoA	Decreased	Decreased
Hepatic CAT I activity	Increased	Increased
Sensitivity to malonyl-CoA	Decreased	Decreased

The lack of insulin and the large flux of fatty acids to the liver means that lipogenesis is inhibited at the level of acetyl-CoA carboxylase and there is the expected decrease in malonyl-CoA concentration. In addition, the sensitivity of CAT I to inhibition by malonyl-CoA is considerably decreased. The level of expression of hepatic CAT I and II proteins also increases several-fold in diabetes. Thus the liver is in the ideal mode for producing excessive amounts of ketone bodies.

It has been suggested that diversion of oxaloacetate to hepatic glucose synthesis (which is also increased in insulin deficiency) may also play a role in the increased rate of ketogenesis by diverting acetyl-CoA from the tricarboxylate cycle. However, the present evidence suggests that this makes a minor contribution. Although the excessive output of ketone bodies by the liver undoubtedly makes the major contribution to their high levels in the blood, it is likely that there is also a degree of underutilization by peripheral tissues. The net result is ketoacidosis and excretion of large amounts of energy as ketone bodies in the urine.

A rare, but intriguing, example of pathological ketosis (ketone bodies up to  $10 \text{ mmol l}^{-1}$ ) is the inborn error of hepatic glycogen synthase deficiency (Figure 8). Here glycogen is virtually absent from the liver so that after short-term fasting (5–10 h) the glucose falls to hypoglycemic levels, plasma insulin is decreased, plasma fatty acids increase, and ketogenesis is switched on. On consuming a meal the pattern is reversed until the blood glucose falls again. This case illustrates the importance of hepatic glycogen (and its mobilization) in the smooth transition of substrate supply from the fed to the fasted state. Treatment in this case was to recommend the consumption of more frequent high-carbohydrate snacks. It is of interest that this particular child suffered no ill effects from the daily exposure to high concentrations of ketone bodies, underlining their role as normal substrates for the brain when available.

## Metabolic Acidosis

The great disadvantage of ketone bodies is that both acetoacetate and hydroxybutyrate are relatively strong acids. When they increase to high concentration there is the expected decrease in the blood pH, the plasma hydrogen carbonate concentration, and the partial pressure of carbon dioxide in blood and body fluids. The symptoms of acidosis include malaise, weakness, anorexia, and vomiting and these may eventually lead to coma. Treatment of diabetic ketoacidosis is to give insulin as soon as possible, usually as a continuous intravenous infusion. This rapidly decreases the raised plasma fatty acids and more slowly lowers the blood glucose and ketone bodies. Prolonged starvation, where the blood ketone bodies may reach  $8\text{--}10 \text{ mmol l}^{-1}$ , does not usually cause a serious disturbance of the acid–base balance. Loss of ketone bodies via the urine occurs but is not excessive. The nonenzymic decarboxylation of acetoacetate to acetone and carbon dioxide can be seen as a primitive mechanism for removing the potential acidotic effects of ketone bodies. The fact that acetone can be converted to glucose by the liver at low rates is an extra bonus.

**Figure 8** Diurnal blood metabolite profile of a child with glycogen synthetase deficiency.

The other common form of metabolic acidosis is lactic acidosis. This can arise because of infection, tissue hypoxia (anaerobic glycolysis), can be drug induced (ethanol, hypoglycemic biguanides), or can arise because of a congenital defect (pyruvate dehydrogenase or pyruvate carboxylase deficiency). In addition to the acidosis caused by lactic acid or ketone bodies there is a group of organic acidurias (some 25–30 different types) in which an inborn error results in the accumulation of an organic acid in the blood and urine. However, frank acidosis is not always associated with these conditions. The key investigation is chromatographic identification of the organic acid.

## Overview

Low lactase levels due to genetic nonpersistence is reported in approximately 70% of the world's adult population. The prevalence is lowest in individuals of northern European descent (15%) and highest in many Asian populations with reports approaching 100%. The prevalence of lactase nonpersistence in individuals of African descent is approximately 70% to 80%. Similar levels are reported for Latinos and those of Eastern European and South American ancestry. Not all individuals with a reduced level of the enzyme lactase experience symptoms with the ingestion of dietary lactose. The presence or absence of symptoms varies with the amount and type of food consumed, intestinal transit time and level of residual intestinal lactase. Individuals with low lactase levels may tolerate a moderate intake of lactose.

Uniform agreement regarding the application and definition of terms identifying lactose nonpersistence has been lacking and has led to confusion and controversy. The 2010 National Institutes of Health Consensus conference on lactose intolerance has underscored the use of an agreed terminology. Hypolactasia is defined as a relative diminution, or very low levels of lactase enzyme activity. Lactose malabsorption, identifies a lactose test result following a lactose challenge resulting in an abnormal rise in breath hydrogen resulting from undigested lactose reaching the colon. The undigested lactose may result in one or more of the following symptoms: bloating, abdominal cramps, flatulence, and diarrhea. Lactose intolerance, is the term used to identify individuals with any of the above clinical symptoms resulting from unhydrolyzed lactose. It is a reliable indicator of unhydrolyzed lactose when properly used and interpreted. Milk intolerance, self reported, may be due to lactose maldigestion but may result entirely or partly for other reasons.

The most reliable method for diagnosing lactase deficiency is determining lactase activity in the small bowel. The test is invasive and expensive. Lactose maldigestion can generally be identified by a breath hydrogen test, the most commonly used test to measure the level of undigested lactose reaching the colon. Bacterial fermentation of the undigested lactose is responsible for the volume of breath hydrogen production. A lactose tolerance test measuring blood sugar rise is also used. Genetic testing is available. Lactose elimination trials represent a noninvasive, no cost alternative, albeit often difficult to carry out and interpret. Small bowel bacterial overgrowth can confound results. Individuals experiencing discomfort with lactose ingestion can elect to consume commercially hydrolyzed milk that is readily available, milk substitutes or alternative food sources equally rich in calcium.

## Historical and Geographic Perspective

The first herd animals, sheep, are reported to have been domesticated approximately 10 000 BC. Herd animals were primarily used for meat and perhaps certain other purposes. The historical record suggests that herd animals during this period were not milked. Evidence that humans milked domesticated animals dates to approximately 4000 to 3000 BC, in northern Africa and southwest Asia. Following that time, dairying spread across Eurasia and into sub-Saharan Africa. Dairying was not, however, adopted by all groups in Asia and Africa who had suitable herd animals. Even as late as AD 1500, the beginning of the great European overseas

expansion, there were sizable areas occupied by nonmilking groups. In Africa the zone of nonmilking centered on the Congo Basin but extended beyond to cover approximately one-third of the continent. In Asia the zone of nonmilking covered the bulk of the eastern and southeastern portions of the continent, including Thailand, Vietnam, China, and Korea as well as the islands to the east. Dairying remained unknown in the Pacific region and in the Americas in pre-European times. Animal milk was not part of their diet. At that time the nonmilking people of Asia, Africa, and the Americas consumed mother's milk as infants, but normally ingested no milk after weaning.

It was striking that adults of all groups whose origins lay in the traditional zone of nonmilking were predominantly maldigesters, usually from 75% to 100% of the individuals tested. Also striking was the fact that the people with low prevalences of lactose maldigestion (northwest Europeans and certain East African pastoral groups) came from a long tradition of consuming milk, much of it in lactose-rich forms. This suggests the geographic or culture–historical hypothesis. The hypothesis is based on the assumption that in the hunting and gathering stage, human groups everywhere were like most other land mammals in their patterns of lactase activity. That is, in the normal individual lactase activity would drop at weaning to low levels, which prevailed throughout life. With the beginning of dairying, however, significant changes occurred in the diets of many human groups. As a result, there may have been a selective advantage for those aberrant individuals who experienced high levels of intestinal lactase throughout life. That advantage would have occurred only in certain situations: Where milk was an especially critical part of the diet, where the group was under dietary stress, and where people did not process all their milk into low lactose products such as aged cheese. Under those conditions, most likely to occur among pastoral groups, such aberrant individuals would drink more milk, would benefit more nutritionally as a result, and would enjoy increased prospects of survival, wellbeing, and of bearing progeny and supporting them. In classic evolutionary terms, the condition of high intestinal lactase activity throughout life, or lactase persistence, would come to be typical of such a group.

## Lactase Nonpersistence

In its pure form, lactose can not be transported across the mucosa of the small intestine. To be absorbed, it must be hydrolyzed by lactase to yield glucose and galactose. These two simple sugars are rapidly and completely absorbed in the normal small intestine. The rate of lactase synthesis is high from birth until the age of 3–5 years. However, between ages 5 and 14 years, many people undergo a genetically programmed reduction in lactase synthesis resulting in only 5–10% of the lactase levels in infancy. This reduction, known as lactase nonpersistence or primary lactase deficiency, is not related to the continued intake of milk or lactose. As noted, less than one-third of the world's adult population is genetically predisposed to maintain a high degree of lactase activity or lactase persistence throughout adulthood.

Lactase persistence in the human population is inherited as a dominant genetic trait. It has been observed that low lactase level is “ancient and globally distributed” predating the appearance of a persistent lactase variant that was naturally selected in dairying regions. Hollox *et al.* report, “the continued adult production of lactase results from the persistent expression of the protein lactase-phlorizin hydrolase which is encoded by the lactase gene (LCT) on chromosome 2”. Swallow notes, “the distribution of different lactase phenotypes in human populations is highly variable and is controlled by a polymorphic element cis-acting to the lactase gene. A putative causal nucleotide change has been identified and occurs on the background of a very extended haplotype that is frequent in northern Europeans, where lactase persistence is frequent”.

Lactase persistence is a likely result of the advent of dairying and the result of natural selection. Samples of ancient human mitochondrial deoxyribonucleic acid (DNA) sequences from ancient skeletons in the early Neolithic Europeans support the hypothesis. Investigators did not observe the allele most often identified with lactase persistence in Europeans suggesting lactase persistence was uncommon in early European farmers thereby reinforcing the cultural–historical hypothesis.

## Lactose Digestion and Gastrointestinal Function

Lactose is hydrolyzed at the intestinal jejunal brush border by the enzyme lactase into its absorbable monosaccharides glucose and galactose. Lactase activity is robust during infancy and as is the case in humans along with most mammals declines after weaning. Accordingly, the general pattern of lactase nonpersistence is a continuous decline in genetically programmed populations. A shifting pattern of lactose digestion and gastrointestinal function are the result of lactase nonpersistence. The pattern can be described and monitored during three distinct clinical phases.

First, there is a decreasing ability to digest the large lactose load consumed during the screening test. It is important to recognize that this is not an all or nothing phenomenon but rather a slowly progressive decline in available lactase activity, and that this decline, as earlier noted, can be influenced by transit time, the vehicle in which the lactose is consumed, and the intake of additional foods along with lactose.

Next, with the continued decline of lactase activity, a point is reached when available lactase activity is no longer sufficient to hydrolyze more modest levels of lactose. Therefore, the consumption of a glass of milk or another product containing the equivalent level of lactose will result in incomplete hydrolysis of the lactose consumed. The individuals so tested frequently do not recognize signs or symptoms associated with the incomplete digestion of lactose.

Finally, with the continued decline of lactase activity with increasing age, individuals become symptomatic as a result of the undigested lactose. The decline in available lactase activity reaches a recognizable clinical threshold with increasing age.

Initially, many reports had treated the population studied as a single unit and had paid incomplete attention to age-specific considerations. Distinctions between secondary lactose malabsorption due to short-term intestinal injury, and primary lactose malabsorption that has a genetic basis, were not always made. This introduced additional confounding variables. Differences in an individual's capacity to hydrolyze and tolerate a lactose challenge dose compared to his or her ability to utilize lesser amounts of lactose found in usually consumed amounts of milk created additional areas of confusion.

When attention is paid to the many factors associated with lactose digestion from infancy to old age, it is possible to place many of the seeming contradictions into perspective. What may have appeared to be incongruities in reported data appear to merge into a relatively predictable pattern of lactose digestion.

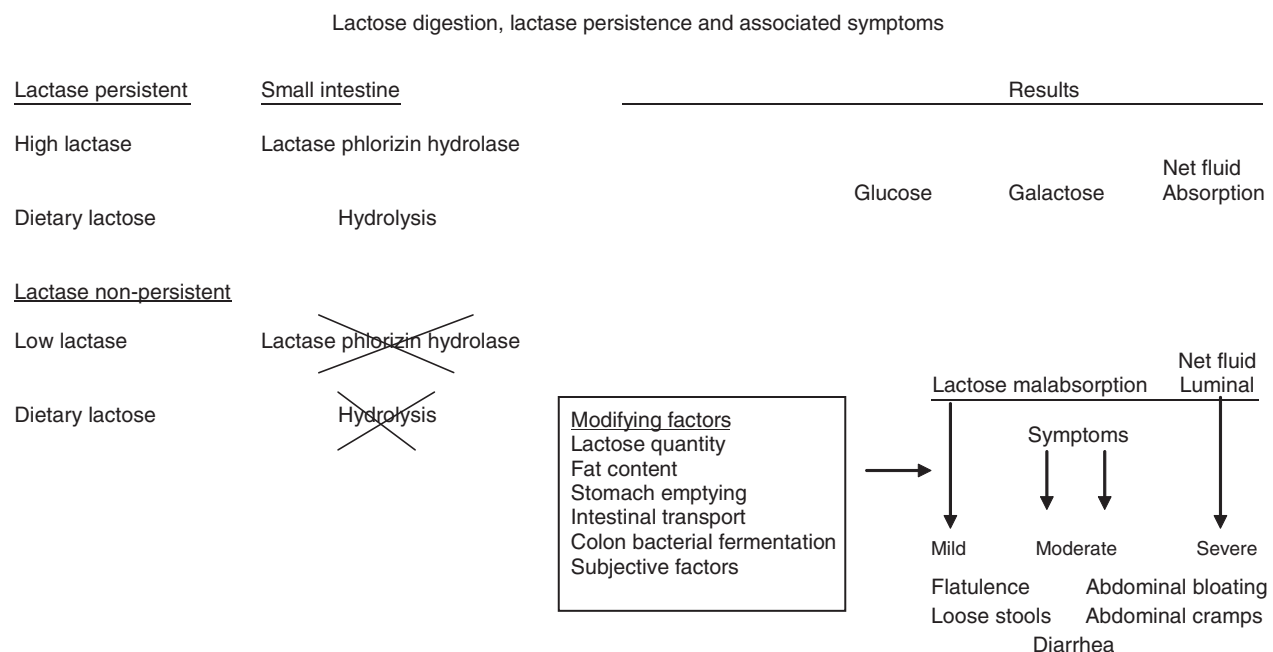

Lactose maldigestion and intolerance are influenced by age, infection, size of the lactose bolus, gastric emptying time, intestinal transit time, individual sensitivities, eating habits, genetics, environment, food ideologies, and cultural patterns. Further, symptoms of lactose malabsorption may also be the result of bacterial fermentation of undigested carbohydrate in the colon. The type and extent of the colonic bacterial profile and the absorption of hydrogen and the volatile fatty acids will influence individual reports of symptoms associated with lactose intolerance. Clearly, lactose malabsorption is not a homogeneous event. Neither is it an all or nothing phenomenon having its origins in a single etiology. Clinical expressions of lactose malabsorption, lactose intolerance, and milk rejection find their origins in one or more of the causes outlined above (Figure 1).

## Prevalence

### Children

A review of reported data on diverse populations support the conclusion that in later childhood and adolescence an important transition in lactose digestion occurs. Below 3 years of age there is lactase persistence. Between 3 and 11 years of age the beginning of a genetically controlled lactose nonpersistence is recognized. Older children and young adults are increasingly unable to digest even modest amounts of lactose. This results in increased symptom production, recognition of discomfort, and avoidance of lactose-containing products that provoke symptoms (Table 1).

A progressive decrease in lactase is noted from approximately 1–5 years of age through adolescence. Reported rates in United States African-American children ranged from 27% lactose maldigestion following lactose testing using a lactose load equivalent to two 8-ounce glasses of milk at 1–2 years to 74% in 11–12-year-old children. The progressive decrease in the ability to hydrolyze a lactose challenge was observed in children of both high and low socioeconomic status. Studies in white children 1–12 years of age identified only 17% of children maldigesting a lactose challenge. Signs and symptom production associated with a reduction in lactose digestion in a child population is difficult to measure due to the nature of the symptoms being reported and the signs observed and the subjective nature of the reports. This is reinforced by a report of 21 African-American girls of 11–15 years of

**Figure 1** Lactose digestion, lactase persistence, and associated symptoms.

**Table 1** Genetically determined lactase levels in healthy individuals by age and lactase persistence

Age	Lactase level	
	Low lactase nonpersistent individual	High lactase persistent individual
Fetal period	Low	Low
Birth	High	High
Weaning	Decline	High
3–12-year-old child	Reduced	High
Adolescent	Low	High
Adult	Lower	Average
Elderly	Lowest	Decline

age indicating 82% had evidence of lactose maldigestion with reports of gastrointestinal symptoms being negligible and breath hydrogen excretion, while remaining high, varied between two time periods. Consistent with the above data, milk consumption studies, both observed and reported, suggest a progressive decline in milk intake with increasing age in the African-American population of children and parallel reports in children from other populations with a high prevalence of lactose maldigestion (Table 2).

Phenotypic lactase nonpersistence needs to be distinguished from secondary lactose maldigestion and intolerance as a result of a variety of other conditions. Secondary lactose maldigestion can be observed with diarrheal disease and infection, celiac disease, allergic enteropathy, Crohns' disease, chemotherapy, radiation, and small bowel resection.

## Adults

The progressive increase in prevalence of lactose maldigestion increases with age reaching reported adult levels of approximately 70% of the world's adult population. The exceptions are populations of northern and central Europeans and some Middle Eastern populations as well as groups of primarily European descent in Australia, New Zealand, and North America. Thus, minority populations in North America and Europe, as well as adult populations in most developing countries are lactose maldigesters (Table 3).

Reported milk drinking patterns of individuals classified as maldigesters vary considerably in adults. Data range from 50% reporting symptoms with one 8-ounce glass of milk, to 75% reporting symptoms with two 8-ounce glasses of milk and 30% reporting not drinking any milk. Nevertheless, caution must be exercised in interpreting reported symptoms and making the diagnosis of lactose intolerance. There can be considerable crossover between individuals who self-identify as intolerant to lactose and are not diagnosed as lactose maldigesters *versus* those in whom the diagnosis was carefully established. More attention to identifying and categorizing symptoms more precisely may help. A recent Finnish study notes flatulence as the most severe symptom in maldigesters whereas abdominal bloating is most frequently reported by individuals self-identifying as lactose maldigesters. Moreover, microbiota may play a role in the presence and intensity of lactose-related symptoms. Data suggest that increased levels of colonic bacteria, as well as their diversity, may play a role, as a result of increased fermentative capacity in reducing the symptoms associated with lactose intolerance.

**Table 2** Patterns of lactose digestion by lactase status

Lactase status	Test results	Symptoms	Lactose intolerance	Milk consumption
Adequate	Normal (–)	0	0	Average (+)
Marginal lactase	+	0/+	0/+	+
Deficiency	–	–	–	–
Moderate lactase	+	0/+	0/+	+
Deficiency	–	–	–	–
Severe lactase	+++	++	++	–
Deficiency	–	–	–	–

Sidney, Phillips, Paige & Bayless.

**Table 3** Prevalence of lactose maldigestion in selected populations

<i>Population</i>	<i>Country</i>	<i>% Lactose maldigestion</i>	<i>Population</i>	<i>Country</i>	<i>% Lactose maldigestion</i>
African-American 18–54 years	USA	75	General 21–65 years	Finland	15

General 20.3 years average	Finland	17	General 17–83 years	Korea	75
Aboriginal	Australia	84	General 15–64 years	Japan	100

### Pregnant Women

The role of lactose digestion in pregnant women is of special interest. Despite the nutritional value of milk during pregnancy, the lactase levels in some individuals in a number of racial and ethnic groups may be insufficient to hydrolyze commonly consumed amounts of lactose resulting in lactose maldigestion and possibly milk intolerance. The Institute of Medicine report notes, that “lactose intolerance among pregnant African-American women may result in their subsequent avoidance of milk”. Other populations may also experience lactose maldigestion and intolerance to milk during pregnancy.

Lactose maldigestion, in pregnant women in our studies as measured by breath hydrogen response to 240 ml of low fat (1%) milk, reinforces the Institute of Medicine's concern with lactose digestion among pregnant African-American women. We report the prevalence of lactose maldigestion in early (13–16 weeks), late (30–35 weeks) and 8 weeks postpartum as 66%, 69%, and 75% respectively. The prevalence in nonpregnant control women was 80% (Table 4).

Accordingly, healthcare providers instructing African-American women on the optimal dietary pattern during pregnancy need to be mindful of a high rate of lactose maldigestion. Implications for fetal growth and development remain to be answered by further study. Furthermore, health providers need to be aware that the presence or absence of symptoms may be unevenly reported by pregnant African-American women; and symptoms do not represent a reliable guide to lactose digestion. Less than 25% of pregnant lactose maldigesting women reported any symptoms with 240 ml of low fat (1%) milk. Symptoms may be further reduced when milk is consumed with other foods. Unanswered is the level of digestion and absorption of a range of nutrients in the consumed milk. Health care providers should discuss with the pregnant woman, her ability to tolerate milk, and where and when appropriate, should educate her as to other food options. In this regard, Kingfisher and Millard report that “Euroamerican staff tended to give advice that was biologically appropriate for them but not for many of their patients, a process reflecting biocentrism”.

### Secondary Lactase Deficiency

Secondary lactase deficiency is distinct from genetically determined loss of lactase with age. Secondary lactase deficiency is frequently associated with diseases of the small intestine. Enteric viruses such as rotavirus and Norwalk agent can induce lactase deficiency by penetration of the enterocyte in the small intestine. Rotaviruses are a principal cause of diarrhea and lactose intolerance

**Table 4** Lactose maldigestion<sup>a</sup> in pregnant and nonpregnant African-American women

<i>African-American women</i>	<i>% Lactose maldigestion</i>
Early pregnancy (13–16 weeks)	66
Late pregnancy (30–35 weeks)	69
Postpartum (8 weeks)	75
Nonpregnant	80

<sup>a</sup>Breath hydrogen rise >20ppm following the consumption of 240 ml of low fat (1%) milk containing 12 g of lactose following an overnight fast.

in infancy. Denudation of the brush border of the jejunal mucosa associated with diarrhea can lead to the loss of the other two disaccharides, maltase and sucrose. Continued diarrhea may also lead to severe complications such as monosaccharide intolerance. Giardiasis and *Ascaris lumbricoides* have also been implicated as contributing to lactose maldigestion. Severe protein malnutrition is frequently associated with lactose maldigestion. Other disease conditions that give rise to secondary lactose maldigestion are celiac disease, gluten-induced enteropathy, and tropical and non-tropical sprue. The mucosal brush border of the small intestine is severely damaged in each case.

## Lactose Digestion and Diet

### Calcium

Dietary calcium is an important element in skeletal development. Dairy products can account for up to three-quarters of dietary calcium in some populations. Milk is a rich source of calcium. Nevertheless, many minorities in the United States and population groups throughout the world drink decreasing amounts of milk after early childhood and little milk as adults. Given the high prevalence of lactose intolerance, alternatives to cow's milk should be identified for those who cannot tolerate lactose and desire a milk alternative. Lactose-intolerant individuals ultimately attribute their discomfort to lactose-containing foods and voluntarily reduce or eliminate their milk intake. Data from National Studies in the United States indicate African-American and Hispanic women have lower intakes of calcium compared with non Hispanic women. An Institute of Medicine Report concludes that the disparity in calcium intake "may be explained in part by the much higher prevalence of lactose intolerance among African-Americans and Hispanics, sometimes resulting in their subsequent avoidance of milk". In general, populations at risk for lactose intolerance report a lower calcium intake as a result of the decline in the intake of milk and milk products. One solution to this problem is to educate lactose-intolerant groups as to alternative calcium-containing foods, reinforce appropriate cultural patterns and dietary practices that include alternatives to milk and identify other culturally acceptable calcium-containing foods. Meeting the calcium requirement with an alternative diet is a challenge but nevertheless is required for many in the community. Although milk may serve as a primary source of calcium, appreciable quantities of calcium can be found in nondairy foods (Table 5).

Clearly it is more difficult to meet the published calcium recommendation with a diet low in whole cow's milk. A review of the tables of food composition reveals a variety of foods that contain acceptable levels of calcium per 100-g portion or other standard portions. Other lactose-modified dairy products including hard cheeses, yogurts, and lactose-modified milk are good calcium sources.

In addition, lactose digestive aids are available and are increasingly used. The digestive aids commercially available include lactase tablets, lactase preparations, lactose-free milk, and prehydrolyzed milk. Live culture yogurt is another alternative to milk. Lactose in yogurt is better digested than lactose in milk. Tolerance to yogurt is thought to be due to the microbial beta-galactosidase activity that digests the lactose.

### Osteoporosis

The role of lactose maldigestion, calcium intake and osteoporosis has been studied. Osteoporosis and osteoporotic fractures are major public health problems. The role of lactose maldigestion and osteoporosis remains unsettled. For example, minority populations consuming small amounts of milk should be at greater risk for osteoporosis. Nevertheless, African-American and Hispanic populations in the United States appear to have a lower risk of developing osteoporosis. Caucasian and Asian women were found to have the highest risk for osteoporosis, with fracture rates of 140.7/1 00 000 and 85.4/1 00 000, respectively. Hispanic and African-American females had lower age-adjusted rates, at 49.7/1 00 000 and 57.3/1 00 000, respectively. A study of gene-identified lactose intolerance in a Dutch Caucasian elderly population is associated with lower dietary Calcium intake and serum Calcium levels but not associated with bone mineral density or fractures. The paradox reinforces the complexity of the disease and the importance of biologic, genetic and as yet undetermined factors in the etiology of osteoporosis.

### Nutrition policy

Apart from the nutritional implications outlined above, there are policy considerations that require attention. Clearly milk has important economic, nutritional, and emotional significance in Western culture, a culture strongly committed to the concept that milk is an ideal food. Yet, lactose digestion should be an important consideration in developing a suitable policy regarding the use of milk and dairy products by the lactose malabsorber and by ethnic or racial groups, among whom high rates of malabsorption prevail. Accordingly, a balance must be struck between dietary guidance and the interests of a diverse population with a large number of lactose maldigesters. For many the continued use of a limited amount of milk may be appropriate and comfortable. For others dietary modification and lactose reduction or elimination may be warranted. The substitution of low-lactose products or alternative foods may be successful. Traditional diets among lactose-maldigesting populations, using little or no milk or dairy products should be respected.

**Table 5** Calcium content in milligrams per 100 g portion or as noted<sup>a</sup>

Canned sardines (3 oz.)	372	Brewer's yeast (2 tbs)	66
Buckwheat pancakes	249	Lobster	65

## Summary

In summary, the principles of genetics and evolution help to explain the emergence of continued lactase activity beyond weaning. Darwin referred to food as a major factor in selective pressures. Lactose digestion illustrates how a certain food, by indirectly favoring the survival of those able to digest that substance, can influence the evolutionary process.

Clinical and nutritional consequences of lactose digestion in adults must be examined in relation to digestion, intolerance, milk rejection, symptoms, and their recognition. Estimates of how frequently milk intolerance is a clinically significant problem in adults vary. The protocol of individual scientific studies can influence interpretation. A balance of factors tend to prevent or minimize symptoms when the stomach, small intestine, and colon can compensate for an increased solute load, but abdominal discomfort or diarrhea occur when these small intestinal and colonic physiologic mechanisms are loaded beyond their capacity. The role of the colonic flora in metabolizing unabsorbed sugar and the importance of colonic salvage of unabsorbed carbohydrate is an important variable in the symptom complex. Secondary lactase deficiency due to infectious gastroenteritis and malnutrition represents a distinct clinical syndrome and must be distinguished from lactose intolerance.

Dietary recommendations must take account of lactose maldigestion. Milk and dairy product consumption will vary among lactose-maldigesting and milk-intolerant individuals. Lactose-reduced or lactose-free products are available to lactose-maldigesting and – intolerant individuals who wish to drink milk and milk-based products. Nevertheless, dietary recommendations must be modified and respectful of those who do not drink milk. Accordingly, appropriate alternatives to milk and other lactose-containing foods must be identified and guidance provided in developing nutritionally equivalent diets.

### Key points

- Understand basic physiology in normal liver and changes in physiology or pathology in liver with disorders.
- Employ general approach to nutritional assessment care of patients with various kinds of liver disorders.
- Translate recent medical literatures, practice-based knowledge, and guidelines to clinical practice to improve the quality of patient care.

### Glossary

**Cholestasis** A condition where bile cannot flow from the liver to the duodenum. It can occur because of an obstruction of the intrahepatic or extrahepatic biliary system, genetic defects, or be acquired as a side effect of several medications

**Dysgeusia** The distortion of the sense of taste

**Gluconeogenesis** A metabolic pathway that results in the formation of glucose from noncarbohydrate carbon substrates such as lactate, glycerol, and glucogenic amino acids

**Glycogenesis** The pathway of glycogen synthesis, in which glucose molecules are combined with chains of glycogen for energy storage

**Glycolysis** The metabolic process that converts glucose into pyruvate

**HELLP** A life-threatening obstetric complication including hemolysis, elevated liver enzymes, and low platelets syndrome

**Hepatoportoenterostomy** A surgical procedure performed on young infants with extrahepatic biliary atresia to allow bile drainage from intrahepatic bile ducts to the small intestine

**Steatohepatitis** A form of liver disease, characterized by fat accumulation and inflammation in the liver

## Introduction

The liver is the largest solid organ and gland in the body, and it plays a major role in complex metabolism and numerous functions, including glycogen storage, lipid and protein synthesis, bile salt production, hormone production, and detoxification. Impairment of the liver can result in numerous consequences throughout the body including nutrition and growth. This article will cover the role of the liver in normal nutrition, including the important functions of bile salt production, macronutrient metabolism, and fat-soluble vitamin absorption, metabolism, and storage. Next the pathogenesis of malnutrition in liver disease will be discussed including the role of the microbiota, starting off with the mechanisms of malnutrition in both acute and chronic liver failure. Specific nutritional issues in liver failure will be addressed, including disturbances in carbohydrates, proteins, and fats metabolism. Nutritional disturbances in the major types of specific liver diseases will be reviewed: hepatocellular, metabolic liver disease, and biliary tract disorders. Nutritional assessment and management of patients with acute, chronic liver disease, and end stage liver disease will be discussed.

## Nutritional aspects and liver physiology in normal liver and liver diseases

### Bile salts

A normal functioning liver will secrete 600–1200 mL of bile to the gall bladder on a daily basis. Bile is composed of bile salts, lecithin, conjugated bilirubin, phospholipids, cholesterol, electrolytes, and water. Bile salts, the predominant component of bile, are synthesized from cholesterol in hepatocytes. The primary function of bile salts lies in its interaction with lipid digestion. Bile salts bind to large fat particles, which alone are insoluble in water, and act on them as an emulsifier, breaking them down into smaller particles called micelles (Fig. 1). Micelles, the product of the fat particle and bile salt structure, aid in the transport of fat to the mucosal membrane for absorption. Cholesterol and fat-soluble vitamins are also incorporated into mixed micelles for proper absorption.

Micellar solubilization is only required for long chain fatty acids. Short and medium chain fatty acids (12 carbons or less) do not require micelle formation for absorption; they enter the portal circulation directly, bound to albumin, and are transferred to the liver

**Fig. 1** Compositions of bile, bile acid excretion, micellar formation in the small intestine, absorption pathways of short, medium, and long chain fatty acids and fat-soluble vitamin, as well as vitamin D metabolism.

for oxidation. Approximately 94% of the micelle forming bile acids are reabsorbed in the ileum and shuttled via the hepatic portal vein bound to albumin back to the liver for re-use.

## Macronutrient metabolism

### Carbohydrates

The liver is responsible for maintaining normal blood glucose concentrations under various metabolic conditions. Among the several metabolic processes that allow this fine regulation are glycogenesis, gluconeogenesis, and glycolysis. The end product of carbohydrate digestion is largely glucose (80%), with the remaining 20% being fructose and galactose; the latter two are quickly converted into glucose in the liver. Once transported into hepatocytes, the glucose molecules are phosphorylated (via glucokinase) and cannot leave the cell unless dephosphorylated with glucose phosphatase. Glucose is either used for immediate energy release or stored as glycogen. Not surprisingly, in a patient with liver disease, glucose intolerance and insulin resistance are common. Cirrhotic patients are prone to developing diabetes. Energy from carbohydrates plays an important role in protein sparing mechanisms, preventing the use of protein as energy.

### Proteins

Protein metabolism occurs in liver, specifically, the deamination of amino acids, urea formation for removal of ammonia, plasma protein synthesis, and in the interconversions between amino acids. Ingested protein is the sole source of the ten essential amino acids, and the primary source of nitrogen necessary for the synthesis of other amino acids. Protein is digested and broken down to amino acids which are absorbed into the circulation and taken to cells throughout the body, primarily the liver where they quickly become combined by peptide linkages. The plasma level of amino acids is tightly controlled and maintained near a constant level. Once the cellular limit of protein storage is met, excess amino acids are degraded and used for energy or stored as fat or glycogen. The liver is the primary site of all amino acid catabolism with the exception of branch-chained amino acid catabolism which occurs in muscle cells. The urea cycle, in which the toxic compound ammonia is converted to urea, occurs solely in the liver. The synthesis of the major plasma proteins albumin, fibrinogen, and globulin also occur in the liver.

Plasma proteins such as albumin and coagulation factors constitute approximately 50% of the proteins synthesized in the liver. In liver disease, decreased synthesis of these proteins has important clinical consequences including ascites from hypoalbuminemia and coagulopathy from decreased synthesis of coagulation factors. In end stage liver disease, hypoglycemia can result from decreased hepatic gluconeogenesis from amino acids. Decreased activity of the urea cycle enzymes result in hyperammonemia and hepatic encephalopathy, the ultimate expression of which can be cerebral edema.

### Lipids

The liver is responsible for the metabolism of lipids via four key processes: fatty acid oxidation for energy, lipoprotein synthesis, the synthesis of cholesterol and phospholipids, and the conversion of carbohydrate to fat for storage. Digested fat is a key source of energy in which after splitting into fatty acids and glycerol, the fatty acid components further split via beta-oxidation into acetyl-CoA. Two molecules of acetyl-CoA become paired together to form acetoacetic acid and are transported to other cells to provide energy in the citric acid cycle.

In cholestatic liver disease there is malabsorption of dietary lipid, and consequent malnutrition. There are experimental data in primates showing that chronic alcohol consumption results in a decrease in liver phospholipids and of phosphatidylcholine. Consequently, the total phospholipid content in the mitochondrial membranes is decreased; mitochondria are altered both structurally and functionally. There is diminished mitochondrial oxidation because of decreased cytochrome oxidase activity, which can be restored by administration of phosphatidylcholine. The extent to which chronic liver disease of etiologies other than chronic alcohol consumption results in similar perturbations is unknown.

### Fat-soluble vitamins

The liver plays a key role in the absorption of the fat-soluble vitamins, A, D, E, and K as they are only successfully absorbed in association with fat and sufficient quantities of bile salts (Fig. 1). The liver is also the primary storage site for several vitamins including vitamin A, E, K, and B<sub>12</sub>. Vitamin A is stored in the largest quantity with amounts sufficient to prevent deficiency for 5–10 months. Stored vitamin D can last for 2–4 months and stored vitamin B<sub>12</sub> can last at least 1 year after cessation of new supply. The liver is responsible for the first hydroxylation of vitamin D to the circulation form, 25-OH vitamin D.

Deficiencies of fat-soluble vitamins are common in liver disease associated with steatorrhea due to the concomitant malabsorption of fat. Vitamin A deficiency can result in anorexia, growth failure, decreased resistance to infections, and night blindness. Vitamin D deficiency results in osteopenia or osteoporosis, as well as rickets in children. The prevalence of fractures is increased

in women with a history of alcohol abuse; deficiencies of vitamin D as well as calcium, phosphorus, and fluoride may all play a role. The deficiency of vitamin E results in neuroaxonal dystrophy, clinically manifesting as peripheral neuropathy and cerebellar disturbances. Vitamin K deficiency results in hemorrhage because of reduced synthesis in clotting factors.

### Trace elements

Zinc deficiency in individuals with cirrhosis may contribute to hypoalbuminemia and dermatitis as well as anorexia from dysgeusia. Deficiency of selenium can lead to decreased synthesis of important antioxidant selenoproteins such as glutathione peroxidase. Little is known about the effect of acute or chronic liver disease on other trace elements.

## Liver in specific hepatobiliary disorders and nutritional management

### Hepatocellular diseases

#### *Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH)*

With the unrelenting rise in obesity worldwide, NAFLD and NASH have become very important causes of liver disease in both children and adults. Children with NAFLD may present before their fifth birthday, with a higher prevalence in male children. Hepatic fibrosis can occur and may even evolve into cirrhosis during childhood. Treatment consists of weight reduction and aerobic exercise. Practice guidance from the American Association for the Study of Liver diseases (2018) discussed though management of NAFLD/NASH (Chalasani et al., 2018).

In adults, NASH and NAFLD have been recognized for at least half a century as chronic liver diseases associated with obesity (with or without noninsulin-dependent diabetes mellitus and with or without hyperlipidemia). NAFLD may account for as much as 80% of cases of elevated liver enzymes in the US. Most adults with the disorders are 110–130% above ideal body weight. The prognosis of NAFLD is good if weight reduction is achieved. NASH is usually slowly progressive but can lead to cirrhosis and the need for liver transplantation in the minority of individuals affected. Progression from non-alcoholic fatty liver to NASH can be influenced by diet and gut microbiota, but there is also genetic predisposition, particularly the presence of the PNPLA3 which is associated with NASH development.

In many patients, NAFLD is a component of the insulin-resistance syndrome known as metabolic syndrome, which is characterized by central obesity, hypertension, hypertriglyceridemia, low levels of high-density lipoprotein-cholesterol, and hyperglycemia. In patients with this syndrome, it is hypothesized that there is greater insulin resistance in muscles and adipose tissue than liver. Those with the BMI class  $>30 \text{ kg m}^{-2}$  have an increased prevalence of each of the five components of the metabolic syndrome. Patients with NASH tend to exhibit a higher intake of saturated fatty acids, total fat, and cholesterol, and a lower intake of polyunsaturated fat, fiber, and vitamins E as an antioxidant. These findings provide a strong rationale for specific dietary modifications in NASH patients. A daily deficit of 500–1000 calories and approximately 150 min per week of aerobic exercise is recommended. Approximately 10% weight reduction from a baseline at a rate of approximately 1–2 pounds a week is generally the successful principle of weight management. Certain foods associated with NAFLD such as sodas and red meats should be avoided, and nuts which are associated with reduced risk of NAFLD should be encouraged (Fig. 2). Primary care physicians should screen for NAFLD in high-risk populations and implement the above therapy along with behavior modification programs as first line treatment. Other therapies include weight-loss medications, protein-sparing modified fasting, and weight-loss surgeries in those who have morbid obesity.

Probiotics are an emerging therapy for NAFLD. Patients with NAFLD have abnormal gut microbiota. They have much fewer Bacteroidetes and greater amounts of *Prevotella* and *Porphyromonas* compared to healthy subjects. Additionally, they have elevated concentrations of *Lactobacillus*, *Escherichia*, and *Streptococcus* and diminished levels of *Ruminococcaceae* and *Faecalibacterium prausnitzii*. These changes may lead to increased activity of toll-like receptors and nucleotide-binding oligomerization domain pathways, resulting in an alteration of the tight junction multiprotein complexes and leading to increased gut permeability. In NASH, high-fat diet can change the composition of the gut microbiota, reducing the prevalence of protective intestinal bacteria and favoring opportunistic pathogenic Gram-negative species that produce lipopolysaccharides that can enter the portal circulation. There, the lipopolysaccharides can bind to toll-like receptor 4 and other co-receptors in the liver associated with inflammation, resulting in NASH development. In rodent models, ingestion of fructose has been shown to increase bacterial endotoxin levels in the plasma. In addition to probiotics, prebiotics such as dietary fiber are considered to have positive effects on health status due to its fermentation into short chain fatty acids by intestinal bacteria.

### Alcohol-associated liver disease

The term alcohol-associated liver disease refers to a spectrum of types of hepatic injury associated with continuous alcohol consumption, ranging from alcoholic fatty liver, alcoholic steatohepatitis, cirrhosis, and hepatocellular carcinoma, typically progressing in that order. Nutritional disturbances in alcoholics are an important cause of morbidity and mortality; all classes of nutrients are affected. Anorexia leads to decreased food intake and subsequent protein-calorie malnutrition. Maldigestion and

**Fig. 2** Influence of various foods on the development of nonalcoholic fatty liver disease (NAFLD). Red meat and soft drinks increase likelihood of NAFLD, nuts decrease likelihood of NAFLD, and fish, legumes, refined grains, whole grains, eggs, dairy, fruits, and vegetables do not change likelihood of NAFLD.

malabsorption can occur secondary to chronic alcohol injury to the small intestinal mucosa. Alcohol consumption is often associated with chronic pancreatic insufficiency which results in steatorrhea and decreased absorption of dietary protein, fat, and fat-soluble vitamins. Chronic alcohol consumption also results in impaired hepatic amino acid uptake and protein synthesis.

In alcoholics, utilization of lipids and carbohydrates is markedly compromised due to an excess of reductive equivalents and impaired oxidation of triglycerides. Alcoholics are often resistant to insulin and exhibit impaired uptake of glucose into muscle cells. Insulin-dependent diabetes is common. Heavy alcohol consumption is frequently associated with deficiencies of a wide variety of micronutrients including the fat- and water-soluble vitamins, particularly folate, pyridoxal-5'-phosphate, thiamine, and vitamin A.

**Table 1** summarizes the five published controlled trials of the effect of oral or enteral nutritional supplements on patients with alcoholic hepatitis. In most, nitrogen balance and protein synthesis improved, although no effect on mortality was shown, perhaps because of the small number of patients studied or the duration of follow-up. In the largest study, at 1 year of follow-up, the experimental group had a significantly better survival: 2/24 or 8% died as compared to 10/27 or 37% of the controls. In general, the effects of parenteral nutrition in alcoholic liver disease are similar to enteral nutritional supplements.

Many studies have examined the effect of oral or enteral nutritional supplementation in patients with alcoholic cirrhosis. Results are summarized in **Table 2**. Many studies are small and of short duration, so it is not surprising that results are inconclusive. Most studies demonstrated an improvement in nitrogen balance and protein synthesis; only one showed increased survival in the treated group. Taken together, these studies suggest that there are benefits to nutritional supplementation in this population. In addition, meta-analyses of nutritional support indicated an improvement in hepatic encephalopathy and fewer episodes of infections. However, more recent trial which compared intensive enteral nutrition to conventional nutrition did not demonstrate additional survival benefit of intensive nutrition. There was an association of increased rates of infection and mortality at 6 months when daily calorie intake was less than  $21.5 \text{ kcal kg}^{-1} \text{ day}^{-1}$  (Crabb et al., 2020).

A variety of international associations have made nutritional recommendations for patients with various types of alcoholic liver disease. The primary and most important recommendation is abstinence, which may be all that is needed in patients with fatty liver. There is no safe amount of alcohol that can be consumed without risk. Weight loss is also an important lifestyle change that patients should implement. Alcohol in combination with obesity is known to synergistically induce liver injury, cirrhosis, and hepatocellular carcinoma. Patients with alcoholic hepatitis should take  $40 \text{ kcal kg}^{-1}$ ,  $1.3\text{--}1.5 \text{ g protein kg}^{-1}$ ,  $4\text{--}5 \text{ g kg}^{-1}$  of carbohydrates, and  $1\text{--}2 \text{ g kg}^{-1}$  of lipids per day. Those with cirrhosis without malnutrition should take  $35 \text{ kcal kg}^{-1}$ ,  $1.3\text{--}1.5 \text{ g protein kg}^{-1}$  and carbohydrates and lipids as recommended for patients with alcoholic hepatitis. Those with cirrhosis and malnutrition should take higher amounts of protein ( $1.5\text{--}2.0 \text{ g kg}^{-1}$ ) and lipids ( $2.0\text{--}2 \text{ g kg}^{-1}$ ) and lower amounts of carbohydrates ( $3\text{--}4 \text{ g kg}^{-1}$ ). Fluid should be restricted to  $2\text{--}2.5 \text{ L day}^{-1}$ ; B-vitamins, folate, thiamine, vitamins C, and K should be routinely supplemented. In addition, patients with cholestasis should take 50% of their dietary lipids as medium chain triglycerides and should be supplemented with the fat-soluble vitamins: A, D, E, and K. The major strategy in the management of alcoholic cirrhosis with ascites and edema is to restrict fluids to  $1\text{--}1.5 \text{ L day}^{-1}$  and to restrict sodium as well. Emerging therapies for alcoholic liver disease include probiotics, farnesoid X

**Table 1** Studies on therapy of alcoholic hepatitis with oral or enteral nutritional supplements.

<i>Design</i>	<i>Patients (n)</i>	<i>Duration (days)</i>	<i>Experimental treatment (EXP)</i>	<i>Control Treatment (CTR)</i>	<i>Mortality</i>	<i>Secondary endpoints</i>
Open label	16	16–42	Oral (standard hospital diet) or intravenous supplement (51.6–77.4 g protein)	None	Not assessed	Nitrogen balance + albumin improved in EXP, CTR not assessed improvement of albumin. Transferrin. RBP
Historical controls	57	30	Standard hospital diet (2500 kcal day <sup>-1</sup> ) + 2200 kcal day <sup>-1</sup> BCAA	Standard hospital diet	NS	Positive nitrogen balance in EXP, delayed hypersensitivity improved
Randomized, controlled	64	21	Standard diet (~2000 kcal day <sup>-1</sup> ) + 65 g standard AA or BCAA	Standard diet, 80 g protein day <sup>-1</sup>	NS	Positive nitrogen balance in EXP, delayed hypersensitivity improved
Crossover	14	6	Nasoduodenal tube, 35 kcal kg <sup>-1</sup> day <sup>-1</sup> , fat/carbohydrate/protein 45/40/15%	3 days standard hospital diet (35 kcal kg <sup>-1</sup> day <sup>-1</sup> )	0/6 contrs. 3/8 treatm	Nitrogen balance improved fivefold at 2 weeks
Randomized, controlled	71	28	Nasogastric tube, 2000 kcal day <sup>-1</sup> , 72 g protein day <sup>-1</sup> , 31% BCAA	Standard diet (1 g protein per kg) + 40 mg day <sup>-1</sup> prednisolone	11/35 TEN 9/36 PRED NS FU: 2/24 TEN 10/27 ( <i>P</i> = 0.04)	No dropouts in PRED, 8 dropouts in TEN; equal improvements of albumin, Child score, Maddrey score; equal rate of infections

receptor (FXR) agonists, and sodium/glucose cotransporter 2 (SGLT2) inhibitors. Practice guidance from the American Association for the Study of Liver diseases (2019) discussed though management of alcohol-associated liver disease (Crabb et al., 2020).

## Viral hepatitis

Patients with acute viral hepatitis are generally not at risk for nutritional deficiencies but they do experience anorexia and cholestasis resulting in a brief period of malabsorption. Patients chronically infected with hepatitis B and C viruses (HBV, HCV) may develop cirrhosis over 10–20 years with of the potential to develop hepatocellular carcinoma. Patients with chronic viral infection with significant alcohol intake, insulin resistance, obesity, cholestasis, cirrhosis, and cancer require additional nutritional assessment as mentioned in other sections of this article. Hepatic steatosis, obesity, and alcohol consumption are risk factors for antiviral treatment failure to achieve virologic response. Antiviral treatment for HBV and HCV with interferons could cause anorexia and further nutritional deficiency. HIV patients who have chronic HBV and HCV co-infection are expected to acquire more nutrient deficits.

## Autoimmune hepatitis

Autoimmune hepatitis most frequently presents itself in both children and adults with a female preponderance. The nutritional assessment and therapy are not different from those of other types of hepatitis. The disease can be accompanied by intestinal diseases such as inflammatory bowel disease or celiac disease, and the nutritional management should take both organ systems into account. Although mild liver function abnormalities are common in celiac disease, there are recent reports of celiac disease in patients with severe liver disease, all of whom demonstrated an improvement in their liver disease with introduction of a gluten-free diet. Recent knowledge has appreciated the influence of the gut microbiota on liver via the gut-liver axis (Fig. 3). Disruption in normal microbiota composition may increase risk of autoimmune hepatitis.

## Hepatobiliary disorders

### Neonatal and infantile cholestatic disorders

Cholestasis is a condition that affects one in 2500 infants; it caused by poor bile flow resulting in increased concentrations of serum bile acids and conjugated hyperbilirubinemia. The major differential diagnoses of conjugated hyperbilirubinemia in the first 30 days of life are extrahepatic biliary atresia, infectious neonatal hepatitis from viruses, bacteria, and parasites as well as the neonatal hepatitis syndrome, for which a large number of specific genetic disorders have now been identified. These include alpha-1-antitrypsin deficiency, progressive familial intrahepatic cholestasis (PFIC I–III), inborn errors of bile salt synthesis, cystic fibrosis-associated liver disease, Alagille syndrome, hypothyroidism, panhypopituitarism, and other neonatal cholestatic

**Table 2** Studies on treating alcoholic cirrhosis with oral and enteral nutritional therapy.

Design	Patients (n)	Duration (days)	Experimental treatment (EXP)	Control treatment (CTR)	Mortality	Secondary endpoints
Randomized, double-blind, crossover	8	12	BCAA (50%) formula	Standard diet (18% BCAA)	1 death (infection)	EXP equal to CTR positive nitrogen balance
Open label	10	4	40 g protein + 40 g BCAA formula day <sup>-1</sup>	2100 kcal day <sup>-1</sup> 80 g protein day <sup>-1</sup>	None	EXP equal to CTR positive nitrogen balance
Randomized, controlled	36	28	50 kcal kg <sup>-1</sup> , 1.5 g protein day <sup>-1</sup>	Standard diet	EXP 2/17 CTR 5/19 (NS)	No differences child score
Randomized, controlled	35 (23 alc.)	23–35	211 kcal day <sup>-1</sup> including 71 g BCAA formula	Standard diet	Improved (P = 0.02)	Improved, albumin improved
Randomized	64	90	Standard diet + BCAA supplement (0.24 g kg <sup>-1</sup> )	Standard diet + casein supplement	None	Nitrogen balance improved in both. BCAA better than standard diet
Randomized	31	28	Casein supplement (1.5 g protein day <sup>-1</sup> , 40 kcal day <sup>-1</sup> kg <sup>-1</sup> day <sup>-1</sup> )	Standard diet	NS	Both groups improved nitrogen balance and albumin
Randomized, controlled	51	12 (months)	Standard diet + casein supplement (1000 kcal day <sup>-1</sup> , 34 g protein day <sup>-1</sup> )	Standard diet	EXP 3/26 CTR 6/25 (NS)	Fewer hospitalizations, improved albumin and visceral protein
Open label	15	38	Increasing amounts of protein via standard diet (1.0–1.8 g kg <sup>-1</sup> day <sup>-1</sup> )	None	None	Increased protein retention through gradual or protein intake
Open label	26	30	Standard diet	None	None	Anthropometric ratios improved
Open label	31	6 (months)	Standard diet + casein supplement (1000 kcal day <sup>-1</sup> , 34 g protein day <sup>-1</sup> )	None	6 deaths/31	Increased albumin, improved cellular immunity

Abbreviations used are as follows: BCAA, branched-chain amino acid; CTR, control group; EXP, experimental group; HRF, hepatorenal failure; NS, not significant.

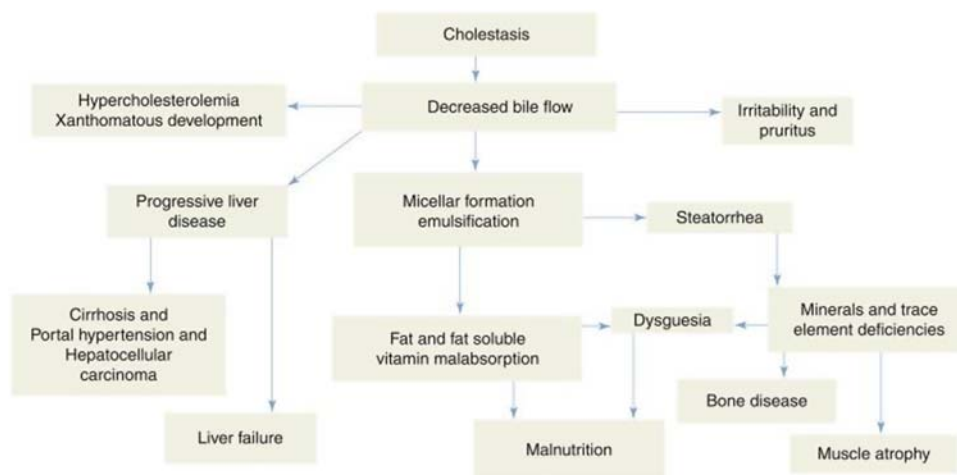

syndromes. Cholestasis and malabsorptive complications usually resolve when the specific treatment is applied in a timely manner; however, children with PFIC and Alagille syndrome tend to suffer from cholestasis and malnutrition without specific therapy such as biliary diversion (in some children with PFIC I and Alagille syndrome) and liver transplantation. Despite hepatoportoenterostomy, which if performed before 60 days of age may at least delay disease progression, these infants often develop malabsorption of fat and fat-soluble vitamins secondary to decreased bile flow and fat emulsification (Fig. 4). Aggressive formula feeding in early infancy period may be needed via nasogastric tube feeding with a high medium chain triglyceride containing infant formula. In other biliary obstructive conditions such as choledochal cyst, bile duct stricture, choledocholithiasis, and tumors or masses (intrinsic and extrinsic) in hepatobiliary regions, a surgical intervention may completely reverse cholestasis and nutrient malabsorption (Tessitore et al., 2021).

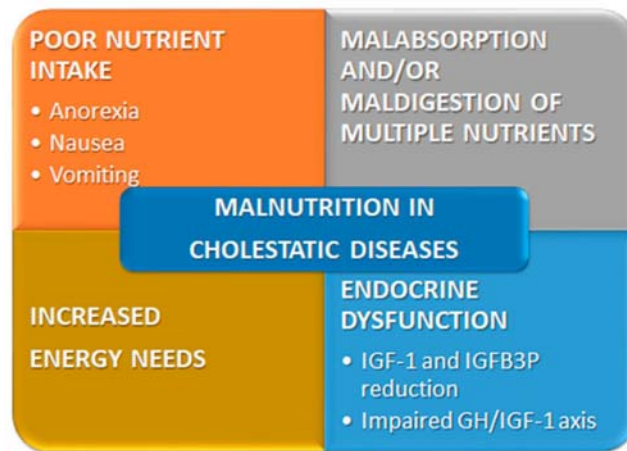

Malnutrition in cholestasis, particularly chronic cholestasis, are influenced by four major factors: poor nutrient intake, malabsorption/maldigestion, increased energy needs, and endocrine dysfunction (Fig. 5). Poor nutrient intake may be due to anorexia which could be caused by a change in amino acid metabolism, resulting in increased tryptophan levels and consequently increased brain serotonergic activity, potentially affecting regulation eating behavior. Malabsorption is due to that lack of bile acids, decreasing the absorption of fats and fat-soluble vitamins. Increased energy need in these patients is thought to be due to a hypermetabolic state induced by thyroid hormone activation by bile acids. Endocrine dysfunction can occur due to decreased production of insulin-like growth factor 1 (IGF-1) and IGF binding protein 3 (IGF-BP3), both produced in the liver, decreasing growth hormone activity and resulting in growth failure in these patients. The nutritional consequences are much the same for all—steatorrhea and malabsorption of the fat-soluble vitamins. Nutritional management is also much the same for all: use of a hydrolyzate or elemental formula rich in medium chain triglyceride and supplementation with vitamins A, D, E, and K, and possibly with additional micro-nutrients such as zinc, iron, magnesium, and calcium. Medium chain triglyceride should be administered with long chain triglycerides in a 1:1 ratio; although long chain triglycerides are poorly absorbed in these patients, some do ultimately get absorbed. Infants and children with cholestasis require higher protein intake than healthy individuals to ensure positive protein balance; diets enriched in branched chain amino acids may be beneficial. Carbohydrates are a major source of energy in these patients. Short chain polymers such as maltodextrin are typically given, but starch can also be administered although bloating and diarrhea may occur in very young patients due to their immature amylase. Water-miscible vitamin E is poorly absorbed; administration of vitamin E solubilized in polyethylene glycol succinate is a more effective way to administer vitamin E to cholestatic infants. Simultaneous administration of other fat-soluble vitamins with this form of vitamin E is expected to improve them as well. To better tailor supplementation, routine monitoring of vitamin concentration every 3–6 months is recommended for infants with cholestasis, or monthly for those with severe cholestasis. Infants with biliary atresia are more likely to have vitamin deficiency, particularly vitamin D deficiency (~82%), despite supplementation relative to other cholestasis etiologies. Ursodeoxycholic acid (UDCA) is the major bile acid from the black bear and has been used in traditional Asian medicine for centuries for the treatment of hepatobiliary diseases. Synthetic UDCA has been used effectively in children and adults with cholestasis to improve bile flow and nutrient malabsorption. After resolution of cholestasis, vitamin supplementation may be discontinued if serum vitamin concentrations are normal with routine monitoring early on.

### Parenteral nutrition-associated liver disease

Premature infants and children with short bowel syndrome are particularly prone to develop this disorder and in the pediatric age group, parenteral nutrition -associated liver disease is usually cholestatic. The cholestasis can be solely intrahepatic or can be

**Fig. 4** Altered physiology of liver and bile flow (cholestasis) leads to nutrient malabsorption, malnutrition, and progressive liver disease.

**Fig. 5** Major factors that determine malnutrition in pediatric chronic cholestatic liver disease. GH: growth hormone; IGFB3P: insulin-like growth factor binding protein 3; IGF-1: insulin-like growth factor-1. This figure is reproduced under the Creative Common CC BY license from Tessitore, M., Sorrentino, E., Schiano Di Cola, G., Colucci, A., Vajro, P., Mandato, C., 2021. Malnutrition in pediatric chronic cholestatic disease: an up-to-date overview. *Nutrients*. 13(8), 2785. <https://doi.org/10.3390/nu13082785>.

associated with cholelithiasis. Parenteral nutrition-associated liver disease can be seen at any age and with any disease etiology resulting in long-term dependence on parenteral nutrition; in adults and older children, steatosis is more common as an initial presentation rather than cholestasis. Potential pathogenetic mechanisms include the gastrointestinal dysfunction associated with the lack of enteral nutrients as well as components of the parenteral nutritional solutions as potential hepatotoxins including amino acids, glucose, lipids (particularly peroxidizable lipids), and photo-exposed multi-vitamins. The most effective management is aggressive administration of enteral nutrients and decrease or discontinuation of parenteral nutrition as early as possible. Providing intravenous fat as fish oil, as well as limiting the overall amount of intravenous lipid may also help in minimizing liver damage seen in association with parenteral nutrition.

### Cholestatic diseases in adults

Primary sclerosing cholangitis most commonly presents itself in association with ulcerative colitis, less commonly with Crohn's disease. The nutritional management of the disorder is essentially like that of other cholestatic disorders; in patients with Crohn's disease of the small bowel, aggressive administration of an elemental diet rich in medium chain triglycerides may be beneficial. Primary biliary cirrhosis, a disease generally presenting itself in young female adults, results in steatorrhea and malabsorption of the fat-soluble vitamins (Fig. 4). Osteoporosis and osteopenia are common. Other cholestatic diseases include common bile duct obstruction secondary to stone, stricture, parasitic infestation, and pancreatobiliary tumors or cancers. It is accepted however that endoscopic interventions should be used as needed in the case of significant biliary obstruction. For prevention of severe osteoporosis supplementation with vitamin D and calcium are needed. Vitamin K and alendronate may be beneficial in increasing bone mineral density. Serum levels of the fat-soluble vitamins should be monitored in high-risk patients and vitamins replaced as appropriate.

### Metabolic liver disorders

Metabolic diseases or inborn error diseases of metabolism mostly are an autosomal recessive disorder resulting in an enzyme deficiency (Table 3). In general, a restriction of the responsible substances which cause abnormal metabolic pathways and noxious intermediates will diminish organ damages such as in galactosemia, hereditary fructose intolerance, tyrosinemia type 1, and urea cycle defects. Liver function improves by galactose and lactose elimination in individuals with galactosemia. The international guidelines for galactosemia treatment, published in 2017, recommend elimination of sources of lactose and galactose from dairy products but allowing small amounts of galactose from fruit, legume, vegetable, or mature cheese (<25 mg/100 g). Despite restriction, long-term complications such as mental disability, speech defects, ovarian failure, and neurologic syndromes can still occur as a result of endogenous production of galactose or minimal exposure to nondairy galactose-containing dietary sources. Some patients with galactosemia could tolerate galactose later in life, and reduction in diet restrictions should be strictly discussed with their physicians and dietitians. Adequate calcium supplements should be considered in this population. Asymptomatic heterozygous mothers should be recommended to avoid dietary galactose during subsequent pregnancies.

**Table 3** Summary of metabolic liver diseases, management, clinical and laboratory monitoring.

<i>Metabolic disorders</i>	<i>Metabolic defects</i>	<i>Management</i>	<i>Laboratory and clinical monitoring</i>
Galactosemia	Galactose-1- phosphate, toxic metabolite accumulates in liver and other organs	Elimination of galactose and lactose (mainly dairy products and breast milk). Appropriate commercial infant formulas (soy formula, lactose- free formulas) for infants. For complete elimination grains, fruits, and vegetables contain galactose such as American persimmon, papaya, tomato, watermelon, etc. Calcium and vitamin D supplementation possible.	Serum glucose for hypoglycemia as a complication in acute phase. Urine reducing Substance, serum galactose for compliant issues IQ test. Infertility from ovarian failure. Bone mineral density. Eye exam for cataracts.
Hereditary fructose intolerance	Accumulation of fructose-1- phosphate in the liver caused by aldolase B deficiency. This substance is a competitive inhibitor of phosphorylase which regulates the conversion of glycogen to glucose	Breast milk and sucrose-free formulas for infants. Restriction of fructose, sucrose, and sorbitol. Only certain vegetables are permitted. Commercial products, medication, and toothpaste may contain small amounts of sucrose.	Monitor growth, liver span, and intellectual development. Renal tubular function needs to be monitored in long-term fructose exposure. No biochemical method for monitoring fructose restriction. Monitor growth, liver span, and intellectual development.
Glycogen storage disease (GSD) (I, III, IV, VI, and IX)	Correct hypoglycemia (less in GSD IV), lactic acidosis, hyperuricemia (in type I), and hyperlipidemia	Continuous nocturnal nasogastric/ gastrostomy tube feeding with formula in infants. Uncooked corn starch (1–2 g kg <sup>-1</sup> every 4 h) in older children and adults. High protein diet (3 mg kg <sup>-1</sup> day <sup>-1</sup> ) in GSD type III only. NTBC in association with dietary treatment.	To maintain normal serum glucose, lipid profile, and especially lactic acid and uric acid in GSD I. Benign and malignant hepatic adenoma in GSD I and III.
Hepatorenal tyrosinemia I	Defects of tyrosine metabolism	Restriction of phenylalanine and tyrosine, and methionine (only if prolonged hypermethioninemia is observed). Low phenylalanine and tyrosine containing formula. Optimal protein diet.	To monitor plasma amino acid profile. To normalize plasma tyrosine and ensure normal growth.
Urea cycle disorders	Deficiencies of urea cycle enzymes	Restriction of upstream essential nutrients to prevent intoxication and supplementation of downstream nutrients. Arginine substitution in severe ornithine transcarbamylase (OTC) deficiency and carbamyl-phosphate-synthetase (CPS)-I deficiency. Avoid catabolism. Ammonia removal with sodium benzoate. Vitamin supplementation (folate and trace elements). Carnitine supplementation if low. Sufficient fluid intake. Avoid hidden nitrogen, e.g., licorice. Liver transplantation in severe OTC and CPS deficiency. Gene therapy (future). Routine phlebotomy if serum ferritin >200g L <sup>-1</sup> in female, >300g L <sup>-1</sup> in male (limited data in children).	Serum ammonia. Urine orotate (defect beyond CPS). Plasma amino acid. Serum electrolytes (hypokalemia from sodium benzoate). Hemoglobin, serum iron, ferritin, and transferrin saturation.
Hemochromatosis	HFE mutation	Low-iron diet. Avoid vitamin C and medications or vitamin supplements containing iron.	To maintain ferritin level <50 µg L <sup>-1</sup> . To document hepatic iron depletion by

**Table 3** Summary of metabolic liver diseases, management, clinical and laboratory monitoring.—cont'd

<i>Metabolic disorders</i>	<i>Metabolic defects</i>	<i>Management</i>	<i>Laboratory and clinical monitoring</i>
Wilson's disease		Copper-restricted diet (copper enriched diet includes chocolate, nuts, legumes, mushrooms, shellfish, and liver).	Liver biopsy or Magnetic Resonance Imaging (MRI).
	Copper accumulation	Copper chelating agents (trientine, D-penicillamine, and zinc).	Total serum copper, ceruloplasmin, urinary copper excretion.
	Secondary to mutations in ATP7B, a copper-binding ATPase	Vitamin E as adjuvant therapy. Vitamin B <sub>6</sub> (pyridoxine) 25–50 mg day <sup>-1</sup> for individuals using D-penicillamine as a chelator. Liver transplantation in severe or fulminant liver disease. Carbohydrate loading with intravenous glucose.	Serial eye exam in individuals with Kayser-Fleischer rings before therapy. To monitor peripheral neuropathy.
Hepatic porphyria (acute intermittent porphyria)	HMB-synthase deficiency	Avoid certain drugs (enzyme inducers), stress, fasting, menstruation, and alcohol. Hematin.	Long-term risk for hypertension, renal insufficiency, and hepatocellular carcinoma.

Infants with tyrosinemia type 1 not only require instant restriction of phenylalanine and tyrosine but also titration of protein intake to allow normal growth and development and to avoid tissue catabolism. The current recommendation is the specific treatment with 2-(2-nitro-4-(3-trifluoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC) coupled with a tyrosine- and phenylalanine-restricted diet including several commercial products containing tyrosine and phenylalanine-free amino acid mixtures supplemented with vitamins and minerals.

Urea cycle disorders present varying degrees of hyperammonemia. In the neonatal period, these disorders present dramatically, with somnolence, poor feeding, vomiting, lethargy, seizures, and even coma from hyperammonemia. In adults and older children, the presentation may be subtler and begin with chronic vomiting, developmental delay, seizures, psychiatric illness, postpartum decompensation, and hyperammonemia associated with valproate therapy, protein overconsumption, or increased catabolism.

Citrin deficiency, or neonatal-onset type II citrullinemia, is a relatively new genetic disorder caused by a homozygous or compound heterozygous mutation in the SLC25A13 gene. With several metabolic abnormalities, different clinical manifestations range from cholestasis, fatty liver, and growth retardation in infancy, to liver dysfunction and neuropsychiatric features in childhood and adulthood. Citrin deficiency is a self-limiting condition in almost all infants, and improving with age. Severe liver dysfunction requiring liver transplantation has been reported. Excessive intake of carbohydrate leads to various symptoms such as fatigue, anorexia, weight loss, neuropsychiatric symptoms, and liver failure, particularly in adult-onset type II citrullinemia. A low carbohydrate intake and a protein- and fat-rich diet with a protein–fat–carbohydrate ratio of 15–25%:40–50%:30–40% are recommended.

As a result of the impairment of NADH shuttling and glucose metabolism, patients with citrin deficiency have an aversion to carbohydrates and a unique preference for high-protein and high-fat foods, in contrast to patients with other urea cycle defects.

In hepatic porphyria, patients usually present neurologic, cutaneous, and gastrointestinal symptoms (especially acute intermittent porphyria) and mild elevation of transaminases.

## Pregnancy and liver disease

Maternal health during pregnancy greatly affects fetal growth and development as well as long term outcomes for both the fetus and the mother. In general, pregnant women lack adequate knowledge on nutrition and would mostly benefit from consultation with trained nutrition practitioners. In pregnant women, due to estrogen effects, serum concentration of triglycerides, low-density and very-low-density lipoproteins, and cholesterol may be twice as high as that of nonpregnant women of the same age.

During pregnancy liver size and histology do not alter. The development of esophageal varices may occur in pregnant women with chronic liver disease as a result of an enlarging uterus creating an increase in venous return from the inferior vena cava to the azygous system. Liver diseases which can evolve as a consequence of pregnancy include intrahepatic cholestasis of pregnancy, acute fatty liver of pregnancy, and hemolysis, elevated liver enzymes, and low platelets syndrome (HELLP). Pregnant women with cirrhosis have a greatly increased likelihood of having protein-calorie malnutrition. NAFLD is associated with increased risk of gestational diabetes mellitus, preeclampsia, preterm birth, C-section delivery, and low birth weight. Management of NAFLD in pregnant women involves lifestyle modification. Weight loss and a Mediterranean diet have been shown to reduce risk of gestational diabetes mellitus.

Breastfeeding is known to be highly beneficial for the infant and can be done despite liver disease for most cases; women with hepatitis B or C infection can breastfeed their infants as long as the infant has received the appropriate prophylaxis and there is no

bleeding or cracks in the nipples. Additionally, breastfeeding has been shown to reduce the risk of the infant developing NASH or hepatic fibrosis from NAFLD later in life.

### Acute liver failure

The nutritional status of someone with acute liver failure versus chronic liver failure can differ greatly. The primary goal of the nutritional management in acute liver failure is supportive. An increase in nausea, vomiting, and anorexia may be associated with acute liver disease which may result in a decreased intake of foods in general. If normal nutritional status before the insult is assumed, the patient will have a much higher nutritional reserve than that of a patient in chronic liver failure. Energy needs can be maintained by providing the Dietary Reference Intake for infants and children, and approximately 30 kcal kg<sup>-1</sup> for adults. Fluid restriction to 70–90% of maintenance may be required if encephalopathy or cerebral edema is present. Hypoglycemia results from impaired gluconeogenesis and depleted glycogen stores. If fluids are provided intravenously, the glucose infusion rate may need to be increased with close monitoring of blood sugar levels.

The provision of adequate protein becomes crucial in fulminant hepatic failure and encephalopathy. Adequate protein must be provided to minimize catabolism which could exacerbate any hyperammonemia present. Excessive protein intake should be avoided as it could increase ammonia levels. Protein recommendations for adults and teenagers are 0.5–1.0 g kg<sup>-1</sup> day<sup>-1</sup>; for infants and children 1.2–1.5 g kg<sup>-1</sup> day<sup>-1</sup>. Additional protein restrictions or an increase in the intake of branched-chain amino acids intake may be beneficial. In health, the ratio of branched-chain amino acids/aromatic amino acids (leucine + isoleucine + valine/phenylalanine + tyrosine) is ~3:1 and in liver failure the ratio may decline to ~1:1, often in association with some degree of hepatic encephalopathy. There is some data to say that normalization of this ratio by administration of branched-chain amino acid formulae can improve hepatic encephalopathy.

### Chronic liver disease

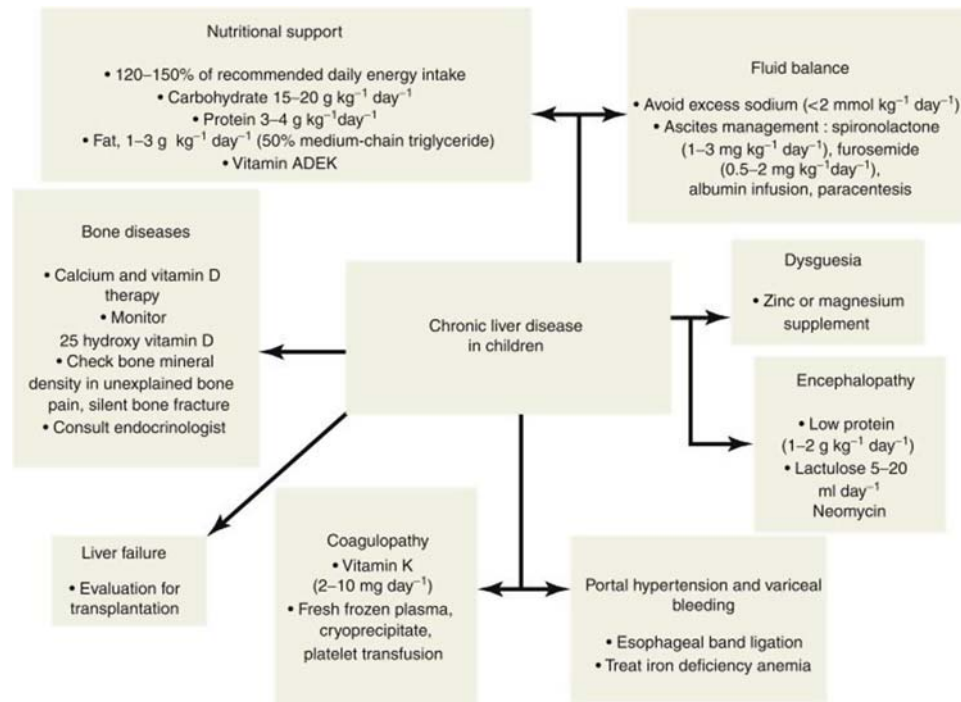

Chronic liver disease is often accompanied by nutritional deficiencies. The goals of nutritional management are to provide adequate energy and protein to prevent energy deficits and protein catabolism and to promote hepatic cell growth. Recommendations for nutritional management of children with chronic liver disease are presented in Fig. 6. Energy needs for adults with chronic liver disease are 30–35 kcal kg<sup>-1</sup> day<sup>-1</sup>. Energy requirements are increased to compensate for the weight loss that often occurs in cirrhosis. Protein should be provided as 0.8–1.0 g kg<sup>-1</sup> for adults and the Dietary Reference Intake for protein should be provided for infants and children; unnecessary protein restriction should be avoided as it may only worsen total body protein losses. Energy from fat is best delivered as medium chain triglycerides due to the frequency of long chain fat malabsorption. Several infant, pediatric, and adult formulas are available with a large percentage of fat in the form of medium chain triglycerides.

Supplementation with fat-soluble vitamins (i.e., A, D, E, and K) in water-miscible solutions is necessary due to the potential for deficiencies associated with fat malabsorption. Serum levels should be monitored regularly to ensure appropriate levels and prevent toxicity. Supplementation with zinc, selenium, iron, and calcium should be given as needed. Copper and manganese should not be supplemented as they are excreted with bile and may build up to toxic levels. Sodium and fluid restrictions may be necessary in cirrhosis characterized with ascites and edema. This can impose difficulty as this restriction decreases the palatability of the diet, further decreasing oral intake.

### End stage liver disease in pre- and post-liver transplantation

The prevalence of malnutrition in cirrhosis is as high as 65–90%, and malnutrition is predictive of survival in patients with liver cirrhosis. The severity of malnutrition is correlated with severity of liver disease and the development of serious complications such as hepatic encephalopathy, ascites, and hepatorenal syndrome. A variety of mechanisms are considered to contribute to malnutrition in cirrhosis (Table 4). Maintaining optimal nutritional status is important in the patient with end stage liver disease both pre- and post-transplant. However, nutritional assessment in end stage liver disease is particularly problematic. In the pre-transplant setting, fluid retention, ascites, and hepatosplenomegaly make body weight an unreliable nutritional index. True decreases in body weight, due to loss of fat stores and lean body mass may not be fully appreciated in solely following weight trends. In the pediatric population, linear growth is often a better indicator of nutritional status. Chronic malnutrition is often present as is reflected in a decrease in linear growth velocity.

Although anthropometric measurements, 24 h creatinine, bioelectric impedance analysis, and indirect calorimetry have all been used to assess nutrition, they are all affected by ascites and peripheral edema. *In vivo* neutron activation analysis and isotope dilution techniques are more accurate ways of assessing body composition but are time-consuming and costly. For practical purposes the indirect assessments of 24 h urinary creatinine excretion to assess body muscle mass and mid-arm muscle area can be used for patients without high volumes of extracellular fluid; in those with ascites the creatinine-height index is a better way of assessing body muscle mass.

**Fig. 6** Management in children with chronic liver disease.

**Table 4** Factors and mechanisms that results in malnutrition in end stage liver diseases and treatment of the causes of malnutrition.

<i>Factors that result in malnutrition in end stage liver diseases</i>	<i>Causes</i>	<i>Management</i>
Decreased dietary intake	Starvation. Nil per os (NPO) status with frequent admissions to hospital.	Aggressive nutritional therapy. Avoid NPO status unnecessary.
Poor dietary intake from nausea and early satiety	Gastroesophageal reflux disease. Gastroparesis. Tense ascites. Small bowel dysmotility. Small bowel bacterial overgrowth (SBBO).	Appetite stimulant. Prokinetic use. Appropriate diuretic dosages. SBBO treatment and prophylaxis with antibiotic (s).
A distortion or decrease in taste sensation (dysgeusia) Malabsorption	Sodium restriction to control ascites. Trace element deficiencies (zinc, magnesium).	Supplement of trace elements.
Increased intestinal protein losses	Atrophy of intestinal villi from starvation, prolonged NPO, gastroenteritis, SBBO, neomycin use. Reduced bile acid pool from cholestyramine for pruritus.	Treat causes.
Hypermetabolism	Protein losing enteropathy from portal hypertension or hidden intestinal diseases (Celiac disease, intestinal lymphangiectasia). Increased sympathetic nervous system activity.  Reduced glycogen storage hyperinsulinism sepsis.	Treat causes.  Measuring the nitrogen balance. Adequate glucose or caloric intake to prevent muscle breakdown. Frequent meals. Treat infection.

Visceral proteins, including albumin, transferrin, prealbumin, and retinol binding protein are typically used in monitoring nutritional status due to the decrease seen in inadequate dietary protein intake, but should be used with caution in liver disease as the synthesis of these proteins also decreased in end stage liver disease. Serum levels of fat-soluble vitamins should be monitored closely as well.

Improving nutritional status before a transplant is imperative because malnutrition affects morbidity and mortality post-transplant. Although the degree of malnutrition may not be able to be reversed, aggressive nutritional support should be implemented to prevent further worsening of the nutritional state and possibly reduce pre- and post-transplant infection and complications. Reduced protein intakes, lactulose use, vegetable protein diets, zinc supplementation, and branched chain amino acid (BCAA)-enriched enteral supplements have been reported to reduce subclinical hepatic encephalopathy confirmed by psychometric test. Although treatment with bisphosphonates is recommended in those with osteoporosis, oral alendronate (not risedronate) may cause esophageal ulcer and could precipitate variceal bleeding.

Sarcopenia is defined by a reduction in muscle mass or muscle wasting and caused by decreased protein synthesis and increased protein degradation, especially in end-stage liver disease. It has been commonly neglected and associated with adverse clinical outcomes. This can be confirmed with dual-energy X-ray absorptiometry (DEXA), CT, MRI, and bioelectric impedance analysis (BIA) and requires rehabilitation strategies (Lai et al., 2021).

Post-transplant nutritional support should not be overlooked as the nutritional deficit is not cured merely by the transplant. Additionally, the surgery itself poses increased nutritional demand for post-surgery healing and support. Nutritional repletion may occur at a more rapid rate than pre-transplant as the patient now has a functional liver in which metabolism and digestion of macro and micronutrients will be improved. Long-chained fat and fat-soluble vitamins therefore should be normally absorbed. A side effect of corticosteroid use after liver transplant is growth hormone deficiency which should be suspected in children with persistent growth failure despite aggressive nutritional therapy. Post-transplant feeding should be started as soon as possible, ideally within 72 h. Muscle mass and fat storage rapidly improve within 3–6 months post-transplant. In children, marked catch-up growth is observed in those with stunted growth before transplantation. Most children catch up in weight to their peers by 1-year post-transplant; however, it may require up to 5 years to catch up in height. Of note, some conditions such as Alagille syndrome have underlying genetic abnormalities that limit growth regardless of liver function. Recombinant growth hormone therapy has successfully treated some of these children without deleterious effect to graft function. Post-transplant metabolic syndrome, fatty liver, and obesity are common complications after transplantation that may occur and should be monitored.

## Conclusion

While the pathophysiology of the liver diseases discussed in this article are quite diverse, a key concept that unifies them is the importance of proper nutritional management in the overall treatment of these diseases. Malnutrition in liver disease is associated with increased risks of morbidity and mortality, affects the outcomes of liver transplantation, and long-term survival, and quality of life. Careful assessment of the nutritional status by primary care takers or multidisciplinary team will initiate appropriate and early interventions. Therefore, it is essential to identify any nutrient deficiencies and specific nutritional needs which allow prompt preventive or corrective treatment.

### Glossary

**Fat-free mass index** Index of muscle mass in relation to height.

**Forced expiratory volume** Volume exhaled with force usually measured after 1 s.

**Resting energy expenditure (REE)** Amount of energy needed to maintain normal body functions at rest, excluding the thermal effect of food and physical activity.

**Spirometry** A pulmonary function test measuring the amount (volume) and speed (flow) of air that can be inhaled and exhaled.

## Introduction

Adequate nutrition is vital for the development and continued health of our lungs. Evidence suggests that prenatal and early-life nutrition affect lung function in later life. Malnutrition is observed in several chronic lung conditions, such as chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF), where there is both an increased energy expenditure and a reduced intake leading to reduced lung function, increased morbidity, and decreased quality of life. Malnutrition with associated multiple micronutrient deficiencies increases the risk of acute respiratory infections. Conversely, obesity may compromise lung function in conditions such as asthma. This article gives a taste of the complex interaction between nutrition and lung disease and presents some of the evidence base for nutritional support.

## Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease is defined as a preventable and treatable disease characterized by chronic airflow obstruction that is not fully reversible. The impairment of lung function is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases. The recent inclusion of 'preventable and treatable' in the definition represents a shift toward a more positive attitude.

COPD includes 'chronic bronchitis' defined by chronic bronchial secretions sufficient to cause expectoration occurring on most days for a minimum of 3 months for 2 consecutive years, and 'emphysema,' the pathological process of permanent destructive enlargement of the airspace distal to the terminal bronchioles without obvious fibrosis. Although pure forms of these two conditions exist, there is considerable overlap in the majority of patients, hence grouping them under COPD.

## Epidemiology

The Global Burden of Disease Study has projected that COPD, ranking sixth as the cause of death in 1990, will become the third leading cause of death worldwide by 2020. Studies around the world estimate that the prevalence of COPD ranges from 7% to 19% and the disease is increasing in women. In developed countries, exacerbations of COPD present the greatest burden on the health-care systems, accounting for 10% of all hospital medical admissions in the United Kingdom and direct costs of COPD are estimated to be 38.6 billion of the European and \$18 billion of the United States health care budgets.

## Etiology

The single most important risk factor for COPD is cigarette smoking with a direct correlation between number of cigarettes smoked and the likelihood of developing the disease. However, nonsmokers also develop COPD (never-smokers comprise approximately 23.3% of those classified as stage II+) and the individual susceptibility to smoking is very wide with only 15% of smokers likely to develop clinically significant COPD. Other risk factors include occupational exposure to dust and chemicals, air pollution, particularly in women in developing countries, and severe hereditary  $\alpha_1$ -antitrypsin deficiency (**Figure 1**). Severe childhood respiratory infections have been associated with reduced lung function and increased respiratory symptoms in adulthood, which may, however, in turn be related to factors like low birth weight.

## Clinical Features

Clinical features include repeated attacks of productive cough, progressive dyspnea, exertional breathlessness, recurrent infections, wheeze, and occasional chest tightness. Clinical respiratory examination may be normal in mild-to-moderate cases. In severe cases, clinical signs reflect pulmonary hyperinflation, hypoxemia, and the development of pulmonary hypertension and right heart failure (*cor pulmonale*) and polycythemia. Clinical classification according to spirometry results is widely used (**Table 1**).

## Differential Diagnoses

Asthma can usually be distinguished from COPD based on reversible rather than irreversible airflow limitation. In the developing world, pulmonary tuberculosis and COPD are common and making the correct diagnosis is essential for management.

**Figure 1** Risk factors for COPD. FEV<sub>1</sub>, forced expiratory volume in 1 s.

**Table 1** Spirometric classification of COPD

Stage	Description	Definition
I	Mild	FEV <sub>1</sub> ≥ 80% predicted
II	Moderate	50% ≤ FEV <sub>1</sub> < 80% predicted
III	Severe	30% ≤ FEV <sub>1</sub> < 50% predicted
IV	Very severe	FEV <sub>1</sub> < 30% predicted or FEV <sub>1</sub> < 50% predicted plus chronic respiratory failure

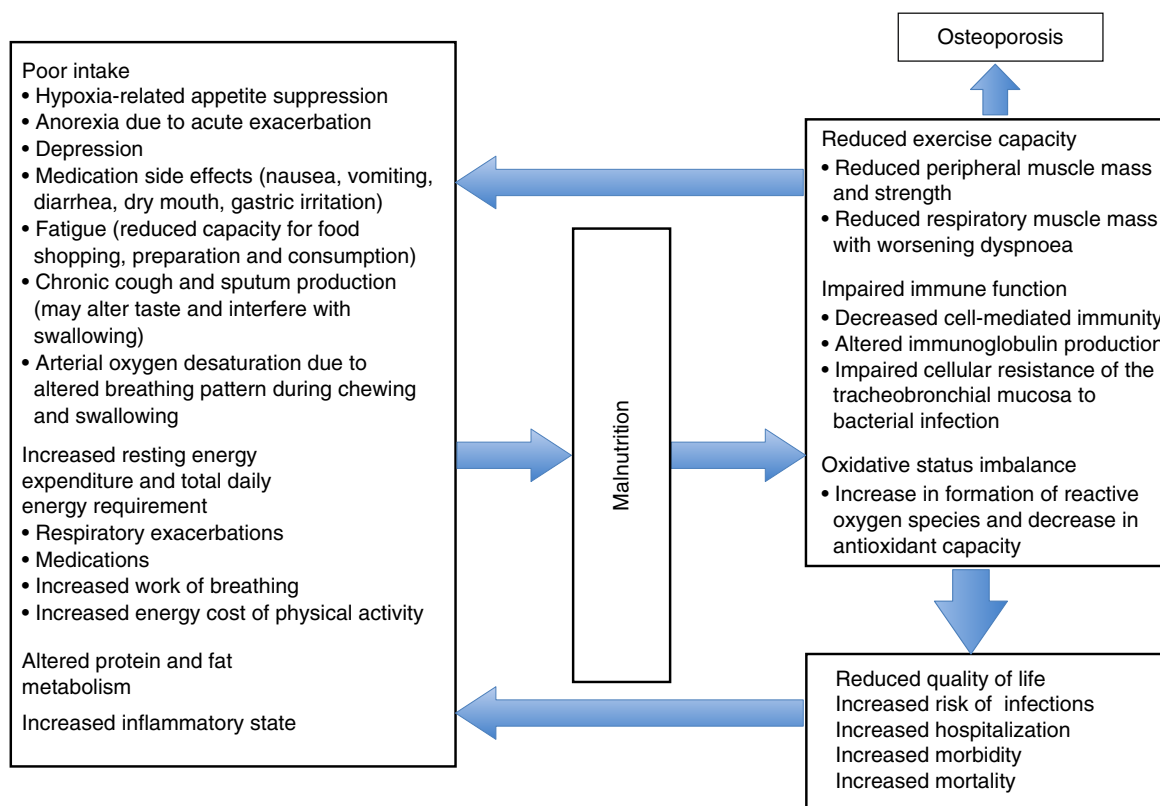

## Pathology

Pathological features include chronic air wall inflammation with airway smooth muscle hyperplasia and bronchial wall thickening, hypertrophy of mucus secreting glands, and a decrease in ciliated cells causing a less efficient transport of mucus in the airways. Small airways become obstructed; alveolar attachments and pulmonary elastic recoil are lost causing restriction of airflow. Emphysema is usually centriacinar with distension and damage affecting the respiratory bronchioles, alveolar ducts, and centrally located alveoli. More rarely, panacinar emphysema or paraseptal emphysema develops in the distal airway structures causing later blebs on the lung surface, giant bullae, or both.

## Nutrition and COPD

Management of COPD needs a multicomponent approach with particular attention to existing comorbidities. Indices of airflow obstruction only poorly predict prognosis although used in classification. Body mass index (BMI), airflow obstruction, dyspnea, and exercise capacity (BODE) index has been proposed to account for the multiple components of COPD. Malnutrition represents an important clinical problem in a subpopulation with COPD and poor indices of nutrition such as low BMI and low fat-free mass index (FFMI) independently confer a poorer prognosis in patients with COPD in terms of mortality, risk of hospitalization, length of hospitalization, and health-related quality of life.

Between 24% and 71% of all COPD patients show some evidence of malnutrition. However, the percentage is higher in those with more severe disease and those in need of hospital admission. BMI is an indicator of poor prognosis, but even patients with a normal BMI may be undernourished. FFMI is a better marker of lean body mass compared to BMI, as it is associated with other

**Figure 2** Malnutrition and COPD.

prognostic indices such as exercise capacity, dyspnea, and percentage of predicted FEV<sub>1</sub> (FEV<sub>1</sub>=forced expiratory volume in 1 s). In up to 25% of COPD patients with normal weight, depletion of FFM can be noted. In malnourished patients, there may be loss of respiratory muscle and diaphragm mass as well as altered regulation of the oxidative phenotype and mitochondrial dysfunction affecting respiratory muscle strength and endurance. However, this does not imply a causal relationship; dyspnea may in turn prevent patients from exercising, contributing to muscle atrophy.

### Reasons for Malnutrition in COPD

The mechanisms of weight loss in COPD are not fully understood. It may be the result of an imbalance between an elevated resting energy expenditure (REE), an elevated total daily energy requirement, and inadequate dietary intake (Figure 2). This imbalance may be further affected by altered protein metabolism suggested by the selective wasting of FFM. Decreased protein intake, particularly during the first days of acute exacerbation, decreased protein synthesis, and increased protein balance turnover have been reported. An increased systemic inflammatory state with elevated proinflammatory markers such as TNF- $\alpha$  may also adversely affect protein metabolism.

### Obesity in COPD

Some COPD patients are obese, resulting in an increased energy cost for physical activity, and extreme obesity decreases lung function. A recent study showed higher survival rates among obese COPD patients (BMI>25) who lost weight. Another study showed that in those patients with a normal BMI or above, a high-carbohydrate diet may be of benefit to promote strength and function.

### Nutritional Support

A 2008 Cochrane meta-analysis of 14 studies on simple nutritional supplementation in stable COPD patients did not identify improvements in anthropometric measures or functional exercise capacity in treated subjects versus control subjects. However, most studies did not use lean body mass as a primary outcome or health-related quality of life, which may be of more importance in COPD. In those studies showing any improvement in functional exercise, the improvements were not maintained when supplementation was discontinued. Nutritional supplementation as part of a multicomponent intervention was not reviewed.

More recently, it has been shown that a combination of nutritional supplementation with low-intensity exercise training increased weight and energy intake as well as exercise capacity and decreased REE and inflammatory cytokines in moderate to severe clinically stable malnourished COPD patients. However, further larger studies are required to examine the potential role of the combination of nutritional supplementation and exercise in the management of malnourished patients with COPD.

Initial examination of the combination of nutritional support and substances like creatine, L-carnitine, and growth hormone releasing factor has shown an increase in lean body mass but has not shown a consistent improvement in endurance or health-related quality of life. Ghrelin stimulates growth hormone secretion, food intake, and weight gain without increasing adiposity unlike other appetite stimulants. It decreases muscle wasting via inhibition of production of anorectic proinflammatory cytokines. Appetite stimulants may, however, exacerbated by steroid medication, cause hyperglycemia.

A higher antioxidant food intake may improve lung function in COPD patients and may also have protective effects on the development of COPD. Studies have also shown a high prevalence of vitamin D deficiency among COPD patients, adversely affecting lung function. Supplementation trials of antioxidants and vitamin D are required before recommendations for routine supplementation can be made.

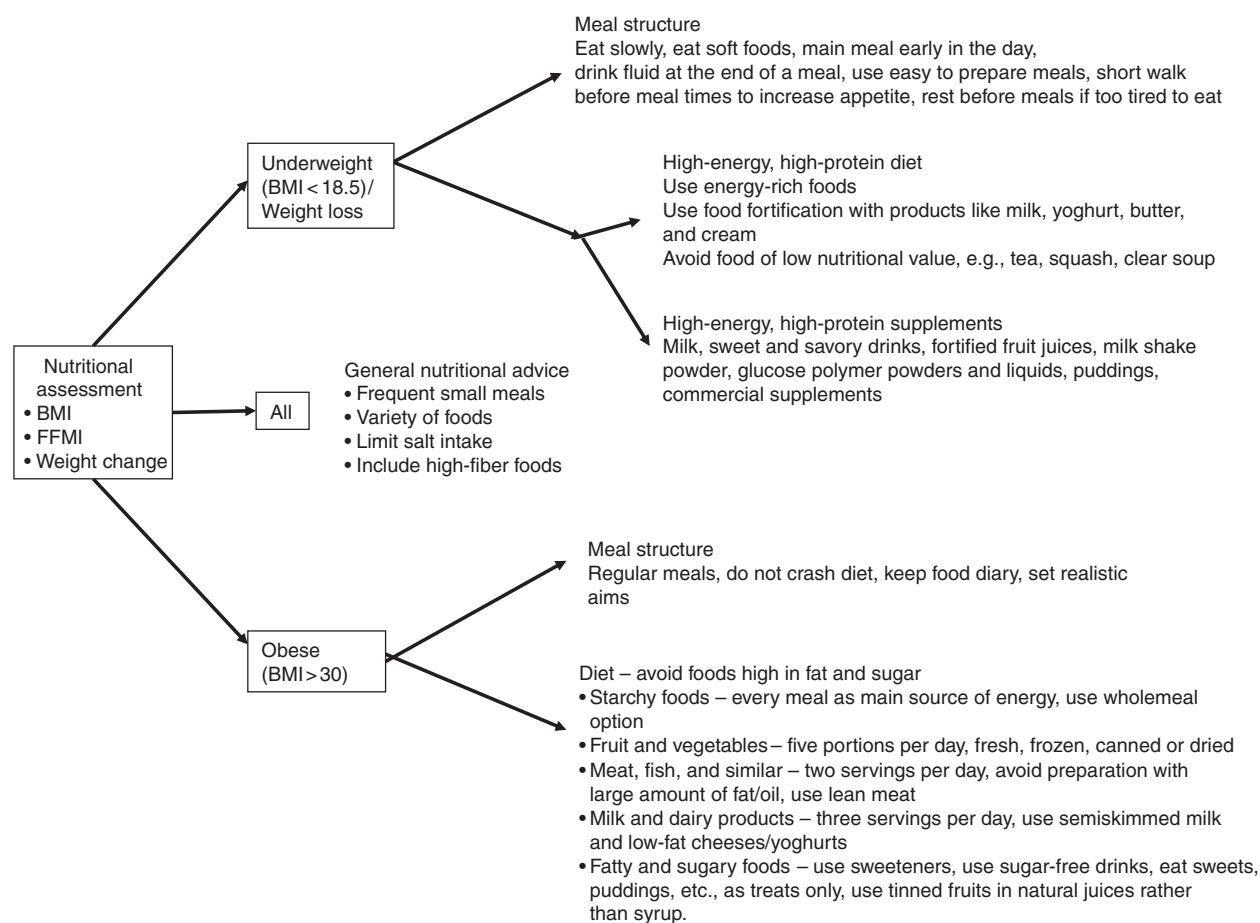

### Type of Nutritional Support

#### Nutritional Advice, Exercise, and Supplementation

Despite the findings of the 2008 Cochrane review, the general logical advice is that nutritional support should be considered in all patients with COPD and it should be included in multidisciplinary pulmonary rehabilitation programs, which have shown some benefits. Individual dietary advice based on a dietary history and an analysis of nutritional status should be arranged for those who are underweight (BMI < 18.5) or obese (BMI > 30), and those whose weight is changing over time (weight loss greater than 10% in the past 6 months or more than 5% in the last month) (Figure 3). Furthermore, if the BMI is low, high-energy, high-protein nutritional supplements should be given in frequent, small amounts (to avoid postprandial dyspnea and satiety and to improve compliance) to increase the total calorific intake. Exercise should be encouraged to augment the effects of nutritional supplementation.

### Tube Feeding

Enteral tube feeding should not be used in COPD patients unless oral intake is unsafe or oral methods of maintaining nutritional status have failed. One should be aware of the risks (Table 4). Although a high-carbohydrate diet produces more carbon dioxide (VCO<sub>2</sub>) and therefore requires increased ventilation to expel the excess CO<sub>2</sub>, there is no additional advantage in stable COPD patients of formulating low-carbohydrate, high-fat enteral feeds compared to standard high-protein, high-energy supplements.

**Figure 3** Nutritional advice in COPD.

However, in patients with acute respiratory problems requiring artificial ventilation, the composition of feeds has a profound effect on gas exchanges. Feeding formulas during ventilation should have low-carbohydrate, high-fat content to reduce VCO<sub>2</sub> and ventilation requirements. Overfeeding negates any beneficial response to high-fat feeds because the conversion of energy into fat involves disproportionately large production of CO<sub>2</sub>. Bolus feeds during ventilation are as effective as continuous feeds.

## Cystic Fibrosis

### Definition

Cystic fibrosis is an autosomal recessive genetic disorder resulting from a mutation of a gene located on chromosome 7q31.3, which codes for a cyclic-AMP-activated chloride channel known as the cystic fibrosis transmembrane conductance regulator (CFTR) expressed in several epithelia. Over 1200 different mutations and 200 polymorphisms have been identified. Mutation  $\Delta F508$  accounts for 77% of CF chromosomes in the white population, whereas 3210+1G>A accounts for 46% of mutations in the black population.

### Epidemiology

CF is the most common fatal genetic condition in Caucasians with a carrier rate of 1 in 25 and an incidence of 1 in 2500 live births. It is less common in the non-white races (1 in 20 000 and 1 in 1 million live births in the black and Oriental populations, respectively), but little is known about its prevalence in developing countries as CF often remains underdiagnosed. Early diagnosis with neonatal screening, aggressive treatment of lung infections, and nutritional support has led to a dramatic improvement in life expectancy. Now, there are more adults than children with CF in many developed countries.

### Pathogenesis

The CFTR mutations lead to dysfunction of the exocrine glands in multiple systems including the skin, gut epithelium, pancreas, liver, and reproductive tract; in the respiratory epithelium, it results in increased resorption of sodium and water. Relative dehydration of the airway lining may predispose to chronic bacterial infection and ciliary dysfunction, leading to bronchiectasis and reduction of lung function.

### Clinical Features

Most children, if not already identified by neonatal screening, present with malabsorption and failure to thrive as well as recurrent chest infections. Lung disease is the primary cause of morbidity and mortality in CF patients. At birth, the lungs appear normal macroscopically, although studies have shown the presence of an active inflammatory process. Progressive cycles of infection

**Table 2** Complications of cystic fibrosis

<i>Respiratory</i>	
• Bronchiectasis	• Respiratory failure
• Pneumothorax	• <i>Cor pulmonale</i>
• Wheeze	• Lobar collapse due to secretions
• Hemoptysis	• Allergic bronchopulmonary aspergillosis
• Nasal polyps	
<i>Gastrointestinal</i>	
• Meconium ileus	• Malabsorption and steatorrhea
• Rectal prolapse	• Distal intestinal obstruction syndrome
• Intussusception	• Gastroesophageal reflux
• Abdominal distension	• Biliary cirrhosis
• Colonic strictures	• Hepatomegaly
• Cholelithiasis	• Portal hypertension
• Obstructive jaundice	• Cholecystitis
• Pancreatitis	
<i>Others</i>	
• Diabetes	• Salt depletion
• Male infertility	• Growth failure/weight loss/failure to thrive
• Amyloidosis	• Psychosocial problems
• Arthropathy	• Osteopenia/osteoporosis
• Delayed puberty	• Stress incontinence (repeated cough)
• Cutaneous vasculitis	

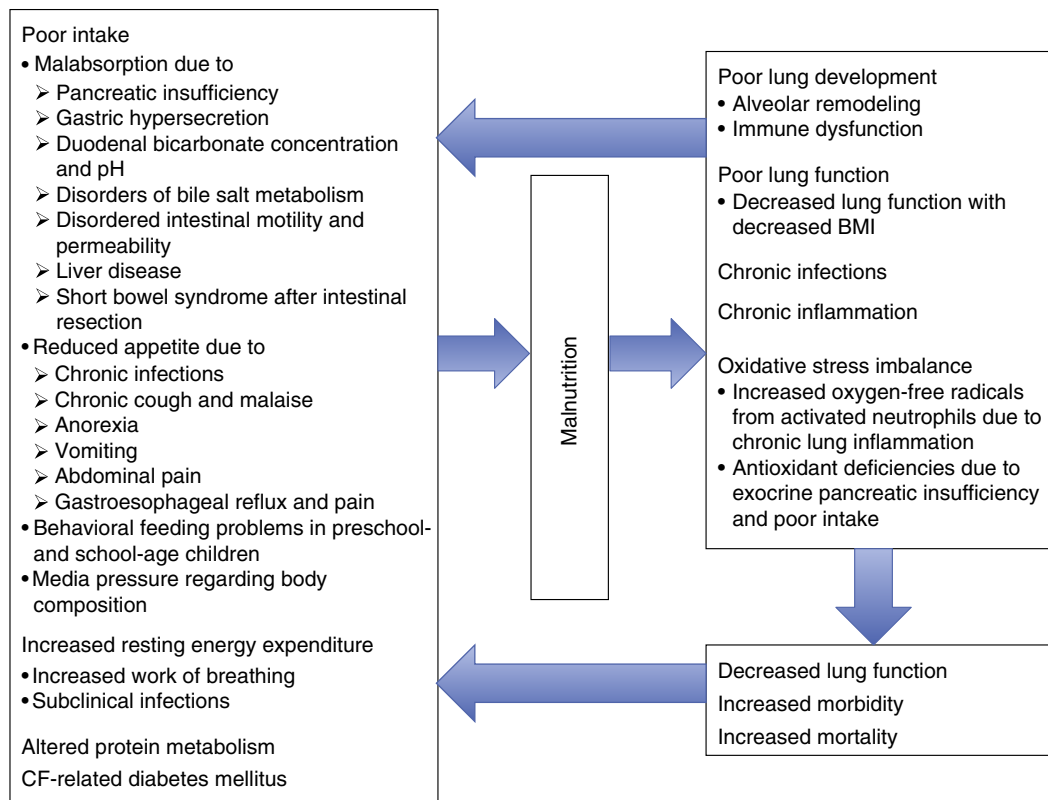

**Figure 4** FEV<sub>1</sub> percent predicted vs. BMI percentile in children 6–20 years of age. Reproduced with permission from Cystic Fibrosis Foundation Patient Registry (2009) *2008 Annual Data Report*. Bethesda, Maryland: Cystic Fibrosis Foundation Patient Registry.

and inflammation lead to bronchiectasis in childhood, and progressive lung damage eventually leads to respiratory failure and death. Initially, the lungs are infected with *Staphylococcus aureus* and nontypable *Haemophilus influenzae*, but later approximately 80% are infected with *Pseudomonas aeruginosa*. Approximately 90% of CF patients have pancreatic insufficiency requiring pancreatic enzyme replacement therapy (PERT). Other features are summarized in [Table 2](#).

### Malnutrition and CF

Malnutrition in CF patients is still one of the main clinical manifestations despite increased knowledge and improved management. Of adults with CF, 60.8% have a BMI below the recommended levels and 15.7% of patients under 20 are below the fifth centile weight-for-age and gender.

A clear link has been shown between good nutrition and prognosis of CF. BMI percentiles in children and BMI values in adults are also directly and strongly correlated with pulmonary function in terms of FEV<sub>1</sub> ([Figure 4](#)).

**Figure 5** Cystic fibrosis and malnutrition.

Furthermore, based on multiple longitudinal and cross-sectional studies, there is an assertion that growth, particularly linear growth, is connected to the evolution of lung health in children who have CF. However, the causal relationship between malnutrition and pulmonary dysfunction remains unclear in CF. There is a suggestion that nutritional status early in life is a determinant for the progression of the lung disease. Studies in infants looking at later lung disease are obviously difficult in terms of ethics but retrospective studies have shown that appropriate nutritional status early in life has a positive effect on lung function later on, suggesting a causal relationship. Malnutrition may affect mechanical lung properties including alveolar remodeling in addition to factors including the activation of cytotoxic T lymphocytes and natural killer cells.

A variety of complex organic and psychosocial factors contribute to malnutrition in CF, which in turn worsens pulmonary dysfunction (Figure 5). Similar to COPD, there is an imbalance of decreased nutrient intake and increased energy expenditure in CF.

### Decreased Intake

Pancreatic insufficiency and other complications may contribute to moderate and severe malabsorption affecting protein and fat-soluble vitamins despite adequate use of enzyme supplements (Figure 5). Reduced appetite due to chronic respiratory infections and other complications, as well as psychosocial factors such as eating disorders in teenagers, further lead to inadequate energy intake in CF patients.

### Increased Energy Expenditure

The REE in severe obstructive lung disease such as CF and COPD is increased partly because of the increased work of breathing. REE is 10–20% greater in CF patients than in healthy controls and this increase appears to be closely associated with declining pulmonary function and subclinical infection. Bronchial sepsis leads to local release of leukotrienes, free oxygen radical, and cytokines, including TNF- $\alpha$ . Interestingly, antibiotics reduce energy requirements of moderately ill patients with chronic *P. aeruginosa*. Furthermore, the presence of even mild lung disease is associated with elevations in REE, indicating that REE could be a sensitive marker of clinical status before lung disease becomes clinically overt. The relationship between protein metabolism and pulmonary function in CF remains unclear.

### Nutritional Support

Nutritional support should be based on complete individual nutritional assessment rather than a generalized approach. Current guidelines advise using weight-for-length in less than 2-year-olds, BMI percentiles for 2- to 18-year-olds, and BMI in the adult population (Table 3). The age of greatest risk of malnutrition appears to be during the first 2 years of life and during early adolescent years. Treatment for nutritional failure may include nutritional advice and behavioral interventions, oral supplements, enteral feeds, and parenteral nutrition (Table 3).

### High-Energy/High-Protein Diet

The encouragement of a high-energy, high-protein diet aiming at 110–200% of recommended daily allowance will produce growth in the majority of children and adults with CF (Figure 6). Malnourished children achieve higher energy intake when more frequent meals are offered. Attention should be given to psychological, social, behavioral, and developmental aspects of feeding. There is evidence that particularly for children 1–12 years of age, behavioral intervention and nutrition counseling should be implemented when a risk of poor growth is present (Table 3).

### Dietary Supplements

For children with growth deficits, adults with inappropriate weight status, and during acute chest infections, oral and enteral supplements should be used to improve weight. Dietary calorie supplements should complement normal food intake and not replace food, following recommended age-dependent quantities (Table 3). A Cochrane review concluded that oral calorie supplements, on top of standard dietary advice and monitoring, do not achieve any additional benefit in the nutritional management of moderately malnourished children with CF in addition to dietary advice and monitoring.

### Enteral Feeding

When oral high-calorie diets and supplements are ineffective, enteral tube feeding may be considered, which is better tolerated by gastrostomy than by nasogastric tube in the long term (Table 4). Reported use of enteral tube feeding suggests that it results in nutritional and respiratory improvements. However, a Cochrane review concluded that its efficacy has not been fully evaluated and data are limited and randomized trials are needed to investigate efficacy as well as when to start enteral tube feeds. Furthermore, these interventions are not free from complications and should be balanced against the possible gains (Table 4). Enteral feeding may lead to gastroesophageal reflux, formula intolerance, and hyperglycemia. Patients receiving supplemental feeds who demonstrate repeated blood sugar levels higher than 11.1 mmol l<sup>-1</sup> during the feed may benefit from insulin given before the feeds. Enteral feeds are usually given for 8–10 h overnight, with at least 40–50% of the estimated energy requirement given via the feed. Most patients tolerate an energy-dense polymeric feed providing at least 1.5 kcal ml<sup>-1</sup> with additional pancreatic enzymes.

**Table 3** Indications for nutritional interventions in cystic fibrosis

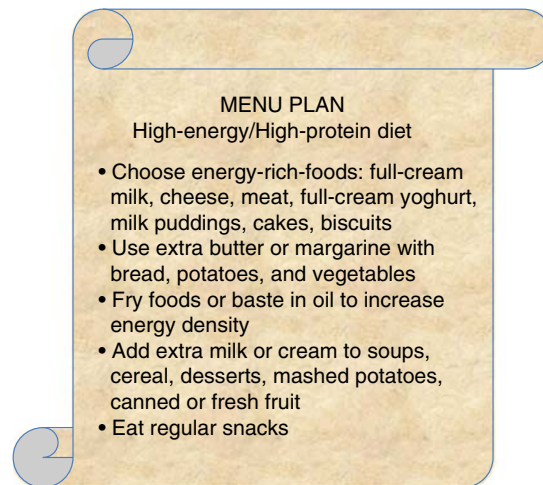

Age group	0–2 years	2–18 years	> 18 years
Nutritional assessment indicator	Weight-for-length percentiles	BMI percentiles	BMI
Care categories			
Normal/routine nutritional care	Normal weight-for-length percentiles and within 2 centile bands of each other	BMI 25–95th percentile	BMI 20–27
At risk/noninvasive nutritional intervention	Weight and height percentiles decreasing with time or no weight gain	BMI 10–25th percentile OR Weight loss over 1–3 months OR Plateau in weight gain over 2–4 months	BMI 18.5–20 OR Weight < 45 kg regardless of BMI OR 5% weight loss over 2 months
Malnutrition/aggressive nutritional support	Weight 2 or more centile bands below length OR Failure of noninvasive interventions to improve nutritional status	BMI < 10th percentile OR Weight falling 2 or more percentile positions OR Plateau in weight gain for 6 months OR Failure of noninvasive interventions to improve nutritional status	BMI < 18.5 OR Weight < 40 kg regardless of BMI OR 5% weight loss over 2 months despite noninvasive nutritional interventions
Overweight/nutritional advice	N/A	BMI > 95th percentile	BMI > 27
Nutritional interventions			
Advice for routine energy intake as indicated for age and sex	Demand breast-feeding or whey-based artificial formulae. Intake of > 200 ml kg <sup>-1</sup> is not unusual. Early weaning not advised	110–200% standards for healthy population	110–200% standards for healthy population
Combined behavioral and nutritional intervention indicated for weight gain	Recommended for children aged 1–2 years	Recommended for age 2–12 years; insufficient evidence for age 13–18 years	Insufficient evidence for effectiveness for adults
Nutritional supplementation (oral and enteral) intervention if indicated for weight gain	Unrestricted demand feeds. Nutritional supplementation if poor growth or surgery for meconium ileus	Recommended	Recommended
Caloric supplementation (per day)	1–2 years 200 kcal	3–5 years 400 kcal 6–11 years 600 kcal > 12 years 800 kcal	800 kcal
Pancreatic enzyme preparations (based on pancreatic status assessment)	Recommended Upper limit: 10 000 IU lipase kg <sup>-1</sup> body weight day <sup>-1</sup>	Recommended Upper limit: 10 000 IU lipase kg <sup>-1</sup> body weight day <sup>-1</sup>	Recommended Upper limit: 10 000 IU lipase kg <sup>-1</sup> body weight day <sup>-1</sup>
Vitamin Supplementation (fat-soluble vitamins A, D, and E)	Recommended in pancreatic insufficient patients	Recommended in pancreatic insufficient patients	Recommended in pancreatic insufficient patients
Vitamin K	Recommended in liver disease and with prolonged prothrombin time	Recommended in liver disease and with prolonged prothrombin time	Recommended in liver disease and with prolonged prothrombin time
Water-soluble vitamins, iron, and calcium supplements	Recommended if deficient or evidence of low intake	Recommended if deficient or evidence of low intake	Recommended if deficient or evidence of low intake
Sodium supplements (only in hot conditions and evidence of sodium deficiency)	Recommended < 1 year 500 mg day <sup>-1</sup>	Recommended 1–7 years 1 g day <sup>-1</sup> , > 7 years 2–4 g day <sup>-1</sup>	Recommended 2–6 g day <sup>-1</sup>

### Parenteral Nutrition

Parenteral nutrition should be reserved for those with a nonfunctioning gastrointestinal tract (e.g., due to prolonged bowel obstruction or gastrointestinal surgery) and the critically ill as it is costly and associated with several risks, including catheter sepsis and metabolic complications such as hyperglycemia.

### Vitamin, Mineral, and Pancreatic Enzyme Supplementation

Malabsorption and pancreatic insufficiency are treated with oral PERT and vitamins (for details, see Table 3). Low fat-soluble vitamin concentrations are associated with poorer clinical status and reduced lung function. In hot conditions and in proven deficiency, sodium supplements are recommended. Anorexia and poor growth may result from chronic salt depletion, and significant

**Figure 6** Menu plan for a high-calorie/high-protein diet.

**Table 4** Advantages and disadvantages of different enteral feeding routes

<i>Method</i>	<i>Advantages</i>	<i>Disadvantages</i>
Nasogastric	<ul style="list-style-type: none"> <li>• Short-term feeding</li> </ul>	<ul style="list-style-type: none"> <li>• Tube reinsertion may be               <ul style="list-style-type: none"> <li>◦ distressing to patient/caregiver/nurse</li> <li>◦ easily removed</li> </ul> </li> <li>• Risk of aspiration</li> <li>• Psychosocial implications</li> </ul>
Nasojejunal	<ul style="list-style-type: none"> <li>• Less risk of aspiration</li> <li>• Short-term feeding</li> </ul>	<ul style="list-style-type: none"> <li>• Difficulty of insertion</li> <li>• Radiographic check of position</li> <li>• Easily removed</li> <li>• Risk of perforation</li> <li>• Abdominal pain and diarrhea unless continuous infusion of feed</li> <li>• Discomfort in nasopharynx</li> <li>• Reflux of bile is facilitated</li> </ul>
Gastrostomy	<ul style="list-style-type: none"> <li>• Cosmetically more acceptable</li> <li>• Long-term feeding</li> </ul>	<ul style="list-style-type: none"> <li>• Increase reflux if present</li> <li>• Local skin irritation</li> <li>• Stoma infection</li> <li>• Granulation tissue</li> <li>• Leakage</li> <li>• Gastric distension</li> <li>• Stoma closes within a few hours if accidentally removed</li> </ul>
Jejunostomy	<ul style="list-style-type: none"> <li>• Reduced risk of aspiration</li> <li>• Long-term feeding</li> </ul>	<ul style="list-style-type: none"> <li>• Surgical/radiology procedure</li> <li>• Risk of perforation</li> <li>• Must be constant infusion of feed</li> <li>• Bacterial overgrowth</li> <li>• Dumping syndrome can occur</li> </ul>

hyponatremia may be accompanied by vomiting. Pancreatic enzymes should be given at the smallest dose possible to control steatorrhea and achieve normal patterns of growth and weight gain. Total fat excretion should be quantified in order to assess efficacy of PERT.

#### ***Appetite Stimulants, Growth Hormones, and Omega-3***

Small randomized controlled trials of the appetite stimulant megestrol acetate noted significant improvement in weight and pulmonary function during the treatment period but gains seem to be short-lived. A Cochrane review is under way to examine the use of appetite stimulants in the management of CF. Important side effects include glucose intolerance and adrenal suppression. Cyproheptadine, another appetite stimulant, may be more promising in terms of side effect profile and long-term effect on weight gain.

Small trials with growth hormone given for 1 year showed improvements in respiratory status and exercise capacity and gains in lean body mass, but larger trials are required to make recommendations. Similarly, although small studies suggested an

improvement in lung function and clinical status, there is not enough evidence on the safety and effectiveness of fish oil supplements in the routine care of CF.

## Asthma

### Definition

Asthma (ancient Greek for 'panting') has no universally agreed definition. It is a heterogeneous disease described in terms of clinical, physiological, and pathological characteristics. Chronic airway inflammation and increased airway hyperresponsiveness to various stimuli lead to paroxysmal airway narrowing that may be reversible with or without treatment.

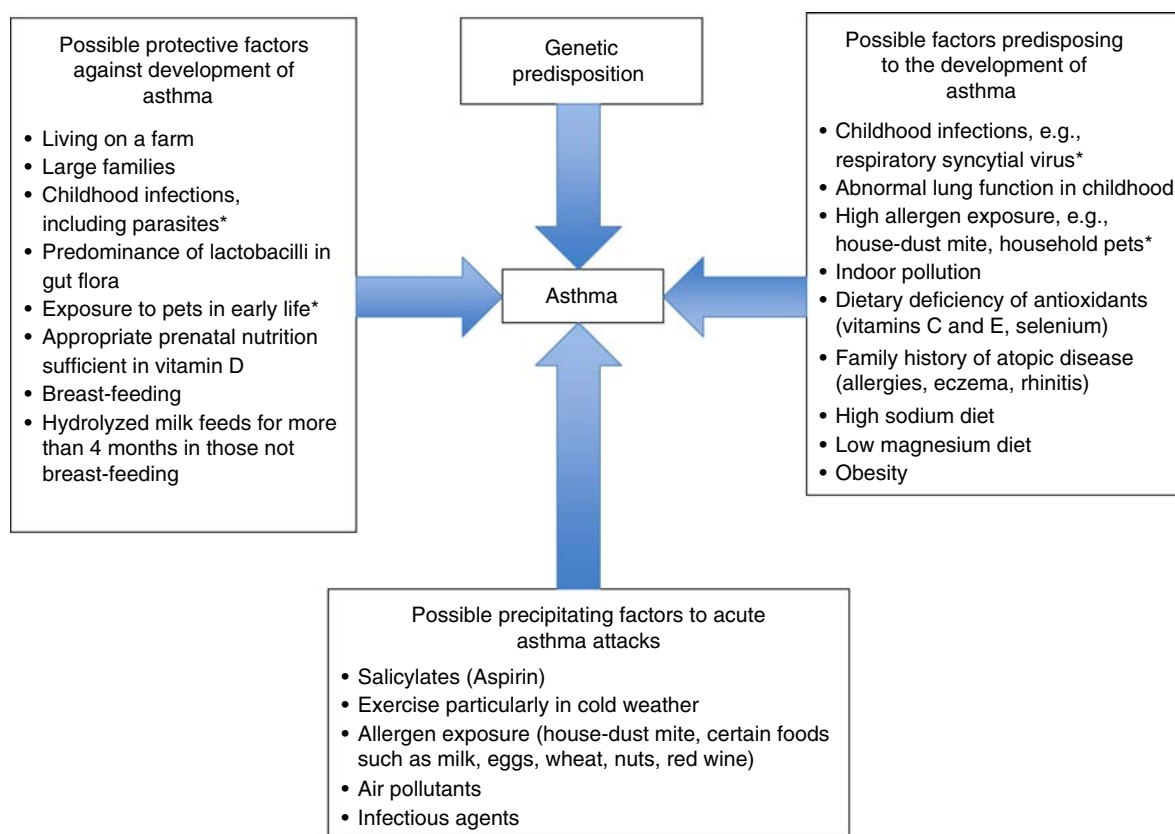

### Epidemiology

Since the 1980s, there has been a worldwide increase in the prevalence of asthma in both children and adults with associated increases in morbidity and mortality. It currently affects 300 million people worldwide, and an additional 100 million persons will be diagnosed by 2025, with huge socioeconomic implications in terms of days lost from school or work, health care visits, etc. For most of the developing world, little or no standardized data are available.

A series of environmental factors and genetic predisposition have been implicated in the development of, or protection from, asthma (Figure 7). Of people with asthma, 50% develop the condition before age 10, and the majority before age 30. The earlier the onset of wheeze, the better the prognosis for disease progression. Boys are more likely to 'grow out' of their asthma.

### Clinical Features

Central to all definitions of asthma is the presence of more than one of the following symptoms: recurrent episodes of wheeze, breathlessness, chest tightness, and cough. Precipitants include exercise in cold weather and viral upper respiratory infections (Figure 7). There is huge variability in symptom presentation between patients, ranging from those with periodic wheezing attacks with asymptomatic periods between exacerbations and patients with persistent, but fluctuating symptoms of breathlessness and wheeze. There is usually a diurnal pattern, with symptoms and lung function being worse early in the morning.

\*There is controversy and conflicting evidence regarding prenatal and early-life exposures.

**Figure 7** Factors implicated in the development of, or protection from, asthma and trigger factors for acute asthma attacks.

**Table 5** Nutritional effects on the development of asthma (primary preventative effects) and symptom control (secondary prophylactic effects)

Nutritional intervention	Evidence	Comments
<i>Primary preventative effects</i>		
Maternal food allergen avoidance during pregnancy and lactation	<ul style="list-style-type: none"> <li>Not related to subsequent development of asthma</li> </ul>	<ul style="list-style-type: none"> <li>May adversely affect maternal and fetal nutrition</li> <li>High-dose exposure may reduce subsequent sensitization</li> </ul>
Early introduction of allergenic foods during weaning	<ul style="list-style-type: none"> <li>Not related to subsequent development of asthma</li> </ul>	<ul style="list-style-type: none"> <li>Small study showed a nonsignificant increase in preschool wheezing with late introduction of egg</li> </ul>
Fish oil supplementation during pregnancy	<ul style="list-style-type: none"> <li>Marginal effects on the reduction in wheeze and cough at 1 year</li> </ul>	<ul style="list-style-type: none"> <li>Reduction in cytokine response to allergens in cord blood</li> <li>No adverse effects observed</li> </ul>
Fish oil supplementation in early infancy	<ul style="list-style-type: none"> <li>Reduces wheeze at 18 months but no effect on asthma by 5 years of age</li> </ul>	<ul style="list-style-type: none"> <li>No adverse effects observed</li> </ul>
Breast-feeding	<ul style="list-style-type: none"> <li>Potential protective effect in relation to early asthma</li> </ul>	<ul style="list-style-type: none"> <li>In line with WHO recommendation</li> </ul>
Hydrolyzed formula	<ul style="list-style-type: none"> <li>Suggested reduction of risk of asthma or wheeze in the first year of life</li> </ul>	<ul style="list-style-type: none"> <li>Formula recommended when breast-feeding is not possible and the infant is at high risk</li> </ul>
Low intake of antioxidants	<ul style="list-style-type: none"> <li>Possible association with higher prevalence of asthma</li> </ul>	<ul style="list-style-type: none"> <li>Disputed by recent meta-analysis</li> </ul>
Higher intake of fresh fruit and vegetable	<ul style="list-style-type: none"> <li>Improved pulmonary function and lower prevalence of asthma</li> </ul>	<ul style="list-style-type: none"> <li>In line with healthy diet promotion for the prevention of cancer and cardiovascular disease</li> </ul>
<i>Secondary prophylactic effects</i>		
Supplementation with antioxidants (vitamins C, E, selenium)	<ul style="list-style-type: none"> <li>Limited evidence of clinical benefits</li> </ul>	<ul style="list-style-type: none"> <li>Selenium supplementation showed improvements in terms of 'clinical evaluation' but not in objective parameters of lung function and airway hyperresponsiveness</li> </ul>
Supplementation with or diet high in fish oil	<ul style="list-style-type: none"> <li>No significant improvement in asthma control</li> </ul>	<ul style="list-style-type: none"> <li>No known adverse effects</li> </ul>
Probiotics	<ul style="list-style-type: none"> <li>No effect on clinical parameters</li> </ul>	<ul style="list-style-type: none"> <li>Decrease in eosinophilia</li> </ul>
Low sodium intake	<ul style="list-style-type: none"> <li>Minimal clinical improvements</li> </ul>	<ul style="list-style-type: none"> <li>High sodium intake associated with increased bronchial hyperresponsiveness</li> </ul>
Low magnesium intake	<ul style="list-style-type: none"> <li>Associated with higher prevalence of asthma</li> </ul>	<ul style="list-style-type: none"> <li>Magnesium used as muscle relaxant in acute asthma attacks</li> </ul>
Weight reduction in obese asthma patients	<ul style="list-style-type: none"> <li>Improved asthma control</li> </ul>	<ul style="list-style-type: none"> <li>Limited evidence of a strict calorie-controlled diet</li> </ul>
Food additive avoidance	<ul style="list-style-type: none"> <li>No effect on asthma control</li> </ul>	<ul style="list-style-type: none"> <li>Restrictive diet seldom used in asthma</li> </ul>

*Note:* The evidence is largely based on observational studies that are often multifaceted making it difficult to differentiate the effects of one exposure or intervention from another.

## Pathogenesis

Asthma represents a spectrum of pathophysiologic processes involving different degrees of airway inflammation and remodeling. At the mild end of the spectrum, there is allergic asthma mainly driven by Th2-mediated inflammatory responses and associated with other allergic comorbidities such as rhinitis and atopic dermatitis. In moderate disease, altered epithelial–mesenchymal communication is observed, leading to the generation of growth factors and cytokines with subsequent sustained inflammation. When the epithelial–mesenchymal component becomes dominant in more severe disease, tissue damage and remodeling can be observed as well as increased mucus secretion with obstruction of peripheral airways.

## Nutrition and Asthma

The relationship between nutrition and asthma has had increased interest over the past 10 years. Some studies have looked at nutritional changes influencing the establishment of asthma, whereas others have concentrated on possible secondary prophylactic measures once the diagnosis of asthma has been made (Table 5).

## Possible Preventative Effects of Nutrition

The evidence for possible preventative effects of nutritional changes is based mainly on observational studies. Most studies are multifaceted and it is often difficult to differentiate the effects of one exposure or intervention from another. Allergenic food avoidance during pregnancy, lactation, and weaning has no effect on the subsequent development of asthma. Supplementation with, or diet high in, fish oil during pregnancy and infancy has only limited effect on asthma development. Low vitamin D status in pregnant

mothers is associated with a higher occurrence of wheeze in their children but further studies are required. Similarly, a higher prevalence of asthma has been reported with lower intake of antioxidants, although a recent meta-analysis does not support the hypothesis of linking vitamin C and E intake to a risk of asthma.

Breast-feeding is recommended over other types of feeding, and in infants at high risk of developing asthma (first-degree relative with atopy) where breast-feeding is not possible, hydrolyzed formula for a minimum of 4 months together with other preventative measures may reduce the risk of developing asthma or wheeze in the first year of life. Inconclusive evidence exists that growth rate during infancy may be related to the risk of development of asthma.

### Secondary Prophylactic Effects of Nutrition in Asthma

Intervention studies could not confirm that supplementation with antioxidants produce clinical benefits in asthma. Better pulmonary function and less asthma have been observed, though, when there is higher intake of fresh fruit and vegetables and it seems to be reasonable to advise a healthy diet. Supplementation with, or a diet high in, fish oil as well as probiotics in asthmatic patients did not show any significant clinical improvement but equally showed no adverse effects with the latter showing a decrease in eosinophilia.

High sodium intake is associated with increased bronchial hyperresponsiveness; however, reducing salt intake results in only minimal clinical improvements. Low magnesium intakes may be associated with higher prevalence of asthma. Magnesium is used in the treatment of acute attacks for smooth muscle relaxation. Studies of long-term oral supplementation trials are limited and further larger randomized trials are required.

Obese asthma patients are advised to reduce weight based on evidence of an association between increased BMI and increased incidence and symptoms of asthma. Not enough evidence exists to recommend a strict calorie-controlled diet as a concomitant intervention with drug-based therapy.

According to a recent Cochrane review, there is no evidence that tartrazine, a commonly used food additive, makes asthma worse or avoiding it improves asthma control. Rarely, intolerance to certain foods may act as a trigger for asthma attacks and they should be avoided like other trigger allergens (Figure 7). A simple exclusion diet may be the most useful diagnostic diet, but strict food diets are seldom used in asthma.

## Other Lung Diseases

### Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is strongly associated with obesity and visceral fat mass and linked to serum leptin, insulin, and IL-6 and TNF- $\alpha$  levels. Early weight reduction with a very low-calorie diet and supervised lifestyle counseling is effective in improving symptoms in obese OSAS patients.

### Bronchiectasis

Bronchiectasis unassociated with other conditions like CF is now uncommon in most developed countries, but remains a problem in developing countries and in certain indigenous populations mainly due to tuberculosis and other lung infections. The nutritional management of bronchiectasis is similar to that of CF and COPD.

### Chronic Lung Disease of Infancy

Chronic lung disease of infancy (CLDI) describes a heterogeneous group of pulmonary disorders that originate from an acute respiratory disorder during the neonatal period, which may lead to chronic lung disease in childhood and adult life. The majority of cases are attributable to bronchopulmonary dysplasia (BPD), which is common in very preterm infants with respiratory distress syndrome. BPD has recently been defined as the requirement of supplemental oxygen for 21 of the first 28 days of life and is further defined according to severity (Table 6).

**Table 6** Definition of bronchopulmonary dysplasia (BPD) according to severity (severity depends on the duration and level of supplemental oxygen and mechanical ventilatory support at 36 weeks postmenstrual age (PMA))

Gestational age	<32 Weeks	≥32 Weeks
Mild BPD	Breathing room air at 36 weeks PMA	Breathing room air by 56 days postnatal age
Moderate BPD	Requirement for <30% oxygen at 36 weeks PMA	Requirement for <30% oxygen at 56 days postnatal age
Severe BPD	Requirement for ≥30% oxygen and/or positive pressure at 36 weeks PMA	Requirement for ≥30% oxygen and/or positive pressure at 56 days postnatal age

Source: Data extracted from Table 1 on Jobe AH and Bancalari E (2001) Bronchopulmonary dysplasia. *American Journal of Respiratory and Critical Care Medicine* 163: 1723–1729, with permission from American Thoracic Society.

**Table 7** Micronutrients: evidence for the effect of deficiency and supplementation on acute respiratory infections

Micronutrient	Deficiency	Supplementation
Zinc	<ul style="list-style-type: none"> <li>Increased prevalence and severity of LRTI</li> </ul>	<ul style="list-style-type: none"> <li>Possible beneficial effects as adjunct therapy on length of symptoms and outcome in acute pneumonia</li> <li>Reduction in LRTI prevalence</li> </ul>
Vitamin A	<ul style="list-style-type: none"> <li>Increased risk of developing ARI</li> </ul>	<ul style="list-style-type: none"> <li>No evidence as adjunct therapy during ARI</li> <li>No evidence as preventative supplementation<sup>a</sup></li> </ul>
Vitamin D	<ul style="list-style-type: none"> <li>Increased risk and severity of LRTI</li> </ul>	<ul style="list-style-type: none"> <li>No evidence yet as adjunct therapy or preventative supplementation</li> </ul>
Iron	<ul style="list-style-type: none"> <li>Increased incidence of LRTI</li> </ul>	<ul style="list-style-type: none"> <li>No overall effect on risk of LRTI</li> </ul>
Selenium	<ul style="list-style-type: none"> <li>Found in premature babies with RDS and associated with CLDI in low birth weight infants</li> </ul>	<ul style="list-style-type: none"> <li>Possible benefits as adjunct therapy in ARI</li> </ul>
Multiple micronutrients	<ul style="list-style-type: none"> <li>Increased risk of LRTI</li> </ul>	<ul style="list-style-type: none"> <li>Limited evidence. Suggested reduction in incident of LRTI similar to zinc supplementation alone</li> </ul>

<sup>a</sup>Apart from in those who are malnourished.

Short-term vitamin A supplementation has been shown to reduce BPD at 36 postmenstrual age (postmenstrual age (weeks): gestational age plus chronological age) in extremely low birth weight infants (<1000 g), but the effects are similar to caffeine that is currently used, and the long-term risk–benefit ratio of vitamin A for neurodevelopment has not been fully established.

Growth failure is common in infants with BPD. They have increased metabolic demands and a relative state of protein-calorie malnutrition. Early growth restriction may increase long-term cardiovascular risks and have adverse effects on respiratory function. Currently, guidelines promote ‘aggressive’ nutrition for extremely preterm infants (born <28 weeks’ gestation), which includes introducing parenteral amino acids from day one and lipids from day two, and using milk fortifiers to increase daily protein and caloric intakes to 4.4 g kg<sup>-1</sup> and 130–150 kcal kg<sup>-1</sup>, respectively.

### Respiratory Tract Infections and Micronutrients

Studies have shown that undernourished children have a relative risk of 1.2 for an increased incidence of any acute respiratory illness (ARI) and 1.9 for lower respiratory tract infections (LRTIs). Single and multiple micronutrient deficiencies as part of malnutrition may be associated with increased prevalence of respiratory disease (Table 7). However, supplementation trials with single and multiple micronutrients in the prevention and as treatment adjunctive of ARIs have so far mainly shown contradictory results and further research is required to make recommendations. There are suggestions that adjunct therapy with zinc during the treatment of acute pneumonia may reduce the length of symptoms and improve outcome. Similar suggestions have been made with regard to selenium supplementations.

For detailed discussion of nutrition and tuberculosis, see article Nutrition and Susceptibility to Tuberculosis (00268).

## Glossary

**Anthropometrics** Body measurements used to determine body fat composition.

**Bioelectrical impedance** A method that uses a small electrical current to measure body composition.

**DEXA scan** A dual energy X-ray absorptiometry scan that uses X-ray beams to measure bone density and/or body composition.

**Endoscopy** A procedure that uses an instrument to look inside the body for diagnostic or therapeutic purposes.

**Protein hydrolysate** A type of formula in which proteins are broken down into smaller peptides by hydrolysis.

## Introduction

The human gastrointestinal tract has an impressive capacitance for water, electrolyte, and nutrient absorption. In some disease states, however, this excess capacity is outpaced by either intestinal secretion or inadequate absorption. Malabsorption is defined as the inability of the gastrointestinal tract to adequately absorb nutrients. Although strictly speaking, malabsorption is distinct and contrasted with maldigestion (inadequate breakdown of nutrients in the intestinal lumen); the therapeutic implications of these two conditions are often similar. Multiple causes of malabsorption exist and reviews of these individual diagnoses can be found in separate sections of this text (e.g., inflammatory bowel disease, cystic fibrosis, short bowel syndrome, etc.). The pathophysiology, symptoms, and nutritional therapies for common malabsorption syndromes have been reviewed.

## Pathophysiology and Symptoms

Malabsorption can occur when any of the several steps in nutrient digestion, absorption, and/or assimilation are interrupted; see **Table 1** for a list of congenital defects in nutrient assimilation. Carbohydrate malabsorption can occur, for instance, when intestinal disaccharidases are reduced in concentration at the enterocyte. The brush border membrane produces four disaccharidases that are important in carbohydrate digestion. These enzymes are sucrase-isomaltase, maltase-glucoamylase, trehalase, and lactase-phlorizin hydrolase. Worldwide, lactase deficiency is the most common type of acquired disaccharidase deficiency. With lactase deficiency, malabsorbed carbohydrate remains in the intestinal lumen and exerts an osmotic pull on fluids and electrolytes, leading to abdominal cramping and loose stools. Malabsorbed carbohydrate can be metabolized by gastrointestinal tract bacteria, and the fermented

**Table 1** Congenital defects in nutrient assimilation. Included are congenital defects that are associated with gastrointestinal symptoms and/or nutritional deficiencies. Congenital defects not included here include multiple defects in amino acid absorption

<i>Disorder</i>	<i>Gene/protein affected</i>	<i>Symptoms</i>
<i>Carbohydrate digestion</i>		
Congenital lactase deficiency	Lactase	Lactose-induced diarrhea
Hypolactasia	Lactase	Lactose-induced diarrhea
Congenital sucrase-isomaltase deficiency	Sucrase-isomaltase	Sucrose-induced diarrhea
<i>Carbohydrate absorption</i>		
Glucose–galactose malabsorption	Sodium-glucose-co-transport (SGLT1); SLC5A1	Glucose-induced diarrhea
Fructose malabsorption	Facilitative fructose transport (GLUT5); SLC2A5	Fructose-induced diarrhea
Fanconi-Bickel syndrome	Facilitative glucose transport (GLUT2); SLC2A2	Diarrhea and nephropathy
<i>Protein digestion</i>		
Enterokinase deficiency	Serine protease 7	Diarrhea and edema
Trypsinogen deficiency	Trypsinogen	Diarrhea and edema
<i>Fat digestion</i>		
Pancreatic lipase deficiency	Pancreatic lipase	Steatorrhea
<i>Fat assimilation</i>		
Abetalipoproteinemia	Microsomal triglyceride transfer protein	Steatorrhea
Hypobetalipoproteinemia	Apolipoprotein B	Steatorrhea
Chylomicron retention disease	Sar1-ADP-ribosylation factor family GTPases	Steatorrhea
Primary bile acid malabsorption	Sodium-bile acid transporter; SLC10A2	Steatorrhea, bile acid diarrhea
Tangier disease	ATP-binding cassette transporter 1	Hepatosplenomegaly
Sitosterolemia	ATP-binding cassette, subfamily G, member 8; ABCG8	Atherosclerosis
<i>Ion and metal absorption</i>		
Congenital sodium diarrhea	Defective Na <sup>+</sup> /H <sup>+</sup> exchange	Secretory diarrhea
Congenital chloride diarrhea	Defective Cl <sup>-</sup> /HCO <sub>3</sub> <sup>-</sup> exchange	Secretory diarrhea
Cystic fibrosis	CFTR	Pancreatic insufficiency, meconium ileus
Acrodermatitis enteropathica	Zinc and iron-regulated transport proteins; SLC39A4	Diarrhea and dermatitis
Menkes disease	Copper transporter	Developmental delay
Primary hypomagnesemia	Paracellin 1; claudin 16	Seizures, deafness and polyuria
Hemachromatosis	Hepcidin, others	Cirrhosis, cardiomyopathy, diabetes
<i>Vitamin absorption</i>		
Folate malabsorption	?	Macrocytic anemia, diarrhea, developmental delay
Congenital pernicious anemia	Intrinsic factor	Macrocytic anemia, developmental delay
Imerslund-Graesbeck syndrome	Cubilin, amnionless	Anemia, proteinuria
Congenital deficit of transcobalamin II	Transcobalamin II	Anemia, diarrhea, developmental delay
Thiamine-responsive megaloblastic anemia	Thiamine transport protein; SLC19A2	Anemia, diabetes, cranial nerve defects
Familial retinol binding protein (RBP) deficiency	Retinol-binding protein 4	Ophthalmologic problems
Selective vitamin E deficiency	Alpha-tocopherol transport protein	Vitamin E malabsorption

In: Kleinman RE, Goulet O, Mieli-Vergani G, Sanderson IR, Sherman P, and Shneider B (eds.) *Walker's Pediatric Gastrointestinal Disease: Pathophysiology, Diagnosis, Management*, 5th edn., p. 290. Hamilton, Ontario: BC Decker.

gas produced is associated with flatulence and bloating. Bacterial overgrowth of the small intestine, as seen with short bowel syndrome, can also be associated with carbohydrate malabsorption.

Steatorrhea, excessive fat in the stools, results from fat malabsorption or maldigestion and can have several causes, most notably pancreatic insufficiency due to cystic fibrosis, chronic pancreatitis, Shwachman-Diamond syndrome, and Johanson-Blizzard syndrome. Failure of pancreatic secretion of lipase, amylase, and other digestive enzymes leads to persistence of dietary fat in the intestinal lumen, causing bloating, abdominal pain, and bulky, foul-smelling, oily stools. The stools often float due to a high gas content and test positive for fat. Patients also complain of blunted appetite and nausea. Other causes of fat malabsorption include hepatobiliary disease with inadequate bile salt circulation, severe mucosal disease, and short bowel syndrome.

The most common cause of protein malabsorption is so-called protein-losing enteropathy. Etiologies include diffuse mucosal disease such as celiac disease or Crohn's disease, elevated right heart pressure with resultant dilatation of lymphatics and leakage of lymph into the lumen, and invasive enteropathies as seen with *Shigella* or *Salmonella* infections. Because protein is a relatively minor component of dietary energy compared with carbohydrate and fat, symptoms of protein malabsorption can sometimes be minimal. However, infectious colitis or exacerbations of inflammatory bowel disease often present with frequent loose stools, which may be bloody. Rarely, congenital etiologies of protein malabsorption include enterokinase and trypsinogen deficiencies (Table 1).

Finally, the malabsorption of various micronutrients can occur in conjunction with or separate from the macronutrient malabsorption syndromes noted above. For instance, steatorrhea can be accompanied by excessive fecal losses of the fat soluble vitamins

A, D, E, and K, as well as calcium and other minerals. Alternatively, atrophic gastritis or surgical resection of the terminal ileum can lead to Vitamin B<sub>12</sub> malabsorption in the absence of any symptoms of diarrhea. Proximal bowel resection can result in iron, zinc and calcium malabsorption. A rare cause of micronutrient inadequacy is abetalipoproteinemia in which fat soluble nutrients are normally digested and absorbed by the intestine but are not delivered to the circulation due to defective transepithelial transport. Other rare causes of micronutrient malabsorption are noted in [Table 1](#).

## General Nutritional Management of Malabsorption

As with all nutritional disorders, a thorough nutritional assessment is needed to plan rational therapy of malabsorption. Important historical points to review include duration of symptoms, underlying etiology of malabsorption, ability to meet nutritional needs by mouth, presence of food allergies, and concurrent medical and surgical problems. The patient's nutritional status (weight, height, body mass index, and their respective percentiles) should be determined. Tests of body composition such as arm anthropometrics, bioelectrical impedance, or DEXA scan should be considered. If the underlying cause of malabsorption is not known, diagnostic gastrointestinal endoscopy, laboratory studies, and/or imaging studies are indicated.

## Specific Nutritional Management of Malabsorption

### Fluids and Electrolytes

Diarrhea is usually the most distressing problem for patients with malabsorption and may cause dehydration. Care should be taken to correct fluid losses with appropriately designed oral rehydration solutions. Even in the setting of massive secretory diarrhea such as seen with cholera infections, oral rehydration solutions are effective at treating dehydration. Recent data have supported the safety and efficacy of oral rehydration solutions of reduced osmolality in children with dehydration from acute diarrhea. An oral rehydration solution with the following composition: glucose 75 mmol l<sup>-1</sup>, sodium 75 mmol l<sup>-1</sup>, potassium 20 mmol l<sup>-1</sup>, base 30 mEq l<sup>-1</sup>, and osmolality 245 mOsm l<sup>-1</sup> is well-suited for the rehydration and maintenance therapy during dehydration due to diarrhea.

In some cases of severe diarrhea, parenteral hydration is the mainstay of therapy. Examples include glucose–galactose malabsorption, congenital chloride diarrhea, microvillous inclusion disease, and tufting enteropathy. These cases, as well as other severe causes of more common malabsorptive syndromes, also frequently require the use of parenteral nutrition therapy.

### Carbohydrate Malabsorption

#### Lactose Intolerance

Lactose intolerance is defined by the occurrence of symptoms after ingestion of lactose, the main carbohydrate in milk. These symptoms may include abdominal pain, bloating, diarrhea, or flatulence. Lactose intolerance is usually secondary to lactose malabsorption caused by a relative deficiency of the disaccharidase lactase, which reduces the ability to digest lactose. Primary lactase deficiency is a condition in which lactase activity falls after weaning around 2 years of age. Secondary lactose intolerance may be temporary and is usually due to mucosal injury associated with a condition or disease such as infectious diarrhea, Crohn's disease, or short bowel syndrome.

In addition to the presence or absence of the lactase enzyme, other factors determine whether a person will have symptoms of lactose malabsorption, including the amount of lactose in the diet, the mixture of lactose with other foods, gastric emptying rate, colonic scavenge of malabsorbed carbohydrate, ethnic origin and age. Although persons of Northern European ancestry commonly maintain the ability to digest lactose into adulthood, primary lactose intolerance is prevalent in African–American, Hispanic, Native American, and Asian populations.

Nutritional management of lactose intolerance consists largely of the removal of lactose from the diet. Lactose is a common ingredient in many foods, including breads, crackers, soups, cereals, cookies, and baked goods. Eliminating or reducing lactose-containing ingredients from one's diet is usually adequate to relieve symptoms. Individuals with primary lactose intolerance may require a permanent dietary change. Individuals with secondary lactose intolerance should eliminate all lactose from their diets for a short period of time ranging from 2 to 6 weeks. If symptoms resolve, lactose may be reintroduced slowly as tolerated by the individual. The amount of lactose that an individual can tolerate is highly variable. Many children can tolerate small amounts of lactose, particularly yogurt or hard cheese, without discomfort. Many adults who consider themselves lactose intolerant can actually tolerate moderate amounts of milk. Lactose intolerant individuals may also tolerate small amounts of lactose consumed over the course of the day better than a large dose all at once.

For individuals who choose to restrict lactose in their diets, a variety of lactose-free and low-lactose food choices are available. Lactose-reduced products, containing 70–100% less lactose than standard foods, are available commercially. Individuals may also choose to consume dairy products with concomitant administration of lactase enzyme tablets or drops.

Frequent consumption of milk and other dairy foods has been associated with better bone health in some studies, and a strict lactose-free diet may not contain adequate amounts of calcium and vitamin D. [Table 2](#) provides a list of some commercially available lactose-free and lactose-reduced calcium supplements.

**Table 2** Commercial calcium supplements

Product	Manufacturer	Mg Calcium/ tablet	IU vitamin D
Citracal Regular	Bayer	500	400
OsCal 500+D	GlaxoSmithKline	500	200
Tums	GlaxoSmithKline	500	0
Calcium Milk Free	Nature's Plus	250	50
Cal-citrate+D	Freeda	250	100
Caltrate 600+D	Pfizer	600	400
Viactiv <sup>a</sup>	McNeil Nutritionals	500	500

<sup>a</sup>This product contains less than 0.5 mg lactose.

### Sucrose

Congenital sucrase-isomaltase deficiency (SID) is the most common congenital disaccharidase deficiency. Patients with this disorder lack functional sucrase, although isomaltase deficiency may be normal or absent. Symptoms of SID can include diarrhea, abdominal pain, and poor weight gain. Dietary avoidance of sucrose or table sugar helps relieve symptoms, and can sometimes help with the diagnosis. Sucraid®, a sacrosidase produced from *Saccharomyces cerevisiae*, is an enzyme that can be given with meals and allows increased tolerance to sucrose.

### Fat Malabsorption: Fat and Fat-Soluble Nutrients

Patients with pancreatic insufficiency are unable to produce and secrete enough enzymes to aid with the breakdown of fats in the intestinal lumen. In studies of normal adults and those with pancreatic insufficiency, pancreatic enzyme secretion needs to be lower than 15% of normal levels before significant steatorrhea is seen (Figure 1). Once clinically significant steatorrhea is determined, recovery of pancreatic function is therefore unlikely.

Historically, patients with pancreatic insufficiency due to cystic fibrosis (CF) were told to minimize symptoms of steatorrhea by limiting dietary fat. However, epidemiologic studies confirmed that this advice led to negative energy balance, undernutrition, and higher mortality rates, compared to communities in which CF patients were treated with high-energy and high-fat diets. The introduction of effective pancreatic replacement therapy has been heralded as one of the most significant breakthroughs in the nutritional management of CF, responsible partly for the substantial increase in lifespan enjoyed by more recent generations of CF patients. In fact, the finding of a lower incidence of growth failure in CF patients diagnosed and treated with aggressive nutritional therapy early in infancy has been used as justification for neonatal screening of this condition.

**Figure 1** Pancreatic enzyme secretion and steatorrhea. Significant steatorrhea ensues when pancreatic function is less than 15% of normal. Reproduced with permission from DiMagno EP, Go VLW, and Summerskill WHJ (1973) Relations between pancreatic enzyme output and malabsorption in severe pancreatic insufficiency. *New England Journal of Medicine* 288: 814. Copyright © 1973 Massachusetts Medical Society. All rights reserved.

Judicious use of pancreatic replacement enzymes is the hallmark of nutritional therapy of CF and other disorders of pancreatic insufficiency. Multiple commercial preparations of porcine pancreatic enzymes are available, most of which contain lipase, amylase, and protease enzymes. A nonporcine pancreatic enzyme is currently under development. The dose is usually titrated to the amount of steatorrhea. If meals take more than 30 min, the dose may be divided with half given before the meal and half given mid-way through the meal. Patients who cannot swallow pills may open the capsules and sprinkle the enzymes into acidic foods.

Another critical aspect of the nutritional management of fat malabsorption is routine supplementation with the fat-soluble vitamins A, D, E, and K. Multiple studies have confirmed that patients with CF, Crohn's disease, and other malabsorptive disorders are prone to micronutrient deficiencies, and some literature suggests that dietary needs for these and other antioxidant nutrients may be increased in settings of infectious and catabolic stress often suffered by these patients. The contribution of fat malabsorption contributing to other important mineral malabsorption, as in the case of calcium or zinc, should also be recognized.

Routine supplementation of fat-soluble vitamins is indicated in patients with fat malabsorption. In addition, serial measurement of fat-soluble vitamin biochemical status is recommended. Because blood nutrient concentrations of these and other nutrients can vary with the concentration of transport proteins, correction for these can aid the interpretation of these lab findings. For instance, vitamin A toxicity should be suspected if the molar ratio of vitamin A: Retinol-binding protein exceeds 1. Vitamin E concentrations, for example, should be corrected for circulating lipids.

Some patients with pancreatic malabsorption may benefit from a diet enriched in medium chain triglycerides (MCTs). MCTs are absorbed directly into the portal circulation and therefore bypass the steps of intraluminal digestion, reesterification, and enterocyte uptake. Therefore, these fats may be a dietary source of fats more easily absorbed in settings of fat malabsorption due to either pancreatic insufficiency or mucosal disease. However, MCT oils are less energy dense than long-chain fats, are more expensive, and do not contain the essential fatty acids alpha-linolenic and linolenic acid.

### Protein Malabsorption

Protein-losing enteropathy (PLE) can also be treated with a variety of nutritional interventions. PLE due to dilated lymphatics as with right heart failure results in leakage of lymphocytes, proteins, and fats into the intestinal lumen. As with fat malabsorption, MCT-supplemented foods and formulas are therefore indicated to allow improved fat absorption in PLE. Fat-soluble vitamin supplementation is indicated. In congenital protein malabsorption syndromes, peptide- or amino acid-based formulas are often helpful.

Mucosal disorders including inflammatory bowel disease, allergic diseases, and celiac disease are other examples of disorders causing protein malabsorption. Once intestinal inflammation is reduced with appropriate medical or nutritional therapy, absorption of protein is usually improved. In *Shigella* infections, some studies have suggested improved nutritional outcomes with a high-protein diet during recovery from the acute symptoms of diarrhea.

### Route of Nutrition in Malabsorption

Several factors need to be considered when recommending whether oral, enteral, or parenteral nutrition should be used in providing nutrition to the patient with malabsorption. These factors include etiology of malabsorption, severity of gastrointestinal disease, and underlying nutritional and medical conditions. Oral nutrition using modified diets as noted above is, of course, the most customary and desirable by physician and patient alike. In cases of mild lactose malabsorption, for instance, modification of a regular, healthy diet to avoid foods high in lactose should be sufficient. In cases where widespread gastrointestinal disease is leading to severe malabsorption, enteral or 'tube' feeding is helpful for two main reasons: (1) use of proprietary formulas specially designed for malabsorption are often indicated, and these formulas may be unpalatable, and (2) enteral feedings, especially with slow continuous 'drip' feedings make efficient use of nutrient transport kinetics, thereby maximizing residual gastrointestinal absorptive function. In severe cases of malabsorption in which tube feedings are unable to achieve adequate nutritional intake, parenteral nutrition may be indicated. Emerging data suggest that serum citrulline, an amino acid synthesized principally by the enterocyte, is a reliable biomarker of mucosal mass and may help distinguish among patients who require parenteral versus enteral nutrition.

### Selection of Enteral Formulas for Malabsorption

A number of commercially available formulas are designed for patients with malabsorption, and these differ with regard to energy density, macronutrient composition, and indicated age. Because infant formulas are often handled in a separate regulatory fashion by governments, infant formulas are usually considered separately from formulas designed for older children and adults. In addition, formulas are also conventionally categorized by the extent of the hydrolysis of their protein source. Categories include intact protein formulas, protein hydrolysate formulas, and amino acid-based formulas. Protein hydrolysate formulas are also sometimes referred to as 'semielemental' formulas, and amino-acid formulas are sometimes called 'elemental' formulas. However, these terms suffer from vagueness and inaccuracies because not all of their macronutrients are semi or completely elemental. Marketing strategies often compound the confusion with misleading formula names. These terms should be discouraged, and the terms that refer to the composition and/or biochemical processing should be used instead.

Patients who have carbohydrate malabsorption from lactose intolerance should use lactose-free formula. Fat malabsorption may call for MCT enriched formula. In cases of protein malabsorption or severe enteropathy, a formula that is a protein hydrolysate or amino acid based would be most appropriate. Because many malabsorption syndromes overlap in terms of the macronutrient affected, as in cases of severe mucosal disease, some formulas are designed for fat, protein, and carbohydrate malabsorption. For example, all formulas designed for use in adults are lactose free, and several formulas contain both hydrolyzed proteins and MCT oils.

## Clinical Management of Malabsorption

Two of the most clinically challenging scenarios for the management of malabsorption are inflammatory bowel disease (especially Crohn's disease) and short bowel syndrome. Both are discussed in separate articles of the text, but are considered briefly below.

### Inflammatory Bowel Disease

Patients with Crohn's disease have widespread and intermittent gastrointestinal inflammation. Some patients with inflammatory bowel disease may require complete bowel rest for several days or even a few weeks to allow time for mucosal healing. To provide nutrition during this period of time, parenteral nutrition may be needed.

Numerous studies have shown that patients with Crohn's disease may safely and effectively achieve clinical remission with primary nutritional therapy. Early literature in the field highlighted the use of protein hydrolysate formulas, which, due to unpalatability, often required administration via a nasogastric or gastrostomy tube. More recent data have confirmed that intact protein formulas, termed 'polymeric' formulas when describing formulas designed for adults, may work as well as protein hydrolysates, and these formulas can be feasibly given by mouth.

As patients are recovering from an exacerbation and begin advancing their diet, patients should temporarily minimize the amount of fiber ingested to decrease trauma to healing mucosa. Patients whose disease affects the small intestine often benefit from temporary avoidance of lactose products as the mucosa heals and brush border membrane enzyme production is restored.

Micronutrients are also needed in the nutritional management of inflammatory bowel disease. Iron supplementation is recommended for anemia due to acute or chronic blood loss. Treatment of inflammatory bowel disease frequently requires the use of steroids, which affects bone density. Calcium and vitamin D supplementation is commonly needed to minimize the osteopenic effects of steroid therapy and/or the effects of malabsorption and chronic inflammation.

### Short Bowel Syndrome

Patients who have suffered acquired or congenital loss of small intestinal surface area that makes them dependent on specialized enteral or parenteral support are said to have short bowel syndrome (SBS). Patients with SBS often malabsorb carbohydrates, proteins, fat, as well as numerous micronutrients, depending on the extent and location of bowel resection, as well as the presence of mucosal disease in the nonresected bowel.

Special attention should be given to exactly what part of the intestine remains as well as the length of the remaining intestine. Some patients may have the terminal ileum removed and are unable to absorb vitamin B<sub>12</sub> and bile acids. Removal of the ileocecal valve increases the risk of bacterial overgrowth. Reduced length also means reduced surface area for the absorption of nutrients and decreased intestinal transit time.

In the immediate postoperative period, parenteral nutrition and gut rest should be used because significant stool output is the norm. Output should be quantified, and electrolytes must be carefully monitored in order to determine appropriate replacement fluids to make up for excess urine, stool, and ostomy losses. Replacement fluids should generally be given separately from standard parenteral nutrition so that they can be adjusted as needed to rapid shifts in fluid and electrolyte status.

As patients recover from surgery, every attempt should be made to feed them enterally as soon as is feasible. Enteral feeds facilitate growth and adaptation of the remaining bowel to allow partial compensation for the missing portion, and several studies have correlated early feeding with better long-term outcome. Attaining independence from parenteral nutrition may take weeks to months to years. **Table 3** outlines an approach to determine feeding advancement in SBS. Although some patients are able to grow well or maintain their body weight with only enteral feeds, many are dependent on parenteral nutrition. Some patients with SBS also have oral feeding aversion due to prematurity, prolonged mechanical ventilation, and/or prolonged orogastric or nasogastric feeding. Gastrostomy tubes are particularly helpful in this regard.

In infants, breast milk should be used if available. The breast milk may need to be fortified to increase calories, protein, or fat. For older patients or infants who are not receiving breast milk, protein hydrolysates or amino acid-based formulas may be better tolerated because the residual bowel more easily absorbs these nutrients. Lactose-free and MCT-containing formulas are often used, as well. Formulas may need to be supplemented with oral rehydration solutions if electrolyte abnormalities persist, particularly with sodium losses through persistent high stool or ostomy output.

Because many patients with SBS are dependent on parenteral nutrition for prolonged periods of time, selenium, carnitine, copper, and zinc blood concentrations should be checked periodically and supplemented if needed. Parenteral nutrition should be cycled off for a few hours each day to help simulate more natural cyclic fluctuations of gastrointestinal hormones. These patients also often have poor absorption of calcium and need calcium supplements to prevent osteopenia, which increases the risk of

**Table 3** Feeding advancement in short bowel syndrome

1. Stool output	
If $<10 \text{ g kg}^{-1} \text{ d}^{-1}$ or $<10$ stools $\text{d}^{-1}$	Advance rate by $10\text{--}20 \text{ ml kg}^{-1} \text{ d}^{-1}$
If $10\text{--}20 \text{ g kg}^{-1} \text{ d}^{-1}$ or $10\text{--}12$ stools $\text{d}^{-1}$	no change
If $>20 \text{ g kg}^{-1} \text{ d}^{-1}$ or $>12$ stools $\text{d}^{-1}$	Reduce rate or hold feeds <sup>a</sup>
or 2. Ileostomy output	
If $<2 \text{ g kg}^{-1} \text{ h}^{-1}$	Advance rate by $10\text{--}20 \text{ ml kg}^{-1} \text{ d}^{-1}$
If $2\text{--}3 \text{ g kg}^{-1} \text{ h}^{-1}$	no change
If $>3 \text{ g kg}^{-1} \text{ h}^{-1}$	Reduce rate or hold feeds <sup>a</sup>
3. Stool reducing substances	
If $<1\%$	Advance feeds per stool or ostomy output
If $=1\%$	no change
If $>1\%$	Reduce rate or hold feeds <sup>a</sup>
4. Signs of dehydration	
If absent	Advance feeds per stool or ostomy output
If present	Reduce rate or hold feeds <sup>a</sup>
5. Gastric aspirates	
$<$ four times previous hour's infusion	Advance feeds
$>$ four times previous hour's infusion	Reduce rate or hold feeds <sup>a</sup>

<sup>a</sup>Feeds should generally be held for 8 h, then restarted at 3/4 the previous rate.

fractures. Iron may also be needed in patients with anemia from decreased absorption secondary to resection of the duodenum or jejunum. Ultimately, weaning from parenteral and enteral nutrition remain the goals of treatment, though lifelong dietary therapy is often needed.

## Summary

Congenital or acquired diseases of the gastrointestinal tract can lead to life-threatening malabsorption of numerous macronutrients and micronutrients. Determining the type and etiology of malabsorption is essential to provide appropriate nutritional and medical therapy. Multiple formulas, supplements, and dietary regimens exist to target specific defects in the digestion, absorption, and assimilation of nutrients. In addition, many new nutrients are undergoing investigation that may become a standard part of care in the future, including probiotics, prebiotics, and various amino acids.

### Key points

- Malnutrition has multiple drivers and a variety of manifestations which are complex and often times interrelated.
- Malnutrition encompasses various conditions/diseases, ranging from wasting and micronutrient deficiencies to obesity.
- Core factors leading to malnutrition include excessive intakes, insufficient food consumption or inadequate utilization of nutrients provided by foods ingested.
- A systems approach incorporating food, health, water and sanitation, education, and social protection is necessary to improve nutrition outcomes.
- Globally many countries are experiencing both under and overnutrition, in essence, the dilemma of overlapping and coexisting forms of malnutrition.

## Introduction

Throughout history, hunger has remained one of the most persistent and devastating problems facing humankind. Although statistics on food insecurity and malnutrition reveal noteworthy improvement in these areas over the last five decades, the current scenario involves factors that undermine the nutrition situation of populations—urbanization, inequities, globalization, environmental calamities, armed conflicts, humanitarian emergencies and health epidemics. In 2020 an estimated 720–811 million people in the world faced hunger, which has been further exacerbated by the COVID-19 pandemic, the effects of climate change, ongoing armed conflicts and the outbreak of war in the Ukraine. This has led to overwhelmed health systems, increased household food insecurity, and reversals in economic growth, all of which could hinder the progress made in addressing undernutrition, particularly among low-income and middle-income countries (LMIC).

Malnutrition doesn't always imply hunger or famine, which is the first association that typically comes to mind. Malnutrition is manifest in many forms and refers to deficiencies, excesses or imbalances in a person's intake of energy and/or nutrients. The resulting consequences cover two broad groups of conditions dealing with deficits and excesses, ranging from emaciation to obesity, which can be defined in terms of undernutrition, overnutrition and micronutrient deficiencies. Simply put, malnutrition is caused by excessive intakes, insufficient food consumption or inadequate utilization of nutrients provided by foods ingested. Insufficient intakes often result from precarious circumstances and inequalities existing at the level of economic resources, education, access to food and safe drinking water, adequate health care and sanitary living conditions. On the other hand, excessive intake of foods high in saturated fats, sugars and industrially processed, refined foods accompanied by decreased physical activity have led to increased obesity and diet-related non-communicable diseases (NCDs).

How malnutrition manifests itself is changing as it is present in various forms in nearly all countries. Currently, there is a global pandemic of overweight and obesity. Simultaneously, the burden of disease in low- and middle-income countries is rapidly changing from communicable to non-communicable diseases. Yet deficiencies in micronutrients and growth are still an issue as seen in rates for anemia as well as wasting, which haven't changed substantially for more than 20 years. The World Health Organization (WHO) estimates that at least one-third of the world's population is affected by micronutrient malnutrition. Moreover, according to the most recent Global Nutrition Report over 2.2 billion adults aged 18 and older are overweight (40% of the global population), of which an estimated 772 million are obese. In effect, no country is free of malnutrition and many households, communities, and regions struggle with all of these forms of malnutrition at the same time. Countries are confronted with the

burden of complex, overlapping and interrelated malnutrition problems, with the combination of under-five stunting, anemia in women of reproductive age, and adult overweight and obesity being the most common. The well documented “double burden of malnutrition” (child undernutrition and maternal overweight/obesity) has evolved into the “triple burden of malnutrition”: under-nutrition, in the form of stunting and wasting, an increasing prevalence of overweight and obesity accompanied by widespread micronutrient deficiencies. These different conditions are connected not only at a physiological level, but also at the level of resources and political will. As obesity and overweight is an extensive subject in and of itself, this article will focus solely on malnutrition in terms of undernutrition and micronutrient deficiencies.

### **Definitions for the discussion of malnutrition**

For clarity, several definitions are presented so as to better understand the context of malnutrition and how to distinguish its various forms.

#### **Malnutrition**

An abnormal physiological condition caused by inadequate, unbalanced or excessive consumption of macronutrients and/or micronutrients. Malnutrition includes undernutrition and overnutrition as well as micronutrient deficiencies.

#### **Overnourishment**

Food and beverage intake that is continuously in excess of dietary energy requirements.

#### **Overnutrition**

A result of excessive food intake relative to dietary nutrient requirements.

#### **Overweight and obesity**

Body weight that is above normal for height as a result of excessive fat accumulation. It is usually a manifestation of overnourishment and/or sedentary lifestyles and a lack of physical activity. Overweight is defined as a Body Mass Index (BMI) of more than 25 but less than 30. Obesity is defined as a BMI of 30 or more.

#### **Protein energy malnutrition**

Classic medical terminology referring to a group of related disorders that include marasmus, kwashiorkor and intermediate states of marasmus-kwashiorkor. This designation implied that malnutrition was a deficiency of protein or energy and, as for other specific deficiencies, suggested that treatment should consist of proteins or calories (energy). Textbooks usually went on to say that Marasmus (extreme thinness) was due to insufficient calories, and Kwashiorkor (edematous malnutrition) was the result of a lack of proteins. This has now been proven incorrect due to the role of deficient intakes of essential micronutrients needed for growth and tissue renovation. Marasmus can occur with excess energy if no nutrients are ingested and Kwashiorkor can become manifest even with excess protein in the diet.

#### **Stunting**

Also known as linear growth, stunting is defined as height/length (cm) for age (months)  $< -2$  SD of the WHO Child Growth Standards median. Low height-for-age is an indicator that reflects the cumulative effects of undernutrition and infections since and even prior to birth. It may be the result of long-term nutritional deprivation, recurrent infections and lack of water and sanitation infrastructures.

#### **Undernourishment**

The state in which an individual's usual food consumption is insufficient to provide the amount of dietary energy required to maintain a normal, active, healthy life.

#### **Undernutrition**

The outcome of poor nutritional intake in terms of quantity and/or quality, and/or poor absorption and/or poor biological use of nutrients consumed as a result of repeated instances of disease. It includes being underweight for one's age, too short for one's age (stunted), precariously thin for one's height (suffering from wasting) or deficient in vitamins and minerals (micronutrient deficiency).

#### **Underweight**

Low weight-for-age in children, and BMI of less than 18.5 in adults, reflecting a current condition resulting from inadequate food intake, past episodes of undernutrition or poor health conditions.

### Wasting

Defined as low weight-for height/length (Weight for height/length  $< -2$  SD of the WHO Child Growth Standards median). Low weight-for-height/length is an indicator of acute weight loss or a failure to gain weight and can be a consequence of insufficient food intake and/or an incidence of infectious diseases, particularly diarrhea.

### Malnutrition and mortality

The 2013 Lancet Series on Maternal and Child Nutrition highlighted that undernutrition, including fetal growth restriction, suboptimum breastfeeding, stunting, wasting, and deficiencies of vitamin A, iodine and zinc, caused 3.1 million deaths annually in children younger than 5 years. This represented a staggering 45% of total child deaths in 2011. Included in this total was the combined distribution of suboptimum breastfeeding and fetal growth restriction in the neonatal period, which resulted in 1.3 million deaths or 19% of all deaths of children younger than 5 years. They provided clear evidence about the importance of undernutrition as a predisposing factor of an increased risk for illness and death and as an antecedent condition of structural and functional limitation. During the acute stage of severe undernutrition, the greater susceptibility of the child to infectious disease has major clinical significance and important consequences for child mortality.

Fig. 1 shows the contribution of different childhood illnesses on child mortality, with pneumonia (30%) and diarrhea (27%) comprising over 50% of childhood deaths. The area within the red circle represents the percentage of deaths that were caused due to the child being undernourished. When compared to a well-nourished child, children with severe, moderate or even mild undernutrition have a higher risk of mortality from these childhood illnesses. As such, undernutrition constitutes an underlying cause for most childhood deaths associated with severe infections. Recent Joint Child Malnutrition Estimates highlight that around 45% of deaths among children under 5 years of age are linked to undernutrition, most of which occur in low- and middle-income countries (LMIC).

Recent data from the United Nations Interagency Group for Child Mortality Estimation shows that despite a global decline in mortality over the past three decades, 5.2 million children died before the age of 5 years in 2019 alone, primarily of preventable or treatable causes (Fig. 2). Almost half of these deaths occurred in the first month of life. Another analysis evaluating the impacts of COVID-19 on childhood malnutrition and nutrition-related mortality in 118 LMICs suggests there could be a 14.3% increase in the prevalence of moderate or severe wasting among children younger than 5 years due to COVID-19-related economic declines. Currently, the interagency joint malnutrition estimates state that there are 45.4 million children under 5 years of age who suffer from moderate or severe wasting. When the projected increase in wasting in each country was combined with a projected yearly average reduction of 25% in nutrition and health services, an estimated 128,605 (ranging from 111,193 to 178,510 for best and worst case scenarios) additional deaths in children younger than 5 years were projected during 2020, with an estimated 52% of these deaths in sub-Saharan Africa. Sub-Saharan Africa remains the region with the highest under-5 mortality rate in the world, an average of 74 deaths per 1000 live births in 2020, 14 times higher than the risk for children living in Europe and North America.

### Nutrition and sustainable development

In 1992, the first International Conference on Nutrition held in Rome called for a global commitment to address the problem of malnutrition. Since then several initiatives have continued to address this challenge. On January 1, 2016, 17 Sustainable

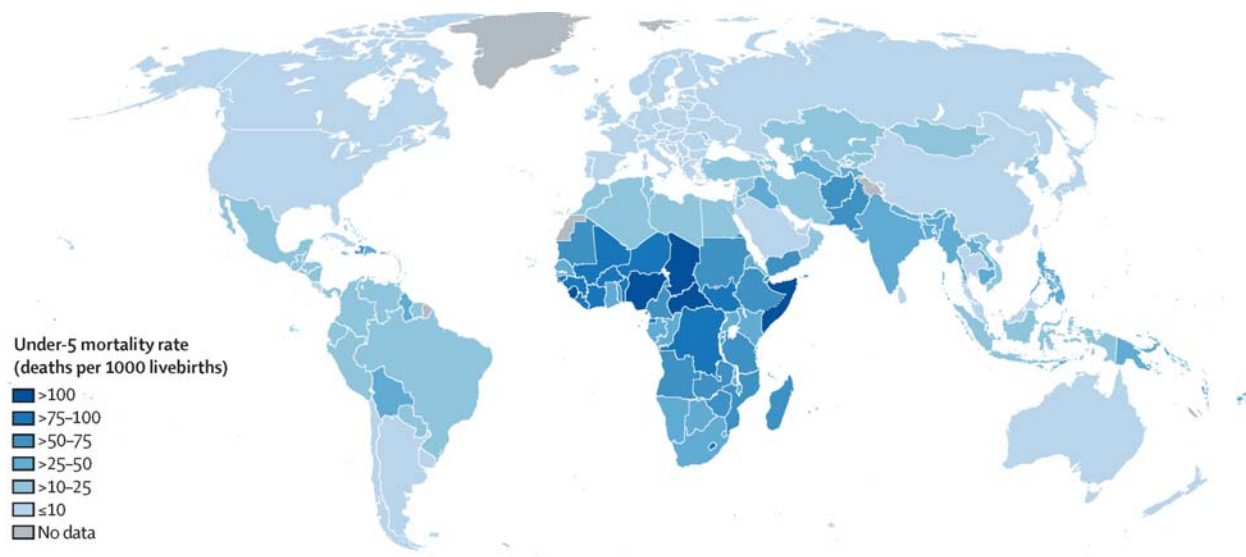

Fig. 1 Undernutrition-related risk of death associated with specific diseases.

**Fig. 2** Under-5 mortality rate in 2019, by country. Source: Sharrow et al. (2022).

**Fig. 3** 17 Sustainable development goals of the 2030 agenda for sustainable development. Source: United Nations (2022).

Development Goals (SDG), also known as the Global Goals, of the 2030 Agenda for Sustainable Development were formally recognized, which had been adopted by world leaders in September 2015 at a momentous UN Summit (see Fig. 3). They built on the success of the Millennium Development Goals (MDGs) with the objective of going further to end all forms of poverty. Moreover, at least 12 of the 17 Sustainable Development Goals contain indicators that are extremely relevant for nutrition, reflecting nutrition's central role in sustainable development. As such, the SDGs are broader in scope with 169 targets which recognize that ending poverty requires fomenting strategies that target economic growth and address a range of social needs including health, education, social welfare, and job opportunities, while taking on climate change and environmental protection. SDG 2, "End hunger, achieve food security and improved nutrition and promote sustainable agriculture", aims to put an end to hunger and ensure access by all people, particularly those in vulnerable situations, including infants, to safe, nutritious and sufficient food all year round by 2030. Also, by 2030, another target aims to end all forms of malnutrition, including achieving, by 2025, the internationally agreed upon targets on stunting and wasting in children under 5 years of age, and to address the nutritional needs of adolescent girls, pregnant and lactating women and older persons (Fig. 4).

**Fig. 4** Reducing stunting: benefit for every dollar spent by country, (discount rate = 3%, final working age = 50). Source: [Horton and Hoddinott \(2014\)](#).

### Human and economic costs

Improving nutrition contributes to productivity, economic development, and poverty reduction by improving physical work capacity, cognitive development, school performance, and health by reducing disease and mortality. As the Copenhagen Consensus Center has shown, an entity that collaborates with the world's top economists to research the best solutions for global challenges, investing in nutrition is critical as poor nutrition perpetuates the cycle of poverty and malnutrition through three main pathways: (1) direct losses in productivity from poor physical status and losses caused by disease linked with malnutrition; (2) indirect losses from poor cognitive development and losses in schooling; and (3) losses caused by augmented health care costs. The economic costs of malnutrition are staggering—several billion dollars a year in terms of lost gross domestic product (GDP).

Since early childhood offers a special window of opportunity to improve nutrition, the bulk of the investment needs to be targeted between pre-pregnancy and 2 years of age. Economic studies show that every dollar spent on nutrition in the first 1000 days of a child's life (fetus to age two) can yield, on average, a savings of \$45 and in some cases as much as \$166.

### Sustainable food systems

The UN's Zero Hunger Challenge (ZHC), launched in 2012, aims for all food systems to be sustainable. This approach is critical as what we eat affects both human and planetary health. Unsustainable food consumption and production constitute the primary causes of the triple planetary crises: climate change, biodiversity loss and pollution. Food systems should take into account their environmental impact, and in so doing, create a vital link between the nutrition agenda and the sustainability agenda of the SDGs. However, in many regions throughout the world, dietary patterns and their associated food systems are linked to child malnutrition, environmental degradation and climate change. Simultaneously, climate change is undermining and reversing the advances made in reducing child malnutrition. In fact, lower income countries bear a greater burden of the negative impacts of climate change. This is due to their economic reliance on climate-sensitive sectors (agriculture and fishing, for example), and to their limited financial, human and institutional capacity for forecasting and responding to the direct and indirect effects of climate change.

Data from the 2021 Global Nutrition Report shows that lower-income countries continue having the lowest consumption of health-promoting foods and the highest numbers of underweight, whereas higher-income countries have the highest consumption of foods with greater environmental and health impacts, and the highest levels of overweight and obesity. Economic and policy support measures for agricultural production primarily target staple foods, dairy and other protein-rich foods of animal origin, especially in high- and upper-middle-income countries. The most incentivized foods at a global scale include various categories of meat, rice and sugar while fruits and vegetables have less overall support, or may even be penalized in some low-income countries.

Moreover, in order to comply with the targets of the SDG 2 by 2030, increasing the supply of healthy foods should be accompanied by lower costs of these foodstuffs so that the population has access to them. This implies both an expansion in the supply of the nutritious foods that constitute a healthy diet and a shift in consumption toward them. As such, corresponding policies that promote changes in food environments and consumer behavior toward healthy eating patterns are also required. Agriculture policies and programs have concentrated so far on commodities and value chains. However, policy-makers are moving beyond the current focus on commodity goods and are beginning to implement actions centered on whole diets and food systems. This holistic approach can be seen in recent initiatives by key international agencies such as the United Nations Food Systems Summit and the Nutrition for Growth Summit and their focus on placing healthy diets and food systems at the forefront of their work. Among

others, a primary goal consists of “Repurposing food and agricultural policy support to make healthy diets more affordable” by reducing the costs of nutritious foods relative to other foods and people’s income.

Dietary habits and the quantities and types of foods consumers demand are also associated with substantial and increasing levels of environmental pollution and resource use. Inadequate diets are both a cause and a symptom of climate change. Current food production and consumption patterns contribute to biodiversity loss, put pressure on natural resources, and provoke Greenhouse Gas (GHG) Emissions and excessive agro-chemical inputs, particularly in developed countries. Industrialized regions are living beyond the planet’s capacity, yet their food systems are too often considered as role models for developing countries. Food systems—both in developed and developing countries—need to be restructured and take into account social, environmental and public health impacts. Biodiversity offers a wealth of untapped potential for livelihoods, health, nutrition and environments. Interdisciplinary collaboration is needed if global efforts are to tackle malnutrition, NCDs and the impact of food on climate change, water and biodiversity. Food production and consumption that is sustainable can safeguard the planet from degradation and lessen the effects of climate change and extreme weather events. In order to be sustainable, it’s essential that diets be healthy as well as being compatible with the sustainable management of natural resources and ensuring social equity. As has been done with nutrition, advocacy for making sustainable food production central to development is essential.

## Types of malnutrition

### Undernutrition

Undernutrition is a physical condition characterized by a nutritional disorder resulting from insufficient food intake (undernourishment) and/or poor absorption and/or poor biological use of nutrients consumed as a result of repeated infectious disease. It encompasses being underweight for one’s age, too short for one’s age (stunted), dangerously thin for one’s height (wasted) and deficient (status and function) in vitamins and minerals (micronutrient malnutrition). Although the terms malnutrition and undernutrition are often used interchangeably, the first is more extensive in scope. In this article both are used interchangeably. Indeed, malnutrition is a nutritional disorder that can manifest itself in distinct forms:

- (a) *Overnutrition*: a result of excessive food intake relative to dietary nutrient requirements. Previously more prevalent in developed countries, but now also appearing in countries with emerging economies.
- (b) *Undernutrition*: as previously defined above. It’s worth noting that different organizations have distinct definitions for this term. Some refer to it as an insufficient intake of nutrients to sustain a state in which the physical function of an individual is impaired to the point where s/he can no longer maintain adequate bodily performance process such as growth, pregnancy, lactation, physical work and resisting and recovering from disease.
- (c) *Secondary undernutrition*: not caused by diet but rather by diseases or pathologies (diarrhea, infections, measles, intestinal parasites, etc.) that prevent the body from absorbing ingested nutrients.
- (d) *Micronutrient deficiency*: when essential micronutrients such as vitamins and/or minerals and trace elements are not present in adequate amounts in the diet.

The last three are common in developing countries, with distinctions being made between acute undernutrition, also known as Moderate Acute Malnutrition (MAM) and Severe Acute Malnutrition (SAM), and chronic undernutrition (stunting). These three situations, and especially undernutrition, are often referred to colloquially as hunger. When in a given place and time, it undergoes a process of escalation that is accompanied by other factors (impoverishment, epidemics, often an increase in mortality), the situation turns into a famine. Undernutrition affects all age groups, but some are particularly vulnerable, mainly children (especially those between 6 months and 5 years, after weaning), the elderly and pregnant and lactating women.

Currently undernutrition is a problem that affects developing as well as industrialized countries, and in both cases, the most economically disadvantaged are those that are most affected. In developed countries, obesity is rapidly extending, especially among the poorest segments of the population, bringing with it an epidemic of nutrition-related NCDs such as diabetes and cardiovascular disease, which increase health care costs and reduce productivity. In developing countries, although undernutrition and micronutrient deficiency diseases continue to be particularly pervasive, the swiftly spreading problem of obesity is also a burden. It is common to find underweight children and obese adults within the same household, both in developed and developing countries. Moreover, UNICEF affirms that in 2020, the nutritional state of the world’s children was characterized by a triple burden of malnutrition-undernutrition, micronutrient deficiencies, and overweight. This triple burden is manifest in multiple forms and often coexists in the same population, household, and even in the same child. As shown in [Fig. 5](#), 88% of countries analyzed faced overlapping burdens of malnutrition.

Manipulating market dynamics and prices fail to address the problem of undernutrition when families have no money to buy enough food or pay for health care expenses. Advocacy linked to human rights and equity should be considered, as well as other initiatives related to income generation, thus justifying government intervention to support those families in need. However, undernutrition also occurs in many families with adequate economic resources, as people do not always know which foods or feeding practices are best for themselves or for their children, in which inadequate marketing practices from industry play a part. It may also be difficult for parents to know whether their children are starting to suffer from undernutrition as growth deficits and micronutrient deficiencies are not easily detected by those without previous training or education on the topic.

The following table shows the main problems of undernutrition throughout the lifecycle ([Table 1](#)).

## Causes of undernutrition

The fundamental drivers of undernutrition and mortality quite often fall outside the nutrition sector and are associated with each country's levels of potential resources (i.e. energy, geography, climate, etc.), as well as with all the factors that condition their use. These include the management of population density in relation to available resources, poverty, social inequalities, the side effects of growth-oriented macroeconomic policies on structural adjustment and the migration to urban areas.

The classification of these causal chains can be simplified into three broad categories:

- food insecurity*: includes problems of food production or supply at the national, regional or household level, as well as problems of families and communities in accessing sufficient amounts of safe and nutritious food for normal growth and development and an active and healthy life. It may be caused by the unavailability of food, insufficient purchasing power, inappropriate distribution or inadequate use of food at the household level. Food insecurity may be chronic, seasonal or transitory and may be induced by a myriad of factors including agricultural and trade policies, wars, famine and climate change, among others.
- inadequate health and sanitation conditions*: The aspects of environmental hygiene include the supply of safe drinking water and food products, sanitation of the environment in all its forms and hygienic practices of the population. Health aspects address the areas of infectious and parasitic diseases on the one hand, and the systems and utilization of health care, on the other.
- inappropriate care and feeding practices*: the concept of the provision of care and feeding practices refers both to care at the household level as well as to the broader aspects of social cohesion and protection at the community or national level. Thus, it encompasses the full range of maternal and child care, with mothers and children constituting the principal at-risk groups. In general, it refers to the attitudes and practices of the members of the household or community toward the most vulnerable members in their social sphere (i.e. available time, food distribution, emotional and material support) as well as the educational level of the caregivers.

The conceptual framework presented in Fig. 6 identifies three levels of causal factors leading to malnutrition in all its forms: immediate, underlying and enabling. It schematically illustrates the multifactorial and interconnected drivers that usually form the conceptual basis of "nutrition security". In other words, adequate nutritional status may be achieved by addressing the different

**Fig. 6** UNICEF Conceptual Framework on the Determinants of Maternal and Child Nutrition, 2020. A framework for the prevention of malnutrition in all its forms. Source: [UNICEF \(2020\)](#).

The American Academy of Pediatrics issued a 2018 policy statement emphasizing the importance and irreversibility of the 1000-day window of opportunity. It highlights the relationship between maternal prenatal and child nutrition in the first 1000 days (~2 years) of life and a child's neurodevelopment and mental health. Health risks both in childhood and as an adult, including obesity, hypertension and diabetes, may be determined by nutritional status during this time period. Adequate calorie intake, essential for growth of both the fetus and child, is not sufficient in and of itself for normal brain evolution and growth. The lack of key nutrients during this critical period of brain development may result in lifelong deficits in brain function even if there is subsequent nutrient repletion. Vital nutrients that support neurodevelopment include protein, zinc, choline, folate, iodine, vitamins A, D, B6, and B12.

### **Socioeconomic factors and inequity**

Poverty is often associated with undernutrition due to reduced access to food, unsanitary living conditions, overcrowding and inadequate child care. Lack of knowledge leads to poor childcare practices, misconceptions about the use of various foods, inadequate feeding practices during illness and inadequate distribution of food among family members. The reduction in the initiation and duration of breast feeding, combined with inadequate weaning practices, are also associated with high rates of childhood undernutrition.

Social problems, such as the physical and emotional abuse of children, maternal deprivation, neglect of the elderly, alcoholism and drug addiction, can lead to the onset of undernutrition. Moreover, cultural and social practices that impose taboos and prohibit given foods, certain diet fads and the precarious conditions that characterize the migration from traditional rural areas to urban poverty zones, also contribute to the development of undernutrition. The following figure depicts highlights from the 2022 State of Food Security and Nutrition in the World, showing the relationship between undernutrition, wealth, maternal education and gender. Their analyses using the most recent data available per country (2015–2021) suggest that worldwide, under-five stunted children are more likely to be male, living in rural settings, poorer households, and whose mothers don't receive formal education. In contrast, obesity among women is most common in urban settings and wealthier households (Fig. 8).

### **Environmental factors**

Overcrowded housing and poor sanitation favor the emergence of frequent infections and infectious disease outbreaks such as Covid-19 and Ebola. Natural disasters, as in droughts or floods, and human-induced disasters consisting of wars and forced migration, produce sudden, prolonged or cyclical food shortages, and can produce undernutrition in large population groups. For example, the war in Ukraine will have various impacts on global agricultural markets, affecting trade, production and prices and undermining food security as well as diet quality. Ukraine and the Russian Federation are major producers and exporters of important food commodities, fertilizer, minerals and energy. Both countries are jointly considered as the world's breadbasket, providing 30% and 20% of global wheat and corn exports, respectively, and 80% of worldwide exports of sunflower seed products. A minimum of 50 countries import 30% or more of their wheat from them, with many African and other LMIC importing more than 50%.

New studies have brought to light the impact of global climate change, which is projected to reduce future crop yields and thus threaten food security and eliminate much of the improvement in child undernutrition levels that would occur with no climate change. It has been estimated that climate change would lead to a relative increase in moderate stunting of 1–29% in 2050 compared to a future without climate change. Climate change would have a greater impact on severe stunting rates, projected to increase by 23% (central sub-Saharan Africa) to 62% (South Asia). Moreover, losses would be exacerbated by the additional loss of food post-harvest due to bad storage conditions as well as inadequate systems of food distribution, thus also contributing to the development of undernutrition, even after periods of agricultural abundance.

### **Global nutrition targets**

Improving nutrition can be considered as one of the key developmental opportunities in the world today (Table 1).

In 2012 the World Health Assembly (WHA) Resolution 65.6 endorsed a comprehensive implementation plan on maternal, infant and young child nutrition (MIYCN), which specified a set of six global interrelated nutrition targets for the year 2025 with the aim to: (1) achieve a 40% reduction in the number of children under-5 who are stunted; (2) achieve a 50% reduction of anemia in women of reproductive age; (3) achieve a 30% reduction in low birth weight; (4) ensure that there is no increase in childhood overweight; (5) increase the rate of exclusive breastfeeding in the first 6 months up to at least 50%; and (6) reduce and maintain childhood wasting to less than 5%. These were extended to 2030 following the same groundwork and rationale as the 2025 nutrition targets established in 2012, and adjusting the targeted levels to newly available data (see Table 2). To a large degree they are aligned with the Sustainable Development Goals target levels to end all forms of malnutrition by 2030, although they aim to maintain the balance between achievability and established objectives, so as to uphold momentum for improving nutrition for health and development.

In addition, global nutrition targets not only refer to the WHA targets for maternal, infant and young child nutrition (MIYCN), but also those focusing on diet-related NCDs. The latter were adopted in 2013 by the WHA and were also to be reached by 2025. They include targets addressing four diet-related NCD indicators in adults: salt/sodium intake, raised blood pressure, diabetes and

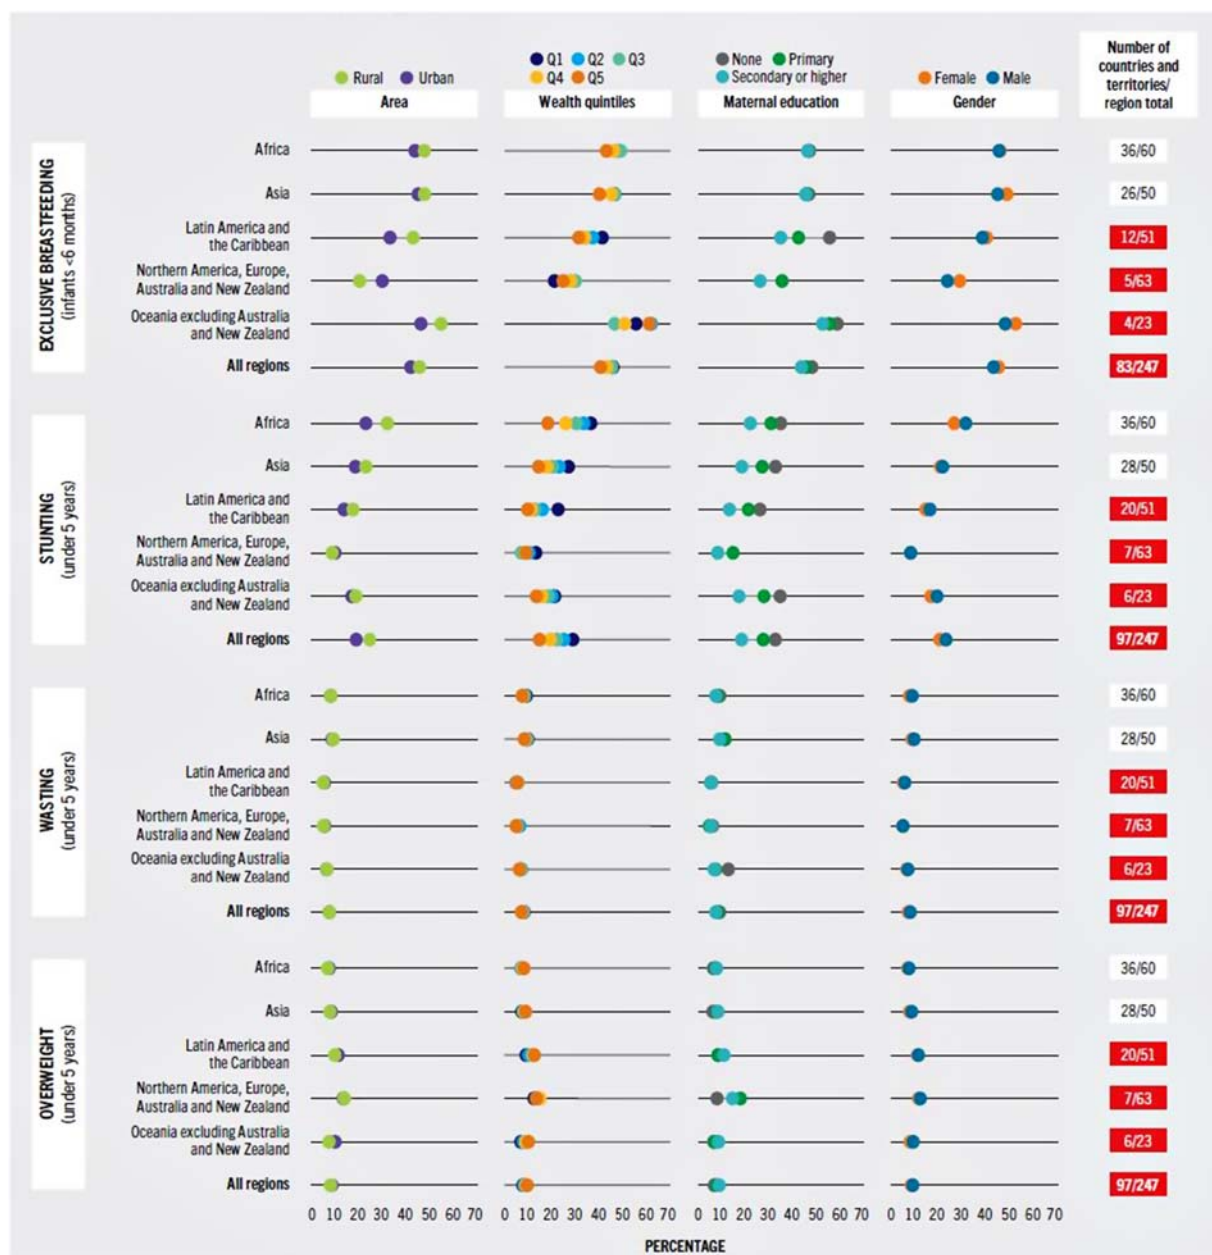

Fig. 8 Inequalities in exclusive breastfeeding and child malnutrition. Source: FAO et al. (2022).

Table 2 Global nutrition targets endorsed by the World Health assembly and their extension to 2030.

	2025 target	2030 target
Stunting (SDG)	40% reduction in the number of children under five who are stunted.	50% reduction in the number of children under five who are stunted.
Anemia (SDG)	50% reduction in anemia in women of reproductive age.	50% reduction in anemia in women of reproductive age.
Low birthweight	30% reduction in low birthweight.	30% reduction in low birthweight.
Childhood overweight (SDG)	No increase in childhood overweight.	Reduce and maintain childhood overweight to less than 3%.
Breastfeeding	Increase the rate of exclusive breastfeeding in the first 6 months up to at least 50%.	Increase the rate of exclusive breastfeeding in the first 6 months up to at least 70%.
Wasting (SDG)	Reduce and maintain childhood wasting to less than 5%.	Reduce and maintain childhood wasting to less than 3%.

Source: WHO and UNICEF (2017).

obesity. As such, the WHA's focus on these two sets of targets has pooled insights from studies evaluating the first 1000 days to prevent or cure child undernutrition, the connection between child undernutrition and the onset of overweight/obesity and NCDs later in life, and guidance on actions that can be applied throughout the life cycle. The NCD targets focus on preventing malnutrition related to unhealthy dietary and physical activity habits in the general population, whereas the principal focus of WHA targets is to decrease malnutrition in mothers and their young children. Thus, the WHA targets are complementary in nature and can enhance efforts to improve nutritional status and the population's wellbeing as a combined set. Both are well aligned with the SDGs, specifically SDG2 (food security and nutrition) and SDG3 (health).

### Progress toward achieving global nutrition targets

As seen in the following figure, the burden of disease varies widely. Among the countries analyzed, the low- and lower-middle-income countries bore the greatest burden of stunting, wasting, low birthweight, and anemia cases whereas the upper-middle and high-income countries had the greatest burden of obesity cases.

According to the 2022 State of Food Security and Nutrition in the World, for the year 2020 in children less than 5 years of age, an estimated 149 million (22%) were stunted, 45 million (6.7 %) were wasted, and 39 million (5.7 %) were overweight. Improvements were observed for 2030 targets on stunting, while childhood overweight was worsening. Children who were stunted were more likely to live in low- or lower-middle-income countries (89% of the 2020 global burden), come from rural areas and have mothers without formal education. Nearly 30% of countries with representation in each subregion of North Africa, Oceania and the Caribbean demonstrated an increase in stunting prevalence. As such, these countries are not moving toward the 2030 target to decrease the number of stunted children by 50%.

Wasted children were also more likely to reside in low- or lower-middle-income countries (93% of the global burden) and come from households with lower economic resources. The levels of wasting remain above the 2030 target of less than 3% in many countries, particularly those in South and Southeast Asia.

It was more common to find overweight children residing in lower-middle- or upper-middle-income countries (77% of the 2020 global burden), coming from wealthier households and having mothers who had completed a minimum of secondary school education. As for the 2030 overweight target of less than 3%, more than half of the countries analyzed in West Africa and South Asia had achieved at least 75% progress, while overweight prevalence was increasing in the majority of countries analyzed in Southern Africa, Oceania, Southeast Asia, South America and the Caribbean.

Low birthweight decreased from 17.5% in 2000 to 14.6% in 2015 at a worldwide level, with most regions showing improvements. However, caution is needed in interpreting these results. Global monitoring of this indicator presents an important challenge with consequential data gaps, as nearly one in three newborns are not weighed at birth.

Exclusive breastfeeding has been progressing steadily. Globally, 43.8% of infants less than 6 months of age were exclusively breastfed in 2020, an increase from 37.1% in 2012. Infants who were exclusively breastfed were likely to come from low- or lower-middle-income countries (84% of the 2020 global number of exclusively breastfed infants), reside in rural areas, live in households with less economic resources, with mothers not receiving any formal education, and were more likely to be female. The majority of regions attained between 25 and 50% of the improvements needed to reach the 2030 exclusive breastfeeding target of at least 70%.

Global data showed that nearly one in three women aged 15–49 years (29.9%) in 2019 were affected by anemia. The trend demonstrated a leveling off, if not a slight reversal, in progress made since 2012 (28.5%). This means that globally, there were 571 million anemic women, whose characteristics included being more likely to come from rural settings, poorer households and not having any formal education. Movement toward the 2030 target of a 30% reduction in anemia was deteriorating for the vast majority of countries representing almost all the regions, especially in North America, Europe, Australia and New Zealand, Oceania and Southeast Asia.

An increase was observed for adult obesity in all regions, augmenting worldwide from 11.8% in 2012 to 13.1% in 2016. Obese adults were more likely to come from upper-middle- or high-income countries (73% of the 2016 global burden, the last year for which data was available), and a higher prevalence was seen among women. Obese women were more likely to come from urban areas and wealthier households (Fig. 9).

The following figure summarizes the progress made toward reaching the 2030 Global Nutrition Targets. It depicts that since the year 2000, overweight in children under five, anemia in women, and adult obesity have been increasing, whereas low birthweight, under 5 child-stunting and exclusive breastfeeding have steadily improved (Fig. 10).

### Severe Acute Malnutrition (SAM)

Severe Acute Malnutrition (SAM) was previously known as Protein energy malnutrition (PEM), or protein calorie malnutrition, and is an important nutrition condition in developing countries due to its high prevalence and its association with high rates of infant mortality, changes in growth and development, decreased ability to work, altogether leading to inadequate social and economic development.

SAM occurs when the diet does not provide sufficient protein, energy substrates (calories), or both, to satisfy the body's nutritional needs. It is usually also associated with a deficiency of vitamins and minerals, essential micronutrients needed for growth and

Fig. 9 Distribution of disease burden by country income level. Source: FAO et al. (2022).

Fig. 10 Global Nutrition Targets. Trends in prevalence (%) and absolute numbers (millions). Source: FAO et al. (2022).

tissue renovation. The term SAM includes severe clinical syndromes of kwashiorkor (edema), marasmus (without edema), marasmic kwashiorkor (edema and the combination of chronic energy deficiency and chronic or acute protein deficiency), as well as mild and moderate cases that are much more numerous than severe forms. The term “malnutrition” is generally used in common vernacular to refer to SAM.

SAM may be of primary or secondary origin. Primary SAM is caused by inadequate nutrient intake. Secondary SAM results from disorders or drugs that interfere with nutrient use, such as cases of diseases accompanied by low food intake, inadequate nutrient absorption or utilization, increased nutritional requirements and/or increased nutrient losses. Although SAM is mainly an issue in early childhood, it may also occur in older children and adults, particularly the elderly.

### **Immunity and SAM**

The main effects observed in SAM occur in the T-lymphocytes and the complement system. The number of lymphocytes originating in the thymus gland drastically decreases and the gland atrophies. The depletion of T-lymphocytes in the spleen and lymph nodes is observed as well. In SAM the production of certain complement components decreases. These deficiencies can account for the great propensity to sepsis by gram-negative bacteria. The resultant changes lead to increased susceptibility to infections and to severe complications.

## **Clinical manifestations and classification**

### **Mild and Moderate Acute Malnutrition (MAM)**

Its main clinical feature is weight loss with notable thinning accompanied by a reduction in subcutaneous adipose tissue. WHO/UNICEF defines Moderate acute malnutrition (MAM) as a weight-for-age between  $-3$  and  $-2$  z-scores below the median of the WHO child growth standards (see section on Anthropometric measures in this article). Criteria for Mid Upper Arm Circumference (MUAC) measurements is having a MUAC from 115 mm to  $<125$  mm. MAM can be due to a low weight-for-height (wasting) or a low height-for-age (stunting) or to a combination of both. Similarly, moderate wasting and stunting are defined as a weight-for-height and height-for-age, respectively, between  $-3$  and  $-2$  z-scores.

MAM affects many children in poor countries. Children with moderate malnutrition are at increased risk of mortality and MAM is associated with a high number of nutrition-related deaths. If some of these moderately malnourished children do not receive adequate support, they may progress toward severe acute malnutrition (severe wasting and/or edema) or severe stunting (height-for-age less than  $-3$  z-scores), which are both life-threatening conditions.

Children with mild to moderate malnutrition tend to be more sedentary and participate less frequently in games and activities that require some degree of physical exertion. Older children and adolescents may show a reduction in their ability to perform strenuous physical work for prolonged periods. Other non-specific manifestations include pallor, apathy, shortened attention span (particularly in school settings) and frequent episodes of diarrhea. Clinical laboratory tests do not contribute to the diagnosis of mild or moderate malnutrition.

### **Severe Acute Malnutrition (SAM)**

In addition to clinical manifestations, the dietary and clinical history of the patient are important for diagnosis. Marasmus is usually associated with food shortages, prolonged semi-starvation, premature weaning, and extended time intervals between the administration of foods to infants and young children. Kwashiorkor is often associated with low protein intake, late weaning with inadequate complementary feeding practices and current or recent episodes of diarrhea or measles. Various bouts of infectious diseases and chronic or recurrent diarrhea occur frequently. WHO/UNICEF classification of SAM is based on presenting with weight-for-height (W/H)  $< -3$  SD or MUAC  $< 115$  mm or edema, of which any are accompanied by complications such as lack of appetite, fever  $\geq 38.5$  °C, hypothermia  $\leq 35.5$  °C, vomiting or severe dehydration. Wasting refers to children that are too thin for their height and is a common manifestation of SAM.

### **Marasmus**

Marked muscle wasting and the extreme reduction of subcutaneous fat in cases with severe non-edematous SAM present with a “skin and bones” appearance. Children with marasmus frequently have 60% or less of the expected weight-for-height and suffer from short stature. Their hair tends to be dry, thin, dull and at times lacking in quantity (Fig. 11).

Children with marasmus often show complications such as acute gastroenteritis, dehydration, respiratory infections and eye lesions due to hypovitaminosis A. Systemic infections can lead to septic shock or disseminated intravascular coagulation syndrome with high mortality rates. Obtaining a medical history plays an important role for the differential diagnosis of SAM secondary to AIDS, tuberculosis, cancer, and other debilitating diseases.

### **Kwashiorkor**

The main feature is mild edema, being palpable without pain and usually presenting in the feet, ankles and legs, but in severe cases possibly extending to the perineum, upper extremities and the face. Many patients have pellagroid skin lesions at the edema sites

**Fig. 11** Nutritional marasmus with severe wasting. Note: Original photo, no need to cite source.

and in areas of pressure or frequent irritation. The skin can be erythematous and shiny in the regions of edema, alternating with areas showing dry, hyperkeratosis and hyperpigmentation that tend to converge. Where the epidermis becomes dark and dry, it splits open when stretched to reveal pale areas between the cracks ("lacquered flaky paint", "crazy pavement dermatosis"), leaving exposed tissues that become infected easily. Subcutaneous fat tends to be preserved, and there may be some degree of muscle wasting. Weight loss, after correcting for edema, is usually not as severe as in marasmus. Children may have short or normal stature, depending on the length of the current episode and their nutritional history (Fig. 12).

The hair is dry, brittle, dull, and can be pulled out easily without causing pain. Curly hair becomes straight and pigmentation changes usually acquiring a brownish, reddish or yellow-white tone. Patients who alternately undergo periods of very poor and relatively good intakes of protein, may present with alternating bands of depigmented and normal hair.

Patients have the same complications as described for marasmus cases, but diarrhea and respiratory and skin infections are more frequent and severe. Apart from diarrhea, they frequently present with anorexia and postprandial vomiting. These general conditions improve as nutrition therapy progresses, without specific treatment for gastrointestinal disorders. Kwashiorkor cases may have infections without fever, tachycardia, shortness of breath or leukocytosis, making diagnosis difficult. The most frequent causes of death are pulmonary edema with bronchopneumonia, gastroenteritis, septicemia and electrolyte disturbances. A differential diagnosis of other conditions that cause hypoproteinemia and edema should be carried out, as well as secondary undernutrition due to alterations in metabolism and protein absorption.

**Fig. 12** Kwashiorkor. Note: As this is public domain, does it need to be cited Source: NARA, Public domain, via Wikimedia Commons.

**Marasmic-kwashiorkor**

This form of edematous SAM combines the clinical features of marasmus and kwashiorkor. The major manifestations are the edema of kwashiorkor with or without skin lesions accompanied by the muscle wasting and subcutaneous fat reduction characteristic of marasmus. In the initial stages of treatment once the edema is resolved, the patient acquires an appearance that is very similar to the child with marasmus. The patient's biochemical profile is characteristic of kwashiorkor and marasmus but the alterations due to severe protein deficiency are those that predominate.

**Long term consequences**

Cognitive development studies indicate a close interrelationship between undernutrition and intellectual development. In recent years there has been progress in improved recovery of neurological development in severely undernourished infants who are systematically stimulated as part of their treatment. Augmented deterioration manifesting in severely undernourished children is usually due to electrolyte imbalance, gastrointestinal disorders, cardiovascular or kidney insufficiency, and compromised immune function to fight off infections. The psychological consequences can also be serious. Severe anorexia, apathy and irritability make it difficult to feed and handle the child, making prognosis more precarious.

Generally speaking, death is secondary to severe infections, bronchopneumonia, gram-negative septicemia, and acute cardiovascular, hepatic and renal failure. The clinical picture may be aggravated by severely insufficient folate, niacin and thiamin levels and/or acute deficiency of potassium, sodium and magnesium as well as chronic deficiency of iron, copper, zinc and chromium. The signs and symptoms of severe vitamin and mineral deficiencies can also play a critical role and may appear during early rehabilitation if an inadequate supply of these nutrients is not provided.

**Chronic undernutrition**

Chronic undernutrition is distinguished from the acute forms (SAM, MAM). A child who suffers from chronic undernutrition experiences delay in his/her growth. This growth retardation is measured by comparing the height of the child with the standard recommended for their age. It indicates a lack of the necessary nutrients over an extended period of time, and thus the increased risk of becoming ill and the subsequent effects of these events on the physical and intellectual development of the child. Chronic undernutrition, although a problem of greater magnitude in terms of the number of children affected, has up until recently received less attention than more acute forms of undernutrition.

**Stunting**

Chronic undernutrition is reflected in stunting, the indicator measuring length/height-for-age and is defined as having a length/height-for-age Z-score that is more than two standard deviations below the age-sex median for a well-nourished reference population. Stunting is a largely irreversible outcome of chronic inadequate nutrition and repeated bouts of infection during the first 1000 days of a child's life.

Specifically, factors that impact on stunted growth and development include poor maternal nutrition and health, inadequate infant and young child feeding practices (non-exclusive breastfeeding and complementary feeding that is limited in quantity, quality and variety), and infection. Special importance is placed on maternal nutritional and health status before, during and after pregnancy, which determines a child's early growth and development, beginning in the womb. Maternal contributors to stunting include inadequate nutrition during pregnancy leading to low birth weight, maternal short stature, short birth spacing, and adolescent pregnancy. The latter impairs nutrient availability to the fetus due to the competing demands of the adolescent mother's own growth.

Stunting has long-term effects on individuals and societies, including: diminished cognitive and physical development, reduced productive capacity and poor health, and an increased risk of degenerative diseases such as diabetes. In fact, stunted children who experience rapid weight gain after 2 years of age show an increased risk of becoming overweight or obese later in life, thus increasing risk of coronary heart disease, stroke, hypertension and type 2 diabetes onset. As for the economic impact, the World Bank estimates show that a 1% loss in adult height due to childhood stunting is associated with a 1.4% loss in economic productivity.

**The role of fetal growth restriction**

The most common definition of intrauterine growth restriction (IUGR) is a fetal weight that is below the 10th percentile for gestational age as determined through an ultrasound. This can also be called small-for gestational age (SGA) or fetal growth restriction. Findings in the Lancet 2013 series highlight the impact of SGA on attributable neonatal deaths. 32 million babies were born SGA, and about 800,000 neonatal deaths and 400,000 post-neonatal infant deaths could be attributed to the increased risk associated with having fetal growth restriction. This relatively recent data contradicts the widespread assumption that SGA infants, as compared to preterm babies, are not at a substantially increased risk of mortality. Additionally, infants who are SGA have an increased risk of growth faltering in the first 2 years of life. Causes of childhood growth faltering are multifactorial, but fetal growth restriction might

be an important contributor to stunting and wasting in children. The Lancet 2013 Maternal and Child Nutrition series demonstrated that about 20% of childhood stunting could have its origins in the fetal period, as shown by being born SGA. As such, there is now impetus to focus attention on preventing SGA by scaling up prenatal nutrition interventions. In 2010, 32.4 million babies were born SGA, with 27% of all births occurring in Low and Middle Income Countries (LMIC).

### Anthropometric indicators for measuring malnutrition

Several measures and anthropometric indices are used to diagnose and classify malnutrition. The choice of a measure or index of choice will depend on its simplicity, accuracy and sensitivity, as well as the availability of instruments to make measurements and the existence of reference standards for interpreting the results. In clinical practice the utilization of reference growth charts for weight, height and BMI for age and weight-for-height is common in the pediatric population. Growth charts consist of a series of percentile curves that illustrate the distribution of selected body measurements in children. The reference standards for anthropometric measurements presented in this article are those used in WHO's Nutrition Landscape Information System (NLIS), a comprehensive data collection system that compiles nutrition-related indicators in standardized form.

### Malnutrition in children

The measurement of weight and height is used for the calculation of indicators such as "weight-for-age", "height-for-age", "weight for height" and the body mass index ( $\text{BMI} = \text{weight kg/height}^2$  in meters). Other anthropometric measures employed are the measurements of arm circumference and head circumference. In statistical terms, it is more appropriate to use standard deviations ("Z-scores") or percentiles to evaluate differences between the patient and the reference standard. This is the preferred expression for anthropometric indicators in surveys. It is the difference between the value for an individual and the median value of the reference population for the same age or height, divided by the standard deviation of the reference population. In other words, by applying Z-scores, one can describe how far a child's weight is from the median weight of a child at the same height in the reference value (Fig. 13).

### Underweight, stunting and wasting

These indicators are used to measure nutritional disorders resulting in undernutrition (assessed from underweight, wasting and stunting) and overweight. Child growth is globally acknowledged as an important indicator of nutritional status and health in populations. The percentage of children with a low height -for- age (stunting) reflects the accumulated effects of undernutrition and infections since and even preceding birth. Thus it can be interpreted as an indication of poor environmental conditions or long-term restriction of a child's potential to grow. The percentage of children who have low weight-for- age (underweight) can reflect "wasting" (i.e. low weight-for-height), indicating acute weight loss, "stunting", or both. As such, "underweight" is a composite indicator and may therefore be difficult to interpret.

**Fig. 13** Proportion of children under age 5 who are affected by stunting and wasting, 2020 (percentage). Source: [United Nations \(2022\)](#).

### Definitions used

- Underweight (thinness): weight for age  $<-2$  standard deviations (SD) of the WHO Child Growth Standards median (Severe underweight:  $<-3$  SD)
- Stunting (short for age): height for age  $<-2$  SD of the WHO Child Growth Standards median (severely stunted:  $<-3$  SD for length/height for age). Children under 2 are usually measured lying down (recumbent length) and those over 2, standing height is taken.
- Wasting: weight for length/height  $<-2$  SD of the WHO Child Growth Standards median (Severe wasting  $<-3$  SD for weight for length/height or BMI-for-age)
- Overweight: weight for height  $>+2$  SD of the WHO Child Growth Standards median

### Interpretation

#### *Underweight*

As weight is easy to assess, this has been the most widely collected indicator. Evidence has shown that the mortality risk of children who are even mildly underweight is increased, and severely underweight children are at even greater risk.

#### *Stunting*

Children who suffer from growth retardation as a result of poor diets or recurrent infections tend to be at greater risk for illness and death. Stunting is the result of long-term nutritional deprivation and often results in delayed mental development, poor school performance and reduced intellectual capacity. This in turn affects economic productivity at the national level. Women of short stature are at greater risk for obstetric complications because of a smaller pelvis. Small women are at greater risk of delivering an infant with low birth weight, contributing to the intergenerational cycle of malnutrition, as infants of low birth weight or retarded intrauterine growth tend to be smaller as adults.

#### *Wasting*

Wasting in children reflects acute undernutrition, usually as a consequence of insufficient food intake or a high incidence of infectious and parasitic diseases, especially diarrhea. In addition, it impairs immune system functioning and can lead to increased susceptibility, severity and duration of infectious diseases as well as increased mortality risk. In the WHO protocols for Severe Acute Malnutrition management, Mid Upper Arm Circumference is also assessed, along with the presence/absence of edema.

#### *Overweight*

Childhood obesity is linked with a higher probability of obesity as an adult, which can result in a variety of disabilities and pathologies, such as diabetes and cardiovascular diseases.

### Malnutrition in adults

The values for body mass index (BMI) are age-independent for adult populations and are similar for both males and females. However, differences in BMI may not correspond to the same degree of fatness in different populations as there may be variations in body proportions.

#### *Moderate and severe thinness, underweight, overweight, obesity*

- BMI  $< 17.0$  indicates moderate and severe thinness
- BMI  $< 18.5$  indicates underweight
- BMI 18.5–24.9 indicates normal weight
- BMI  $\geq 25.0$  indicates overweight
- BMI  $\geq 30.0$  indicates obesity

#### *Moderate and severe thinness*

A BMI  $< 17.0$  indicates moderate and severe thinness in adult populations. This has been associated with increases in illness in adults studied in three continents and this is considered a reasonable further limit to choose as a cut-off point for moderate risk. A BMI  $< 16.0$  is associated with a markedly increased risk for ill health, poor physical performance, lethargy and even death; as such this cut-off point is considered a valid extreme limit.

#### *Underweight*

The cut-off point of 18.5 for underweight in both genders has less scientific validity as a cut-off point for moderate and severe thinness but is considered a reasonable value for use pending further, comprehensive studies. The proportion of the population with a low BMI that is considered a public health problem is closely linked to the resources available for correcting the problem, the stability of the environment and government priorities. Approximately 3–5% of a healthy adult population have BMIs  $< 18.5$ .

## Micronutrient malnutrition

### Micronutrient deficiencies

More than 2 billion people are deficient in micronutrients such as vitamin A, iodine, iron, zinc and folic acid. Malnutrition due to the lack of vitamins and minerals (micronutrients) can make its appearance in a variety of ways. Fatigue, reduced learning capacity or impaired immunity are just a few examples. These nutrients are called micronutrients since the body requires them in small amounts for growth, development and to maintain health. The combination of different ecological factors such as climate, low production, availability and consumption of certain micronutrient rich foods, cultural patterns that limit the consumption of given foods and poverty induced food restrictions contribute to mapping a specific region's particular micronutrient and health profile. In regions with a high prevalence of undernutrition, associated micronutrient deficiencies occur, which contribute to the symptoms that appear. Or they may remain in an asymptomatic subclinical phase, without apparent clinical expression, thus giving rise to the expression "hidden hunger". This represents the phenomenon of a chronic lack of vitamins and minerals that often has no visible warning signs, so that those affected may not even be aware of it. Nevertheless, micronutrient deficiencies inevitably lead to significant negative health consequences.

Recent data from the 2021 Lancet series on maternal and child undernutrition show a high prevalence of vitamin A deficiency in Africa and South Asia. Data for zinc is limited but the few countries with this information suggest that almost 50% of all children are affected by zinc deficiency. Likewise, an estimated 60% of children under 5 years of age in LMIC have anemia (with higher rates for those aged 6–24 months), and very few improvements have been observed over the past decade. This review suggests that the high prevalence of micronutrient deficiencies in LMICs can be attributed to inadequate consumption of nutritive complementary foods as well as excessive losses caused by infectious conditions such as diarrhea.

Unlike many other impediments to social and economic development, micronutrient deficiencies can be reduced with relatively inexpensive investments in public health, agriculture and education. The technology exists to solve many of these deficiency states. However, they persist for various reasons, including the lack of awareness among policy makers on the importance of resolving the issues, as well as the lack of knowledge by program planners about their consequences and the strategies available to combat them.

In recent decades the research community, governments, development agencies and non-governmental organizations (NGOs) have made considerable progress in identifying the population groups that have the greatest risk of micronutrient deficiencies and in developing programs for short term improvement of given deficiencies. Food-based strategies have been emphasized, focusing on the promotion of producing and consuming micronutrient-rich foods as a sustainable solution to the problem of micronutrient deficits. Actions include improving access, availability and the consumption of foods rich in vitamins and minerals. The benefits of these food based strategies are that they not only address improving the intake of certain nutrients, but also enhance the overall situation in terms of food and health.

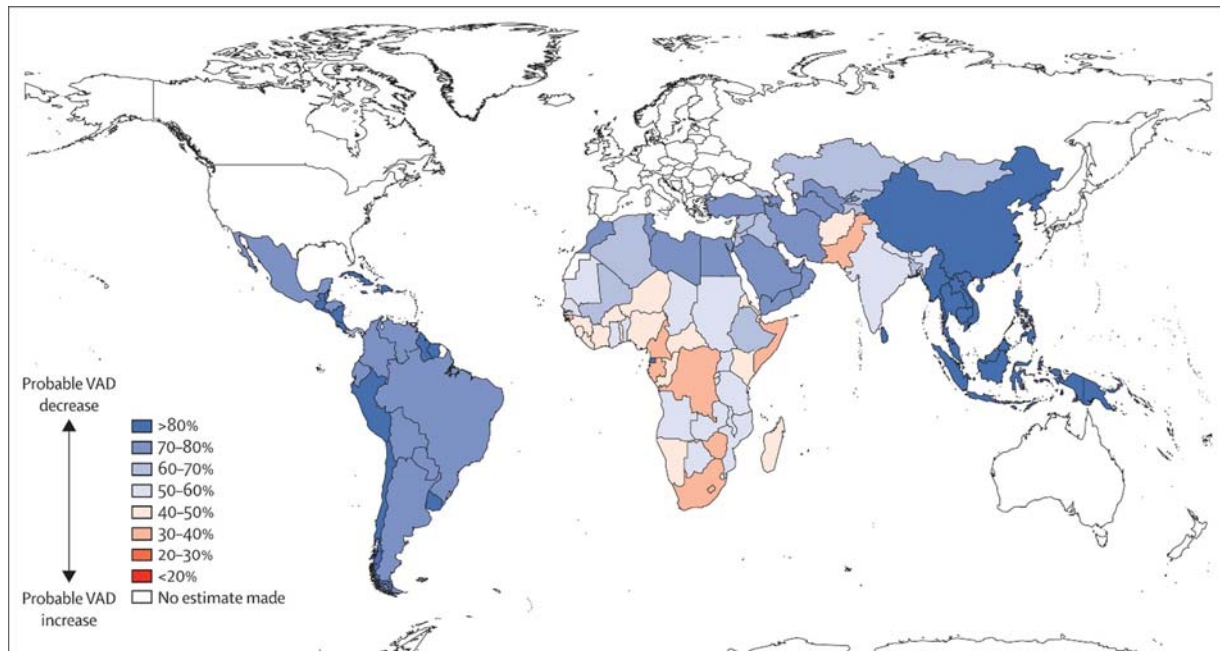

Globally, the three micronutrients having the greatest repercussions for public health are vitamin A, iron and iodine as their deficiency poses a major threat to the health and development of populations worldwide, particularly children and pregnant women in low-income countries. The magnitude of their impact can be seen in the following figures. Other micronutrients of relevance also exist, such as folate, zinc and calcium and the reader is referred to the supplementary materials for more information on the extensive topic of micronutrient deficiencies. The international community has emphasized these micronutrients since it is very difficult to meet their recommended intake levels without having access to an adequate variety of foods that ensure diet diversity (Figs. 14–16).

## Conclusions

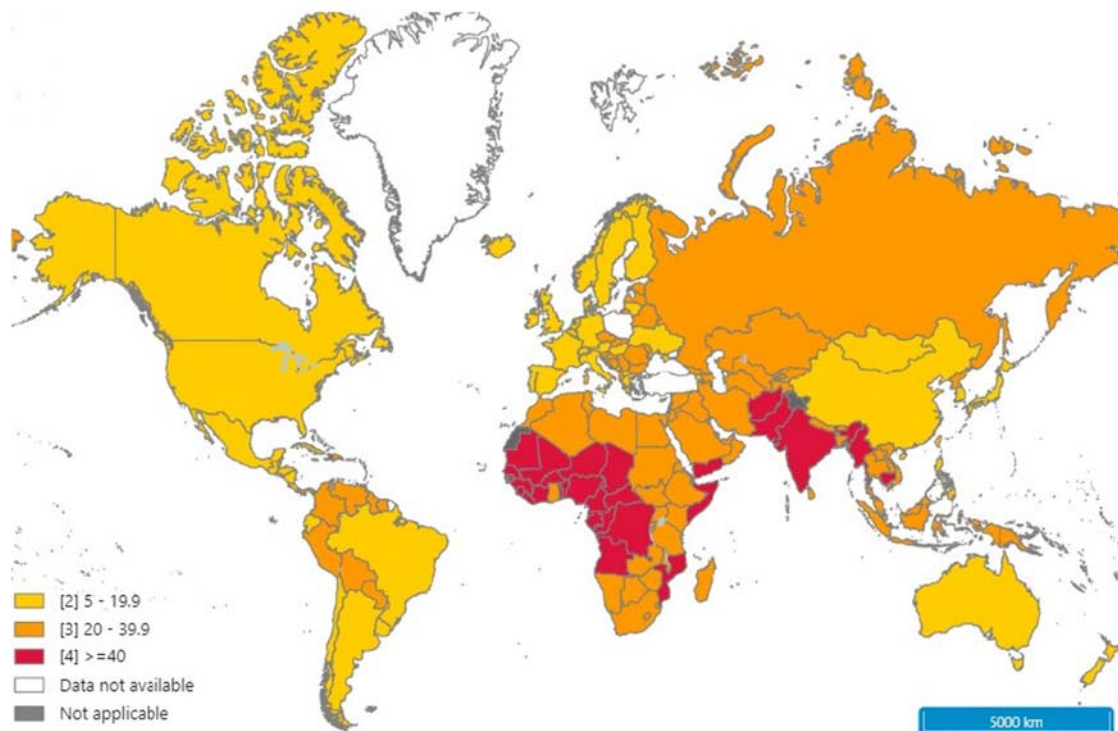

Decreasing wasting, stunting, underweight, micronutrient deficiencies, overweight, obesity and diet-related NCDs is critical for achieving several of the Sustainable Development Goals. However, no single country is on track to meet global nutrition targets. Although progress has been made since 2012, improvements have been modest and advances in reducing undernutrition in women and children have been fluctuating. Maternal and child undernutrition yield inadmissibly high prevalence rates, especially for low-income countries and for the poorest population segments in middle-income countries. The most recent evaluations show improvements in reducing stunting in children and underweight in women, as well as reductions in iodine deficiency-primarily through actions involving food fortification. Wasting has improved in certain countries, but still remains an important challenge in others. Although there have been small gains in exclusive breastfeeding rates, partial breastfeeding after 1 year of age shows no improvement. Low birthweight, anemia in children and women and zinc deficiency have also remained largely unchanged, whereas obesity is increasing globally. Socioeconomic inequalities persist and continue to curb the rate of progress worldwide. Moreover, the COVID-19 pandemic has disrupted health systems and, together with the conflict in Ukraine, has worsened household food insecurity, reversed economic growth, and could set back advances made in undernutrition across LMICs.

Achieving the 2030 global nutrition targets will require massive and coordinated efforts among key stakeholders. Fortunately, we have evidence based data to guide which actions will be effective that can be scaled up and maximize the utilization of resources to address the challenges presented. The following figure summarizes the recent review on recommended interventions published in the Lancet 2021 Series on maternal and child undernutrition. In addition, the Series also highlights the importance of providing critical nutrition interventions within the first 1000 days of life (early pregnancy up until the first 2 years of child life). It is necessary

**Fig. 14** Estimated global prevalence in of children under five with biochemical Vitamin A Deficiency (VAD). Source: [Stevens et al. \(2015\)](#).

to strive for continued political commitment and cooperation among the wide range of relevant stakeholders, both in the public and private sector, and to implicate those in the area of nutrition as well as in other fields. Governments, international partners, civil society, non-governmental organizations and the private sector have a key role in the creation of healthy environments and conditions providing affordable, accessible and sustainable healthy dietary choices for communities and especially for those most at risk of malnutrition in all its forms ([Fig. 17](#)).

## Glossary

**Cachexia** Loss of weight, and fat and muscle mass, caused by disease and loss of appetite in people who are not trying to lose weight.

**Enteral feeding** Delivery of nutrients, in the form of special solutions, to the stomach or small intestine through a tube, i.e. 'tube-feeding'.

**Nosocomial pneumonia** Pneumonia contracted while in hospital, 2–3 days after admission.

**Parenteral nutrition** Delivery of nutrients through a tube inserted into a vein, because the intestine is nonfunctional.

**Pathognomonic** Characteristic or diagnostic of a specific disease.

**Percutaneous** Delivery of nutrients into the stomach or intestine by a tube passed through the abdominal wall.

**Primary malnutrition** Malnutrition due to inadequate or excessive food intake.

**Secondary malnutrition** Malnutrition caused primarily by illness, infections, or disease.

## Introduction

In its broadest context, malnutrition is a state of having an inappropriate nutritional status with respect to one or more macronutrients (water, electrolyte, protein, or fat) or micronutrient (vitamin or mineral) constituent of the body. This imbalance can be a deficit, leading to an insufficient supply or content of the nutrient (undernutrition), or an excess, leading to an excessive content or overloading of the organism with a nutrient (overnutrition). The six possible causes for all nutrient deficiencies have been summarized as: inadequate intake, impaired absorption, increased wastage, impaired utilization, increased destruction, and elevated requirements. Correspondingly, overnutrition and excesses can result from reciprocal defects, that is: Hyperphagia, hyper-absorption, increased retention; decreased destruction, and decreased requirements.

As discussed in the previous article, the term 'primary' malnutrition relates almost exclusively to the first of these mechanisms, that of inadequate or excessive ingestion of nutrients from the diet. It is concerned with food consumption and intake. Secondary malnutrition, in contrast, concerns the disturbed and disordered handling of nutrients. When diseases or abnormal physiological conditions interfere with the normal disposition of nutrients ingested from the diet, this is the basis of a situation of 'secondary' malnutrition.

## Causes of Secondary Under- and Overnutrition

A representative, but not exhaustive, list of diseases and conditions producing secondary undernutrition is provided in **Table 1**, and of secondary overnutrition in **Table 2**.

**Table 1** Diseases and conditions associated with secondary macronutrient or micronutrient undernutrition

---

Inadequate nutrient absorption
Gastric abnormalities: Gastric atrophy
Pernicious anemia
Intestinal abnormalities: Celiac disease
Inflammatory bowel disease
Intestinal cryptosporidiasis
Radiation enteritis
Chronic intestinal pseudo-obstruction HIV/AIDS
Hepatobiliary abnormalities: Cystic fibrosis
Biliary obstruction
Pancreatic insufficiency
<i>Increased nutrient excretion</i>
Gastric disorders: Gastric adenoma
Intestinal abnormalities: Laxative abuse
Peptic ulcer
Gastrointestinal fistula
Colonic adenoma
Amebiasis
Hookworm
HIV/AIDS
Schistosomiasis
Hepatic disorders: Hepatic cirrhosis
Endocrine disorders: Diabetes mellitus
Hypoadosteronism
Renal Disorders: Fanconi syndrome
Hemodialysis; peritoneal dialysis
<i>Increased destruction or use of nutrients</i>
Endocrine disorders: Hyperthyroidism
Chronic disease: Cardiac cachexia
Cancer cachexia
Cystic fibrosis
Bone marrow transplants
Infections: Pulmonary tuberculosis
HIV/AIDS
<i>Decreased utilization of nutrients</i>
Lead poisoning
Menkes' copper storage disease

---

The basis for suspecting secondary malnutrition is that there is evidence of deficiency or excess, but foods and nutrients are presumably being consumed in adequate amounts. Once the suspicion emerges, three distinct diagnostic principles need to be addressed: (1) the confirmation of dietary intake, and estimation of its adequacy; (2) the diagnosis and classification of abnormal nutritional status; and (3) the diagnosis of the functional, physiological, or pathological origins of disordered nutrient disposition.

**Table 2** Diseases and conditions associated with secondary macronutrient or micronutrient excess (overnutrition)

---

Increased nutrition absorption
Wilson's disease
Hemochromatosis
<i>Increased nutrition retention</i>
Prader–Willi syndrome
Hypercorticotesteroidism
Hyperpituitarism
Acute tubular necrosis
Chronic renal failure
<i>Decreased destruction of nutrients</i>
Hypothyroidism

---

The evaluator must remain attuned to the nutritional status of patients, clients, or populations, and sensitive to the possibility of a nonprimary origin of any under- or overnutrition.

### Coexistence of Primary and Secondary Malnutrition

It is important to recognize the potential for the simultaneous coexistence of primary and secondary malnutrition in the same individual. Primary malnutrition in the free-living populations can be associated with famine conditions (crop failure, conflict, natural disaster, and refugee crisis), in which sufficient food is simply not available. Alternatively, it can arise from the poverty of landlessness or urban marginalization, where food is not accessible given the household income. A large number of communicable diseases with consequences of poor nutrient absorption, retention or utilization, such as parasitoses, tuberculosis or HIV/AIDS, are common in these situations of deprivation and misery. To the extent that a disease process produces anorexia or dysphagia, or even psychic depression, the net effect is to reduce total intake of dietary energy and nutrients. Whatever, malabsorptive or nutrient-wasting components of the underlying disorders will further compromise the nutritional state.

### The Reverse Paradigm: Underlying Pathology Revealed by Detection of Abnormal Nutrition

In clinical medicine, a type of 'reversal of roles' often occurs. Rather than primarily recognizing the presentation of the underlying pathology, recognition of an abnormal nutritional status without a dietary explanation leads to the diagnosis of the underlying disorder before any specific (pathognomonic) sign or symptom has yet occurred. For instance, the Prader-Willi syndrome of pathological obesity would initially present as common obesity. Similarly, in hypercorticotestoidism (Cushing's syndrome), abnormal fat deposition and weight gain can be the changes that lead to the recognition of the underlying pituitary or adrenal dysfunction.

Classically, in type 2 diabetes, unexplained weight loss is a presenting complaint when polyuria is mild or absent. Moreover, with common forms of childhood gastrointestinal disorders, such as celiac sprue or Crohn's disease, arrested linear growth is often the first clue that something is clinically awry. It provokes the diagnostic inquiry that leads to the recognition of the bowel pathology. In milder presentations of cystic fibrosis, a similar growth failure occurring in infancy can indicate an underlying pathological disorder.

In fact, the entire roster of conditions listed in **Tables 1 and 2**, as well as others of a similar nature, are subject to being diagnosed as the result of a secondary change in nutritional status. The practical message is that the nutritional specialist, physician or nonphysician, may be the first person to whom the secondarily malnourished patient is referred, and the acumen of recognizing a secondary causation will guide the case to an appropriate clinical diagnostic program to uncover (and hopefully address and remedy) the underlying medical or surgical problems. Overarching guideline principles for uncovering secondary malnutrition states are provided in **Table 3**.

### Diagnosis of Secondary Malnutrition

In general terms, a common set of principles applies for assessment of nutrient status whether the bases are primary, secondary, or a combination of both. These principles include: body composition measures, hematological and biochemical (biomarker) values, functional variables, and clinical signs and symptoms. It is more productive to focus here on the nuances, caveats, and distinctions for the detection of altered nutrition due to background conditions beyond spontaneous food intake.

#### Caveats for the Diagnosis of Secondary Excess Nutrition

The conditions that cause increased retention of energy and hypometabolism are listed in **Table 2**. When it comes to overweight and obesity, the absence of clear-cut overeating (which can be difficult to detect) combined with other characteristic signs of the different

**Table 3** Three diagnostic principles related to secondary malnutrition

<i>Assessment of dietary and nutrient intake:</i> A quantitative and qualitative evaluation of usual dietary intake by a nutritionally trained practitioner or clinical dieticians serves to exclude the possibility that the situation is not primary (low or excessive intake) in nature and suggests a secondary basis for the nutritional problem. Caveat: In certain situations, a combination of reduced intakes and nutritional stress due to poor absorption, retention, or utilization may coexist.
<i>Assessment of nutritional status:</i> This includes measures of anthropometry and body composition, hematological status, biomarkers, and functional indicators, as well as clinical (physical) evaluation.
<i>Diagnosis of underlying cause(s) of secondary nutritional imbalance:</i> It is important, where possible, to identify the underlying entities that are causing the nutritional problem, such as absorptive or hormonal problems, to enable (where possible) a direct remedial approach to the cause of malnutrition and to orient management based on any pathophysiological knowledge about the underlying disease.

entities should raise suspicion. Excesses of vitamins and minerals may not easily be detected because the homeostatic control of circulating concentrations confounds biochemical diagnosis. Excessive urinary excretion rates of the nutrients or their metabolites often provide better indications than blood levels when micronutrient overload is the issue.

### **Caveats for the Diagnosis of Secondary Undernutrition**

Undernutrition due to disease and dysfunction obviously requires establishment of the following: (1) the existence of deficiencies; and (2) the factors other than underconsumption that are influencing the deficiency states. The cut-point for diagnosing macronutrient undernutrition is a body mass index (BMI) of  $<18.5 \text{ kg m}^{-2}$ . However, with the worldwide pandemic of overweight, recent weight loss of 10% or more of usual body weight may be a more sensitive and reliable indicator of an incipient undernutrition problem. Weight problems diagnosed in this manner would certainly be detectable well before the BMI will have fallen to the aforementioned criterion.

Ill patients with adequate or excessive body mass indices can manifest metabolic substrate metabolism reminiscent of the severe malnutrition syndromes of adult kwashiorkor or marasmus (inanition). Moreover, fluctuations in weight under acute or semiacute situations often reflect changes in fluid balance. This is also the situation in patients with end-stage renal failure undergoing chronic dialysis. Methods such as bioelectrical impedance, dual X-ray absorptiometry, or isotope dilution in association with indirect calorimetry can assess true lean- and fat-mass status of patients with apparently normal body mass.

Hematological evaluation is important in nutritional assessment. A low hemoglobin, hematocrit, or red cell count signifies anemia, but in individuals with associated diseases, anemia can have a series of origins (hemolytic, hypoproliferative) that are non-nutritional and will not respond to nutritional therapy.

Biochemical evaluation for nutrient deficiency status in patients with associated disease is fraught with caveats and limitations. Two classes of nutritional deficiency are sometimes defined: in type 1 deficiencies, nutritional desaturation of tissue stores occurs, circulating levels of nutrients reflect the total body nutrient status and specific nutrient deficiency syndromes manifest (e.g., iron deficiency and anemia); in type 2 deficiency, there is homeostatic conservation of tissue, circulating concentrations of nutrients, such that blood concentrations remain virtually unaltered in the face of depletion. Typically, type 2 deficiencies manifest with growth failure or general signs of undernutrition. Deficiencies of zinc and magnesium, among others, fall into this second category. Inflammation and infection are stimuli that directly alter the circulating concentrations of nutrient indicators. Ferritin and circulating copper are elevated, whereas zinc, iron, and vitamin A concentrations are depressed with activation of the acute-phase response to injury or inflammation. In liver disease, depressed production of binding proteins can alter the usual indicators of nutritional status as a consequence of hepatic pathophysiology itself, rather than preexisting secondary malnutrition. Finally, it almost goes without saying that attempting biochemical nutrient evaluations from blood samples taken during concurrent infusion of micronutrient solutions in parenteral nutrition regimens – especially without a period of distribution and equilibration – will not reflect the tissue stores and total body reserves of the respective nutrients of interest.

Functional indicators of nutritional status have been applied to the assessment of secondary malnutrition and have been plagued by pitfalls. This applies to tests of nitrogen status, immune function, and hepatic protein secretion. Tests such as creatinine excretion, white blood cell counts, and cutaneous delayed hypersensitivity energy, as well as decreased serum albumin, transferrin, transthyretin (prealbumin), and retinol-binding protein concentrations are sensitive to alteration by stress and injury. Failure to recognize distortion from stress underlies an early fallacy in surgical nutrition, in which low values for albumin, lymphocyte counts, and prealbumin, together with anergy, predicted poor postoperative outcomes. This misconception justified aggressive preoperative parenteral nutrition and albumin infusions, with little impact on predicted outcomes. In these situations, it was the stress and injury of the underlying disease, rather than nutritional status that was producing the abnormal values of the biomarkers. Recently, insulin-like growth factor has been advanced as a sensitive indicator of protein status in older patients, but whether it is confounded by nonnutritional features of disease remains to be clarified.

### **Management of Secondary Malnutrition**

Secondary malnutrition has many faces and facets. It may have to be addressed both in a public health sense for communicable diseases such as parasitoses or HIV/AIDS, and in a medical care context for disorders that are particular and clinical in nature, such as hereditary or degenerative diseases.

#### **Principles of Management**

The first principle is to identify the underlying functional, physiological, or pathological cause of the malnourished state. If the condition is curable, then the management issues are simplified. For instance, if a person is dehydrated because of hyperglycemic diuresis in uncontrolled diabetes mellitus, the short-term management involves administration of exogenous intravenous fluids to restore normal hydration; however, restoring adequate diabetic control to the patient would be the long-term and definitive solution. The undernutrition and growth failure due to undetected celiac disease is easily eliminated by institution of a gluten-free diet. With inadequate nutrition in cystic fibrosis, adequate management of pulmonary problems and digestive-enzyme deficiencies

should allow patients to recover and maintain normal nutrition on a balanced oral diet. Thus, medical or surgical address of the underlying disorder, where possible, is the primary tool for management of secondary undernutrition.

### Public Health Approaches

The management of the secondary iron deficiency attributable to hookworm or schistosomiasis can be achieved both by anthelmintic medications or supplemental iron to compensate for parasite-induced losses. In countries where HIV/AIDS is rampant, efforts for its prevention are fundamental. A food-security crisis grips the whole society in AIDS endemic areas, and this must be relieved with food and economic assistance. The wasting syndromes produced by tuberculosis are best addressed proactively by prevention of transmission and early detection. However, when primary prevention fails, as in the aforementioned infections, efforts to enhance the enteral intake of infected members of the community are particularly essential for their comfort and well being.

### Dietary Management of Secondary Overnutrition

The dietary management of secondary overnutrition would logically include restricted intake of the nutrients accruing in excess. This is not always facile or feasible, however, due to the intrinsic complexity of foods and beverages, where most are sources of multiple essential micronutrients. Marked reduction in total energy intake can also jeopardize the intake of proteins and essential fats. For the metal-storage afflictions such as Wilson's disease and hemochromatosis, removing copper and iron from the diet, respectively, are the fundamental elements of management. Some additional benefits can be gained by blocking the metals' absorption, as with high doses of zinc in Wilson's disease or with strong black tea (tannins) in hemochromatosis. Fundamentally, however, the management of metal-storage diseases requires some interventions to selectively remove the overload – by chelating agents in Wilson's disease and recurrent phlebotomy in hemochromatosis. In a related variant condition, African hemosiderosis, common among Bantu in southern Africa, removing concentrated iron sources from the diet, specifically the iron-loaded traditional beers, provides effective long-term control.

### Dietary and Nutritional Management of Secondary Undernutrition

The syllogism for dietary and nutritional management is to get enough nutrients into the body to restore nutritional adequacy and balance, taking any chronic barriers to uptake and retention into consideration. The blend of nutrients must be tailored to the specific absorptive or utilization problems, for example, compensatory fat-soluble vitamins in water-miscible forms with severe fat malabsorption, and extra doses of highly available iron with chronic blood loss. These can be delivered within a dietary context with supplements and fortified vehicles, in nonacute conditions. Even nondietary routes have been devised as in the treatment of vitamin D deficiency due to Crohn's disease with tanning bed ultraviolet B radiation.

When accumulated undernutrition is dangerously advanced, absorptive barriers are especially severe or nutrient losses are excessive, more concerted nutritional intervention is required. Intensive therapy can be delivered by three routes: orally, with special diets supplemented by liquid formulas; enterally, with liquid formulas perfused by intragastric or intrainestinal feeding tubes; and parenterally, with intravenous formulas infused into peripheral or central veins. Up to 50% of patients on dialysis have protein-energy malnutrition, which may continue undetected. For end-stage renal patients, intradialytic alimentation (adding nutrients to the dialysis fluids) has been used to reduce nutrient loss. Each approach has its distinct costs, special potential, and limitations and risks, and has been explored and refined in the context of age, physiological status, and specific disease states or surgical indications.

Tailoring of nutrient delivery is required with both enteral and parenteral nutrition, depending on the pathophysiology of the underlying conditions. Both hypo- and hypermetabolic states can occur; indirect calorimetry with metabolic carts is in vogue for prescribing energy delivery in intensive care. When pulmonary compromise is present, the balance among macronutrients is important to minimize carbon dioxide formation in metabolism.

Maintaining abundant amino acid supply promotes protein-sparing and prevents loss of lean tissue in catabolic states. Enrichment of enteral or parenteral regimens with branched-chain amino acids or keto-analog amino acids has been devised to compensate for the metabolic defects of nitrogen handling in hepatic or renal failure states. The objective of nutritional support in patients with liver failure is to provide adequate macronutrients to ensure the specific substrates for energy and protein synthesis and integrity of normal hepatic tissue function, without inducing or accentuating encephalopathy or otherwise aggravating hepatic insufficiency.

In juvenile cholestasis, large amounts of fat-soluble vitamin supplements and medium-chain triglycerides are usually required for optimum growth. With protracted secretory diarrheal diatheses, fluid and electrolyte balance may be the primary concern, followed by macro- and micronutrient nutriture, invoking the institution of parenteral feeding. Cancer cachexia is a major secondary consequence of disseminated neoplasms. It is tempting to prescribe aggressive nutritional support, but a caveat is that certain nutrients acting with certain neoplasms favor the tumor's growth and dissemination. To the extent that various forms of cachexia are partly driven by catabolic responses mediated by proinflammatory cytokines, antagonists directed at counteracting their action hold promise for retarding the nutrient-wasting in various forms of cachexia.

With intensive nutrition, there are risks and adverse consequences intertwined with the benefits. A variation of the refeeding syndrome, that is, hyperalimentation complications from excessive energy substrate perfusion or infusion, can produce hypophosphatemic and hypokalemic episodes. Improper formulation of fluids or liquids with micronutrients can cause deficiency or toxicity states in chronic nutritional support. The hazards of indwelling catheters are multiple, from phlebitis of the veins to sudden dislocation or migration. Fluid overload and sepsis are the most troubling complications of intravenous parenteral nutrition.

For tube-feeding enteral alimentation, tube placement is the crucial element. With nasal placement of the tube, there is a finite risk of respiratory tract inflammation and infection from aspiration of formula and secretions. In hospital, enteral nutrition is a risk factor for nosocomial pneumonia. An alternative site for long-term administration of tube-feeds is percutaneous placement of an intragastric feeding tube under endoscopic control.

Aggressive nutritional support, with its attendant expense and potential morbidity, in critically ill patients remains controversial. In terms of cost-benefit analysis, the use of the intensive formats of enteral artificial nutrition seems to be cost effective to reduce post-hip-fracture hospital stay in underweight women and for preoperative nutritional support, if carried out at home. Preoperative parenteral nutrition has been judged as prohibitively expensive for the small reduction in postoperative morbidity that it produces.

## Conclusions

Dietary intake is the most important determinant of over- or undernutrition, but it is not the only influence on an individual's nutritional status. A series of extrinsic environmental factors or intrinsic clinical or physiological disorders can alter the absorption, retention, utilization, and integrity of nutrients. These give origin to secondary malnutrition states. Primary (dietary origin) and secondary (environmental, pathological) factors often combine within the same individuals. From a public health perspective, the goal is to implement broad policies and programs that increase the availability of specific nutrients imperiled by the local environmental problems, for example, iron in hookworm infested areas, while addressing the primary diseases. In the clinical setting, management requires diagnosing and managing the underlying pathological states interfering with nutritional health while providing compensatory measures to correct secondary nutritional imbalances.

### Introduction

Asthma is a chronic inflammatory disease that develops in early childhood, though onset later in life is not atypical. Modern nutrition research has focused on the health benefits of specific nutrients, as well as dietary patterns, in preventing and treating such chronic conditions. The increased prevalence of asthma in recent decades has paralleled changes in environmental exposures and dietary patterns that likely are causing the increased prevalence of asthma, though specific cause-effect associations are hard to discern. In this article we will first examine the epidemiology, etiology, and management of asthma. We will then describe the dietary factors that are associated with a higher or lower risk of asthma or of asthma severity. Our approach in examining nutrition and asthma associations has been to identify specific nutrients and dietary practices that have been shown to be consistently associated with increasing or decreasing risk or severity of asthma as shown thorough repeated publication of human studies in the scientific literature, often reported in systematic reviews and meta-analyses. Some nutrition interventions can be readily examined in randomized, controlled trials (RCTs), but observational data is also important particularly for examination of factors such as

breastfeeding and dietary patterns. In summary, data published in the last decade has shown a substantial increase in the body of knowledge supporting diet (e.g., related to the increased prevalence of obesity) as a risk factor for developing asthma, though other practices, including breast feeding, fruit and vegetable consumption and intake of specific nutrients including vitamin D and n-3 LCPUFA, are protective and may be useful in decreasing the severity of symptoms in patients with asthma.

## Overview of asthma

### Epidemiology

Asthma affects an estimated 26 million people in the US, 70% of them adults. Worldwide approximately 250 million people are believed to have a diagnosis of asthma. In the US, asthma accounts for 13.9 million office visits for adults, 500,000 hospitalizations and two million emergency department (ED) visits per year. Of the estimated 25 million asthmatics in the US, most of their annual costs incurred are from the five to ten percent of patients with severe asthma. Approximately 3000 deaths occur annually, and most of these deaths occur outside the hospital. A recent study of the effect of age on asthma mortality showed that age >55 y conferred a 5-fold increased risk of death from asthma compared to younger adults and children (Tsai et al., 2012). Predictors of fatal asthma include three or more ED visits for asthma in the past year, an asthma hospitalization or ED visit in the past month, overuse of short-acting beta 2 agonists, a history of intubation or ICU stay for asthma, and patient characteristics, such as low socioeconomic status, female sex, and non-white ethnicity. In 2007, the incremental cost due to asthma was \$56 billion in the United States, and the costs are much higher worldwide (Barnett and Nurmagambetov, 2011). It is estimated that up to 25% of all “adult-onset” asthmatics have a workplace trigger for their disease. 5–20% of all asthmatics suffer partial disability that affects their ability to work, and 40%–80% lose considerable income because of their disease.

### Definition of asthma

In the 2021 Global Initiative for Asthma (GINA) guidelines, the definition of asthma highlights the facts that asthma is a “heterogeneous disease characterized by chronic airway inflammation” involving a history of episodic respiratory symptoms (shortness of breath, cough, wheezing) with “variable expiratory flow limitation” (GINA, 2021). Lung function testing such as spirometry is needed to help determine both the expiratory airflow abnormalities and airway hyperreactivity. Characterization of asthma also includes measuring fraction of nitric oxide in exhaled breath (FeNO) and peripheral blood eosinophil counts. While FeNO is not a standardized test for the diagnosis of asthma, recent evidence-based summaries suggest that a high FeNO level (e.g., >44 ppb) in breath has a very good positive predictive value for the diagnosis of asthma (Wang, 2017). Furthermore, skin prick testing and *in vitro* IgE specific assays can determine if a person with asthma has an antibody response to antigens in the environment. Sputum eosinophilia is another asthma marker, but is rarely used clinically, and is not part of the standard definition or work-up.

### Development of asthma

Asthma is a complex syndrome and not a singular disease. Multiple sub-types of asthma exist in adulthood, though this is less true in early childhood. Asthma most commonly develops at a young age, and it remains difficult to diagnose before age three. Upper respiratory viral illnesses, particularly rhinovirus and respiratory syncytial virus, and environmental allergens combine to trigger an upper and lower airway inflammatory response in susceptible individuals. The contribution of air pollution and environmental events, including wildfires, to the development of asthma and to asthma attacks in children is becoming well-recognized. Several theories describe asthma pathogenesis broadly. One is the “atopic march” that states that allergic inflammation of the airways naturally follows eczema or atopic dermatitis in young children. Secondly, the “hygiene hypothesis” suggests that allergic inflammation results from changes in the patterns of exposure—less infections, more contact with indoor allergens like house dust mite—that many children now experience at a very young age in recent decades. Dietary changes characterized as adoption of the “Western diet” have also been associated with the increased prevalence of asthma seen over the past 50 years. Current research focuses on the hypothesis that such environmental and dietary changes may increase the risk of asthma development in early childhood by multiple mechanisms, including changes to the intestinal microbiome, which can then alter the development of immune function, increasing the risk of developing a type 2 pattern of inflammation which can lead to allergic sensitization to some environmental antigens (i.e., “allergens”). These factors may act on the infant *in utero* via maternal exposures (e.g., obesity related to Western diet, smoking, air pollution) or after birth (e.g., lack of breastfeeding, Western diet, decreased microbial exposure in urbanized settings). Delivery by caesarian section increases the risk of asthma development in early childhood via effects on immune development perhaps resulting from a decreased perinatal stress response related to delivery, altered development of the infant microbiome, or perhaps because of prophylactic use of antibiotics in such cases. Finally, genetics also plays a role, with infants of parents with atopic disease having a higher risk of developing asthma (Renz and Skevaki, 2021).

Inflammation of the airways is a defining feature of asthma and selective recruitment by leukotrienes, cytokines, and chemokines help direct trafficking of key effector cells to the airways. The key effector cells in asthma include eosinophils, basophils, T-helper Type 2 cells (Th2), and mast cells. The Th2 cytokines, interleukin (IL)-4, -5, and -13 or their receptors are all targets of novel therapies to dampen type 2 inflammation. Mast cells in the bronchial smooth muscle are important in the persistence of abnormal

airway hyper-responsiveness and chronic airway inflammation in difficult-to-control asthma. In addition to this pathway, lung group-2 innate lymphoid cells (ILC-2) in the lung drive an eosinophilic airway inflammatory response. Alarmins such as IL-33 and thymic stromal lymphopoietin (TSLP) are secreted by airway epithelial cells in response to cigarette smoke, pollutants and microbes and trigger activation of the ILC2 cells, which in turn increase IL-5 levels and eosinophilic recruitment.

Asthma has long been considered an eosinophil-predominant inflammatory airway disease; there is an established correlation between peripheral blood eosinophilia and worse outcomes from asthma and increased eosinophil numbers in induced sputum samples are found in most severe asthmatics (Louis et al., 2000). Eosinophils are bone marrow derived granulocytes that have long been recognized as the main mediator cells in allergic asthma. In addition to releasing varying cytokines and chemokines, they have been found to also release toxic granular proteins all of which promoting Th2 inflammation as well as airway epithelial damage (Dunn and Wechsler, 2015).

These findings support previous evidence that link airway inflammation and abnormal airway physiology indicating that reducing airway inflammation with corticosteroids improves airway function. While the classic eosinophilic pathogenesis of asthma does not adequately explain the subgroups of asthma, this pathway has driven novel drug development over the past decade.

### Management of chronic asthma

The 2021 GINA guidelines (GINA, 2021) have simplified prior asthma guidelines that detailed often complex, progressive management actions within different steps of care. The medications have been repositioned to deemphasize “controller” inhaled corticosteroids (ICS) and “rescue” short acting beta2 agonist bronchodilators. Instead, the preferred regimen is now a combination of ICS and the long-acting b2-agonist (LABA) formoterol to be used as needed in mild asthma cases or scheduled and as needed for moderate asthma. Patient adherence with prescribed asthma therapy in the US is very poor and it is hoped that this simplified prescription will improve this. The important aspect of patient education and open communication between physician and patient must be emphasized. Emphasis placed on the two aspects of the written asthma action plan—(1) daily management and (2) how to recognize and handle worsening asthma. Discussions should also include physical, emotional, and environmental stressors that contribute to asthma symptoms, including diet and nutrition.

The past 7 years have brought a transformation in asthma care for the most severe asthmatics. There is now a panel of home-based injection monoclonal antibody therapeutics that can be deployed based on severe asthma patient’s eosinophil count ( $>150/\mu\text{L}$ ) and associated comorbidities. Omalizumab was the first monoclonal antibody approved in 2003. It binds to IgE and has been approved for patients with refractory allergic asthma that has been shown to decrease exacerbations, inhaled corticosteroids, and improved asthma-related quality of life measures in refractory asthmatics (Busse et al., 2011; Strunk and Bloomberg, 2006). In 2015, the approval of IL-5–neutralizing monoclonal antibodies (mepolizumab, reslizumab) for severe asthma led to remarkable clinical benefit in severe, corticosteroid-requiring asthma associated with sputum eosinophilia. That has been followed by benralizumab, a novel monoclonal antibody (mAb) that binds to the  $\alpha$  chain of the interleukin 5 (IL-5) receptor (IL-5R $\alpha$ ), a receptor expressed by mature eosinophils, eosinophil-lineage progenitor cells and basophils (Rothenberg and Hogan, 2006), and dupilumab, a dual IL4/IL-13 receptor blocker approved for asthma and chronic sinusitis with nasal polypsis. Future therapeutics targeting the alarmins are expected soon. Together, these advanced therapeutics greatly expand the armamentarium to more severe asthma patients and reduce the risk and harm that results from asthma exacerbations.

## The role of nutrition in prevention and management of asthma

### Breastfeeding

Breastfeeding has multiple immediate health benefits for infants, providing optimal nutritional support and decreased risk of infection in infancy, but also provides many long-term health benefits, including a possible decrease in the risk of asthma (Victora et al., 2016). In addition to being rich in nutrients, breastmilk provides many immunologic factors that protect the infant against infection and can shape the development of the immune system (Dawod et al., 2021). Breastfeeding is also an important determinant of intestinal microbiota composition during infancy for many reasons, including the presence of human milk oligosaccharides that increase the growth of beneficial microbiota including bifidobacteria (Ho et al., 2018). The composition of an infant’s microbiota directly affects early immune development and is associated with risk of allergic disease, including asthma (Renz and Skevaki, 2021). For many years it has been assumed that breastfeeding protects against the development of asthma through a variety of mechanisms, including effects on immune development and decreased risk of early lower respiratory tract infections which can increase the risk of asthma. The principal evidence for this comes from epidemiologic studies associating breastfeeding “level” (i.e., exclusive vs. supplemented) and duration with risk of asthma and allergic disease in infancy and later in childhood. As pointed out in a recent review, the evidence is mixed from these studies with some showing decreased risk of asthma and others showing no benefit (Miliku and Azad, 2018). Possible reasons for this lack of consistency include the difficulty of defining the extent (full, predominant, or partial) and duration of breastfeeding. It may also be important to determine whether infants feed from the breast or from expressed, stored milk (which could affect immune factors in milk). The risk of asthma development during the first few years of life (typically by 3–6 years of age) is relatively low, which can also make it difficult to define associations in epidemiologic studies that are not quite large. Fortunately, it is useful to examine the risk of wheezing as an endpoint because wheezing in infancy is itself predictive of later asthma development (Miliku and Azad, 2018). Many studies have examined the association of

breastfeeding with a risk of wheezing as a proxy for risk of asthma. A recent meta-analysis examined the association of breastfeeding with wheezing during infancy in infants with an elevated risk of asthma due to family history. The study found that breastfed infants had 32% lower odds of wheezing by 1 year of age compared to infants never breastfed (Harvey et al., 2021). In summary, the current evidence indicates breastfeeding can reduce the risk of wheezing in high-risk infants and may also reduce the risk of asthma in all infants, but the evidence for this latter point is not conclusive.

### Probiotic supplements

A limited number of studies have examined the efficiency of probiotic supplementation in the treatment and the prevention of asthma during infancy and childhood. This strategy is based on the benefit of some commensal microbiota in regulating infant immunity and possibly decreasing the risk of type 2 inflammation developing in infancy and contributing to the risk of asthma (Renz and Skevaki, 2021). Probiotic supplements used in infancy and childhood typically include *Lactobacillus* or *Bifidobacterium* species. A recent meta-analysis of nineteen randomized trials using such probiotics in infancy did not show an overall benefit in preventing the development of asthma or wheeze during infancy or early childhood (Wei et al., 2020). A subgroup analysis showed a decreased risk of wheeze in infants with atopic disease, suggesting a benefit in high-risk infants. Probiotics have also been evaluated in randomized trials among asthma patients during childhood to determine if severity of disease could be diminished. A meta-analysis of such studies found a shift away from type 2 cytokine production (IL-4) in favor of type 1 cytokine production (IFN- $\gamma$ ) and a decrease in asthma episodes but not in other measures of asthma severity or pulmonary function (Lin et al., 2018). On balance, the use of probiotics to decrease the development or severity of asthma is not strongly supported by these findings. The underlying mechanistic rationale for such studies has merit, however, and future research in this area is warranted, including examination of the role of probiotics in treating asthma symptoms in adults.

### Obesity and asthma

Asthma prevalence has increased in the US in recent decades at a time when the prevalence of obesity has also increased. This association is not a coincidence as there is ample evidence that obesity increases the risk of asthma in both adults and children and is also associated with greater asthma severity (Ali and Ulrik, 2013). Multiple mechanisms appear to be involved including chronic inflammation, mitochondrial dysfunction, Th17-induced neutrophilia, macrophage dysregulation, hormonal changes, lipid metabolism, insulin resistance, and body mechanics (Baffi et al., 2016; Shore and Cho, 2016). Other well-described abnormalities in obesity and metabolic syndrome, accelerated formation of advanced glycation end products (AGEs) and alterations in arginine metabolism that may be modulated by the anti-inflammatory incretin, glucagon-like peptide-1 (GLP-1) (Milutinovic et al., 2012; Ojima et al., 2013; Singh et al., 2015). Obesity, which is defined in adults as a body mass index (BMI; kg body weight/[height in meters]<sup>2</sup>) >30, has a negative effect on the mechanics of breathing, and these effects are more pronounced as BMI increases. Thus, individuals with or at risk of asthma may have more severe diseases at higher BMIs because of the mechanical constraints on breathing imposed by obesity.

In addition, obesity causes local and systemic inflammation by multiple mechanisms (Ali and Ulrik, 2013). Local inflammation in adipose tissue deposits can result from local tissue damage related to adipocyte size, oxygenation of the local cells and tissues, and cell death related to these stresses. Markers of oxidative damage are increased in obesity, partly because of this tissue damage. As a result, inflammatory cells are attracted to and accumulate in adipose tissue, particularly abdominal adipose tissue. These cells include macrophages and T cells, particularly Th1 cells which drive type 1 inflammation by production of cytokines such as IFN- $\gamma$ . These local effects can eventually produce systemic inflammation as indicated by elevated plasma cytokines, such as IL-6, and acute phase proteins, including C-reactive protein (CRP). While this phenomenon is well-characterized in obesity, the effect of such inflammation on asthma development is not clear. In addition, hormonal changes that occur in obesity can have direct effects on local and systemic inflammation. In particular, the hormone leptin, which is increased in obesity, enhances development of Th1 cells and thus promotes type 1 inflammation. Additionally, the hormone adiponectin has anti-inflammatory effects but is decreased in obesity. However, this bias toward type 1 inflammation, which could dampen type 2 inflammation that is common in allergic asthma, does not decrease the risk of asthma development, as far as is known, but obese individuals with asthma do have a phenotypically different type of inflammation with less pronounced eosinophilic inflammation than lean individuals (Ali and Ulrik, 2013). In children with asthma, a predominance of systemic type 1 cytokines is seen rather than the type 2 predominance seen in lean asthmatics (Nyambuya et al., 2020).

Information on the association of obesity with asthma in children has increased substantially in recent years. In case-control studies performed in children and adolescents, BMI is consistently associated with an increased risk of having asthma (Azizpour et al., 2018). In addition to the factors mentioned above, it is thought that common genetic factors may be associated with both obesity and asthma, and early life events may lead to epigenetic effects on immune function that could predispose to an increased risk of either or both conditions (Azizpour et al., 2018; Ali and Ulrik, 2013). Fortunately, weight loss in children can have some beneficial effects on asthma-related inflammation and quality-of-life indicators though improvements in pulmonary function have not been consistently shown in children, though improved pulmonary function has been shown in weight loss for adults (Okoniewski et al., 2019). Bariatric surgery in adults often results in greater weight loss than other interventions and has also been shown to improve asthma severity based on clinical indicators including medication usage and the occurrence of severe asthma exacerbations requiring emergency medical interventions (Hossain et al., 2021).

## Vitamin D

Vitamin D affects immune function and has been hypothesized to have a benefit in treating asthma due to its ability to dampen inflammatory T-cell immunity (e.g., Th17 cell activity), enhance regulatory immunity (e.g., Treg cell activity), and enhance anti-viral innate immunity, thus decreasing the risk or severity of viral infection-induced exacerbations in asthma patients (Shabana et al., 2019). A meta-analysis using individual participant data examined the effect of vitamin D supplementation of asthmatic children and adults on the occurrence of asthma exacerbations from seven published studies (Jolliffe et al., 2017). Vitamin D dosing regimens were varied, ranging from infrequent (every 2 m) high doses (e.g., 120,000 IU) to daily RDA-level doses (e.g., 500 2000 IU), to a combination of the two. The main outcome examined was the relative risk of severe exacerbations (needing either systemic corticosteroid treatment or ER attendance). The analysis found that severe exacerbations were reduced in the vitamin D treatment group relative to the control group using either a need for systemic corticosteroid treatment (showing a 31% reduction in incidence) or ER attendance (odds ratio, 0.46) as the case definition. Patients with poor vitamin D status (<10 ng/mL) tended to benefit more than those with better status. A subsequent RCT published in 2021 in 192 children with asthma with low plasma vitamin D (Lu et al., 2021) showed no benefit using time to a severe asthma exacerbation as the primary endpoint. In summary, vitamin D supplementation of asthma patients can be beneficial in decreasing severity of asthma exacerbations, presumably by regulating immune activity.

Asthma is often diagnosed in early childhood and its development can be influenced by prenatal exposures, perhaps including maternal vitamin D status. Three RCTs of prenatal vitamin D supplements (800 IU daily, or 400 IU daily with a higher loading dose of 2400 or 4000 IU), when analyzed individually, did not show any reduced risk of asthma or recurrent wheezing when analyzed individually (Brustad et al., 2019; Goldring et al., 2013; Litonjua et al., 2020), but a combined analysis of two of these (Wolsk et al., 2017) and a meta-analysis of all three (Li et al., 2019) did show a beneficial effect of prenatal supplementation on reducing risk in the vitamin D treatment group by approximately 25%. Wheezing itself may result from causes other than asthma (e.g., a respiratory tract infection) so some caution is warranted in concluding that wheezing is always specific to asthma. Observational data also show, as analyzed in the same meta-analysis (Li et al., 2019), a reduced risk of recurrent wheezing in association with higher maternal vitamin D intake. Taken together, these studies are consistent with higher maternal vitamin D intake reducing the risk of asthma in their offspring during early childhood. However, some caution is warranted as the meta-analysis (Li et al., 2019) showed a U-shaped relationship between maternal intake during pregnancy and wheezing/asthma risk in children, with risk decreasing to a nadir at approximately 800 IU/d, but with increased risk seen at higher levels.

## Long-chain polyunsaturated fatty acids (LCPUFA)

The Western dietary pattern is typically rich in the n-6 PUFA linoleic acid (18:2n-6) from a variety of sources including corn oil. After consumption, linoleic acid can be efficiently elongated to the LCPUFA (a 20 or 22 carbon PUFA) arachidonic acid (AA; 20:4, n-6), which has many biological activities. AA can also be ingested directly from meat and eggs. AA is abundant in cell membranes and can affect immune cell responses as it is a precursor for the production of immune mediators including prostaglandins (PG) such as PGE2 produced by the cyclooxygenase (COX) pathway, and leukotrienes (LT) such as LTB4 produced by the 5-lipoxygenase (5-LOX) pathway. PGE2 promotes type 2 inflammation via effects on both T and B lymphocytes such as promotion of IgE production which is important in allergic responses. PGE2 also induces fever, vascular permeability to facilitate inflammation, and can induce the pain response. Not surprisingly, suppression of the COX pathway is one mechanism employed in pharmacology to produce common, over-the-counter non-steroidal anti-inflammatory drugs (NSAIDs). LTB4 causes bronchoconstriction, increases vascular permeability, and attracts neutrophils and eosinophils to sites of inflammation. LTB4 can also enhance inflammation by stimulation production of pro-inflammatory cytokines by innate immune cells, and by promoting T cell function. Dietary n-3 PUFA, such as  $\alpha$ -linolenic acid (18:3, n-3), are found in flaxseed and canola oils and are less abundant in the Western dietary pattern than linoleic acid and can also act as precursors for LCPUFA production including eicosapentaenoic acid (EPA; 20:5, n-3) and docosahexaenoic acid (DHA; 22:6, n-3), though this elongation is very inefficient. However, EPA and DHA are abundant in some foods, primarily cold-water fish such as salmon, and are also commonly available now in supplements. Intake of n-3-containing plant oils, fish containing EPA and DHA, and supplements containing fish oil or purified EPA and DHA, is increasing because of the well-characterized anti-inflammatory properties of EPA and DHA. As with n-6 PUFA, these n-3 PUFA are incorporated in cell membranes, though EPA and DHA are always found at much lower levels than AA and are also available as precursors for production of immune mediators. The n-3-derived mediators tend to have anti-inflammatory properties while the n-6 mediators can promote inflammation. The n-3 LCPUFA and their mediators act via several mechanisms. First, EPA is a competitor of AA in the COX and 5-LOX pathways and thus can reduce the production of PGE2 and LTB4 to a limited degree, but the PGE3 and LTB5 mediators produced from EPA are also less inflammatory than PGE2 and LTB4 produced from AA. In addition, EPA and DHA serve as precursors for pro-resolving mediators termed resolvins that dampen and resolve inflammation by a variety of mechanisms. DHA, in addition, serves as a precursor for two additional classes of pro-resolving mediators, maresins and protectins. EPA and DHA can thus act via these mechanisms, as well as via other mechanisms not described here, to decrease inflammation. As a result, EPA and DHA are being evaluated as interventions (via diet or supplements) to reduce inflammation for many chronic inflammatory conditions, including asthma (Miles et al., 2021; Panigrahy et al., 2021; Djuricic and Calder, 2021).

As with vitamin D, prenatal exposure to n-3 LCPUFA has been examined as a protective factor for development of asthma in early childhood. Several cohort studies have examined usual dietary intake of fish containing n-3 LCPUFA by pregnant women

and by infants and children in relation to risk of developing asthma as reported in a meta-analysis (Yang et al., 2013). Fish consumption during pregnancy was not associated with lower risk of asthma in offspring but intake of fish during infancy and early childhood was associated with a 25% lower risk of developing asthma during follow-up periods ranging from 1 to 6 years. Similarly, infants ingesting higher levels of LCPUFA from breastmilk had a 29% lower risk of asthma over a period of 5 years. In summary, observational data suggest that exposure to n-3 LCPUFA may prevent development of asthma in children. These studies have the shortcoming of all observational studies in that other factors related to n-3 LCPUFA intake may be the cause of this association. To address such concerns, several placebo-controlled, randomized trials have examined the effect of prenatal n-3 LCPUFA supplements on risk of developing wheeze or asthma in offspring. Seven trials involving EPA plus DHA supplementation in the third trimester of pregnancy with children being followed for periods ranging from 6 m to 16 y (Lin et al., 2020). Since asthma and wheeze are difficult to distinguish in infants these endpoints were combined. The pooled analysis found that the relative risk of asthma/wheeze decreased by 19% in the LCPUFA group relative to the “placebo” oil (olive, soy, or a vegetable oil) group. The risk of asthma alone was not reduced when examined separately. Subgroup analysis showed that LCPUFA supplementation of high-risk children (those with a family history) had a 35% reduction in asthma/wheeze and in studies with higher doses of n-3 LCPUFA ( $\geq 2$  g/d) these supplements produced a 39% reduction in asthma/wheeze. The quality of the evidence from these trials was judged to be relatively low, which reduces confidence in the conclusions and suggests that more studies addressing study design issues should be undertaken. Also, long-term use of high-dose n-3 LCPUFA can decrease blood clotting and thus increases the risk of bleeding which is a risk that also requires further evaluation. In contrast to using high-dose supplements, a recent controlled intervention trial in asthmatic children that increased fish intake over that of the control group did show decreased pulmonary inflammation, though not improved pulmonary function (Papamichael et al., 2019). This partial benefit suggests that food interventions may be useful and would avoid risks of high-dose supplements.

Fewer studies have been done with n-3 LCPUFA in adults to prevent or treat asthma than have been done in childhood. Adult intake of fish and n-3 LCPUFA in observational studies has not associated with a lower of risk of developing asthma (Yang et al., 2013). Several therapeutic interventions have been done in adults with asthma but, as discussed in a recent review (Willemssen, 2016), and reconfirmed in a more recently published intervention trial (Lang et al., 2019), there is not consistent evidence from these studies that n-3 LCPUFA is an effective intervention for diminishing severity of asthma, though some indicators of inflammation were diminished in these studies.

### Amino acid supplementation and asthma

Dietary supplementation of various amino acid formulations is common practice, including in patients with chronic illnesses. Several recent studies have added significantly to our understanding of the impact of supplemental amino acids on asthma. Creatine may be the most popular amino acid supplement in the general population, but data suggests that creatinine may be the most disadvantageous amino acid in asthma. In an ovalbumin exposure mouse model of asthma, it was shown that creatine at a dose  $0.5 \text{ mg kg}^{-1} \text{ day}^{-1}$  worsened eosinophilic lung inflammation and airway hyper-responsiveness (Vieira et al., 2007). On the contrary, other amino acids appear to have some beneficial effects in asthma. For example, undenatured whey protein, a cysteine source, appears to increase antioxidant capacity in the lungs and improve airway hyperresponsiveness in asthmatics with exercise-induced symptoms. Also, L-arginine and L-citrulline could potentially act as bronchodilators and anti-inflammatory treatments. L-arginine is a semi-essential amino acid that can be enzymatically converted into nitric oxide by the nitric oxide synthase (NOS) enzymes. Dysregulation of arginine metabolism is a paradigm linked to multiple diseases, including obesity, metabolic syndrome, as well as asthma. This paradigm has led to the testable hypothesis that L-arginine supplementation is beneficial in cardiovascular disease (Bahadoran et al., 2016; Pahlavani et al., 2014) and sickle cell disease (Morris et al., 2013) among others. From these studies, we have learned that there are other factors to consider, such as asymmetric dimethylarginine (ADMA), which can accumulate and lead to impaired NO production (Bratt et al., 2011; Linderholm et al., 2014; Sibal et al., 2010). A recent clinical trial of L-citrulline supplementation in individuals with asthma found that L-citrulline increased fractional exhaled NO and modestly improved forced expiratory volume in 1 s (FEV1), especially in females with late-onset asthma (Holguin et al., 2019). We and others have found in murine models that manipulation of L-arginine content in the airway compartment via L-arginine treatment or inhibition of the arginase enzyme decreases airway inflammatory cell counts, lung lavage cytokine levels, airways hyperresponsiveness, and arginase activity (Mabalarajan et al., 2010). L-arginine, L-citrulline, and L-glutamine supplementation and metabolism will continue to be a focus of research in asthma, particularly given the low cost and widespread availability of these potential treatments.

### Antioxidants

Oxidative stress during asthma can contribute to the severity of asthma symptoms and it is thus logical to consider how use of antioxidant nutrients might be useful in treating, or perhaps preventing, asthma (Sahiner et al., 2018). Vitamins C and E are the two principal vitamin antioxidants, though minerals like iron, zinc and selenium can also contribute to the activity of antioxidant proteins. Observational and small intervention studies have been conducted to examine the relationship between vitamins C and E and asthma. The results are quite heterogeneous and do not support use of these vitamins to treat asthma, though a possible benefit for vitamin C in exercise induced asthma has been reported (Wilkinson et al., 2014; Moreno-Macias and Romieu, 2014; Milan et al., 2013). The role of selenium in asthma has also been considered but supplement use has not been examined, though

selenium deficiency does occur in some regions of the world where supplements may be useful for improving status and treating underlying deficiency symptoms (Norton and Hoffmann, 2012).

### Fruits and vegetables

Fruits and vegetables contain many antioxidants including vitamins C and E, carotenoids and other phytochemicals such as flavonoids, isoflavonoids and polyphenolic compounds that have antioxidant properties. For these reasons, many studies of varied design have examined the association of fruit and/or vegetable intake with asthma and a meta-analysis has examined 58 articles reporting such studies (Hosseini et al., 2017). Most studies were in children or adolescents with only 17 done in adults. Most studies were cross-sectional, 8 were case-control studies, 13 were cohort studies and only 7 were clinical trials. Studies were conducted in over 20 different countries. The authors of the meta-analysis focused on primary prevention studies reporting the risk of asthma or wheeze, and on secondary prevention studies reporting changes in the severity of asthma or wheeze. Overall, higher fruit intake was not associated with the odds of having asthma but was associated with 39% lower odds of having more severe asthma, but only two studies examined asthma severity. Higher fruit intake was also associated with 6% lower odds of having wheeze. Higher vegetable intake was associated with 6% lower odds of having asthma. Fruit and vegetable intake together were not associated with odds of having asthma. While combining studies with different design carried out in different ages and in different regions is challenging, these results support the role of a healthy dietary pattern including fruit and vegetable intake as being protective, to a limited degree, against development of asthma. The mechanism of protection is also uncertain when examining the intake of whole foods but does allow for consideration of dietary recommendations directly.

### Magnesium

Magnesium deficiency has been associated with asthma but the mechanism underlying this association is not clearly understood. Magnesium may be anti-inflammatory and can inhibit the effect of calcium on causing smooth muscle contraction, for example in airways. Magnesium is given intravenously as an acute treatment for asthma exacerbations because it seems to have several biological effects attenuating asthma, including relaxation of smooth muscle cells, stabilization of mast cells, and counteracting bronchoconstriction. Oral magnesium supplementation has been examined in several RCTs with asthma patients and, as reported in a recent meta-analysis, a beneficial effect was seen on pulmonary function (increased FEV1 after 8 weeks of supplementation, but not at other timepoints) but other pulmonary function and clinical endpoints did not improve leading the authors to conclude that oral magnesium cannot be recommended at this time as an asthma treatment (Abuabat et al., 2019).

### Conclusion

Several lines of evidence demonstrate the benefits of good nutrition, including maintaining a healthy body weight, in decreasing the risk and severity of asthma. This is true during pregnancy, infancy, and early childhood for the prevention of asthma in early life. Factors that have shown benefit include prevention of overweight and obesity, consuming higher levels of vitamin D and n-3 LCPUFA than are currently common in Western countries, providing breastfeeding in infancy for nutritional benefit and likely also for optimizing development of the intestinal microbiota. Studies in adults have been less frequent but there is a demonstrated benefit of weight loss for adults with obesity. Data suggest that a “healthy diet” including abundant fruits and vegetables is also of benefit in decreasing the risk and severity of asthma, though much of this data is observational. Use of RCTs is easier in single nutrient interventions and is providing evidence that vitamin D and n-3 LCPUFA intake are beneficial for preventing and perhaps decreasing severity of asthma. These findings are generally consistent with findings for other chronic inflammatory conditions, suggesting that maintaining a healthy body weight, optimizing intake of specific immune-modulating nutrients as well as of fruits and vegetables, and optimizing diet for development of health-promoting commensal microbiota (at least during infancy with breast-milk), protect against chronic inflammatory diseases, including asthma.

### Key points/objectives

Recommendations for nutritional management of major burns:

- The nutrition support should be adapted to REE, approximated by indirect calorimetry, multiplied by a factor of 1.2–1.4, and metabolic capacity.
- Enteral nutrition should be initiated early using a high-carbohydrate, high-protein, and low-fat formula.
  - Carbohydrate should be the primary energy source (>50–60% energy) but should not exceed the body's ability to assimilate substrate (7 g/kg/day).
  - Fat should provide < 15% of energy.
  - Protein intake of 1.5–2.0 g/kg/day should be provided to limit lean body mass (LBM) loss.
  - Vitamins C, D, E, and K and trace elements, copper (Cu), selenium (Se) and zinc (Zn), should be supplemented. Further studies are required to determine if glutamine supplementation is beneficial and to recommended micronutrient supplementation doses.

- Hyperglycemia should be managed with intensive insulin therapy. Recommendations for nutritional management of minor burns:
  - In robust patients, sufficient oral intake of a high-protein, high-carbohydrate diet should be encouraged along with supplementation of micronutrients to meet daily recommended intake (DRI) to facilitate wound closure.
  - Selected patients with pre-existing malnutrition or at risk for malnutrition such as children and elderly, may require nutrition support to achieve complete wound healing.

### Glossary

**Anabolism** net accumulation of protein stores in response to hormones. This may be endogenous in recovery from injury or exogenous in response to administered steroids

**Catabolism** the net breakdown of protein and fat stores as a response to injury or stress

**Hypermetabolism** reflects an increase in whole body energy consumption above normal values. Patients are considered hypermetabolic when their resting energy expenditure (REE) is 10% or more above normal

**Major burn** burns covering greater than >10% total body surface area (TBSA) in elderly, >20% TBSA in adults, and >30% TBSA in children, initiating a prolonged, systemic inflammatory response

**Minor burn** burn covering less than 20% TBSA with inflammation localized to the injury site.

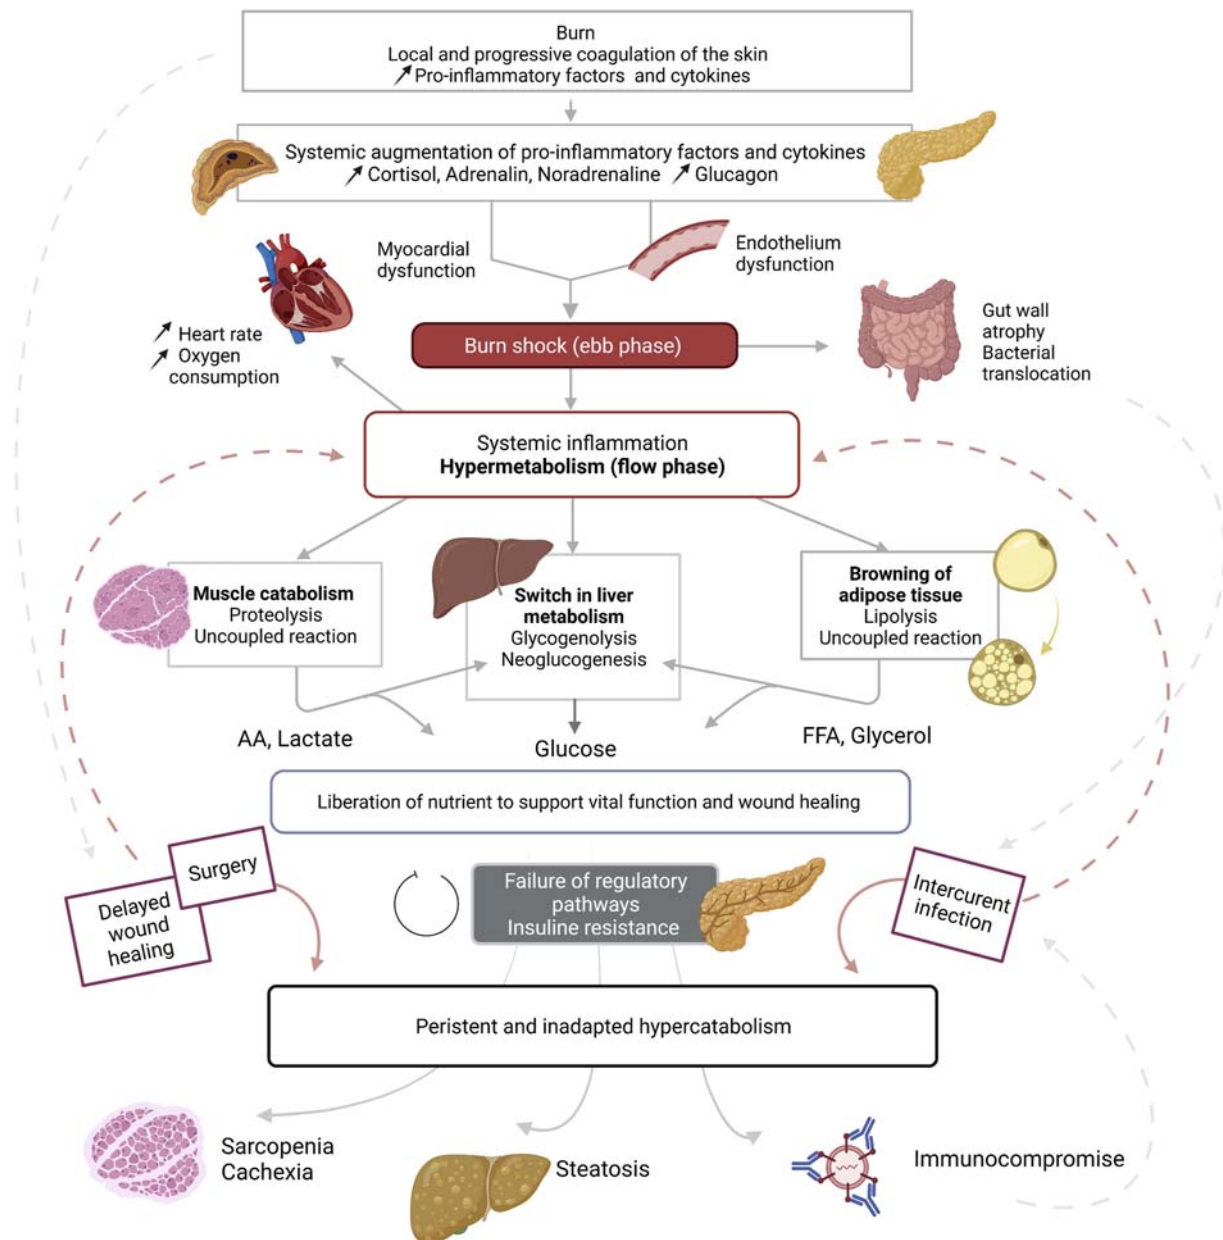

**Nutrition support** providing enteral and/or parenteral nutrition to treat or prevent malnutrition

### Introduction: pathophysiology of burn injury and metabolism

The majority of burns sustained are thermal injuries caused by scald or flame; however, tissue damage can be induced by other agents, including friction, cold, heat, radiation, chemical, or electrical. Treatment options vary based on the mechanism of injury as well as the depth and size of burn. Superficial (affecting only the epidermis) and superficial-partial thickness (deeper, but still contained to the epidermis) burns are anticipated to heal spontaneously and do not require intervention beyond aseptic dressing changes. Deep partial thickness (extending into the dermis), full thickness (extend through the full dermis), and fourth-degree burns (involving deeper tissue, such as muscle or bone) require careful management including antimicrobial dressings and surgery. Surgery involves excising the burn until a viable wound bed is reached followed by restoration of the epidermal layer by autologous skin graft taken from a donor site on the patient.

Major burns, commonly categorized as >10% TBSA in elderly, >20% TBSA in adults, and >30% TBSA in children, are unique as they set off an immediate systemic and local stress response that, unlike sepsis and trauma, persists for a prolonged period. This persistent inflammatory reaction will lead to major metabolic disorder and organs dysfunction (Fig. 1). Extensive destruction of the skin induces the release of stress hormones and pro-inflammatory mediators. The immediate response comprises endothelial and acute heart dysfunction leading a state of shock and a hypometabolic response that lasts for ~72–96 h. The gut develops mucosal atrophy due to hypoperfusion and edema, enabling bacterial translocation. The systemic response rapidly evolves into a hypermetabolic phase fueled by the release of stress hormones (catecholamines) and cytokines, that can persist for years following the initial injury. The heart goes into hyperdynamic overdrive, increasing circulation and blood flow to increase oxygen and nutrient delivery. Increased stress signaling causes changes in metabolic demand. Protein is degraded to deliver energy for hepatic function. White adipose tissue changes to brown adipose tissue allowing for increased lipolysis with the accompanying expression of lipotoxic intermediates, such as triglycerides, free fatty acids, and diacylglycerols (DAG), all of which are transferred to the liver. Despite an increase of gluconeogenesis, the liver is unable to metabolize all the accumulating substances and hepatomegaly develops. Hyperlipidemia and hyperglycemia with insulin resistance are present, which worsens the hypermetabolic and inflammatory state. Furthermore, intercurrent complication and surgical intervention trigger inflammatory reactions. If hypermetabolism cannot be diminished or decreased, holistic catabolism ensues with decrease of the lean body mass, and subsequent immunocompromized, multiple organ failure and death.

It is not feasible to halt the hypermetabolic response, but complementary strategies are available to diminish its magnitude. Thermoregulation by increasing ambient room temperature and using occlusive dressings reduces REE by limiting the need for heat production. Early excision, within 72 h of injury, and closure of the burn wounds leads to substantially reduced REE and subsequent improvement in mortality rates. Anabolic treatment such as oxandrolone, insulin, metformin, growth hormones and propranolol, can also be used to promote wound healing. At present, beta-adrenergic blockade with propranolol is probably the most efficacious anti-catabolic therapy in the treatment of burns. However, early and adequate nutrition support remains the cornerstone in addressing this hypermetabolic response, as prolonged catabolism is associated with delayed wound healing and increased incidence of organ failure, infections and death (Porter et al., 2016). The inflammatory response, triggered almost immediately after injury, is intended to create an environment that fosters wound healing. During the brief hypometabolic period (ebb

**Fig. 1** Simplified physiopathology of systemic effect of major burn lesions (created with Biorender).

phase) following initial injury the body draws primarily on endogenous energy sources to maintain vital functions; In major burns this extensive inflammation can become uncontrolled resulting in an hypermetabolic state (flow phase) with persistent hypercatabolism to support it. (Jeschke et al., 2020). Aggressive nutrition support is required to counteract the potentially devastating effects of persistent hypercatabolism.

## Nutrition after major burn

### Nutrition during the acute phase

The purpose of nutrition is to provide adequate macro- and micronutrients for tissue regeneration, to limit the deleterious effects of hypermetabolism, and to support immune function. A nutrition focused assessment should be conducted by a qualified clinician before initiating nutrition support. A review of patient's pre-injury nutrition status which can include anthropometric data, biochemical data, nutrition intake, physical examination, and functional status will help to guide the nutrition intervention (Table 1). Mechanism, extent, site and time since injury should also be considered during assessment. In addition to mechanically

**Table 1** Clinical assessment of factors influencing nutrition status of burn patients

\*Biochemical measure should be interpreted within context of clinical picture.

<i>Domain</i>	<i>Indicators</i>
Anthropometric	Height Weight Body mass index (BMI) or ideal body weight Weight history
Biochemical *	Electrolytes Blood glucose Renal function (creatinine, urea) Inflammatory markers (C-reactive protein, white blood cell count)
Nutrition intake	Diet history (diet restrictions, allergies, changes in diet intake, use of oral supplements or nutrition support, etc.)
Nutrition focused physical exam	Evidence of muscle or subcutaneous fat loss (including sarcopenia and cachexia) Evidence of adiposity or obesity Fluid accumulation or edema
Functional status	Ability to perform usual activities

ventilated patients, those with major burns, inhalation injuries, failure to maintain LBM with oral intake or selected patients with less extensive burns but at risk for malnutrition, should be considered for initiation of nutrition support. The elderly, children, and obese patients with evidence of sarcopenia are groups at risk for under nutrition. Burn patients require frequent reassessment of their nutrition care plan as wound healing, physical therapy and medical complications can all affect nutrition needs.

### Timing and route of nutrition support

In the first days following injury, energy production from endogenous sources in reaction to the inflammatory syndrome is increased due to a catabolic state and is sufficient to meet energy requirements. Full nutrition support in this phase may lead to overfeeding as exogenous nutrition cannot abolish endogenous energy production, and organs are unable to process the excess substrate. However, early enteral nutrition (EN), is recommended to maintain gastrointestinal (GI) trophicity (Wise et al., 2019). The American Society of Parenteral and Enteral Nutrition (ASPEN), European Society of Parenteral and Enteral Nutrition (ESPEN) and the Society of Critical Care Medicine (SCCM) recommend initiating EN within 12 h of injury, and as early as 4–6 h after injury to achieve maximal benefit (Wise et al., 2019; McClave et al., 2016; Rousseau et al., 2013). Early EN results in improved gut mucosal integrity which decreases incidence of bacterial translocation, enhances wound healing and LBM maintenance, modulates stress hormone levels and immunoglobulin production, and may improve EN tolerance for the duration of hospitalization. Once the patient is adequately resuscitated and hemodynamically stable, EN can be advanced to goal as quickly as tolerated.

EN is the preferred form of nutrition support; however, parenteral nutrition (PN) may be required for patients with non-functioning GI tracts, EN intolerance or unable to achieve goal EN in a reasonable time. There is no consensus on the appropriate timing of PN initiation. PN is avoided in many burn units due a historical reporting of increased risk for complications including hyperglycemia, infection, liver malfunction and mortality. The role of PN may require review, as improved infection control techniques and judicious prescribing to limit energy overfeeding and hyperglycemia have been demonstrated to be effective at increasing protein intake in pediatric patients without increasing incidence of blood or respiratory infections (Carson, 2018).

### Increased energy expenditure

#### Pathophysiology

Thermal injury elevates resting energy expenditure (REE) via increased basal metabolic rate, tissue regeneration and thermoregulation (Fig. 2). Acute events, such as sepsis, fever and surgery, may punctuate the initial phase causing physiological stress and significant variation in energy requirements. In the presence of oxygen all macronutrients, including carbohydrate, fat, and protein, will be used to produce energy, either in the form of ATP or heat via oxidation, resulting in carbon dioxide and water formation. Degradation of amino acids will lead to the formation of nitrogen derivatives which are eliminated in the urine as urea.

**Fig. 2** Variation in resting energy expenditure from 1 week to 6 months following burn injury. Increase in predicted resting energy expenditure is correlated with the extent of burn injury. Reproduced from Jeschke, M.G., Finnerty, C.C., Herndon, D.N. et al. (2007) *Crit. Care* **11**, R90.

### Requirements

REE can be approximated via indirect calorimetry by measuring the amount of inspired oxygen (VO<sub>2</sub>) and the amount of expired carbon dioxide (VCO<sub>2</sub>) using the following Haldane transformation of Weir's equation:

$$\text{REE (Kcal / day)} = 1.44 \times [(\text{VO}_2 \text{ (mL / min)} \times 3.94) + (\text{VCO}_2 \text{ (mL / min)} \times 1.11)]$$

In this formula the nitrogen derivatives are not considered leading to an error of 2–4%. Indirect calorimetry is the accepted gold standard for determining measured REE in the clinical setting (McClave et al., 2016). Minimum weekly repeated measures during acute hospitalization, or more frequently if there are changes in clinical status, are recommended to guide provision of nutrition support (Rodriguez et al., 2011). Generally, a brief measurement is taken during a steady state, when a patient is resting with no additional stresses, then extrapolated to predict energy expenditure for a 24-h period. Expensive equipment, clinician time and agitated patients with unstable oxygen requirements are common barriers to the use of indirect calorimetry.

Predictive equations are a popular substitute to estimate REE when indirect calorimetry is not available. The adapted Toronto formula correlates best with measured REE in the adult population, where Curreri, Harris-Benedict, Schofield-HW, and World Health Organization equations overpredict REE (Rodriguez et al., 2011). For pediatric patients, the Galveston equation is commonly recommended to predict energy requirements in the absence of indirect calorimetry (see *Monitoring* section, Table 3) (Rodriguez et al., 2011; Clark et al., 2017). Predictive equations should be used with caution as energy expenditure fluctuates during treatment and recovery, and fixed formulas often lead to underfeeding during periods of highest energy utilization and overfeeding late in the treatment course. Energy goals should be adapted based on clinical events and clinician expertise.

When using indirect calorimetry or predictive equations, a correcting factor of 30%, obtained by multiplying the REE by a factor of 1.2–1.4, results in predicted total energy expenditure (TEE) (Rodriguez et al., 2011). TEE considers energy expended on clinical activities, such as dressing changes, surgery, passive physiotherapy, and targets patient weight maintenance.

### Substrate-specific requirements

#### Protein

##### Pathophysiology

Increase in skeletal muscle protein synthesis accompanies burn injury; however, it is surpassed by the concurrent hypercatabolic response, resulting in net losses of muscle proteins and systemic release of amino-acids. Amino acid efflux from skeletal muscle facilitates other vital metabolic processes in burn patients, such as gluconeogenesis, wound healing, immune response and hepatic protein synthesis. Major predictors of the magnitude of protein catabolism are age, weight and delay in definitive surgical treatment. Intercurrent sepsis episodes can also increase protein catabolism. Metabolic alterations interplay with protein metabolism, with hyperglycemia linked to increased muscle protein catabolism. Unabated, protein losses can exceed 150 g/day in severe burns leading loss of LBM in excess of half a pound of skeletal muscle daily. This can delay healing and significantly contribute to the long-term morbidity of burn survivors.

##### Requirements

Nutrition should supply sufficient exogenous protein to be used as a substrate for wound healing in order to spare the LBM protein pool. Nitrogen balance studies compare the difference between nitrogen intake and nitrogen losses and are a common clinical tool to assess for adequate protein provision. When using the Lee and Hatley formula a positive nitrogen balance of 2–4 g/day creates a desirable environment for anabolism. Two factors can affect the accuracy of these results in burns patients. Total urinary nitrogen

(TUN) is approximated by adding 4 g/dL to urinary urea nitrogen (UUN); however, this may be inappropriate during the acute burn phase of inconsistent ureagenesis (Clark et al., 2017). Secondly, major burns can lose an additional 20–25 g/m<sup>2</sup> TBSA per day from wound exudate. A proposed solution is to add a correcting factor of 1.25 to TUN losses to account for wound exudate losses (Clark et al., 2017). Caution should be applied when using this formula as actual nitrogen losses can vary significantly from the proposed constants depending on the extent of injury.

$$\text{Nitrogen Balance} = 24 - \text{hour protein intake} - [1.25 \times (\text{UUN} + 4)]$$

As well documented in the critical care literature, visceral proteins should not be used as a nutrition marker in the acute or post-acute setting as they are subject to fluid shifts and hepatic reprioritization.

At present, protein recommendations are generally based on expert consensus and established institution practices. Supplying supranormal doses of protein does not reduce the catabolism of endogenous protein stores, but it does facilitate protein synthesis, particularly in skin, and reduces negative nitrogen balance. Accepted clinical practice guidelines recommend protein doses of 1.5–2.0 g/kg/day in thermally injured adults (McClave et al., 2016; Rousseau et al., 2013). Burn specific studies suggest that doses of greater than 2.2 g/kg/day did not have effects on net protein synthesis and should be carefully monitored as there is an increased risk of developing azotemia (McClave et al., 2016; Rousseau et al., 2013). In the pediatric population recommended protein doses range from 2.5 to 4.0 g/kg/day with the International Society of Burn Injury recommending 3 g/kg/day (Wise et al., 2019; Rodriguez et al., 2011).

## Fat

### Pathophysiology

Under prolonged adrenergic stress, major modifications of fatty tissue are observed. The energy storing white adipocytes switch their morphology into energy releasing “beige” adipocytes by adopting brown fat characteristics, a phenomenon called “browning”. Heat production by uncoupled reaction and lipolysis are increased. Triglyceride (TG) reserves in adipocytes are broken down into glycerol and free fatty acids (FFA) and released in the blood stream to be metabolized by essential organs as a substrate for ATP production. Lipid profiling analysis over time revealed a prominent elevation of saturated fatty acid, mono-unsaturated fatty acid and omega-6 (w-6) polyunsaturated acid (PUFA). In cases of major burn injury, the rate of lipolysis significantly exceeds the capacity of metabolism. At most 30% of FFA are oxidized for energy, compared to up to 90% in starvation. The remaining 70% of FFA are recycled and undergo re-esterification in adipose and non-adipose tissue resulting in a futile cycling of energy substrates. Circulating FFA, particularly palmitic and oleic are pro-inflammatory and cause endoplasmic reticulum stress and apoptosis, leading to reduction in fat  $\beta$ -oxidation and worsening of the imbalance between FFA release and metabolism. The heart, muscles, kidneys and particularly liver are infiltrated by ectopic fat stores (i.e., steatosis) contributing to organ dysfunction. The regulatory pathway which is mediated by insulin, is inefficient due to a high peripheral insulin resistance. In most patients, FFA and TG concentrations normalize over a four-week period, but enhanced lipolysis can persist years after the initial injury resulting in adipose tissue wasting and systemic lipotoxicity. The modulation of the adipose tissue response to burn injury is now a major therapeutic target.

### Requirements

The current understanding of altered fat metabolism after burn injury favors a high-carbohydrate, low-fat diet. While high fat intake doesn't diminish proteolysis, low-fat nutrition support has been shown to reduce infectious morbidity and shorten length of stay (LOS) in burn patients. A minimum of 2–4% of energy should be supplied from fat to avoid essential fatty acid deficiency. General expert consensus is that fat should make up 3–15% of energy requirements. While trying to minimize fat intake, titration of fat calories may be required to meet energy requirements while respecting the body's upper limit of glucose utilization (see *Carbohydrate* section). These low-fat recommendations may be difficult to achieve in the clinical setting as commonly available commercial, liquid formulas tend to provide 29–45% of energy as fat. This has led some burn centers to fortify existing formulas to achieve a more desirable macronutrient distribution, but this is not always feasible given available resources.

It is also prudent to account for non-dietary fat calories. Commonly used for sedation, 1 or 2% propofol infusion delivers 1.1 kcal/mL of fat and can significantly contribute to metabolic alterations if the additional fat calories are not accounted for in the nutrition care plan.

Composition of administered fat should also be considered. Omega-3 (w-3) and w-6 PUFAs, and their derivatives are predominantly derived from exogenous sources and considered essential in promoting and resolving inflammation following trauma by providing a source of resolvins, eicosenoids, and prostaglandins. Omega-6 fatty acids, the most common fat source in enteral and parenteral formulas in the United States, have been shown to encourage inflammation which may exacerbate the already heightened inflammatory response of burn patients. Lipids that contain a high percentage of w-3 fatty acids are metabolized without promoting proinflammatory molecules and have been linked to enhanced immune response, reduced hyperglycemia, and improved outcomes. An omega 6:3 ratio closer to 1:1 could enhance the immune response. As more research becomes available, the role of different fat source and provision of total fat calories may require reassessment.

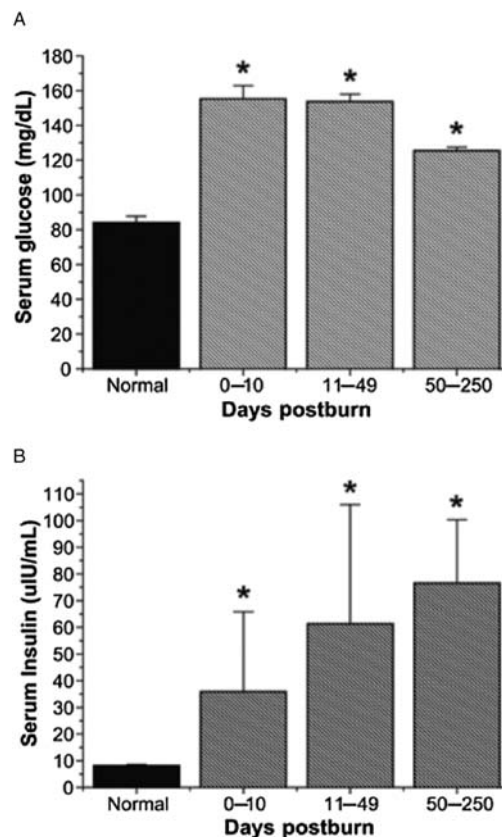

## Carbohydrate

### Pathophysiology

A state of hyperglycemia beginning within the first hours of injury is associated with major burns (Fig. 3). Release of large quantities of catecholamine, glucagon and corticoids immediately following injury induces breakdown of glycogen in the liver. Increased proteolysis and lipolysis release the substrates necessary for gluconeogenesis, pyruvate, lactate, glycerol, and amino acids, in large quantities. As a result the rate of glucose release from the liver is increased two-fold. These physiological reactions liberate abundant endogenous energy reserves to allow for continued maintenance of vital functions and cell regeneration.

Two phenomena contribute to prolonged imbalance of carbohydrate metabolism and concurrent hyperglycemia in burn patients. First the glucose metabolism pathway is deeply altered. Anaerobic glycolysis prevails, allowing for limited production of ATP. Pyruvate and lactate formation are promoted, with subsequent gluconeogenesis via an extremely ATP-consuming reaction. Secondly, regulatory pathways are inefficient. Exogenous glucose infusion does not fully inhibit hepatic glucose production and despite gradual elevation of fasting insulin levels, hyperglycemia persists (Fig. 3). The mechanisms underlying this insulin resistance are poorly understood, and could result from direct hyperglycemic action of catecholamine, glucagon and cortisol, by alteration of insulin-receptor signaling by cytokine as monocyte chemoattractant protein-1 and interleukin-6 and/or from organelle dysfunction in the peripheral cell secondary to cellular stress responses, resulting in reduced glucose assimilation. The persistence of insulin resistance during the flow phase could also be due in part to the catabolic decrease in muscle mass seen with severe injury, since skeletal muscle is responsible for 70–80% of whole body insulin-stimulated glucose uptake.

Burn patients with poor glucose control have shown worse outcomes, including a significant risk of infectious complications, especially wound infections, pneumonia and bacteremia, which are potentially explained by altered immunity, impaired wound healing, reduction in graft take, enhanced muscle protein catabolism, and overall increase in mortality. Retrospective studies and a prospective randomized trial have further confirmed that good glucose control is beneficial in terms of post-burn morbidity and organ function.

**Fig. 3** Major burn injury leads to vast inflammatory stress responses, hyperglycemia, and hyperinsulinemia. Levels of fasting serum glucose (A) and insulin (B) were measured at various time points postburn and compared with non-burned children. Bars represent mean; error bars correspond to SEM. \*Statistical difference between burned children versus non-burned children,  $P < 0.05$ . Reproduced from Jeschke, M.G., Finnerty, C.C., Herndon, D.N. et al. (2012) *Ann Surg* 255, 370–378.

## Requirements

Carbohydrates remain the preferred energy source for burn patients as high-carbohydrate diets impart a protein-sparing effect and promote wound healing. Ideally >50–60% of energy in the diet should come from carbohydrate (Rousseau et al., 2013; Carson, 2018). At minimum of 2 g/kg/day of carbohydrate should be provided to meet baseline adult glucose requirements, but carbohydrate intake should not exceed 5–7 g/kg/day or 5 mg/kg/min, the maximum rate the body is able to oxidize glucose. This is important to note as energy requirements may exceed the body's metabolic capacity to assimilate substrate. In this case, providing a limited amount of dietary fat can diminishes the need for carbohydrates and ameliorates glucose tolerance. If glucose is given in excess of what can be utilized, it leads to hyperglycemia, the conversion of glucose to stored fat, glucosuria and dehydration (Rodriguez et al., 2011). Although a large prospective randomized controlled trial (RCT) is lacking, a recent review was consistent with current recommendation for high carbohydrate diet by demonstrating possible clinical benefits including less pneumonia, less wound infections, shorter hospital LOS, less acute respiratory distress syndrome, shorter healing time, and lower rates of sepsis. Use of fiber containing formulas is encouraged, as high opioids doses for pain management can lead to significant constipation.

## Complementary treatment

Exogenous insulin is often required to manage hyperglycemia in the acute phase. Exogenous insulin can help achieve normoglycemia while conferring the additional benefit of stimulating muscle protein synthesis and improving wound healing (Rousseau et al., 2013; Rodriguez et al., 2011). While the exact cut off for benefit is not defined, maintaining blood glucose levels below 130 mg/dL using intensive insulin therapy has been shown to reduce mortality and morbidity in burn patients (Rousseau et al., 2013). Severely burned patients who received insulin infusions, in conjunction with a high-carbohydrate, high-protein diet, have improved donor site healing, LBM, bone mineral density, and decreased LOS. Intensive insulin therapy should be closely monitored given the risk of hypoglycemia which can quickly increase risks of morbidity and mortality (Rodriguez et al., 2011; Clark et al., 2017). Due to the concern that cellular response to exogenous insulin could be limited by organelle dysfunction, alternative strategies to improve glucose assimilation in peripheral cells and to decrease gluconeogenesis, including the use of metformin and the PPAR-agonist fenofibrate, are being investigated.

## Micronutrients and specific amino acids

Micronutrients, consisting of vitamin and mineral, are nutrients required in very small amount to enable proper metabolism, as they function to maintain the structure of enzymes or as enzyme cofactors. A major burn sets off a metabolic sequela that increases the body's need for specific micronutrients and amino acids above normal levels to enable wound healing.

## Glutamine

### Pathophysiology

Supplementation of specific amino acids, particularly glutamine (GLN) and arginine, is the ongoing subject of research. GLN is the main energetic substrate for enterocytes and lymphocytes. GLN deficiency can lead to intestinal epithelial barrier dysfunction, with in vitro and in vivo studies demonstrating that GLN is an essential nutrient for lymphocyte proliferation, cytokine production, macrophage phagocytic plus secretory activities, and neutrophil bacterial killing. Significant decrease in GLN plasmatic concentration is observed in major burns, and is postulated be due to a major increase in hepatic consumption for gluconeogenesis. A small, randomized study reported a positive effect of GLN supplementation in the burn population with significant mortality and LOS reductions. A reduction in bacterial translocation and therefore gram-negative infections is also reported by a small double-blinded, RCT.

### Requirements

For units choosing to supplement GLN, the current recommendation is to administer 0.3–0.5 g/kg/day enteral GLN for 10–15 days starting with the initiation of EN for patients with burns >20% TBSA and adjusting doses for patients with a body mass index >35 kg/m<sup>2</sup> (Rousseau et al., 2013). Caution should be used when supplementing GLN in patients with hepatic failure, renal failure, septic shock, or high dose vasopressors as it can lead to accumulation of urea and ammonia. A study and systemic review using high dose GLN supplementation and lower dose parenteral GLN supplementation showed no benefit and a trend toward increased 28 day and 6 month mortality in critically ill patients with multi-organ failure. However, the systemic review did show a signal toward reduced hospital mortality in burn patients, prompting the RE-ENERGIZE multicenter RCT. The RE-ENERGIZE trial recently closed, seek to evaluate the effect of enteral GLN supplementation in 1200 burn patients and should clarify the potential role for GLN supplementation. This large multicentre trial however indicates that glutamine has no beneficial effect in terms of mortality and incidence of infections (Heyland et al., 2022 NEJM in press).

## Vitamins

Ascorbic acid (vitamin C), cholecalciferol (vitamin D),  $\alpha$ -tocopherol (vitamin E), and menaquinone (vitamin K) have all been reported as depleted in burned patients and deficiencies are suspected to contribute to delayed wound healing and immune dysfunction after major burn injury. Supplementation of these vitamins at pharmacological doses has been proposed to improve outcomes.

Vitamin C acts to reduce damage to capillaries from reactive oxygen species, stabilize endothelial membranes and limits their permeability during initial shock (Blaauw et al., 2013). Two clinical trials were able to demonstrate high dose vitamin C infusion during resuscitation were effective at decreasing fluid volume needed for stabilization, resulting in less edema, and in one case less respiratory impairment, without inducing renal failure. While pharmacological doses of vitamin C during resuscitation appear safe, more research is needed to determine optimal doses. During wound healing, vitamin C is paramount for the synthesis and cross-linking of collagen to restore basement membrane and dermal collagen matrix.

Vitamin C and E work in tandem to scavenge free radicals and dispose of toxic oxidants, with vitamin C acting as a regenerator of oxidized vitamin E. By limiting oxidative damage to cell membrane structure there is the potential to improve end organ function and wound healing. Burned children show tissue storage of vitamin E decrease by half as early as three weeks after injury. Burned children supplemented with a combination of vitamins C, E, and zinc showed decreased malondialdehyde, which is a marker of oxidative stress, and needed significantly fewer days to heal compared to un-supplemented children.

Systemic inflammatory response syndrome, bleeding, decreased intake and absorption of vitamin D, organ and metabolic dysfunction, and decreased sun exposure during hospitalization and recovery as part of scar management leads to a high prevalence of vitamin D deficiency following large burns. Long-lasting impairment of burn scar tissue and adjacent tissue to effectively activate vitamin D has been shown, with impairment observed for up to seven years after injury creating an environment for chronic deficiency. While more work needs to be done to elucidate the preferred form and dose of vitamin D supplementation, there is agreement DRI doses are insufficient for repletion and maintenance (Blaauw et al., 2013).

Malabsorption, limited enteral intake, antibiotic therapy, and multiple surgical procedures puts burn patients at risk of vitamin K deficiency. Ninety-one percent of burned children showed below expected values of vitamin K for the first four weeks post-burn, however, clinical relevance remains unclear as no relationship was found between serum values and prothrombin time or activated partial thromboplastin time.

While clinical benefits of pharmacological doses of vitamins are being investigated, clinicians should ensure complimentary vitamins are provided to at minimum meet DRIs (Blaauw et al., 2013).

## Trace elements

Trace elements (TE), Cu, iron (Fe), manganese (Mn), Se, and Zn are essential to catalysis reactions in enzyme systems and enabling electron transfer; particularly for reduction of reactive nitrogen and oxygen species, innate and adaptive immune defenses, energy metabolism and tissue repair (Table 2) (Berger et al., 2007). Inflammation immediately following burn injury decreases circulating TEs, while rapid uptake by the liver, spleen and kidney induces a relative depletion of Fe, Se, Zn while Cu and Mn levels increase. Without replacement, TE losses from wound exudate and peri-operative blood loss can lead to biochemical deficiencies of Cu, Fe, Mn, Se and Zn by the end of the first week. Clinical signs of deficiency have only been reported at late stages of recovery, when increased requirements for skin healing have completely depleted the body's stores (Berger et al., 2007). TE deficiencies are linked to poorer outcomes, specifically Cu deficiency which has been linked to fatal arrhythmias.

Evidence of clinical benefit of TE supplementation remains sparse. In a small, randomized trial, TE supplementation was associated with higher circulating plasma and skin tissue content of selenium and zinc with improved wound healing and fewer pulmonary infections. A meta-analysis confirmed decreased infectious episodes but failed to prove significant effect on wound healing, LOS or mortality.

Antioxidant protocols, which combine vitamin and TE supplementation, aim to reduce inflammation following burn or traumatic injury through their interplay against free radicals. Reduced energy expenditure and pro-inflammatory cytokine were observed after introduction of antioxidant protocol in a cohort of patients. A large study of critically ill patients failed to confirm any benefit with similar supplementation. A large, RCT in burn patients is needed to assess efficacy.

## Monitoring of nutrition support

Careful clinical monitoring of abdominal pain and distention, vomiting, and bowel function are prudent to ensure safe EN administration. There is conflicting data about the validity of gastric residual volumes as an accurate marker of EN tolerance; however, some centers continue to use them as part of routine monitoring. Paralytic ileus of the stomach and colon is a common consequence of large volume fluid resuscitation, and insertion of a post-pyloric feeding tube can help enhance EN tolerance in the early acute phase despite gastroduodenal dysfunction (Rousseau et al., 2013; Rodriguez et al., 2011).

Under delivery of EN is an established problem in burn units with frequent interruptions to EN infusions, such as for surgeries, dressing changes and tests, resulting in formula equivalent of up to 930 kcal/day not being infused. A variety of strategies can be implemented to minimize feed interruptions or compensate for lost infusion time. Burn centers have demonstrated success at

**Table 2** Roles of trace elements in burn metabolism (not exhaustive) (Berger and Shenkin, 2007). DRI doses of micronutrients may be sufficient for minor burns; however, strong consideration should be given to providing therapeutic doses of intravenous (IV) micronutrients for burns that exceed 20% TBSA. Following a review of available burn literature, Blaauw et al. propose that daily IV doses of 500–700 µg Se, 4 mg Cu, and 40 mg Zinc for 2–3 weeks following major burn is safe and does not require specific blood concentration monitoring (Blaauw et al., 2019). Mn and Fe should be provided to meet DRI values. IV supplementation is recommended as absorption by enteral route may be variable. Patients receiving continuous renal replacement therapy (CRRT) may also require higher TE doses (Pantet et al., 2019).

<i>Trace element</i>	<i>Effect</i>
Copper	Humoral and cellular immunity Wound healing: collagen synthesis, lysyl oxidase Fatal arrhythmias
Iron	Oxidative stress reduction: superoxide dismutase enzymes Humoral and cellular immunity Cofactor in oxygen-carrying proteins Wound healing: elastin and collagen synthesis
Selenium	Humoral and cellular immunity Modulation of inflammatory response: activation of the transcription factor NFκB Oxidative stress reduction: component of the active site of glutathione peroxidase (in neutrophils)
Zinc	Humoral and cellular immunity: lymphocyte function Wound healing: protein synthesis, DNA replication Modulation of inflammatory response: activation of the transcription factor NFκB Oxidative stress reduction: superoxide dismutase enzymes
Manganese	Metabolic pathways Wound healing: mucopolysaccharide and glycoprotein synthesis Oxidative stress reduction: superoxide dismutase enzymes

achieving prescribed EN goals after implementing volume-based feeding protocol, where hourly infuse rates are adjusted to meet 24-h formula volume targets. Intra-operative feeding of patients with protected airways is gaining popularity as adult and pediatric studies have demonstrated increased total calories and protein delivered compared to traditionally fasted patients, with no increased risk of mortality, wound infections, pneumonia or aspiration using both gastric and post-pyloric feeding tubes.

Nutrition support should continue until the patient demonstrates their oral intake is adequate to meet nutrition demands. Oral nutrition supplements and foods fortified to increase calorie and protein density can aid in achieving oral energy and protein goals.

## Nutrition during recovery

### Metabolic disturbance during recovery and long-term effects

The hypermetabolic response to burn is essential to maintain organ function and whole-body homeostasis under demanding trauma conditions; however, persistent metabolic alteration can be disruptive to recovery. Children recovering from 30% TBSA or greater burns were shown to have a significant elevation in cortisol, catecholamines, cytokines and acute phase proteins compared to their non-injured counterparts. Indirect calorimetry revealed measured REE exceeding predicted REE. Persistent negative skeletal muscle protein balance has been demonstrated for the first year following burn injury. Significant hepatomegaly and cardiac dysfunction, including increased heart rate and cardiac output, also persisted into the recovery phase. Epidemiological studies report an increased risk of morbidity and mortality in the long term due to cardio-circulatory complication after extensive burns in pediatric and adult populations, although the precise pathophysiology has not been elucidated. Significant growth delays are seen in children, with data showing it take 1–2 years for pediatric burn patient to grown again and improve on their height and weight percentile. Lasting effects of burn injury are likely underestimated, and long-term follow-up and treatment of severely burned patients is therefore mandatory.

**Table 3** Process for nutritional assessment and monitoring of patients with burn injury

LBM = lean body mass, EN = enteral nutrition, PN = parenteral nutrition, TEE = total energy expenditure, MREE = measured resting energy expenditure, REE = resting energy expenditure, TBSA = (burn size) total body surface area, CI = caloric intake over previous 24 h, HBE = Harris Benedict Equation, T = average temperature over previous 24 h (°C), PBD = post burn day, DRI = daily recommended intake.

**Nutrition Assessment**

- Identify patients requiring initiation of nutrition support:
  - mechanically ventilated
  - >20% TBSA burns
  - inhalation injury
  - failure to maintain LBM with oral intake
  - malnourished or high risk for becoming malnourished (elderly, children, obese with sarcopenia)
- Conduct nutrition focused exam (see Table 1)

**Initiation of nutrition support**

- EN is strongly preferred over PN
- Choose high protein, high carbohydrate, low fat formula
- Consider PN if:
  - non-functioning GI tract
  - intolerant to EN
  - unable to achieve goal EN in a reasonable time
- Initiate trophic EN within 4–6 h of injury for maximal benefit
- Once patient is adequately resuscitated and hemodynamically stable advance to goal feeds as quickly as tolerated

**Determining Nutrition Requirements**

Nutrient	Requirements	Monitoring
Energy	Indirect calorimetry: $TEE = MREE \times 1.2-1.4$ Predictive Equations Adults: Toronto Equation: $REE = -4343 + (10.5 \times \%TBSA) + (0.23 \times CI) + (0.84 \times HBE) + (114 \times T) - (4.5 \times PBD)$ $TEE = REE \times 1.2-1.4$ Predictive Equations Children: Galveston Infant (0–1 year) $2100 \text{ kcal/m}^2 + 1000 \text{ kcal/m}^2 \text{ burn}$ Galveston Revised (1–11 years) $1800 \text{ kcal/m}^2 + 1300 \text{ kcal/m}^2 \text{ burn}$ Galveston Adolescent (12–16 years) $1500 \text{ kcal/m}^2 + 1500 \text{ kcal/m}^2 \text{ burn}$	Minimum weekly repeated measurements or reassessment with clinical changes Clinical evidence of underfeeding: <ul style="list-style-type: none"> <li>• LBM loss</li> <li>• Poor wound healing</li> </ul> Clinical evidence of overfeeding: <ul style="list-style-type: none"> <li>• Hyperglycemia</li> <li>• Fatty liver infiltration</li> <li>• Increased infections</li> </ul> Monitor for long term weight changes
Protein	Adults: 1.5–2.0 g/kg/day Children: 3.0 g/kg/day	Nitrogen Balance = 24-h protein intake – [1.25 x (UUN + 4)] Wound closure Evidence of LBM loss/muscle wasting Hyperglycemia following implementation of appropriate insulin management
Carbohydrate	>50–60% of total energy intake Adults: Minimum: 2 g/kg/day Maximum: 5–7 g/kg/day or 5 mg/kg/min	
Fat	3–15% of total energy intake Adults: Minimum: 2–4% of energy Maximum: 25–35% of energy Account for non-dietary fat calories (i.e. Propofol) in nutrition care plan	Evidence of inadequate fat administration: <ul style="list-style-type: none"> <li>• Essential fatty acid deficiency</li> </ul> Evidence of excess fat administration: <ul style="list-style-type: none"> <li>• Hypertriglyceridemia</li> <li>• Steatosis</li> <li>• Deposition of adipose tissue</li> </ul>
Micronutrients	2–3 weeks IV micronutrients for >20% TBSA burns <ul style="list-style-type: none"> <li>• Selenium 500–700 µg/day</li> <li>• Copper 4 mg/day</li> <li>• Zinc 40 mg/day</li> </ul> Minimum micronutrient doses to meet DRI Consider additional vitamin C, D, E and K supplementation	Suggested micronutrient doses are considered safe if routine blood concentration monitoring is not available.

**Table 3** Process for nutritional assessment and monitoring of patients with burn injury

LBM = lean body mass, EN = enteral nutrition, PN = parenteral nutrition, TEE = total energy expenditure, MREE = measured resting energy expenditure, REE = resting energy expenditure, TBSA = (burn size) total body surface area, CI = caloric intake over previous 24 h, HBE = Harris Benedict Equation, T = average temperature over previous 24 h (°C), PBD = post burn day, DRI = daily recommended intake.—cont'd

**Monitoring of nutrition support**

Ongoing monitoring of EN tolerance

- abdominal pain and distention
- vomiting
- constipation or diarrhea

Implementation of strategies to optimize EN delivery

- insertion of post-pyloric feeding tubes
- volume-based feeding protocols
- peri-operative feeding protocols

**Cessation of nutrition support**

Patient can maintain nutritional status via oral diet. Clinical evidence includes:

- caloric intake equal to predicted energy requirements
- stable weight
- wound closure
- improving functional status

**Nutrition requirements**

Data on the optimal diet as patients progress from the acute post-burn phase to recovery is virtually non-existent. As the hypermetabolic state can persist for over a year post-injury, a high calorie and protein diet may be required to meet elevated energy requirements and replete muscle mass lost because of prolonged critical illness. Weight maintenance or targeted weight gain can be used a marker of overall nutritional adequacy. Resistance exercise is recommended to improve LBM and prevent burn-wound contracture. Level of physical activity and persistent open wounds will impact nutrition requirements. Improvements in functional status are anticipated in the setting of adequate nutrition and physical therapy. Targeted intervention by a dietitian may be warranted in instances of weight loss, failure to close wounds or functional decline.

**Nutrition support after minor burn**

Minor burns do not incite the same hypermetabolic response as there is less tissue to regenerate. Energy and protein requirements may rise slightly above baseline, but the inflammatory response remains local so systemic hypercatabolism is not expected. In the absence of preexisting comorbidities or malnutrition, a healthy adult should have adequate nutritional stores to fully recover a few weeks after excision and grafting surgery. Pediatric, elderly and patients with preexisting comorbidities may require nutrition support to facilitate wound closure, even for relatively minor burns.

Initial trauma, pain and change in eating environment due to hospitalization, makes pediatric patients, especially those under three years of age, prone to anorexia. Close monitoring of oral intake and weight is vital in both hospitalized and ambulatory patients. Hospitalization and initiation of EN may be required if a child is unable to maintain their weight. Adequate pain control is a priority in restoring normal appetite.

Elderly patients are at higher risk of developing malnutrition following a minor burn or having delayed healing of superficial burns or donor skin sites due to higher incidence of preexisting undernutrition and decreased LBM. Beginning as early as age 40, humans lose an average of 0.6% of LBM per year, producing a “sarcopenia of aging”. Elderly patients also require more exogenous protein than younger patients since they have a blunted anabolic response to dietary protein that requires a greater concentration of serum amino acids to initiate muscle protein synthesis. Adequate nutrition and physical activity are vital to maintaining LBM, functional status and independence during hospitalization and recovery.

Finally, burns occur disproportionately in low socioeconomic status population, even in high-income countries. This population is particularly at risk for nutritional deficiencies. There are several validated tools available to help screen for and diagnose malnutrition. Screening on admission then weekly thereafter can help identify patients that would benefit from nutrition support.

There are no specific nutrition recommendations for the management of minor burns; however, general recommendations to promote wound healing in cases of chronic wounds or during the peri-operative period may be applicable. Transient oral supplementation of Vitamin A, B12, C, D, essential amino-acids, w-3 fatty acids, protein, Zn, and Cu could be proposed but supplementary studies are needed to evaluate the benefit. Adequate oral intake to promote rapid wound healing and maintain functional status should be encouraged in all patients, with nutrition support and micronutrient supplementation prescribed on a patient-by-patient basis.

## Conclusion

Nutrition support is a vital component in addressing the hypermetabolic response to burn injury and to support wound healing and maintain essential organ functions. Profound alterations of fat, protein and carbohydrate metabolism and increased energy requirements makes the nutrition management of burn patients challenging. Strong evidence favors early EN with a high carbohydrate and protein and minimal fat formula. Supplementation of specific vitamins, TE and GLN at pharmacological doses are attempted to enhance outcomes, but further studies are required to confirm benefits. While most patients with minor burns will not require nutrition intervention, patients at risk of undernutrition may require nutrition assessment and targeted nutrition to facilitate wound healing.

Harris Benedict Equation:

Men :  $BMR = 66.5 + (13.76 \times \text{Weight in Kg}) + (5.003 \times \text{height in cm}) - (6.755 \times \text{age in years})$

Women :  $BMR = 655 + (9.563 \times \text{Weight in Kg}) + (1.850 \times \text{height in cm}) - (4.676 \times \text{age in years})$

### Glossary

**AIDS** Acquired immunodeficiency syndrome – a severe disease of the human immune system caused by the human immunodeficiency virus (HIV).

**Antiretroviral drugs (ARVs)** Drugs used to treat HIV.

**Antiretroviral therapy (ART)** Treatment with combinations of several drugs against HIV.

**Body mass index (BMI)** Calculated as weight in kg per height in meters squared; often used as an indicator of overall nutritional status.

**CD4 cells** A subgroup of lymphocytes which are targets of HIV infection. Destruction of CD4 cells is both a cause and a marker of HIV/AIDS disease progression; therefore blood CD4 count is often used to measure the degree of immunodeficiency.

**HAART** Highly active antiretroviral therapy; treatment for HIV/AIDS combining at least three antiretroviral drugs.

**HIV** Human immunodeficiency virus – a family of closely related viruses which infect and destroy the human immune system.

**Lipodystrophy** Altered proportion and distribution of body fat, often as a consequence of antiretroviral therapy and associated with blood lipid abnormalities.

**NFκB** A gene transcription factor with a central role in inflammatory responses.

### Introduction

HIV infection and nutrition are intimately linked at many levels: biological, clinical, social, and economic. Nutritional problems have been a defining characteristic of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) since the early years of the epidemic. In Africa, AIDS was first recognized as ‘slim disease’ because sufferers experienced severe weight loss. HIV infection can lead to malnutrition, although poor diet can in turn speed disease progression. In contrast, in high income countries, HIV/AIDS and antiretroviral therapy (ART) for the disease have been associated with abnormal fat metabolism and distribution and with chronic diseases associated with overnutrition. Thus HIV/AIDS is a challenge to nutritionists working at both the individual patient level and the public health level globally (**Figure 1**).

### HIV/AIDS

AIDS is a disease of the human immune system caused by HIV. HIV is transmitted through direct contact of a mucous membrane or the bloodstream with a body fluid, such as blood, genital secretions, or breast milk of someone who is infected with the virus. The transmission most commonly occurs during sexual contacts and from mothers to infants during pregnancy, at delivery or through breastfeeding. HIV can also be transmitted through transfusion of blood products or injection with contaminated needles.

**Figure 1** Clinical and socioeconomic pathways whereby HIV/AIDS can cause weight loss.

HIV infects and destroys cells of the immune system, resulting in immunodeficiency. Key cells involved in this process are the CD4 subclass of lymphocytes. The number of CD4 cells in the blood is often used as an indicator of the degree of HIV-induced immunodeficiency, that is, disease progression. A low number of CD4 cells is associated with an increased risk of opportunistic infections which are infections which do not normally cause disease in otherwise healthy people but which do in people who are immunosuppressed. Common opportunistic infections include *Pneumocystis jirovecii* pneumonia, disseminated cryptococcosis, and cerebral toxoplasmosis. In addition, certain infections such as tuberculosis can occur more frequently and cause more serious disease among HIV-infected people than among HIV-uninfected people.

HIV-immunosuppressed individuals are also at higher risk of developing cancers such as Kaposi sarcoma, invasive cervical carcinoma, Burkitt, immunoblastic, or primary central nervous system lymphomas.

There is currently no cure for HIV infection or AIDS. Vaccines have been investigated but are not publicly available at the moment. Current treatment for HIV infection is based on highly active antiretroviral therapy (HAART). This consists in a combination of at least three drugs belonging to at least two types or 'classes' of antiretroviral agents (ARVs). HAART has significantly improved prognosis and quality of life for people living with HIV. However, access to treatment remains a challenge throughout the world, especially, but not only, in resources-poor countries.

## Effects of HIV/AIDS on Nutritional Status

### Calories and Macronutrients

HIV, like many infections, raises metabolic rate. Among asymptomatic patients at an early stage of HIV infection, resting metabolic rate is increased by about 10%. Acutely ill patients may have higher resting metabolic rates but this is offset by their lower level of activity so that total energy expenditure may not be increased. They may also be anorexic so that acute illness is not the best time to try to improve nutritional status. There is evidence that weight loss during HIV infection is more a result of decreased food intake owing to anorexia than it is to raised metabolic rate owing to infection. When patients receive therapy for HIV or opportunistic infections and begin to feel better, their energy needs to support regain of weight and increased activity can become very high, up to 50% greater than normal healthy requirements. Provision of adequate food to cover the extra energy needs can be difficult for many in low income countries.

Although energy needs change during HIV infection, there is no evidence that protein needs, as a percent of food energy, are changed. Therefore, it is usually best to meet energy needs through increased intake of a balanced diet which will then provide adequate protein.

Tissue lost during illness and that regained during recovery may differ in proportions of fat and lean. There is a tendency for increased central fat deposition and a loss of lean tissue as a result of this weight cycling. This can have important implications for health since loss of lean tissue is associated with decreased ability to work or manage other aspects of daily living as well as with increased risk of mortality. On the other hand, given the role of central fat in regulation of the immune system and in increasing systemic inflammation, it is possible that increased central fat has short-term health benefits for HIV-infected people at high risk of infectious disease, even though it may increase their long-term risk of chronic diseases. This is an area requiring considerable further research.

## Micronutrients

Anorexia and increased wastage of some micronutrients during illness, for example, fecal zinc losses during diarrhea, may result in deficient micronutrient status. However, infections change plasma levels of many markers of micronutrient status as part of the normal acute phase response and this does not necessarily imply changed micronutrient status itself. Therefore, it is not always easy to determine the effects of HIV/AIDS on micronutrient status. The best indication of inadequate micronutrient status has come from intervention trials which in some cases have shown benefits of improving micronutrient status in HIV/AIDS (*see* Micronutrient Intervention Studies).

Antioxidant micronutrients may be especially important because infection is an oxidative stress: the immune response to combat infection involves generation of activated oxygen metabolites and increased energy expenditure. High cellular oxidant levels can lead to increased inflammation through regulation of the transcription factor, NFκB. Although inflammation is an essential part of the response to infection, both inflammation and activated oxygen metabolites can cause tissue damage. Therefore inflammation and production of oxygen metabolites must be controlled and limited to the site of the immune response. Adequate status of antioxidant micronutrients – vitamin E, vitamin C, and selenium – is needed for this.

## Gastrointestinal Function

Nutrition and gastrointestinal function are obviously intimately linked. HIV infection can disrupt these links. HIV and opportunistic infections can lead to diarrhea, malabsorption, and nutrient wastage with consequent macro- and micro-nutrient deficiencies. Nutritional deficiencies can further impair immune functions and the ability to repair damaged tissues.

## Nutritional Intervention Studies

### Macronutrient Intervention Studies

Many governments, nongovernmental organizations, religious, and other community groups have responded to the crisis of malnutrition in HIV/AIDS patients by various types of food and nutrition interventions. Many projects are small scale and few have been formally evaluated. Where evaluations have been conducted, the effectiveness of the program for improving nutritional status, health, and survival has generally been disappointing.

A Cochrane systematic review of macronutrient interventions for people with HIV/AIDS found evidence that interventions increased protein and energy intake but no evidence that this had any benefits for weight, body composition, or health. However, trials were few, fairly small, and conducted mainly in high income countries where undernutrition is fairly uncommon.

Since that review there have been a few macronutrient intervention studies among malnourished or food insecure HIV-infected people in low income countries. Provision of macronutrient supplements, as extra food rations or specific composite foods such as fortified blends or lipid-based supplements, can in some cases and in the short term increase body mass index (BMI) or improve compliance with ART. However, there has been little or no documented benefit for health or survival. Reasons for this are currently unclear. It may be that macronutrient deficiencies, even among malnourished HIV-infected people, are not limiting factors for health. It may be that diarrhea and anorexia limit intake and thus effectiveness of the foods provided. It is also possible that the foods provided are not consumed in sufficient amounts, because of sharing or selling, to have detectable benefits for health.

One area where macronutrient intervention trials have been conducted and programmes evaluated is management of severe malnutrition among HIV-infected young children. In HIV-endemic countries, a high proportion of children referred to malnutrition wards are HIV-infected. A recent meta-analysis has shown that mortality rates are higher for HIV-infected than uninfected malnourished children and are above target levels even in facilities with high quality care as evidenced by low mortality rates among HIV-uninfected children. For those HIV-infected children who do survive, it seems that weight gains are similar to gains of uninfected children. It is important to test HIV status of children admitted for severe malnutrition in high HIV prevalence areas in order to permit simultaneous management of HIV infection with ARVs and opportunistic infections (prophylaxis and treatment), and, hopefully, improve survival. It is notable that nutritional care of HIV-infected malnourished children has usually been initiated on malnutrition wards, not in clinics managing HIV. Fortunately some clinics managing HIV services for prevention of mother-to-child HIV transmission are beginning to incorporate into their services interventions to prevent severe malnutrition rather than to worry later about treating it.

### Micronutrient Intervention Studies

Micronutrient interventions appear to have somewhat greater impact on health of HIV-infected people than do macronutrient interventions. This may be because, compared with macronutrients, micronutrient deficiencies are more important limiting factors for health of people with HIV or simply because micronutrient supplements are easier to deliver in the face of anorexia and are less likely to be shared or sold. There is evidence that vitamin A supplements have similar benefits for reducing mortality and diarrhea among HIV-infected children as among other children. Multiple micronutrient supplements have decreased mortality of HIV-infected adults. Multiple micronutrients given to HIV-infected pregnant Tanzanian women improved many aspects of maternal and child health. However, these studies were conducted before the widespread availability of ARVs in the communities and it

is unclear whether micronutrient interventions would have added benefits when given with ARVs. Furthermore, there is very limited information regarding the optimal micronutrient supplements for efficacy and safety among different patient groups.

The micronutrient intervention data is from research trials and, although micronutrient supplements are often taken by people with HIV/AIDS in high income countries and micronutrient interventions have been implemented in some parts of Africa, there is little programmatic evidence for the effectiveness of these interventions, mainly because of lack of evaluations. It seems to be generally assumed that providing nutrients to people with nutritional deficiencies must be beneficial but, in fact, the experience with macronutrient interventions for people with HIV/AIDS indicates that this is not necessarily true. Demonstration of program effectiveness is essential for program sustainability.

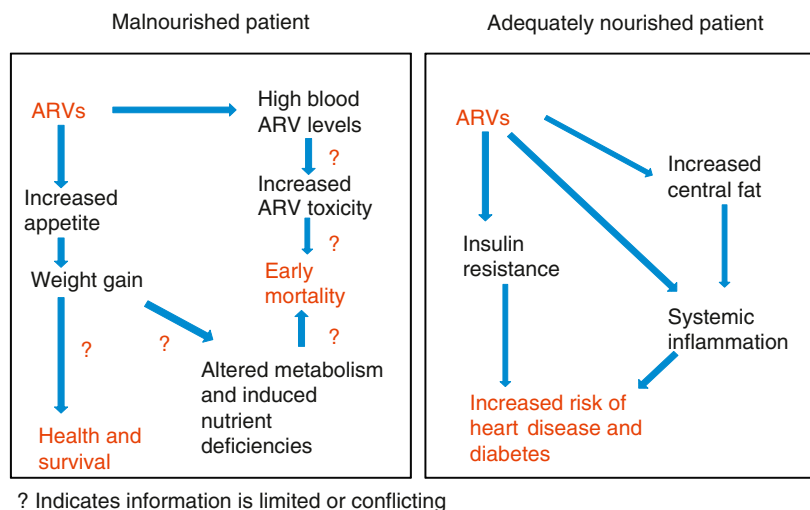

## Interactions Between Antiretroviral Drugs and Nutrition

ARVs to decrease viral load and improve health, although they do not cure the infection, have been available in high income countries for many years and in Africa during the past decade. Treatments are constantly improving but continue to have side effects, such as nausea or taste abnormalities, which can affect dietary intake. Many ARVs need to be taken with food and, as mentioned above (see Effects of HIV/AIDS on Nutritional Status), treating the infection can lead to regain of weight which requires additional food. Therefore, increasing availability of ART may actually be increasing rather than decreasing the need for nutritional support of people with HIV/AIDS (Figure 2).

There is evidence that provision of ART can improve growth in children. It may not be possible to completely restore adequate growth in HIV-infected children since stunting, that is, poor length growth, is generally irreversible after age about 2 years. There is some danger that additional weight will then be deposited as fat. Children and their carers should be provided information about healthy eating and exercise, similar to that provided for HIV-uninfected children but possibly even more important.

One side effect of some ARVs is altered proportion and distribution of body fat referred to as lipodystrophy. Partly not only in association with cycles of weight loss and gain (see Effects of HIV/AIDS on Nutritional Status) but also as a result of some ARVs themselves, there is a tendency toward decreased peripheral fat and increased central fat. This has cosmetic and social implications which in the past may have decreased compliance with ART. There are more important metabolic effects as well such as increased plasma cholesterol and triglycerides and increased insulin resistance. As for HIV-uninfected people, these abnormalities are associated with increased risk of chronic diseases such as cardiovascular disease and diabetes. Newer drugs do not have such strong lipodystrophic effects so changing regimen may ameliorate the problems. Other interventions which could potentially promote deposition of lean rather than fat tissue are provision of androgenic drugs, supplementation with micronutrients, or exercise. Although historically it may have been odd to worry about excess fat deposition in Africa, even poor African countries are now undergoing the nutrition transition as evidenced by rising prevalence of overweight and obesity. It will require sensitive and intelligent nutritional counseling to promote good nutrition and exercise for preventing overweight and chronic diseases among HIV-infected Africans who have been more usually worried about weight loss and malnutrition.

There is some evidence that ARVs are metabolized differently, that is, more slowly, among malnourished people and this may lead to increased drug toxicity. Differences in metabolism and toxicity, although supported by only limited evidence, are not surprising given that drug metabolism and excretion involve enzymes which often have micronutrients as cofactors and may use oxidative metabolism. In Africa with the ART roll-out, it has now become apparent that, unlike in high income countries, starting ART is associated with a high mortality in the first few months of taking the drugs. Mechanisms for the high early mortality are still

**Figure 2** Interactions between antiretroviral drugs (ARVs) and nutrition.

under review but one risk factor which consistently remains significant even in multivariable analyses controlling for CD4 count and co-infections such as tuberculosis, is malnutrition, as represented by low BMI. Low BMI, in addition to being associated with loss of lean tissue, may be a marker for metabolic derangements such as low plasma phosphate. There is concern that when ARVs are first provided and recovery begins, increased metabolic rate could further lower the phosphate problem causing a refeeding syndrome with increased risk of death.

## Infant Feeding and HIV/AIDS

One topic in the area of nutrition and HIV which has attracted huge amounts of research, commentary, and concern is HIV and infant feeding. Early in the epidemic it became apparent that HIV can be found in breast milk and that breastfed infants can acquire the infection from their mothers (about 15% of infants of HIV-infected mothers). Mother-to-child transmission can also occur *in utero* (to about 7% of infants of infected mothers) and at delivery (to about 15% of infants of infected mothers) (Figure 3). With the advent in Africa around 2000 of single dose nevirapine, an ARV, to mothers and infants at delivery, the proportion of infants infected at delivery decreased so that breastfeeding became the major mode of mother-to-child HIV transmission.

In high income countries HIV-infected mothers have access to ART during pregnancy and at delivery and are advised not to breastfeed. Therefore few infants in these countries become HIV-infected. However, in low income countries, notably in Africa where HIV prevalence is highest, not breastfeeding is associated with a high risk of morbidity and mortality from other infectious diseases. Furthermore, safe and nutritious alternatives to breast milk are not available or affordable for many African women. HIV-infected African women and health services supporting them have been faced with very difficult decisions regarding the best infant feeding mode. Not only do women need to make a feeding decision in the absence of specific information about their own child's risk of infection, but also they need to consider the social implications of not breastfeeding in societies where breastfeeding is almost universal and not breastfeeding advertises a positive HIV status.

World health organization (WHO) has regularly updated its recommendations based on research on HIV and infant feeding. Whereas this was done for the best of reasons – to save children's lives – the rapidly changing recommendations have resulted in some confusion among women and health care workers. Current recommendations are to provide ART to women during late pregnancy and at delivery and to the mother or infant throughout the period of breastfeeding. Although this has been shown to reduce mother-to-child transmission to less than 10% in research studies, this is an expensive recommendation to implement – not primarily in terms of drug costs but more because of costs of health workers' time needed – and so is not yet widely implemented in Africa.

It has recently become apparent that even those children of HIV-infected mothers who escape HIV infection themselves are at increased risk of nutritional and health problems compared to HIV-unexposed children. These HIV-exposed, uninfected children tend to be smaller than HIV-unexposed children and to suffer more episodes of serious morbidity and higher mortality. It is as yet unclear whether nutritional or other interventions can improve these children's growth and health.

## Social and Economic Interactions with HIV/AIDS

In HIV-endemic Africa, HIV/AIDS is not only a disease of individuals but also of the whole society. HIV/AIDS strikes mainly young and middle-aged adults who are at their most economically productive ages. These adults are normally also the main carers of young

**Figure 3** Estimated rate and timing of mother-to-child HIV transmission under different treatment conditions.

children. Loss of caring capacity for children can cause them long term health and emotional problems. Additional financial losses occur because other family members are needed as carers, because of overt medical costs or less obvious costs such as for transport to clinic visits, or because of funeral expenses. Therefore HIV infection of one member of a household can affect the entire household and can be devastating to families, many of whom are near the poverty line already in Africa.

The best approaches for improving nutrition of HIV-infected individuals and HIV-affected families are not clear. Should individuals be targeted on the basis of low BMI or on the basis of food insecurity? Which types of food support and which type of targeting are most cost-effective for outcomes in the patient? Should we also be considering family outcomes such as family members in employment and children in schools? What are the ethics of providing food support to HIV-affected food insecure families in areas where large proportions of the whole population are food-insecure? There is an urgent need for research addressing these questions.

## Conclusions

Since early in the HIV/AIDS epidemic it has been clear that nutrition plays an important role. Paradoxically, nutrition may be of even greater importance with the increased availability of ART. The problems are complex and multifactorial and there remain many questions as to how best these can be solved, particularly in Africa where both the HIV epidemic and nutritional problems are most widespread and acute. Evaluation of nutrition intervention programmes in HIV care is essential since nutrition interventions may be expensive but can be justified if they improve patient and family outcomes.

## Key points

- Despite technological and scientific advances in the last years, intestinal parasitic infections remain a leading cause of morbidity and mortality worldwide, affecting mostly under privileged populations, living in areas with tropical weather and limited access to health services and sanitation.
- Both soil-transmitted helminths and protozoa are the main causes of intestinal parasitic infections.
- Diarrhea caused by intestinal parasitic infections affects millions of people and is one of the major causes of mortality in children under 5 years of age.
- Intestinal parasites affect the nutritional status of the host, and malnutrition is the primary cause of immunodeficiency, which in turn, increases the risk of parasitic infection.
- Infection with intestinal parasites cause dysbiosis, local and systemic inflammation and gut permeability.
- The main nutritional consequences of parasitic infections include malabsorption, nutrient loss, anorexia, which in turn cause stunting, micronutrient deficiencies and anemia in the host.
- Treatment for parasitic infection have been available for years. Prevention needs to be a priority particularly in endemic populations.

## Introduction

Intestinal parasitic infections (IPI) and malnutrition are very common in children of low and middle income countries (Zavala Gomez, 2017). IPI, obesity and micronutrient deficiencies account for more than 10% of the global disability-adjusted-life-years (DALYs) (Ng et al., 2014; Black, 2014).

Intestinal parasites are a broad number of organisms that require a host for their own survival and that live in the gastrointestinal (GI) tract. IPI continue to be public health concerns worldwide, affecting mainly low-income countries. They occur in regions that have poor living conditions, poor sanitation, limited access to safe drinking water, and with tropical and subtropical weather (Harhay et al., 2010). IPI are considered endemic in some regions of the world such as Africa, Central and South America, Eastern Europe

and South East Asia, and they can also be found, to a lesser extent, in some high income countries (World Health Organization, 2013, 2018; Brooker et al., 2006; Kantzanou et al., 2021). Children from rural communities are at highest risk of infection, due to the lack of health, sanitation and water supply services and due to behavioral risks, such as frequent outdoor exposure and poor personal hygiene (Strunz et al., 2014).

The IPI are mainly caused by soil transmitted helminths (STHs) and by intestinal protozoan, and infections by both are highly prevalent worldwide (Table 1). The majority of the STHs infections are caused by *Ascaris lumbricoides* (roundworm), *Necator americanus* and *Ancylostoma* spp (hookworm), and *Trichuris Trichuria* (whipworm) (Brooker et al., 2006; World Health Organization, 2013). It is estimated that approximately 1.5 billion people worldwide are infected with STHs, and according to the World Health Organization (WHO), more than 260 million preschool-age children and over 560 million school-age children live in areas where infections are prevalent (World Health Organization, 2013). Amoebiasis, caused by *Entamoeba histolytica*, and giardiasis, caused by *Giardia* are among the most common protozoan infections. In developing countries, the prevalence of reported amoebiasis ranges from 10 to 40%, and in developed countries is mainly observed in travelers or immigrants from countries with high prevalence of infection (Shirley et al., 2018). *Giardia duodenalis* is considered to be the most prevalent intestinal parasite present in humans, ranging from 20 to 30% in developing countries, and 2–7% in developed countries (Dixon, 2021). Both, amoebiasis and giardiasis are among the top causes of severe diarrhea across ages worldwide, and are considered one of the leading causes of diarrhea in children from developing countries (Lanata et al., 2013; GBD 2013 Mortality and Causes of Death Collaborators, 2015).

Despite the efforts and improvements in health programs and initiatives, IPI are still one of the major causes of global morbidity and mortality, and rate reductions have been slow in many developing countries. Mortality associated to diarrhea due to IPI account for approximately 800,000 reported deaths of children under 5 years of age and approximately 1.3 million deaths in the general population (GBD 2013 Mortality and Causes of Death Collaborators, 2015). The IPI change the immune response of the host both systemically and locally, thus, impairing its function, and leading to complications both acute and chronic (Brosschot and Reynolds, 2018). Overall, IPI cause inflammation, dysbiosis, diarrhea, malabsorption, acute and chronic blood loss, reduced work capacity in adults, and stunting and impaired cognitive development in children (Koruk et al., 2010; Jourdan et al., 2018; Pullan et al., 2014). IPI may also affect the nutritional status of the host leading to protein-energy malnutrition and micronutrient deficiencies, and recently, it has been observed that it may also be associated with obesity (Jourdan et al., 2018; Zavala et al., 2016). The parasitology, the effect on the nutritional status of the host and its mechanisms as well as IPI treatment and prevention will be discussed in the present article.

## Parasitology

Intestinal protozoa have a direct life cycle where transmission typically occurs via the fecal-oral route (Price, 2017). They can be classified according to their effect on human health as “pathogenic” or “non-pathogenic”. Pathogenic protozoa such as *Giardia lamblia*, *Entamoeba histolytica* and *Cryptosporidium* can cause acute diarrhea and dysentery, malabsorption, blood loss and reduced growth (Zavala Gomez, 2017). “Non-pathogenic” protozoa such as *Entamoeba coli* (*E.coli*) and *Endolimax nana*, are usually not associated with illness or clinical symptoms, though recently it has been observed that *E. coli* may be associated with obesity in children (Zavala et al., 2016).

STHs refer to the intestinal worms that are transmitted through contaminated soil. Infection occurs by ingestion of eggs (e.g., *A. lumbricoides* and *T. trichiura*) or by penetration of the skin (e.g., by hookworm larvae). The Global Burden of Disease Study 2010 estimated that STHs rank first among all neglected tropical diseases in DALYs, with 5.1 years lived with disability (Pullan et al., 2014). These DALYs were estimated using multiple studies associating STHs with moderate and severe anemia, micronutrient deficiencies and reduced growth (Pullan et al., 2014).

**Table 1** Estimated population infected with intestinal parasites worldwide.

Parasite	Approximate number of infected population (millions)
<b>Soil transmitted helminths</b>	
<i>Ascaris lumbricoides</i>	800–1100
<i>Trichuris trichuria</i>	600–800
<i>Necator americanus</i> and <i>Ancylostoma duodenale</i>	600–700
<b>Protozoa</b>	
<i>Giardia</i>	200
<i>Entamoeba histolytica/dispar</i>	500

Source: CDC (2021), WHO (2021).

### *Ascaris lumbricoides*

Ascariasis is the most common human helminthic infection globally. *Ascaris lumbricoides* reside in the lumen of the small intestine and are very large: adult females are 20–35 cm, and adult males are 15–30 cm (Dold and Holland, 2011). Infection occurs when infective eggs are swallowed, then reach the small intestine, where the eggs hatch and larvae invade the intestinal mucosa. The larvae then reach the lungs via systemic circulation, where they mature, are coughed and then swallowed. When they reach the small intestine, they develop into adult worms that produce eggs that are excreted in the feces. The fertilized eggs develop infective larvae after 18 days or more. Adult worms can live up to 2 years and usually do not cause acute symptoms. However, heavy infections may cause intestinal obstruction and potentially perforation (Centers for Disease Control and Prevention, 2018).

### Hookworms

The two main hookworms that cause IPI are *Ancylostoma duodenale* and *Necator americanus*, though recently, it has been suggested that *A. ceylanicum* could be an emerging parasite that may also infect humans (Centers for Disease Control and Prevention, 2018). Hookworms reside in the lumen of the small intestine, typically the distal jejunum where they can live up to 5 years. While in the small intestine, the female worms can produce up to 10,000 (*N. americanus*) or 25,000 (*A. duodenale*) eggs per day which are passed out in the feces. Eggs hatch within 48 h and the free larvae can survive for 3–4 weeks in favorable conditions. The larvae penetrate the skin of the human host, and travel to the heart, from there to the lungs, where they are coughed and then swallowed. Once in the small intestine, the larvae become adults and they attach to the intestinal epithelial producing blood loss. Intestinal hookworm infections can also be asymptomatic (Centers for Disease Control and Prevention, 2018).

### Schistosomes

Various species of *Schistosoma* cause Schistosomiasis, and they require specific snail intermediate hosts as part of their life cycle. In the snail, infective cercariae is produced and released, and then penetrate the human through the skin. In the human host, the cercariae becomes schistosomulae and migrates to the lung, then the heart and finally to the liver, where it develops (Basch, 1991). The mature worms, both male and female, leave the liver, copulate and reside in different locations (depending on the species), such as the mesenteric veins in the small or large intestine. The eggs are eliminated via feces or urine (Centers for Disease Control and Prevention, 2018).

### *Trichuris trichiura*

The adult worms of *Trichuris trichiura* live in the colon for approximately 1 year. The infective stage of the *T. trichiura* begins with the intake of embryonated eggs present in soil-contaminated hands or food. When the eggs reach the small intestine, they hatch and the larvae transit to the colon where they mature into adult worms. The adult worms stay in the colon attached to the intestinal mucosa, where the female worms shed their eggs, which are later excrete in feces. Once in the soil, the excreted unembryonated eggs become embryonated after several stages becoming infective (Centers for Disease Control and Prevention, 2018; Harhay et al., 2010).

### *Strongyloides stercoralis*

Even though there are several species of *Strongyloides*, the major contributor of infection in humans is *Strongyloides stercoralis*. *S. stercoralis* has two life-cycles: the free-living cycle and the parasitic cycle. Also, autoinfection may occur. In the parasitic cycle, the filariform larvae from contaminated soil penetrates the skin of a human host at contact. Then, the larvae migrate to the small intestine, where they become adult female worms. The females produce the rhabditiform larvae in the submucosa of the small intestine, then transit through the colon and, are either excreted in the stool, or cause autoinfection. Autoinfection, when left untreated, may be responsible for persistent infection (Centers for Disease Control and Prevention, 2018; Jourdan et al., 2018).

### *Giardia lamblia*

Infection with *G. lamblia* can occur when a person swallows its cysts from contaminated water, food, hands, surfaces, or objects, or by fecal-oral route. Cysts are immediately infectious when passed in the stool or shortly afterward, and can survive several months in cold water or soil. After swallowing, *Giardia* cysts get to the small intestine where each cyst releases two trophozoites (excystation), that feed from the nutrients of the human host. In the lumen of the small intestine, the trophozoites multiply and, either attach to the mucosa by the sucking disk of the ventral surface, or stay free. The cysts are found in the stool of infected humans after encystation when transiting to the colon (Centers for Disease Control and Prevention, 2018; Dixon, 2021).

### *Cryptosporidium* spp

*Cryptosporidium parvum* and *C. hominis* are the leading causes of human cryptosporidiosis. Its transmission is mainly through contaminated water or food with feces, or by direct contact with infected animals or humans. After ingestion, the sporozoites

are released and get to the GI tract where they undergo multiplication (asexual and sexual), then oocysts develop and sporulate. The oocysts can be either excreted in feces (thick-walled oocysts) or produce autoinfection (thin-walled oocysts). The excreted oocysts are infectious. Infection with *Cryptosporidium* spp. and genotypes results in a wide range of signs and symptoms (Centers for Disease Control and Prevention, 2018; Fayer et al., 2000).

### *Entamoeba histolytica*

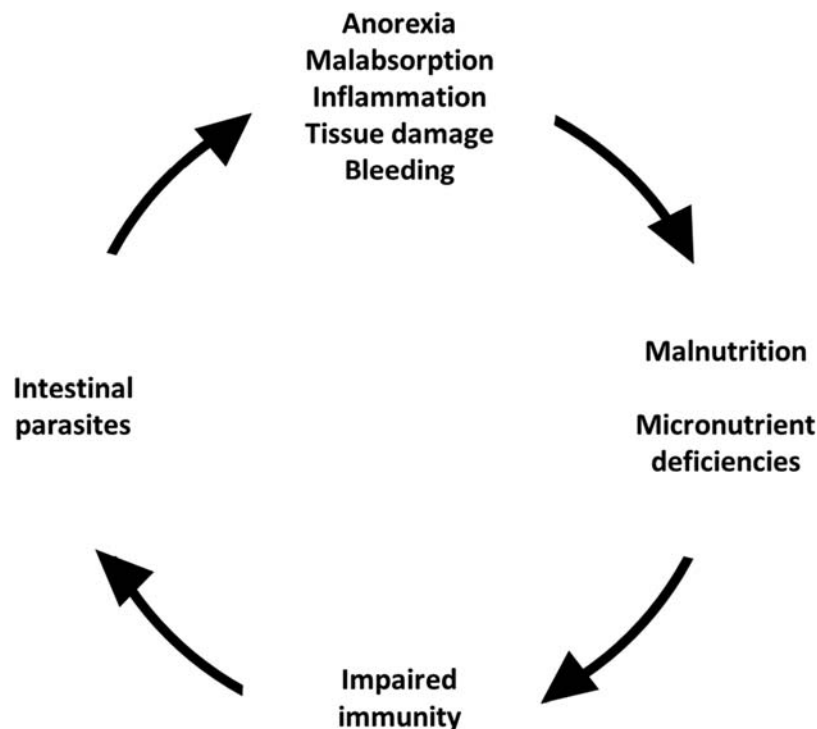

*Entamoeba histolytica* is as a pathogenic amoeba responsible for the infections of millions of people in the world due to fecal contaminated hands, food or water. Following ingestion, trophozoites are released in the small intestine after excystation, and then travel to the large intestine. Once there, three kind of infections may happen. The non-invasive infection is when the trophozoites remain in the large intestine, and the host is a carrier, passing cysts in the stool. While cysts can be infectious outside the human body, trophozoites cannot. The majority of infections restricted to the lumen of the intestine are asymptomatic. The intestinal infection is when the trophozoites invade the intestinal mucosa causing abdominal pain and diarrhea. Lastly, the extra-intestinal infection happens when the trophozoites reach blood vessels and travel to the liver, the brain and the lungs (Centers for Disease Control and Prevention, 2018; Ravdin and Petri, 1990).

### Parasites and nutrition

IPI and malnutrition are bidirectionally linked. As seen in Fig. 1, intestinal parasites can cause malnutrition and malnutrition is the primary cause of immunodeficiency, which in turn, increases the risk of infection (Katona and Katona-Apte, 2008).

The interactions between host nutrition and GI parasites follow mechanisms that include alterations of gut microbiota, inflammation, and gut permeability. The most common nutritional adverse effects of intestinal parasitic infection are stunting, anorexia, malabsorption of fat and carbohydrates, reduced lactase activity, decreased transit time, reduced nitrogen retention, anemia and micronutrient deficiencies (Table 2). It is important to clarify that in most cases parasitic infections remain asymptomatic. The manifestation of adverse effects and the severity of these effects depends on the host immune and inflammatory response, initial nutritional status of the individual or the population, genetics, comorbidities and most importantly the intensity of the parasite infection (Quihui-Cota et al., 2004; Sackey et al., 2003; Zavala et al. 2018).

The type of nutritional adverse effects is dependent on the morphology, feeding and reproductive mechanism of each intestinal parasite. For example, parasites which feed on blood are associated with iron deficiency and anemia, while larger parasites (i.e., *Ascaris lumbricoides* and tapeworms) tend to be associated with abdominal pain, malabsorption and stunting.

**Fig. 1** Intestinal parasites and malnutrition vicious cycle. Original figure with information from Holmes and Coop (2011), Katona and Katona-Apte (2008).

**Table 2** Symptoms and nutritional effects of intestinal parasites.

	<i>Ascaris lumbricoides</i>	<i>Hookworm spp.</i>	<i>Schistosoma</i>	<i>Trichuris trichiura</i>	<i>Strongyloides spp.</i>	<i>Giardia intestinalis</i>	<i>Cryptosporidium spp.</i>	<i>Entamoeba histolytica</i>

Fluid and electrolyte loss								X

The effects that IPI have on the microbiota and immune response are discussed as follows, including the main nutritional adverse effects of IPI, which are anorexia, malabsorption and nutrient losses.

### Gut microbiota, inflammation and gut permeability

GI parasites have been shown to increase gut permeability and intestinal inflammation (Allain and Buret, 2020). One of the mechanisms is through the effect they have on the composition of the microbiota. The gut microbiota is defined as the array of living microorganisms (bacteria, viruses and fungi) in the human gut that are important for maintaining and developing of the intestinal barrier, and also for stimulating immune homeostasis and immune response (Berg et al., 2020). Infections with intestinal parasites have been shown to cause microbiota dysbiosis which results in gut permeability and translocation of bacterial metabolites that lead to low-grade systemic inflammation (Oriá et al., 2016). For instance, STH infection alters the composition of the microbiota directly by the secretion of products with antimicrobial activity such as glycoproteins, immunomodulatory proteins, and miRNAs, and also by altering the intestinal mucus of the host (Brosschot and Reynolds, 2018). In addition, infection with STH is known to promote a type 2 immune response both systemic and locally in the intestine, characterized by the production of T-helper type 2 cells and anti-inflammatory cytokines, such as interleukin 10 (IL-10) (Zavala et al., 2018; Brosschot and Reynolds, 2018). Though an anti-inflammatory immune response is necessary to eradicate the parasite, the response is not efficient enough due to the overall effect STH have on the immune response, both direct and indirect (Brosschot and Reynolds, 2018).

The inflammation caused by IPI can affect the intestinal barrier, where the innate immune response contributes to the lesions caused in the epithelial cell (Garzón et al., 2017). Also, IPI can affect the intestinal barrier by causing cell damage through binding directly to cell surfaces or disrupting the epithelial cells (Garzón et al., 2017). A disturbed intestinal barrier limits its ability to repair itself, and may lead to gut permeability. The inflammation associated to increased gut permeability as a consequence of parasitic infections may compromise growth and cognitive development in children and increase the risk of chronic diseases in the adult (Garzón et al., 2017; Goto et al., 2009). The severity of the inflammation, both systemic and intestinal, the dysbiosis and the gut permeability caused by the IPI, will depend on the nutritional and immune status of the host.

### Loss of appetite and anorexia

Appetite loss and anorexia are common in people infected with intestinal parasites, which has been explained by the symptoms associated with infection, changes in the gut microbiome and inflammatory molecules released to face the parasitic infection (Holmes and Coop, 2011). In many cases parasitic infection remains asymptomatic, but in other cases (heavy infections) parasitic infection (helminths and protozoa) can cause nausea, abdominal pain, flatulence, and distension and discomfort, while protozoan intestinal parasites can also cause vomiting, diarrhea, or dysentery. For instance, hookworms and *Strongyloides stercoralis* stimulate abdominal pain, nausea, and anorexia. As mentioned before, intestinal parasites can also disrupt the gut microbiome composition,

and start inflammatory responses involving molecules as leptin and adiponectin, which are well known appetite regulators (Fata et al., 2019).

### Maldigestion and malabsorption

Intestinal parasites can physically and metabolically disrupt macro- and micronutrient absorption. Heavy infections can cause damage and obstruction of the mucosa of the intestine, or cause flattening or thickening of villi, which damages the absorptive surface area and reduces absorption of macro- and micro nutrients. In addition, parasites such as hookworm and *Entamoeba histolytica* can cause damage to the cells, diminishing their absorptive properties and limiting active transport processes (Mohammadi et al., 2015).

Maldigestion and malabsorption main symptom is diarrhea, which is the leading cause of childhood malnutrition and second cause of mortality among children under 5 years of age (Parashar et al., 2003). For example, chronic strongyloidiasis is generally asymptomatic, but a variety of GI manifestations may occur, including diarrhea. In the case of *Entamoeba histolytica*, when the mucosa is invaded, severe dysentery and associated complications can occur; severe chronic infections may lead to further complications such as peritonitis, perforations, and the formation of amebic granulomas. Infected persons with *Giardia* can also experience severe diarrhea and malabsorption. Acute giardiasis develops after an incubation period of 1–14 days (average of 7 days) and usually lasts 1–3 weeks. Symptoms include diarrhea, abdominal pain, bloating, nausea, and vomiting. In chronic giardiasis the symptoms are recurrent and malabsorption and debilitation may occur. Immunocompetent patients infected with *Cryptosporidium* spp. may present diarrheal illness that is self-limiting, typically resolving itself within 2–3 weeks. In immunocompromised patients' infection can lead to more severe complications, such as life-threatening malabsorption and wasting. Diarrheal illness in all cases may be accompanied by fever or fatigue.

### Nutrient losses

Direct and indirect loss of nutrients is the most important mechanism by which intestinal parasitic infections compromise the nutritional status of the host (Hesham et al., 2004). Direct losses occur during the feeding and burrowing of blood-sucking and tissue invading parasites, such hookworm, *Schistosoma* spp. and *Trichuris trichiura*, or due to vomiting and diarrhea. Blood and tissue ingested by the parasites contributes to one part of the nutrient loss. Hookworms, for instance, cause iron deficiency anemia due to blood loss at the site of intestinal attachment of adult worms, especially in heavy infections. However, the highest contribution to nutrient loss is due to lesions caused by feeding and burrowing activity; these lesions usually continue bleeding after the parasites have moved to another feeding/burrowing place (Crompton, 2000).

The passage of schistosome eggs through the intestine often causes tissue damage and blood loss, and thus, has been associated with iron-deficiency anemia (Friedman et al., 2005). Another mechanism is the accelerated disposal of erythrocytes damaged by the intestinal parasites to the lumen (Kapczuk et al., 2020).

Similarly to hookworms, loss of blood and anemia are the most common nutritional effects of *Trichuris trichiura* infection. *Trichuris trichiura* feeds from tissue secretions rather than blood, but there is blood loss due to the parasite-induced lesions (Stephenson et al., 2000). Anorexia, vomiting and diarrhea are associated with light and moderate infections, while more severe symptoms such as intestinal inflammation, abdominal pain and rectal prolapse are associated with heavy infections (Stephenson et al., 2000).

Indirect losses are caused by inflammatory and immunological mechanisms which are stimulated to fight the parasitic infection and repair tissue damage (Rivera et al., 2003). Local inflammation at the site of the parasite often accompanied by lymphocytic infiltration of tissues cause further damage to the mucosa, augmenting maldigestion, malabsorption, and nutrient losses as more damaged cells are shed. Activation of the systemic inflammatory system, that is, the acute-phase response, is a general reaction of the body to pathogen invasion or tissue damage. It results in a widespread cytokine-mediated catabolic response, which increases the catabolism of macro and micronutrient reserves (Grimble, 1990). This process is also associated with anorexia, which decreases nutrient intake, increases losses of amino acids, minerals, and vitamins in the urine and feces, and finally leads to protein-energy malnutrition, micronutrient deficiencies, stunting and impaired cognitive development, especially among children.

Another indirect way of losing nutrients is through competition of nutritional sources between the host and the GI parasites. For instance, there is evidence concerning competition for nutrients from tapeworm (Alroy and Gilman, 2020). *Diphyllobothrium latum* concentrates large amounts of vitamin B12 in its tissue. Thus, B12 deficiency and megaloblastic anemia has been reported in children and adults infected with tapeworm (Jimenez et al., 2012). Also, it has been suggested that zinc competition in the gut during *Giardia* infection is one of the causes of zinc deficiency (Astiazarán-García et al., 2015).

### Treatment

In Table 3, the recommended drugs against intestinal parasites are shown. For the treatment of the STHs, the WHO recommends albendazole (400 mg) and mebendazole (500 mg). These are effective, inexpensive and easy to administer by non-medical personnel. In addition, they have been tested extensively and have been used in millions of people with few and minor side-effects (Anon, n.d.).

**Table 3** Recommended drug according to parasitic infection.

Treatment	Ascaris lumbricoides	Schistosoma <i>Hookworm spp.</i>	Trichuris trichiura	Strongyloides <i>spp.</i>	Giardia intestinalis	Cryptosporidium <i>spp.</i>	Entamoeba histolytica
Mebendazole	X	X	X				
Albendazole	X	X	X		x		
Praziquantel		X					
Tricabendazole		x					
Thiobendazole				x			
Ivermectine				x			
Metronidazole					x		X
Tinidazole					x		X
Secnidazole					x		
Nitazoxanide						x	
Spiramycin						x	
Clindamycin						x	
Nitazoxanide							
Paromomycin						x	

Even though the pathology of schistosomiasis is caused mainly by the eggs trapped in tissue, treatment with praziquantel has been shown to improve periportal fibrosis and splenomegaly, as well as physical fitness, appetite and school performance. Also, iron supplementation can improve iron status after anti-helminth treatment (Gryseels et al., 2006).

For giardiasis and amoebiasis, treatment has been available for several decades. There are no effective remedies for infection with *Cryptosporidium* spp. In chronically infected HIV-positive patients, treatment with multidrug regimens usually results in rapid resolution of the diarrhea and, in many instances, eradication of the parasite (Gilles and Hoffman, 2002; Rossignol, 2010).

## Prevention

In 2012, the WHO published a roadmap to overcome the global impact of neglected tropical diseases. For intestinal parasites, WHO and partners have targeted to treat 50% of pre-school and school-aged children by 2015, and reach 75% coverage by 2020, which was not achieved (World Health Organization, 2010).

Mass drug administration (MDA) is currently being used to control STH infections. However, there are several obstacles for these programs to be successful, including the lack of access to the anthelmintic drugs, inadequate funding to expand existing MDA programs or to implement new ones in areas that do not currently have them, deficient geospatial and population prevalence data to guide focused targeting of MDA, potential development of drug resistance to existing anthelmintic, among others. In addition, for these programs to be sustainable, MDA programs require reinforcement with improved water quality, sanitation, and hygiene (WASH). Water and sanitation are critical to preventing reinfections or new infections of all intestinal parasites.

## Conclusion

Despite the advances in science and technology in the past years, IPI are still a major cause of mortality and morbidity worldwide, affecting mainly children living in developing countries. The effects the IPI have on the nutritional status are varied and may last for years, affecting the development and work capacity of the hosts. Even though some progress has been made, progress is slow, and there is still a need for effective programs and treatments that are accessible to the population, particularly targeting children.

### Glossary

**Cell-mediated immunity (CMI)** The principle host defense against TB mediated primarily by T lymphocytes rather than antibodies

**Droplet nuclei** Microscopic particles (1–5 mm in diameter) that can be expelled when a person coughs, sneezes, shouts or sings. The droplets produced by an infectious TB patient can carry tubercle bacilli and can remain suspended in the air for prolonged periods of time.

**Undernutrition** A type of malnutrition caused by the lack of food or failure of the body to absorb or assimilate nutrients properly

**Hematogenous re-seeding** The process by which bacilli make their way back to the lung through the bloodstream where they infect all parts of the lung

**Bacillus of Calmette and Guérin (BCG) vaccine** A tuberculosis vaccine used in many parts of the world containing an attenuated strain of tubercle bacillus developed by repeated culture on medium containing bile.

Undernutrition is an important risk factor for the development of tuberculosis (TB) both at the individual level and at the population level. Undernutrition profoundly affects cell-mediated immunity (CMI), and CMI is the principal host defense against TB. Although these concepts may be widely accepted, the relative and attributable risks of TB due to undernutrition are not well known. Moreover, the effects of specific nutrients have not been established. Recent evidence suggests that overweight and obesity may actually decrease the risk of developing TB. This article will summarize available evidence on the relationship between nutritional status and the risk of TB.

Understanding the link between undernutrition and susceptibility to TB is based on a conceptual model for the transmission and pathogenesis of TB (McMurray, 2007). *Mycobacterium tuberculosis* is transmitted by the aerosol route when an individual who has pulmonary or tracheobronchial TB produces droplets containing viable *M. tuberculosis* by coughing. The moisture content of smaller droplets evaporates quickly and the resulting “droplet nuclei” are the main vehicle for airborne transmission of TB. In most people, the innate and adaptive immune responses control the infection without overt symptoms or other clinical manifestations of TB disease. In a small minority of individuals, estimated to be ~5%, the immune response will not control the infection, and the infection progresses to active TB disease known as “progressive primary TB.” The risk of progression, however, is much greater in persons with immune systems weakened by undernutrition, HIV infection, immunosuppressive medications, and extremes of age. In persons whose immune systems successfully control the primary infection, mycobacteria may remain viable within granulomas for years or decades. One in four humans are believed to be latently infected with TB in this way. Approximately 10% of individuals with latent TB infections develop active TB disease in their lifetime (called secondary TB disease). Annually approximately ten million develop active TB disease globally. The risk of an infection progressing to active TB disease depends on the host’s immune system and the microbe’s infectious dose and pathogenicity. The influence of nutritional status on host defenses is a central theme of this article.

Once the inhaled mycobacteria reach the alveoli, alveolar macrophages bind and internalize the bacilli activating these macrophages that then produce pro-inflammatory cytokines such as tumor necrosis factor-alpha (TNF- $\alpha$ ) and other chemokines (McMurray, 2007). These chemical messengers recruit macrophages and other immune response cells to the site of infection. In some individuals, the bacilli are destroyed at this stage, but in others, as the inflammatory response progresses, the mycobacteria and infected macrophages are taken in the draining lymph to the hilar and mediastinal lymph nodes, leading to activation of the acquired or adaptive immune system. From these lymph nodes, bacilli and infected phagocytes flow into the thoracic duct and the blood stream, disseminating to potentially every organ or tissue in the body. Bacilli make their way back to the lung through the bloodstream where they infect all parts of the lung in a process known as hematogenous re-seeding which apparently occurs in all infected individuals. Blood-borne organisms establish “secondary” granulomas, in which the organisms may persist despite an active immune response, and which are often the sites of secondary TB disease described above.

Mycobacterial antigens are presented to CD4<sup>+</sup> (helper) and CD8<sup>+</sup> (cytotoxic) T lymphocytes in the lymph nodes initiating the CMI (McMurray, 2007). The population of TB-specific T lymphocytes expands and circulates to sites of active infection where they produce macrophage-activating cytokines such as interferon-gamma (IFN- $\gamma$ ). The combination of IFN- $\gamma$  and TNF- $\alpha$  from phagocytes further activates macrophages to inhibit mycobacterial growth. During this period, the host begins to express evidence of a TB-specific T-lymphocyte-mediated immune response as manifested classically by a positive tuberculin (PPD) skin test. The process by which macrophages inhibit or destroy mycobacteria may also cause local tissue destruction and necrosis. Immunological feedback mechanisms modulate the intense inflammatory response to limit tissue damage while controlling the infection. Nevertheless, local tissue destruction in the lungs can lead to formation of cavities, characteristic of contagious, reactivation TB.

While there is little evidence of increased risk of primary infection, the risk of progression from infection to disease increases substantially in undernourished individuals (Cegielski and McMurray, 2004). This is likely due to the adverse effects of undernutrition on CMI which is essential for control of mycobacterial growth. Protein undernutrition clearly compromises CMI. Experimental animal studies have demonstrated that even modest protein deprivation impairs host responses to BCG vaccination and tuberculin skin test responsiveness after aerosol exposure to *M. tuberculosis*. Protein repletion rapidly restores these responses. Protein from the diet and from somatic stores is crucial for many aspects of host defense against TB as described above. Essential amino acids play important physiological roles apart from serving as building blocks for protein synthesis. Other macronutrients may also influence the immune system, especially fatty acids, including *n*-6 and *n*-3 polyunsaturated fatty acids (PUFA) (McFarland and et al., 2008). *n*-3 PUFA have a direct influence on immune cell membrane composition and function, as well as on the production of eicosanoids and other inflammatory mediators. High intakes of long chain *n*-3 PUFA dampen inflammatory responses and ameliorate chronic inflammatory conditions such as rheumatoid arthritis, potentially at the cost of increasing susceptibility to infection including TB (see below). The balance *n*-3 and *n*-6 PUFA may be a key determinant of their effects on the immune system and disease resistance (McFarland et al., 2008).

Recent findings suggest that chronic excess caloric intake may actually decrease the risk of TB (Leung et al., 2007). A 2009 study from China demonstrated that persons who were overweight and obese had  $\sim 1/4$ th to  $\sim 1/5$ th the risk of developing TB, respectively, compared with persons having normal body mass index. These findings have been corroborated by a contemporaneous cohort study from Peru which found that those with premorbid BMI > 25 kg/m<sup>2</sup> had approximately 1/3rd the risk as compared to those with BMIs in the normal range (18.5–25 kg/m<sup>2</sup>) (Aibana et al., 2017). These findings are consistent with other studies which are described below. The mechanisms by which excessive body mass decreases TB incidence are ripe for investigation. Recent research demonstrates that adipose tissue may be a reservoir for non-replicating *M. tuberculosis*, and that such bacilli accumulate triacylglycerol in intracytoplasmic lipid bodies visible with appropriate staining by regular light microscopy (Garton et al., 2008). A triacylglycerol synthase-encoding gene (*tgs1*) in *M. tuberculosis* is a member of the DosR regulon that may control the development of a non-replicating “persister” phenotype in the mycobacteria. Induction of the isocitrate lyase gene, *icl1*, in these mycobacteria allows a shift to utilization of lipids as a source of carbon and energy (Garton et al., 2008). Indeed, Roth speculated that obesity may have provided an evolutionary advantage during TB epidemics in the past, predisposing to obesity the modern day descendants of the survivors (Roth, 2009). Taken together, these recent data suggest the presence of a non-replicating bacterial population which persists especially in adipose tissue. Such mycobacteria may stop replicating or replicate more slowly, decreasing the probability of active TB disease.

Vitamin A may affect resistance to TB by altering the innate and the adaptive immune response to *M. tuberculosis* (Aibana et al., 2017). Vitamin A is necessary for the function of the respiratory mucosa and the integrity of pulmonary epithelial tissues. Retinol modulates the maturation of dendritic cells which are needed for antigen presentation and T-cell priming. Retinoic acid fosters the T-helper (Th)-1 response against *M. tuberculosis*. Moreover, it also modulates T-regulatory cells and downregulates Th-17 cells. Lastly, all-trans-retinoic-acid may have direct antimycobacterial properties as it disrupts lipid metabolism.

Vitamins of the B complex and vitamin C play important roles in B-cell mediated humoral immune responses, but at present there is less evidence for their role in CMI. Vitamin B<sub>12</sub> may be an exception to this generalization; B<sub>12</sub> repletion in patients with pernicious anemia has been shown to reverse skin test anergy. The antioxidant functions of vitamin C, vitamin E, selenium, and glutathione have critical roles in protection against oxidative stresses, including reactive oxygen intermediates that play effector roles in cellular immunity as described below. Vitamin E may have other effects on both cellular and humoral limbs of the immune system as well especially in relation to *n*-3 PUFA. Vitamin E also stimulates the Th-1 response which is critical for suppressing *M. tuberculosis*.

Vitamin D may have a role in anti-TB immunity through activation of macrophages (Cegielski and McMurray, 2004; Cegielski and Vernon, 2015). Induction of a cell-surface receptor for the vitamin D metabolite, 25-hydroxycholecalciferol, as well as the hydroxylase which forms 1,25-dihydroxycholecalciferol, appear to be part of the mechanism that helps these cells destroy the pathogen. These vitamin D effects are linked with production of the endogenous antibiotic peptide, cathelicidin. Two cross-sectional studies on vitamin D metabolism in relation to TB have focused on the molecular and cellular mechanisms of the interaction rather than on the direction of causality (reviewed in Cegielski and McMurray (2004)). Cells recovered by bronchoalveolar lavage (BAL) and peripheral blood mononuclear cells from TB patients both produced 1,25(OH)<sub>2</sub>D<sub>3</sub>, the amount correlating with the number of CD4<sup>+</sup> T lymphocytes but not with other cell types. CD4<sup>+</sup> T lymphocytes in BAL fluid from TB patients expressed specific receptors for 1,25(OH)<sub>2</sub> vitamin D<sub>3</sub> but not 25(OH)D<sub>3</sub>. Since 1,25(OH)<sub>2</sub>D<sub>3</sub> can improve the capacity of macrophages to kill mycobacteria, these results support the conclusion that cellular interactions mediated in part by 1,25(OH)<sub>2</sub>D<sub>3</sub>

may be important in resistance to TB. In a prospective study, 1103 persons with HIV had their vitamin D levels measured at the time of antiretroviral therapy initiation. Subjects were followed monthly. This study found that, after adjusting for confounders, compared to participants with sufficient vitamin D levels, those with vitamin D deficiency (serum 25(OH)D3 levels <20 ng/mL) were significantly more likely to develop TB disease (Odds Ratio 2.89; 95% confidence interval: 1.13–7.41). Those with vitamin D insufficiency (serum 25(OH)D3 levels <20 ng/mL) did not have a significantly elevated risk of TB disease (Odds Ratio 1.14; 95% confidence interval: 0.60–2.18). However, a randomized double-blind trial that provided vitamin D supplementation to individuals with vitamin D insufficiency did not find a difference in the incidence of pulmonary tuberculosis between those receiving the supplementation and the control group (Ganmaa et al., 2020).

Dietary mineral deficiencies also affect CMI. Zinc deficiency interferes with T cell replication and maturation leading to lymphopenia. Zinc deficiency is also associated with elevated glucocorticoid levels that suppress cell-mediated immunity. Iron plays a critical role in support of CMI, however, iron is also critical to the replication of mycobacteria and other pathogens. Mycobacteria have evolved intense iron-scavenging mechanisms, and iron deficiency may have worse consequences for the microbe than the host. Conversely, iron overload in the reticuloendothelial system may increase susceptibility to TB. Indeed, a meta-analysis has found an association between SLC11A1 mutations in Asian and African populations and increased TB disease incidence. Thus, the impact of iron on susceptibility to TB is difficult to predict.

Despite the seemingly clear pathways through which nutrition affects CMI and resistance to TB, the evidence in humans linking undernutrition to TB risk is indirect and surprisingly weak from the perspective of scientific rigor. Early research on the interaction of nutrition and TB was exhaustively reviewed in the classic text by Scrimshaw, Taylor, and Gordon (Scrimshaw et al., 1968). The studies in humans were either ecological or uncontrolled observational studies. For example, studies of the sharp increases in TB incidence and mortality in France and Germany during the two World Wars, in the Netherlands during the famine of 1944–1945 (the hunger winter), or in the Warsaw ghetto during World War II, do not isolate the effects of undernutrition from the impact of extreme crowding, social and environmental degradation, lack of medical services, and catastrophic social circumstances. Another notable study of this era includes the Papworth experiment which studied the impact of a suite of socioeconomic interventions on TB. TB patients were ensured a job and were given adequate nutrition and lodging after their discharge from sanatoria. There was a dramatic decrease in TB disease incidence among children under 5 years of age who were born within the Papworth settlement as compared to the rate prevailing at the time in England: 0 vs. 1217 cases/100,000 person-years (Bhargava et al., 2012). While highly suggestive, again, these studies are unable to isolate the effect of undernutrition from the effects of poor housing, overcrowding, lack of medical care, poor hygiene, social disruption, and poverty. Although much of this observational evidence is scientifically weak, it constitutes a large body of repeated observations supporting a relationship between undernutrition and TB. In addition, the decline in TB in the global North prior to the mid-20th Century advent of modern *anti*-TB chemotherapy and widespread BCG vaccination is often ascribed to improvements in living conditions, especially nutrition, a concept championed in seminal work by Thomas McKeown (McKeown and Record, 1962). The remainder of this article summarizes the evidence from observations in human populations and from experimental animal models with relevance to human TB.

Three ecological studies present compelling evidence that undernutrition, isolated to some extent from other confounding circumstances, plays a direct role in TB morbidity and mortality (Cegielski and McMurray, 2004; McMurray and Cegielski, 2007). During World War I, neutral Denmark exported the bulk of its meat, fish, poultry, and dairy products to support the war effort elsewhere so the local diet lacked these protein-, vitamin-, and mineral-rich foods. During that period, TB rates increased similar to the warring countries. In 1918, however, Germany blockaded Denmark making exports impossible, creating a local surplus of these foods. TB rates in Denmark plummeted while rates in the neighboring countries continued to increase unabated. The second study involves the Trondheim, Norway, Naval Training School, where an extremely high rate of TB among recruits in the early 20th century was ascribed to crowding, poor housing, and unhygienic conditions. TB rates did not decrease after improved housing and hygiene were provided. On the other hand, when the diet was fortified with milk, margarine, cod liver oil, whole wheat bread, and fresh fruits and vegetables, TB morbidity promptly declined to the prevailing level for young adults of that area. After WWII, Leyton reported on British and Russian prisoners of war (POW) held in the same German POW camps, sharing the same living conditions and diet, except the British received Red Cross food supplements amounting to 30 g protein and 1000 kcal per day. In a subsequent radiographic survey, the TB rate among the British POW was only 1.2% while the rate in Russian POW was 15%–19%. In the malnourished prisoners, TB was more severe, the onset was more rapid, and patients died rapidly with large pulmonary cavities and massive tissue breakdown. Granuloma formation was poor in the malnourished prisoners, supporting the idea there was a deficit of CMI in this group.

Protein–energy undernutrition compromises CMI and may exacerbate TB, however, TB itself can adversely affect nutritional status. Understanding the temporal relationship between the onset of undernutrition and the development of TB is crucial to correctly assess any possible cause–effect relationship. Cross-sectional and case–control studies generally suffer from the same flaw: Patients with and without TB disease are compared in terms of their concurrent nutritional status. While these studies demonstrate substantial macro- and micronutrient deficits in TB patients, they are not useful in determining the effect of undernutrition on susceptibility to TB because TB causes undernutrition. The intrinsic uncertainty over the chronological sequence of cause and effect in case–control and cross-sectional studies become intractable.

The effects of undernutrition on the immune response to mycobacterial proteins closely related to the CMI required for resistance to infection with *M. tuberculosis*, namely delayed-type hypersensitivity (DTH) responses, have been studied following BCG vaccination. Satyanarayana et al. showed that milder grades of undernutrition did not affect the tuberculin skin test response 6 months after immunization with BCG, but children with kwashiorkor were skin test negative (Satyanarayana et al., 1980).

Chandra and Newberne demonstrated that the DTH skin test response to tuberculin was reduced in protein–energy undernourished children and adults (Chandra and Newberne, 1977). Among TB patients, PPD skin test reactivity was directly proportional to serum transferrin level, a sensitive indicator of protein undernutrition. Similarly, malnourished children did not develop skin test responses to tuberculin as often or as large after BCG vaccination as did well-nourished children. Importantly, this defect has been demonstrated even in modest protein–energy undernutrition. A study of interferon gamma release assays (IGRA) among children in Bangladesh found that undernourished children (BMI z-score < -2) were more likely to have lower levels of interferon gamma response to *M. tuberculosis* antigens and were also more likely to have indeterminate IGRA results.

After intestinal bypass surgery for morbid obesity, patients experience rapid weight loss and malabsorption due to their short-circuited bowels (Snider, 1982). In several case series, the postoperative incidence of TB was 10- to 100-fold higher than historical or population comparison groups. Similarly, partial gastrectomy for ulcer disease was shown to predispose men to TB, especially among men whose weight was <85% of ideal.

The unique strength of cohort studies is nutritional status is measured prior to the onset of TB. Only a handful of cohort studies have examined the relationship between micronutrients and TB incidence. In the 1940s, Getz and coworkers enrolled a cohort of 1100 men who were free of TB at baseline, and followed them for up to 5 years with serial clinical, radiographic, and laboratory examinations (Getz et al., 1951). Plasma vitamin A levels were low in 13 of 16 men (81%) who developed TB compared to 318 of 1058 (30%) of those who did not. Similarly, plasma vitamin C levels were low in 100% of the subjects who developed active TB compared to 117 of 1013 (11%) of those who did not. Exposure to TB did not differ between the groups. In a Finnish study on cancer prevention, investigators randomized 26,975 healthy male smokers aged 50–69 years to supplementation with tocopherol, beta-carotene, both, or neither (Hemilä et al., 1999). The subjects were followed for a mean of 6.7 years. In >173,000 person-years of follow-up, 167 cases of TB were detected. Higher intakes of fruits and vegetables were associated with lower risk of TB (the adjusted relative risk of TB was 0.4; 95% confidence interval, 0.24–0.69). This study is noteworthy for its size and data quality, however, detecting TB through hospital discharges selects TB patients who were sick enough to require hospital admission. Lower dietary intakes of key nutrients may have been associated with higher rates of hospitalization rather than (or in addition to) higher rates of TB. More recently, a case-control study nested in a prospective cohort of 6751 HIV-negative household contacts of persons with TB in Peru, studied the impact of premorbid vitamin A and E deficiency on incident TB (Aibana et al., 2017). In this study, 180 individuals developed active TB disease. Vitamin A deficiency was associated with a ten-fold higher risk of incident TB disease (Odds Ratio: 10.53; 95% confidence interval, 3.73–29.70) and baseline alpha-tocopherol deficiency was associated with higher risk of incident TB disease (Odds Ratio: 1.59; 95% confidence interval, 1.02–2.50).

As part of the long-term follow-up of participants in large-scale BCG vaccine trials in Georgia and Alabama, Comstock and Palmer reported the incidence of TB was 2.2 times higher in children with 0–4 mm subcutaneous fat than in children with 10 mm subcutaneous fat (Comstock and Palmer, 1966). Cegielski examined the relationship between undernutrition, as determined in the first National Health and Nutrition Examination Survey (NHANES-1), and TB incidence as ascertained in the NHANES-1 Epidemiological Follow-up Study (Cegielski et al., 2012). NHANES-1 was a cross-sectional survey based on a representative sample of the US population from 1971 to 1975. In the Follow-up Study, the adult subjects of NHANES-1, aged 25–74 years at baseline, were followed up until 1992. Having body mass index (BMI), average skin-fold thickness, or mid-upper arm cross-sectional muscle area in the lowest decile of the population increased the adjusted hazard of TB from 6- to 10-fold, controlling for other known risk factors for TB.

In a related vein, three massive studies focused on “body build” as a risk factor for TB incidence (Palmer et al., 1957; Edwards et al., 1971; Tverdal, 1986; Snider, 1987). Palmer et al. reported on the relationship between TB incidence and naturally acquired delayed-type tuberculin sensitivity among nearly all US Navy recruits from 1949 to 1951. Of 68,754 subjects with follow up data, 8704 (12.7%) had tuberculin sensitivity recorded as >0 mm induration. During 4 years of follow-up, 109 developed TB: 28 among those with 0 mm skin test reactions, 29 among those with 1–9 mm reactions, and 57 among those with 10 mm or greater reactions. Later, these investigators related the risk of TB to the recruits’ height and weight data on a stratified random sample of 1138 subjects. TB incidence was 75/105 for those 15% or more below the median weight for height, decreasing to 19/105 for those at least 5% overweight for height. Edwards et al. extended this study to more than 823,000 Navy recruits and found that TB developed 3-fold more often in young men 10% or more below their ideal body weight compared with those 10% or more above their ideal body weight. Rather than attribute these results to nutritional status, the authors concluded that there was an association between “body build” and risk of TB disease. The relationship between body build and TB was reviewed by Snider in 1987. One study stands out. Norway screened 42%–85% of the population older than age 14 years for TB with radiography from 1963 to 1975. Height and weight were measured accurately for approximately 80% of those screened. As reported by Tverdal et al. more than 1.7 million Norwegians were followed up via the national notification system through 1982 (i.e., 8–19 years of follow-up; mean, 12.1 years). A total of 2531 incident cases of TB were identified. The incidence of pulmonary TB declined logarithmically with increasing BMI for both sexes, all age groups, and at all durations of follow-up. The age-adjusted incidence of pulmonary TB was five times higher in the lowest BMI category than in the highest. Even though the study was based on BMI, Tverdal argued that the observed relationship was a function of body build, not nutritional status. Comstock suggested body build may influence susceptibility to TB because of differences in pulmonary mechanics, but no data supporting this hypothesis exist. Interpreting the findings in terms of unknown factors associated with body build rather than the most obvious explanation, i.e., nutritional status, discounts the relationship between body weight, caloric intake, and energy expenditure. A more nuanced view may be that body habitus is a function of genetic endowment and of nutrient intake plus physical activity, each of which affects the incidence of TB in complex ways.

A unique study of the effect of micronutrient supplementation on TB incidence was reported by Downes in 1949 (Downes, 1950). In a controlled trial among the families of black TB patients in the Harlem ghetto of New York City, 194 of 218 families under public health supervision were examined and divided into two groups matched for family size. The families were allocated alternately to receive vitamin and mineral supplements versus no supplements. The two groups were similar in terms of prior attack rates and mortality from TB, prevalence of TB at the start of the study, sputum smear positivity among the index cases, and relation of the index case to the rest of the family. In addition, the groups were similar in terms of their economic status, crowding, and eating habits. After 5 years of follow-up, the risk of TB in the control group was 2.8-fold higher than the supplemented group. However, there was substantial nonadherence with the supplements. Compared with those who actually took the vitamin supplements throughout the observation period, the risk of TB in the control group was 5.9-fold higher. Therefore, vitamin supplementation substantially reduced the risk of TB among family contacts of active TB cases.

Experimental animal models allow investigators to elucidate the causal links between nutritional deficiencies, immune system function, and TB in ways not possible in human studies. The link between diet, antimycobacterial immunity, and resistance to TB has been investigated in a highly relevant guinea pig model of low-dose pulmonary TB that mimics the pathogenesis of TB in humans (Smith and Harding, 1977; McMurray et al., 1981; McMurray and Bartow, 1992; McMurray, 1998; Chan et al., 1996). Moderate, chronic deficiencies of protein and other nutrients (e.g., zinc, vitamin D) induced in guinea pigs had many of the metabolic hallmarks of human dietary deficiencies. Groups of BCG-vaccinated and nonvaccinated guinea pigs were given different diet treatments and then challenged with an aerosol containing a low dose of virulent *M. tuberculosis*. Antigen-specific immune responses in vitro and in vivo were assessed several weeks later and the ability of the guinea pigs to control the infection was determined quantitatively by culture of viable mycobacteria from the lungs and spleens.

Moderate, chronic protein deficiency (modeled by a 10% ovalbumin-based diet) over several weeks resulted in a dramatic loss of CMI in infected guinea pigs. Protein deprived animals had much smaller DTH reactions, and their T lymphocytes proliferated poorly to PPD in vitro and produced significantly less interleukin (IL)-2, IFN $\gamma$ . Macrophages from protein malnourished guinea pigs produced less TNF $\alpha$  in response to infection with virulent *M. tuberculosis*. Protein-deficient guinea pigs were unable to form mature, well-circumscribed granulomas in the lung. BCG-induced protection was diminished by protein deficiency. Protein undernutrition altered the numbers of CD4<sup>+</sup> and CD8<sup>+</sup> T cells in the spleen and bronchotracheal lymph nodes draining the infected lung. Thus, protein deficiency was accompanied by impairment of the normal trafficking of T lymphocytes that would be required for the formation of protective granulomas due, perhaps, to diet-induced changes in the production or function of chemokines, or by perturbations in the expression of adhesion molecules on T cells or endothelial cells.

Macrophages from TB patients are known to produce suppressive factors for T cells, including transforming growth factor-beta (TGF- $\beta$ ). Alveolar macrophages effectively down regulate T cell activation to mitigate potentially damaging pulmonary inflammation in response to inhaled antigens. Alveolar macrophages from protein-deficient guinea pigs exerted a 10-fold greater suppression of T cells compared to cells from normally nourished animals, perhaps due to the greater levels of TGF- $\beta$  produced by these cells. Recombinant human TGF- $\beta$  injected daily into guinea pigs infected with virulent *M. tuberculosis* suppressed T cell functions and impaired bacillary control in a manner similar to dietary protein deficiency. Thus, macrophages from protein-deprived guinea pigs appear to be more suppressive for T lymphocyte functions, and this suppression may be mediated, in part, by overproduction of TGF- $\beta$ .

One of the most important findings from this model is that the profound loss of T cell-mediated resistance that accompanies chronic dietary protein deprivation was substantially and rapidly reversible. Protein-deficient, BCG-vaccinated guinea pigs given a normal diet beginning on the day of pulmonary challenge with *M. tuberculosis* displayed DTH reactivity and control of bacillary growth within a few weeks that were indistinguishable from those in BCG-vaccinated animals that had never been protein deficient. Similar results were observed in protein-malnourished mice. Using a high-dose, intravenous challenge model, Chan and colleagues observed many of the same T cell defects that have been reported in low protein guinea pigs, including inability to control the virulent infection, impaired granuloma formation, and recovery of resistance following refeeding with an adequate diet (Chan et al., 1996). These studies confirm the fundamental nature of the effects of protein deprivation on susceptibility to TB even when host species, and infection dose and route are altered.

Guinea pig and mouse models of low-dose, pulmonary TB have been used to demonstrate the significant effects of dietary n-3 PUFA on TB resistance (Garton et al., 2008). Guinea pigs fed a diet enriched in fish oil or transgenic *fat-1* mice producing n-3 PUFA endogenously were more susceptible to infection with virulent *M. tuberculosis*. Immune cells from *fat-1* mice or cells from wild-type mice cultured in medium containing n-3 PUFA produced less TNF $\alpha$ , IL-6, and IL-1 $\beta$ , and exhibited reduced oxidative burst and impaired phagosome-lysosome fusion. These n-3 PUFA-enriched macrophages were significantly impaired in their ability to control *M. tuberculosis* over several days of culture.

This article has reviewed and critiqued published studies in human populations and in relevant animal models covering the in vivo evidence relating the risk of TB due to nutritional status and nutritional factors. Although TB is clearly related to undernutrition, the risk relative to specific levels and types of protein-energy deficiency and micronutrient deficiencies remain to be defined. Analysis of the NHANES-1 Epidemiological Follow-up Study provides plausible estimates of a 6- to 10-fold increase in relative risk among undernourished adults as well as a substantially decreased risk in overweight and obese individuals. Severe protein-energy deficiencies may increase the relative risk more than mild or moderate undernutrition, but severe undernutrition affects fewer people, even in low-income countries, except during famines, war, natural disasters, pandemics, etc. Mild to moderate protein-energy or micronutrient deficiencies affect more people at risk for TB, so prevention efforts should target those groups as well. The population attributable risk of TB due to undernutrition may be substantial, especially in populations where both TB

infection and undernutrition are prevalent. Undernourished individuals have an increased likelihood of primary or latent infection progressing to active disease. In populations with substantial latent TB infection, the occurrence of undernutrition may be an important determinant of the incidence of reactivation TB. In many developing countries, the risk of becoming infected with TB is as high as 1%–2% per year of life. The United Nations Food and Agriculture Organization estimates that one billion people face food insecurity. When combined with an estimate of two billion people latently infected with *M. tuberculosis*, even modest decreases in resistance affecting such large numbers of people may result in substantial increases in TB incidence. The potential public health impact of undernutrition on the global incidence of TB was summarized in a US Surgeon General's Report on Nutrition and Health, which emphasized that undernutrition was the leading cause of acquired, correctable immune system dysfunction throughout the world (US Public Health Service, 1988). Population groups at highest risk for poor nutrition are also at high risk for TB; poverty is the common denominator.

### Key points

- To define enteral nutrition support.
- To describe the indications for enteral nutrition.
- To provide a summary of the types of enteral nutrition and disease-specific formulations.
- To provide an overview of the types of access devices and infusions available for the provision of enteral nutrition.
- To list the common complications of enteral nutrition.

### Introduction

Enteral nutrition (EN) (also known as enteral feeding or tube feeding) is a method of providing nutrients directly into the stomach or intestines through a thin flexible tube when a person cannot receive food orally. It is used in patients who have a functional gastrointestinal (GI) tract that can adequately digest and absorb food, but in whom oral intake is inadequate to maintain or restore optimal nutritional status. Inadequate oral intake could arise from conditions such as difficulty swallowing, altered mental status, or loss of appetite. There are several routes of delivery for EN (Tariq et al., 2020). Depending on the individual patient's needs, feeding

tubes can be placed via the mouth or nose and advanced into the stomach (orogastric, nasogastric tube) or duodenum (oroenteric, nasoenteric tube) (Boullata, 2021). Tubes can also be placed percutaneously via the abdominal wall into the stomach (gastrostomy) or the small intestine (jejunostomy). EN is generally considered the safer and most physiologic method of delivering nutritional support and therefore, is preferred over parenteral or intravenous nutrition support (Pironi et al., 2020). In this article, the use of enteral feeding is reviewed.

## Types

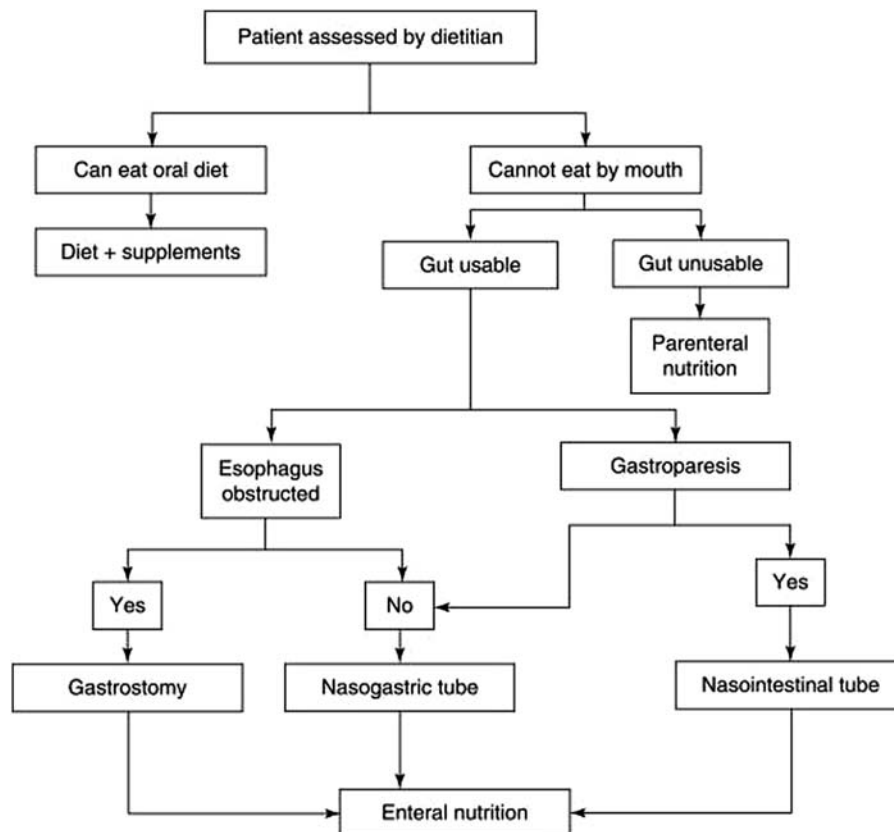

EN requires liquid formulas to be administered through a tube into the GI tract. Once it has been decided that an individual is a candidate for EN, the tube type and appropriate route of access for tube placement can be selected. In general, feedings administered through oral or nasal tubes is indicated for periods lasting less than 2 weeks, whereas, when enteral feeding is required for a longer duration of time, more permanent tubes (gastrostomies and jejunostomies) are utilized (Boullata, 2021). The route of access that is selected for enteral feeding depends on multiple factors:

1. Length of time that enteral feeding will be administered.
2. Degree of risk for aspiration or device displacement.
3. Patency and function of the upper GI tract.
4. Anticipated/planned or history of prior GI surgery with altered upper GI tract anatomy.
5. Nutrition administration issues such as volume and formula viscosity (Fig. 1).

## Access

### Orogastric or nasogastric route

Short-term feeding tubes should be used for patients who are expected to receive EN for less than 2 weeks or for whom a percutaneous feeding tube is not an option (Bischoff et al., 2020). Complications of long-term use can include sinus irritation and infection. Orogastric and Nasogastric tube placement are among the most common types of enteral access and can be used to safely

**Fig. 1** Algorithm for nutritional support. Reproduced from Encyclopedia of Human Nutrition, Enteral Nutrition, Adults 2005.

administer short-term EN ([Pash, 2018](#)). Orogastric and nasogastric tubes pass through mouth and nose, respectively into the stomach and are used when there is adequate GI function. They do not require surgery and can be placed by a nurse or physician at the patient's bedside. Orogastric and nasogastric tubes are made from silicone or polyvinyl, and vary in length from 30 to 43 inches (76–109 cm) with diameters of 8–14 French (~2.5–4.5 mm). Bolus or continuous infusions can be used to administer feedings.

### **Oroenteric, nasoduodenal or nasojejunal route**

Similar to orogastric and nasogastric tubes, although longer, these tubes are also used for short-term feeding (2 weeks) in patients with conditions where the stomach needs to be bypassed for feeding. Such conditions include gastric dysmotility, nausea or vomiting. Feedings via this route require an infusion pump for administration. Tubes can be placed at the bedside or with endoscopic or fluoroscopic guidance ([Pash, 2018](#)). If placed at bedside, abdominal radiographs can help confirm proper placement of the tube.

### **Percutaneous endoscopic gastrostomy (PEG) or percutaneous endoscopic jejunostomy (PEJ)**

PEG tubes are used in patients who will need long-term feedings lasting longer than 4 weeks ([Bechtold et al., 2016](#)). Requiring moderate to deep sedation, the PEG tube can be placed directly into the stomach through the abdominal wall using an endoscope. Some PEG tubes are designed to allow attachment of a jejunal extension to permit feeding or administration of medications either in the stomach or small bowel. Advantages of PEG tubes include options for long-term use, reasonable cost, and relative ease to maintain. PEG tubes should not be used for feeding patients with small bowel obstructions or moderate risk of aspiration. In patients with small bowel obstruction, PEG tubes are sometimes used as palliative measure to decompress (empty) the stomach, but not for feeding. The tube diameters that are commonly used range from 6 to 8 mm (18–24 French). In general, small-diameter tubes should be avoided in patients who require administration of medication to avoid frequent clogging of the tubes ([group SEss et al., 2011](#)).

Percutaneous endoscopic jejunostomy (PEJ) tubes are also used in long-term feeding, in patients who require enteral feedings for more than 4 weeks ([Zhu et al., 2012](#)). PEJs can safely feed patients with gastric resection, gastric dysmotility, and patients with a higher risk for aspiration. The PEJ tube is more difficult to insert, requiring a higher skill level, and can be placed percutaneously under endoscopic guidance or surgically. Additionally, because the tubes are typically smaller in size, they may clog more easily. Overall, PEG and PEJ tubes, if maintained properly, can function well with few complications. It should be noted that both feeding gastrostomy and jejunostomy tubes can be placed under radiographic guidance or surgically when the endoscopic method is not clinically appropriate or a physician with endoscopic expertise is not available.

### **Feeding formulas**

A wide selection of enteral feeding formulas are commercially available. Although the composition of formulas varies widely, almost all formulas are nutritionally complete when administered in the appropriate quantities ([Hassan-Ghomi et al., 2017](#)). Since 1989, the US Food and Drug Administration has used the term “Medical Foods” to define EN products, meaning they must be used under the supervision of a physician. Formulas are selected based on an assessment of the patient's age, medical condition, nutritional status, and gastrointestinal tract functional ability to absorb and digest nutrients. Nutrition related factors that are also incorporated in the formula selection process include ([Tariq et al., 2020](#)): the patient's energy, protein, and fluid requirements ([Boullata, 2021](#)), the patient's need for fiber modifications, and ([Pironi et al., 2020](#)) the patient's food allergies and intolerances such as gluten sensitivity. The types of formulas are classified below:

#### **Feeding formula classification**

1. Polymeric formulas: The most commonly used of the enteral feeding formulas, polymeric formulas can be used orally or through a feeding tube. These formulas contain intact proteins, oligosaccharides, and with fat partly as long-chain triglycerides (LCT) and partly as medium-chain triglycerides (MCT). Lactose and gluten-free, polymeric formulas are also low in osmolality ([Muscaritoli and Pradelli, 2021](#)).
2. Elemental formulas: These formulas are used for patients that have malabsorptive conditions, which may include short gut syndrome, Crohn's disease ([Sharma et al., 2021](#)), or pancreatitis ([Petrov et al., 2009](#)) among other conditions. These formulas require less digestion than polymeric formulas, so they are often used in patients with impaired digestion or absorption. Elemental formulas are amino acid based and are hyperosmolar. Semielemental diets have a mix of peptides and free amino acids, with a lower osmolality than the elemental diets. They are considerably more expensive than standard formulas.
3. Disease-specific formulas: These formulas are designed to provide specific nutrient needs based on the underlying illnesses. They are intended for patients who have specific metabolic requirements in the context of liver, renal and pulmonary diseases, diabetes, and metabolic disorders ([Anand, 2017](#)). They may be enriched with branched-chain amino acids (BCAA), glutamine, omega-3 fatty acids, and arginine whereas others might have a high-fat content. Effectiveness of disease-specific formulas is controversial due to mixed research results.

4. Modular formulas: These formulas are designed for supplemental use. They may add calorie or protein density and can be used to tailor tube feedings to individual nutritional needs as a supplement to commercial enteral formulas. Specific nutrient composition of the patient can be customized. Disadvantages include the risk of bacterial contamination from excessive handling of formulas ([Perry et al., 2015](#)).
5. Blenderized foods: Blenderized enteral preparations are whole foods that are mechanically hydrolyzed into a semi-liquid/liquid form and delivered via feeding tube. Although there has been a surge of consumer enthusiasm for commercially available blenderized formulas, historically, some patients have utilized this method of delivering “homemade” formula. Advantages of this type of enteral support is that it more closely mimics food ingestion in the normal state. Disadvantages include greater risk of enteral tube clogging due to the viscosity.

## Compositions

### Polymeric formulas

These formulas are the standard formulas that are most commonly used for enteral feedings. They contain whole proteins, complex carbohydrates, and mostly LCTs for fat with varying percentage of free water ([Hojsak et al., 2020](#)).

Standard formulas provide 1.0 and 1.2–2.0 kcal/mL of formula. This affects the free water provided per milliliter, as a 1.0 formula provides ~85% free water and a 2.0 formula provides ~70% free water.

On average, carbohydrate percentage ranges from 51% to 57% and formulas may include or omit fiber. Polymeric formulas contain a moderate amount of fat with percentages ranging from 29% to 33% to meet essential fatty acid needs and contain a mix of LCT and MCT, with the majority coming from LCT. Sources of fat are of vegetable origin and include corn, canola, soybean, sunflower, and safflower oils.

Standard formulas contain intact protein including casein, egg albumin, and whey protein among others sources. Protein may have the most variability in standard formulas and is one of the deciding factors of which formula will be chosen. Protein percentages often range from 14% to 19%.

### Elemental or semielemental formulas

These formulas require less digestion than polymeric formulas because they contain protein and carbohydrates that have been partially or fully hydrolyzed and require minimal digestion. They do not contain lactose or fiber and are used for patients that have impaired digestion ([Tiengou et al., 2006](#)).

The protein in these formulas are in the form of peptides, fat as LCT or MCT or a combination of both, and carbohydrates as partially hydrolyzed starch maltodextrins to facilitate digestion and absorption.

Elemental formulas provide 1–1.5 kcal/mL. Fat from plant sources such as corn oil, soybean oil and canola oil provide 1–5% of calories and protein from hydrolyzed casein, whey, or soy protein, among other sources, provides 12–20% of total calories.

## Disease-specific formulas

### Diabetic

Diabetic formulas often contain a mix of soluble and insoluble fibers, with a composition of 31–40% carbohydrate, 42–49% fat, and 17–20% protein content. Lower in carbohydrates and higher in fat, diabetic formulas also contain fiber to help in maintaining glycemic control by slowing gut transit and the absorption of glucose. Consequently the high-fiber and high-fat content of diabetic EN formulations, may cause slow gastric emptying which could be problematic for diabetic patients with gastroparesis ([Vallumsetla et al., 2019](#)). It is important to avoid overfeeding diabetic patients to prevent hyperglycemia. In patients with diabetes that is difficult to manage, the initial use of standard formulas with insulin, as needed for glycemic control, is appropriate with the use of diabetic formulas.

### Renal

Renal formulas are designed to provide optimal nutrition whilst minimizing blood urea nitrogen, maintaining water and electrolyte balance, and reducing accumulation of toxic products in the body. These formulas also contain a lower electrolyte content as well as lower potassium, phosphorus, and magnesium, and are concentrated to reduce volume for fluid restriction ([Rees et al., 2021](#)). They provide 1.8–2 kcal/mL, have less protein at 7–18%, 34–58% carbohydrates, and 35–48% fat.

Renal patients receiving dialysis require an increased amount of protein due to protein loss during dialysis. If a patient has not begun dialysis treatment and a protein restriction is indicated, renal formulas may have too much protein. There are specialized renal formulas available with a very low protein profile, providing only approximately 10% of calories from protein ([Rees et al., 2021](#)).

The need for a decreased electrolyte formula will depend on dialysis and subsequent serum electrolyte levels and urinary output. If a patient is receiving continuous renal replacement therapy, there may be no need for a renal formula. Volume status and electrolyte labs will dictate whether this formula is required. These formulas will meet the recommended dietary intake (RDI) for renal patients if the patient receives on average one liter of enteral formula daily.

### **Hepatic**

The disease-specific formulas for liver disease contain higher proportions (40–50%) of the BCAAs (valine, leucine, and isoleucine) and lower levels of aromatic amino acids (AAAs) (tryptophan, tyrosine, and phenylalanine) to counteract a BCAA:AAA imbalance. Patients with hepatic encephalopathy tend to have decreased levels of BCAAs and increased levels of AAAs. An altered ratio may increase AAA transport through the blood–brain-barrier, causing a “false neurotransmitter effect” that could precipitate encephalopathy (Yirui et al., 2021).

Energy density is slightly increased in these enteral formulas containing 1.5–2 kcal/mL of fluid, allowing for full caloric provision in smaller volumes which can help circumvent delayed gastric emptying and complaints of fullness, while meeting fluid restrictions. Recent clinical trials examining the benefit of BCAAs in these patients have been inconclusive.

### **Pulmonary**

The metabolism of macronutrients produces carbon dioxide, with the breakdown of carbohydrate producing the greatest amount. Based on these concepts, an enteral formula was developed with the intent to minimize carbon dioxide production by containing reduced carbohydrate and higher fat content. The fat content in these formulas comprises 50% and is derived from soy or corn oil versus approximately 30% in standard formulas; protein comprises 7–18%, carbohydrates 34–58%, and 1.8–2 kcal/mL (Yirui et al., 2021).

### **Immune enhancing**

Specialized formulas have been designed to improve immune function in the immunocompromised critically ill patient. Specifically patients admitted with traumatic injuries, burns or requiring major abdominal surgeries and at high risk for development of infections and other ICU and postsurgical complications. These formulas may include arginine, glutamine, omega-3 fatty acids, probiotics, nucleic acids, and fiber and often are peptide-based to help maximize absorption (Ding et al., 2020).

#### **Arginine**

Arginine is not a traditional “essential” amino acid, but becomes a conditionally essential amino acid during periods of stress, including burns and trauma. It is important for T-cell functioning, collagen synthesis and production of growth hormone, prolactin, somatostatin, insulin, and glucagon (Breuillard et al., 2012). Following trauma and surgery, there is a drop in arginine synthesis. Multiple studies have demonstrated a decrease in postoperative infections and hospital length of stay in patients when using an arginine-containing formula in conjunction with other immune-enhancing ingredients, particularly, omega-3 fatty acids.

#### **Glutamine**

Glutamine is the most abundant nonessential amino acid in the body and, like arginine, it becomes a conditionally essential amino acid in states of stress. It is the preferred fuel source for the small bowel enterocyte, which is thought to help maintain its structure and function during times of stress. In septic and malnourished patients, muscle glutamine is depleted, and it is hypothesized that in these patients the availability of glutamine lymphocytes and the gut is reduced, resulting in increased risk of sepsis. Although enteral formulas designed to improve immunity have given mixed results, glutamine supplementation has not been shown to be harmful and has reduced complications in patients with bone marrow transplantation, after surgery, and in those with critical illness and burns (Ma et al., 2018). Studies using parenteral glutamine have generally been more positive than those employing enteral glutamine, although the data are still limited.

#### **Omega-3 fatty acids**

The fatty acids found in fish oil, called eicosapentaenoic (EPA) and docosahexaenoic (DHA), are precursors of prostaglandins and thromboxanes that alter the prothrombotic effects of similar compounds derived from linoleic acid. They promote anti-inflammatory cascade under stress conditions and may be beneficial in patients with acute respiratory distress syndrome and severe acute lung injury.

#### **Probiotics**

The administration of a probiotic with EN may have a role in reducing septic complications in patients with transplantation, major abdominal surgery, and severe trauma. Differences in species of probiotics may have different effects of variable impact on patient outcomes. One report of adverse outcomes in a randomized trial in patients with severe pancreatitis has generated some concern about the broad usage of probiotics in critically ill patients (Xie et al., 2018).

## Modular

These formulas can provide macronutrients and micronutrients separately and can be used to provide additional calories or protein. Typically modular formulas contain only one or two macronutrients and are used to enhance other formulas. Protein modular products are powders and must be mixed with water before administration. Carbohydrates come in the form of glucose polymers and fat as triglycerides of long-chain polyunsaturated or medium-chain fatty acids. Some modular formulas can be combined with liquid vitamins and minerals for individualization for patients with unique needs. Normally, modulars are added to meet nutritional needs in patients who have disproportionate requirements.

## Indications and contradictions

EN is the preferred method of feeding patients who cannot eat, absorb, or use a normal diet in the presence of a useable GI tract. The following are indications for EN ([Bischoff et al., 2020](#); [Saarnio et al., 2014](#)):

1. Critical care patients, including those with trauma and burns, and also after major surgery.
2. Anorexia in patients with malignant disease, sepsis, liver and renal failure, and inflammatory bowel disease (IBD).
3. Upper GI obstruction or ulceration of the pharynx, esophagus, stomach, and duodenum may prevent the ingestion of normal food. Examples of these conditions are cancer, central nervous system disorders, and stenosis following ulceration.
4. Short bowel and severe malabsorption: In controlled trials, enteral diets are not better absorbed than normal food. Therefore, the presence of a short bowel *per se* is not an indication for enteral feeding. However, some patients with severe malabsorption may benefit from the use of elemental diets.
5. IBD: In IBD, enteral feeding is used in the following situations:
  - i. Profound anorexia preventing the ingestion of a normal diet.
  - ii. Abdominal discomfort due to partial bowel obstruction or intestinal inflammation.
  - iii. In Crohn's disease, controlled trials have suggested that enteral feeding can induce a remission comparable to that seen with steroids.
6. Dementia: Patients unable to feed themselves because of mental changes.
7. Fistulas of the distal small bowel or colon.
8. Nausea or vomiting. Patients who suffer from nausea or vomiting due to a gastric disorder can be fed into the jejunum.
9. Recurrent aspiration. Formula should be delivered through a jejunostomy.
10. High nutritional requirements that are not being met by oral intake (mostly applying to patients with burn injury who require increased nutrient intake).
11. Cancers of the head and neck.
12. Dysphagia associated with disabling neurologic conditions including amyotrophic lateral sclerosis (ALS) and multiple sclerosis (MS).
13. Neoplasms: Advanced primary and secondary intracranial tumors.
14. Coma.
15. Severe head injuries.
16. Cerebrovascular accidents.
17. Transition from parenteral nutrition.

The following are contradictions for EN ([Bischoff et al., 2020](#)):

1. Mechanical obstruction that cannot be bypassed.
2. Intractable vomiting or diarrhea refractory to medical management.
3. Extreme malabsorption.
4. Short bowel syndrome (100 cm small bowel remaining).
5. Paralytic ileus.
6. High output fistula.
7. Peritonitis.
8. Mild GI bleeding.
9. Hemodynamic instability.
10. Inability to access GI tract.
11. Imminently terminal disease.
12. Aggressive interventions not desired.

## Methods of infusion

Enteral feedings can be administered by continuous drip, bolus feedings, or intermittent infusions. The method selected depends on the stability of the patient, gastric emptying rate, caloric and protein needs, patient mobility and central access route ([Deane and Chapman, 2021](#)).

Continuous drip – Tube feedings are administered for 24 h with minimal interruptions. An advantage of this type of feeding is that it may be tolerated well in critically ill patients. A disadvantage is that an infusion pump is usually required, to ensure accuracy of volume is delivered. Initiation typically begins at 25–50 mL/h and is increased by 50 mL/h every 4–8 h (McNelly et al., 2020).

Intermittent infusions – Larger volumes (240–480 mL) are administered 3–6 times per day infused over longer periods (30–60 min). This type of feeding may result in more adequate volumes being administered. Another advantage is that it allows some time off of feedings and the feedings are usually given by a gravity drip over period of 30 min to 1 h. The gravity feeding system is less expensive than a pump. A disadvantage may be intolerance to the higher rates of administration. Initiation of feeding begins with 1/2–1 can per feeding increased by 1/2 can per feeding per day until the goal is met (McNelly et al., 2020).

Bolus feed – Bolus feeding is the preferred method because it allows the patient more freedom, is easier to use, takes less time, and is cheaper. The bolus method does not require a pump and can be given in larger volumes (240–480 mL) administered 3–6 times per day over short periods of time (10–15 min). Rapid installation of feeding into GI tract can be given by syringe or funnel. The majority of patients tolerate this method. To avoid aspiration the bolus feeding must be given when the patient is sitting or reclining at 45°. Initiation of feeding begins with 1/2–1 can per feeding and can be increased by 1/2 can per feeding per day until the goal is met (Hubbard et al., 2019).

EN is viewed as the safest and most efficacious method to support nutritional status in patients who are unable to eat orally. When administered properly, enteral feeding is associated with improved clinical outcomes and reduced infectious complications and is the preferred form of nutritional support.

## Potential challenges

Enteral nutrition has several favorable indications, although there are several challenges that may limit its use. For individuals who consume enteral nutrition by mouth, its long-term use may be limited by poor palatability. On a broader scale, there would be concerns of availability and costs, particularly for specialty formulas and supplies, in several regions of the world. Additional contemporary challenges include supply chain issues brought on by the coronavirus disease 19 (COVID-19) pandemic and increased costs related to inflation. These practical barriers would need to be considered when recommending the use of enteral nutrition therapy.

## Summary/conclusions

Enteral nutrition provides essential nutrients and can be a potentially lifesaving therapy for individuals who are unable to sustain caloric intake per oral route. Although minor complications may result from this form of therapy, if patients are chosen appropriately and close attention to components of the enteral formulation are taken, these patients would benefit greatly. Management of enteral nutrition is most effective when done through a multidisciplinary approach, utilizing the expertise of physicians, pharmacists, dietitians, nurses, case managers, and social workers.

The prevalence of nutritional problems in developed societies is a cause of growing concern. At one end of the nutritional spectrum, the obesity 'epidemic' is spreading at an alarming rate. At the other end of the spectrum, protein–energy malnutrition and nutrient deficiencies are also common, especially in the elderly and in those with disease. **Table 1** shows the frequency of specific vitamin deficiencies and underweight (body mass index  $<20 \text{ kg m}^{-2}$ ) in people aged 65 years or older, residing in the United Kingdom. Complimentary information on protein–energy status can be obtained by considering simple criteria, such as those used by the 'Malnutrition Universal Screening Tool' (MUST) (**Figure 1**). This tool, which depends on weight loss and body mass index (and an acute disease effect, which does not normally apply to community patients), has been used to help estimate the distribution of malnutrition in the United Kingdom. Approximately 2% of individuals with medium and high risk of malnutrition are in hospital, 5% in care homes, and the remaining 93% in the community, of which 2–3% live in sheltered housing. Similar distributions are thought to exist in other countries although in low-income countries, the proportion of malnourished people in institutions is expected to be even less than in more developed countries. National surveys in various countries have demonstrated that malnutrition is common on admission to institutions, for example, approximately 28% among those admitted to hospitals in the United Kingdom (MUST criteria). This means that national strategies to combat malnutrition must consider its origins and causes in the community and attempt to prevent them at an early stage. However, because there are so many people who are discharged from the hospital in a malnourished state, often more malnourished than on admission, there should be an opportunity to identify them before discharge from the hospital and initiate treatment there, which can continue in the community. The same principles apply to individuals attending hospital outpatient clinics. The use of a consistent framework for identifying and treating malnutrition within

**Table 1** Proportion of subjects aged 65 years or older with selected vitamin deficiencies and body mass index  $<20 \text{ kg m}^{-2}$

Free living (%)		Institutions (%) <sup>a</sup>		Criteria	
Vitamin deficiencies					
Folate deficiency	29	35		Red blood cell concentration	<345 mmol l <sup>-1</sup>
Severe deficiency	8	16			<230 mmol l <sup>-1</sup>
Thiamine deficiency	9	14		Erythrocyte transketolase activation coefficient (ratio)	>1.25
Vitamin B <sub>12</sub> deficiency	6	9		Plasma concentration	<118 pmol l <sup>-1</sup>
Vitamin D deficiency	1–2	1–5			<12 mmol l <sup>-1</sup>
Vitamin C deficiency	14	40		Plasma concentration	<11 mmol l <sup>-1</sup>
Severe deficiency	5	16			<5 mmol l <sup>-1</sup>
Underweight	3	16		Body mass index	<20 kg m <sup>-2</sup>

and between care settings is important in facilitating continuity of care during the patient journey from one setting to another. Unlike other screening tools, MUST was developed for this specific purpose and adopted nationally in a number of countries with this in mind.

This article focuses on the treatment of malnutrition (rather than obesity) in the home setting. This treatment includes dietary counseling and fortification, oral nutritional supplementation (mixed macro- and micronutrient supplements), and artificial nutritional support (enteral tube feeding (ETF) and parenteral nutrition (PN)). The simplest and most commonly used treatment involves oral nutritional support, which is considered before home enteral tube feeding (HETF) and home parenteral nutrition (HPN).

## Oral Nutritional Support

### Dietary Counseling and Fortification

Dietary counseling, usually provided by a dietitian, is an integral part of oral nutritional support. It includes advice on dietary fortification, which is often the first-line treatment of malnutrition in the home and other care settings. Counseling may involve advice on eating patterns (e.g., eating certain types of snacks at particular times of day) or addition of energy- and protein-rich food ingredients (e.g., cream, milk, oil, butter, sugar, and skimmed milk powder) to meals. Commercial energy- and protein-containing supplements can also be used to improve intake without substantially altering the intake from normal food and drink. The use of nutritionally fortified food snacks as part of the diet may improve both the intake and the status of micronutrients. However, the success of these dietary strategies is limited in patients with severe anorexia, those living in poverty and due to other social factors, and in those with inadequate motivation. Thus, patients may find it difficult to purchase, manipulate, or prepare their meals.

Financial or other forms of social support, such as help with shopping, cooking (or provision of 'meals on wheels'), and help with eating, may do much to improve intake in some individuals. Although dietary counseling, with or without dietary fortification, is widely used in clinical practice, there is little research supporting its clinical efficacy in patients at risk of malnutrition in developed countries.

### Oral Nutritional Supplements

Mixed macro- and micronutrient liquid sip feeds and other oral nutritional supplements (bars, powders, and puddings) are widely used in the treatment of malnutrition in the community setting. A systematic review of 78 randomized controlled trials (RCTs) (including 44 RCTs from the community setting) suggests that oral nutritional supplements can improve energy and nutrient intakes, improve body weight (or attenuate weight loss), and improve a number of functional and clinical outcomes in various patient groups (Table 2). Meta-analyses of RCTs involving hospital and community settings suggest significantly lower mortality and complications in favor of oral nutritional supplements (typically  $1.05\text{--}2.5\text{ MJ day}^{-1}$  (250–600 kcal) daily). The evidence base in care homes is more limited, but a recent systematic review suggests that oral nutritional supplements can produce clinical or functional benefits, such as improved healing of pressure ulcers and fewer infections.

For some patients, nutrition via the oral route is either unable to meet the nutritional requirements (e.g., patients with a poor appetite) or contraindicated (e.g., a cerebrovascular accident patient with aspiration and intestinal failure). For such patients, HETF and HPN may be required, although the treatment is usually initiated in hospital.

### Artificial Nutritional Support: Home Parenteral Nutrition and Home Enteral Tube Feeding

Patients suffering from chronic conditions often prefer to be treated in the familiar surroundings of their home rather than in hospital. When the treatment involves sophisticated techniques, it is essential that either the patient or the caregiver is adequately trained to distinguish between problems that can be easily remedied at home and those that need expert advice and treatment in hospital. With the increasing pressure for hospital beds and the increasing cost of hospital care, many forms of treatment that were previously restricted to the hospital environment have extended to the community, including renal dialysis, cytotoxic drug therapy, HETF, and HPN. HETF has grown rapidly so that its prevalence in several developed countries is now several times greater than in hospital. In contrast, PN is still practiced less commonly outside hospital than in hospital and is likely to remain so in the foreseeable future. Both forms of treatment have led to the development of professional teams specializing in nutritional support in both the hospital and the community. These teams deal with problems ranging from simple day-to-day management issues to difficult ethical problems, such as concerning withholding or withdrawing nutritional support.

### Origins and Development

The first report of HPN appeared in 1970 in North America and in the late 1970s in Europe. The number of people receiving HPN has increased considerably since then but remains substantially lower than that for HETF (Figure 2).

**Table 2** Summary of significant functional and clinical outcome improvements following oral nutritional supplementation in community patients from randomized controlled trials

<i>Patient group</i>	<i>Functional/clinical outcome</i>
Chronic obstructive pulmonary disease	Respiratory muscle function Hand grip strength Walking distances
Elderly	Reduced number of falls Increased activities of daily living Muscle power
HIV/AIDS	Cognitive function
Liver disease	Lower incidence of severe infections Lower frequency of hospitalization
Malignancy	Immunological benefits
Osteoarthritis	Increased activities of daily living <sup>a</sup> Improved osteoarthritis index <sup>a</sup>

<sup>a</sup>Nutritional supplement also containing immunoglobulin G (90 mg).

**Figure 2** Estimated growth in point prevalence (amount of feeding taking place at a given point in time) in home enteral tube feeding (HETF) and home parenteral nutrition (HPN) in the United Kingdom.

HETF is a much older technique than HPN, with the first reports appearing centuries ago. Accurate information on the number of people receiving HETF is difficult to obtain, because HETF tends to be initiated from many centers, and centralized reporting and record keeping in most countries are not fully established. There has been rapid growth in HETF attributable to developments in tube technology (flexible fine-bore tubes) and endoscopic procedures for placement of gastrostomy tubes (facilitating easier initiation and management of long-term feeding), as well as the development of home care services provided by commercial enteral feeding companies. In many developed countries, there is considerably more ETF taking place in the community than in the hospital. In the United Kingdom, there has been a steady growth in the number of people receiving HETF, and in 2007, it was estimated that there were approximately 30 000 people receiving this treatment at a given point in time (point prevalence). As with HPN, HETF is less common in Europe than in North America and is practiced substantially less in Eastern Europe, India, and China than in high-income industrialized countries in the West.

In addition to differences in the prevalence of HETF and HPN between countries, there are also differences in practice of HETF and HPN within countries, which are unlikely to be due to chance. For example, the point prevalence of HPN in the United Kingdom varied from 3.7 to 22.5 patients per million of the population in 2006. This is likely to be due to availability of expertise and support staff, resources to fund treatment, reimbursement policies, and attitudes/policies toward the use of artificial nutrition.

The wide variations in the prevalence of home artificial feeding throughout the world are related to health-care economies. There is a relationship between expenditure on health care, as a percentage of gross domestic product (GDP), and the incidence of HPN and HETF. In India, Pakistan, and Africa, where spending on health is low, home artificial nutrition is less common. In Western Europe, where health care accounts for a greater proportion of GDP, home artificial nutritional support is more common. In the United States, with an even greater expenditure on health care, the prevalence of HPN and HETF is higher than anywhere else in the world.

## Indications

### Home Enteral Tube Feeding

The indications for HETF are different for adults and children. In adults, the most common indications are neurological disorders of swallowing resulting from cerebrovascular accidents, Parkinson disease, and obstructive lesions of the upper gastrointestinal tract. These mainly affect older individuals so that in various countries approximately half of HETF is administered to individuals aged 65 years or older. In children, HETF is usually used in conditions that lead to failure to thrive, such as cerebral palsy, cystic fibrosis, congenital malformation, and metabolic disorders. As with HPN, one of the main differences in the indications for HETF between countries concerns malignant disease. In North America, ~40% of people receiving HETF have been reported to have malignant disease and more than 50% in Italy. In the United Kingdom, as in many other countries, the proportion of patients receiving HETF with cancer has steadily grown over time. The main malignancies in the United Kingdom are head and neck tumors and malignancies of the upper gastrointestinal tract (mainly obstructive oropharyngeal and esophageal cancers). The age distribution of people receiving HETF is influenced by the indications. Because disorders of swallowing (due to strokes, motor neurone disease, and other neurological conditions) and cancer of the upper gastrointestinal tract tend to occur in older age groups, adults receiving HETF tend to be elderly (with more than 65% of those in the United Kingdom being older than 60 years, 43% older than 70 years, and 19% older than 80 years in 2007). In recent years, there has been a trend to provide HETF to an older and more disabled population. Recent surveys in the United Kingdom suggest that approximately one-third of patients are house or bed bound and nearly half require total help to manage their tube feeding. Because the majority of these patients with high levels of disability are at home (spending <1% of their time in hospital), there are resource implications associated with the provision of health care by the under-recognized and underappreciated voluntary caregivers. Approximately 20% of those receiving HETF are children, and many children who started HETF because of cerebral palsy or congenital handicap continue tube feeding into adulthood.

## Home Parenteral Nutrition

The main indications for HPN are Crohn disease, mesenteric vascular ischemia, motility disorders, surgical complications (e.g., enterocutaneous fistulae), and malignant disease. Patients receiving HPN are usually younger than those who receive HETF, although there is an overlap. There are also differences between the practices of HPN in different countries. One of the main differences concerns malignant disease. In the United States, 40–50% of patients receiving HPN have been reported to have cancer, and similar, if not higher, percentages have been reported in some European countries, such as Italy. Early reports from the United Kingdom and Denmark suggested that only a small proportion of HPN (~5%) involved patients with cancer, although this has increased with time. For example, in the United Kingdom, it has steadily increased so that by 2007 more than 15% of patients starting HPN had cancer. There has also been an increase in age (due at least partly to the increasing use of HPN in patients with cancer and mesenteric vascular ischemia) so that by 2007 nearly one-third of all patients receiving HPN in the United Kingdom were older than 60 years.

## Organization

The organization and management of HETF and HPN have evolved over time. For example, delivery of feeds and equipment to the first patients who received HPN or HETF was undertaken by the hospitals that initiated the treatment. As the number of patients receiving such treatment increased, commercial organizations have established an organizational infrastructure for delivering feed and ancillary equipment through a national and international network. Some companies employ doctors, nurses, and other staff so that they can provide most of the care, although this practice varies from country to country. In many countries, there is joint care between commercial companies and the national health-care systems.

HETF is initiated by many centers or hospitals, and some patients are followed up as outpatients. However, it is impractical to follow up many severely disabled patients in hospital, because they are house bound. Patients receiving HPN are often managed by centers with expertise in nutritional problems (e.g., in France, Denmark, and the United Kingdom). It has been suggested that all patients on HPN should be managed at such centers, but traveling to distant centers may require considerable time, effort, and expense. It is possible for patients to be managed more locally, especially if they are uncomplicated. It remains to be demonstrated if locally managed patients have better satisfaction and similar outcomes as those managed by larger centers. Of course, it is possible to have a system that combines local care and more distant specialist care when required.

Funding arrangements also vary. In several countries, home nutritional support is either totally or partially funded by the National Health Service, but payment may also be provided by private insurance and individual patients. Sometimes, confusion exists about the funding arrangements even in the same country, and this may limit and delay the use of HETF or HPN.

Patient organizations have developed in some countries, such as Patients on Intravenous and Nasogastric Nutrition Therapy (PINNT) in the United Kingdom. This organization provides support and information to people on home feeding, and it contributes to all levels of the operation of the British Association for Parenteral and Enteral Nutrition (BAPEN), through which it influences policy and decision making. Furthermore, as the feeding equipment for use at home was found to be impractical because it was originally designed for hospital use, PINNT has redesigned the equipment specifically for home use.

## Standards of Care

Several surveys have identified inadequacies in training, support, and follow-up of patients receiving HETF and HPN. Specific problems include lack of written instructions about how to manage simple problems that may arise during feeding, lack of telephone contacts for use in emergency, lack of confidence, and inadequacy of equipment for home use. Such surveys have also highlighted the importance of a multidisciplinary approach and the need to undertake home visits to assess the status of severely disabled patients who cannot easily attend a hospital. Pressure on hospital beds has meant that some patients are discharged home before they have been adequately trained, and the care of such patients is sometimes passed on to other health-care workers who have little experience of home nutritional support. Because HPN is relatively uncommon in the population, general practitioners may have never encountered patients on this form of therapy and are therefore poorly equipped to manage them. The needs of patients may change during the course of their treatment; therefore, there is a need to establish an organizational infrastructure for continuity of care for HETF and HPN over time and from one health-care setting to another. Many hospitals do not have a nutrition team or policies that embrace the needs of people receiving artificial nutrition at home.

A series of guidelines for the management of artificial nutrition in the community have been developed by BAPEN ([Tables 3 and 4](#)). The guidelines cover aspects of training before discharge from hospital (although training can take place at home) and the support required from trained specialist staff once the patient is at home. A national and local organizational structure for delivering the support would aid the process.

## Monitoring

The basic elements of monitoring are similar for both HETF and HPN. They include an assessment of the activity of the underlying disease, the nutritional and metabolic state of the patient, and complications associated with nutritional support ([Table 5](#)). The clinical history alerts the attending health professional to the general well-being, as well as the likelihood of specific problems,

**Table 3** Standards of practice for home enteral tube feeding (HETF)

<i>Structure</i>	<i>Process</i>	<i>Outcome</i>
There will be a training program for the health-care professionals involved in the care of patients receiving HETF.	Discharge planning will be performed only by professionals who have the necessary experience or who have undertaken a course of training in the topic.	The patient has confidence in the hospital team planning his or her discharge.
There will be a model of care for patients needing HETF.	The members of the multidisciplinary team will be involved in writing the 'mission statement' on which the model is based.	The patient will know the benefits, aims, and objectives of the HETF team.
There will be a relaxed, quiet area suitable for private discussion.	There will be a caring and compassionate atmosphere with adequate time for discussion.	The patient will feel able to express his or her fears and expectations.
The discharge planning documentation will include sections on domestic, family, and social circumstances.	The nutrition team will evaluate, with the patient and family, how HETF will alter his or her way of life.	The patient will believe that the feeding system can be integrated into an acceptable way of life.
There will be written patient/carer learning goals of HETF.	A designated nurse or dietitian will be responsible for teaching the patient according to his or her individual capacity for learning.	The patient will be able to demonstrate the necessary skills and achieve all the learning goals.
There will be an instruction manual for HETF.	Information and procedures will be regularly updated in order to reflect developments and innovations in tube feeding, access, nutrients, and delivery systems.	The patient will perform therapy based on current practice.
A relative, friend, or appropriately trained health-care professional will be available to deliver therapy if the patient is unable to do so.	The nurse/dietitian will help the patient identify the most appropriate carer. A community nurse will be given the opportunity to visit the patient in hospital and observe therapy before the patient is discharged.	The patient has confidence that safe care will be available at home.
Access to the gastrointestinal tract will be achieved by a tube suitable for long-term use.	The patient, nurse, and doctor will choose the most appropriate tube and access site.	The patient will use a feeding tube that is acceptable and accessible.
There will be a policy for sharing care with the patient's general practitioner (GP).	The GP will be contacted and a shared care protocol agreed.	The patient will know the responsibility of each health-care professional.
Written information describing HETF will be available for the GP.	The hospital team will provide the GP with the information before the patient is discharged, together with the discharge date and on-call telephone numbers.	The patient will have confidence in his or her GP's knowledge of HETF.
There will be written procedures for the management of feeding tubes.	The nurse/dietitian will adapt the procedures according to the patient's physical skills and domestic circumstances.	The patient's daily life will not be restricted by prolonged inappropriate procedures.
There will be a written prescription for the enteral feed (and other prescribable items).	The patient's GP will be contacted and advised on how to prescribe the feed.	The patient will have the enteral feed available at home on the day of discharge.
There will be an on-call system for providing expert advice to the patient by telephone day and night.	The nurse/dietitian/doctor will explain the system to the patient and identify the professions involved.	The patient will know the names and telephone numbers of health-care professionals to contact in case of emergency by day or night.
Information will be available describing how the nutrient solutions and supplies will be provided following discharge.	The nurse/dietitian will explain the ordering system and discuss storage, depending on the patient's home circumstances.	The patient will know how to obtain supplies and store them, and dispose of unwanted material.
There will be a postdischarge monitoring protocol, established by the nutrition team.	Monitoring will be performed by a designated health professional as defined by the protocol.	The patient will know what the follow-up arrangements are.

such as dehydration, electrolyte imbalance (e.g., diarrhea), local infection (e.g., local redness and swelling near the catheter exit site or peristomal area), blocked tubes and catheters, and so on. Catheter-related sepsis is an important complication of PN, and aspiration pneumonia is an important complication of ETF. The patient/caregiver should have written instructions about basic procedures, which aim to reduce complication rates, and how to deal with simple problems and to recognize those that they cannot readily deal with. Specialist advice should be available 24 h a day. The frequency of complications depends at least partly on the support provided by health professionals.

Dietary intake should be monitored, especially in patients whose clinical status is changing. Appropriate dietary advice may facilitate return to normal oral feeding in some patients. In those with a swallowing difficulty, it may be necessary to assess whether swallowing has improved, with input from speech and language therapists, so that unnecessary HETF is not continued when full oral feeding becomes possible. Studies in the United Kingdom suggest that 15% of patients receiving HETF can revert to full oral feeding after 1 year. Blood tests should be carried out at intervals to check for metabolic stability and specific nutrient deficiencies (e.g., vitamins, minerals, and trace elements) and toxicities. The frequency with which tests are carried out depends on

**Table 4** Standards of practice for home parenteral nutrition (HPN)

<i>Structure</i>	<i>Process</i>	<i>Outcome</i>
There will be a training program for health-care professionals involved in the care of patients receiving HPN.	Discharge planning will be performed only by professionals who have the necessary experience or who have undertaken a course of training in the topic.	The patient has confidence in the hospital team planning his or her discharge.
There will be a mode of care for patients needing home intravenous nutrition.	All members of the multidisciplinary team will be involved in writing the 'mission statement' on which the model is based.	The patient will know the beliefs, aims, and objectives of the HPN Care Team.
There will be relaxed, quiet area suitable for private discussion.	There will be a caring and compassionate atmosphere with adequate time for discussion.	The patient will feel able to express his or her fears and expectations.
The discharge planning documentation will include sections on domestic, family, and social circumstances.	The nutrition team will evaluate with the patient and family how the HPN will alter his or her way of life.	The patient will believe that the feeding system can be integrated into an acceptable way of life.
There will be written patient/carer learning goals for HPN.	A designated nurse will be responsible for teaching the patient according to his or her capacity for learning.	The patient/carer will be able to demonstrate the necessary skills and achieve all the individual learning goals.
There will be an instruction manual for HPN.	Information and procedures will be regularly updated to reflect developments and innovations in venous access, nutrient solutions, and delivery systems.	The patient will perform therapy based on current practice.
A relative, friend, or appropriate health-care professional will be available to deliver therapy if the patient is unable to do so (e.g., parent or guardian of a child).	The health-care professional will help the patient to identify the most appropriate carer. The district nurse will be given the opportunity to visit the patient in hospital and observe therapy before the patient is discharged.	The patient has confidence that safe care will be available at home.
Venous access will be achieved by a central venous catheter suitable for long-term use.	The patient, nurse, and doctor will choose the most appropriate catheter and access site.	The patient will use a central venous catheter that is acceptable and accessible.
There will be written procedures for the management of central venous catheters.	The nurse will adapt the procedures according to the patient's physical skills and domestic circumstances.	The patient's daily life will not be restricted by prolonged inappropriate procedures.
There will be a policy for sharing care with the patient's general practitioner (GP).	The GP will be contacted and a shared care protocol agreed.	The patient will know the responsibility of each health-care professional.
Written information describing HPN will be available for the GP.	The hospital teams will provide the GP with the information before the patient is discharged, together with the discharge date, and on-call telephone numbers.	The patient will have confidence in his or her GP's knowledge of HPN.
There will be a written prescription for the nutrition solutions (and other prescribable items).	The patient's GP will be contacted and advised on how to prescribe the feed.	The patient will have the feeding solution available at home on the day of discharge.
There will be a list of the required equipment, e.g., refrigerator, infusion pump, syringes, sterile gloves, and telephone.	Before discharge, the patient's home health authority will be provided with the list and asked to arrange supply by making local arrangements or establishing a contract with a commercial supplier.	The patient will have all the necessary supplies at home on the day of discharge.
There will be an on-call system for providing expert advice to the patient by telephone day and night.	The nurse will explain the system to the patient and identify the professions involved.	The patient/carer will know the names and telephone numbers to contact in case of emergency by day or night.
Information will be available describing how the nutrient solutions and supplies will be provided following discharge.	The nurse will explain the chosen supply system and discuss storage depending on the patient's home circumstances.	The patient will know how to obtain supplies, store them, and dispose of unwanted material.
There will be a postdischarge monitoring protocol, established by the nutrition team.	Monitoring will be supervised by the nutrition team.	The patient will know the date of the first outpatient visit and what monitoring will be performed.

the patient (e.g., whether the patient is receiving HETF or HPN), the duration of feeding, the extent of oral intake, and disease activity.

### Outcome

The most important predictor of the outcome in patients receiving home artificial nutritional support (enteral or parenteral) is the underlying disease. Therefore, mortality statistics strongly depend on the initial indications. Nevertheless, a few conclusions can be

**Table 5** Some complications associated with parenteral nutrition and enteral tube feeding

	<i>Parenteral nutrition</i>	<i>Enteral tube feeding</i>
Mechanical	Catheter malposition Insertion trauma (e.g., pneumothorax, brachial plexus injury, cardiac arrhythmia)  Catheter blockage, kinking, or occlusion Catheter embolus Air embolus Clot embolus (from catheter tip) Lack of access site	Tube malposition (e.g., into lung) Insertion trauma; perforation of esophagus, stomach, and small bowel; peritonitis and peristomal leakage and inflammation Tube blockage, e.g., kinking or occlusion
Feed/flow	Nutrient overload (e.g., hyperglycemia, infusional hyperlipidemia)	Diarrhea or constipation
Infections	Catheter-related sepsis Infected feed/administration set	Bloated abdomen/cramps Regurgitation/aspiration of feed Infected feed administration set
Metabolic	Fluid and electrolyte disturbances Hyperglycemia Deficiency syndromes, e.g., trace elements and vitamins Nutrient overload (see above) and toxicity (e.g., some trace elements)	Infection around gastrostomy Fluid and electrolyte disturbances Deficiency syndromes (rate with standard feeds given to typical patients) Hyper/hypoglycemia
Organ tissue dysfunction	Abnormal liver function, intestinal atrophy, metabolic bone disease	Mainly disease-related, abnormal liver function
Psychological	Anxiety, depression, disturbance in self-image, social isolation	Aspiration pneumonia Anxiety, depression, disturbance in self-image, social isolation
Financial	Economic issues vary from center to center and country to country	Economic issues vary from center to center and country to country

made. First, the complications associated with artificial nutritional support vary but are reported to be responsible for less than 3–5% of deaths. Second, the outcome is dependent not only on the type of disease but also on the stage of the disease (e.g., patients with advanced HIV who start HPN are only expected to survive a few months, whereas patients with less-advanced disease are expected to survive longer). Third, the outcome of patients receiving HPN and HETF for a variety of conditions is available from the British Artificial Nutrition Survey (**Table 6**). For patients on HPN, overall mortality at 1 year is 13%, with 19% returning to oral feeding and the majority continuing with HPN. Patients with Crohn disease often have a good prognosis (with 2.5% mortality and 38% returning to oral feeding within 1 year). For patients on HETF, typically an older patient group, mortality is higher overall (36% at 1 year) and the outcome varies according to age and condition. The outcome data for two common conditions in adults and children receiving HETF are shown in **Table 6**.

**Table 6** Twelve-month outcomes for patients receiving home enteral tube feeding (HETF) and home parenteral nutrition (HPN)

<i>Continuing</i>		<i>Discontinuing</i>			
<i>Continues (%)</i>		<i>In hospital (%)</i>	<i>Transferred to oral (%)</i>	<i>Withdrawn/refused (%)</i>	<i>Died (%)</i>
HETF					
All adults ( <i>n</i> =33 955)	47.1	0.6	15.3	0.8	36.3
Cerebrovascular accident ( <i>n</i> =11 621)	51.1	0.4	9.6	0.5	38.3
Esophageal cancer ( <i>n</i> =2406)	23.8	1.0	24.9	1.3	49
All children ( <i>n</i> =6946)	70.6	0.5	20.8	0.7	7.3
Cerebral palsy ( <i>n</i> =977)	87.9	0.3	5.6	0.2	5.9
Congenital handicap ( <i>n</i> =607)	85.5	1	7.1	0	6.4
HPN					
All adults ( <i>n</i> =538)	63.6	1.1	19.3	3.2	12.8
All children ( <i>n</i> =79)	64.6	1.3	19.0	0	15.2

Assessments of quality of life, using EuroQol, suggest that the majority of patients receiving HETF and HPN have some problems (moderate or extreme) with mobility, self-care, usual activities, pain/discomfort, and anxiety/depression (five EuroQol dimensions). Mean quality-of-life scores (0, 'worst imaginable health state'; 100, 'best imaginable health state') in adults receiving HPN ( $53 \pm 18$ ) are higher than those for adults receiving HETF ( $42 \pm 27$ ), but both are considerably lower than the scores obtained from the general population, even when adjusting for age. For HETF patients, quality-of-life scores have been found to be similar for those living at home and those in nursing care.

### **Intestinal Transplantation**

In some patients with irreversible intestinal failure, intestinal transplantation can be considered as an alternative to long-term PN. The first intestinal transplantation in humans was undertaken in the early 1960s. Limitations in technical expertise and immunosuppressive therapy meant that none of the original patients survived beyond 76 days. From 1985 to 1990, a series of 20 patients were given cyclosporine, but only two patients were able to resume normal nutrition and most of the grafts failed. The development of new immunosuppressive agents, particularly tacrolimus, resulted in renewed interest in intestinal transplantation. Furthermore, since 1990, there has been greater standardization of patient selection, operative procedures, and postoperative care mainly in centers specializing in intestinal transplantation. The total international experience is still limited with less than 2000 patients reported in 2009 (1031 children and 733 adults). Some of the transplants were isolated intestinal grafts, others were intestinal–liver transplants, and the remaining few were multivisceral transplants that included the small intestine. Better graft and patient survival rates have been reported more recently, especially in the more experienced centers. For example, in North America, the 1-year graft survival rate for intestinal and multiorgan transplants increased from 52% in 1997 to 75% in 2005. The associated patient survival increased from 57% to 87%, but in more recent years centers with greater experience have reported a 1-year survival rate more than 90%. Early referral appears to be associated with better outcome. One study that assessed the quality of life reported an improvement after transplantation and less dependency on narcotics.

It appears that intestinal transplantation has become a realistic lifesaving option for some people who cannot be maintained on HPN. However, it is not yet the treatment of choice in patients who can be successfully maintained on HPN without noteworthy complications. Nor is it the treatment of choice in patients who are likely to deteriorate rapidly from other causes, such as aggressive multisystem disease, or likely to improve so that they can resume oral nutrition (e.g., patients with healing intestinal fistula or those with short bowel syndrome, in which benefits from intestinal adaptation may continue for up to 1–3 years). A better understanding of the immune response to the transplanted intestine and better immunosuppressive therapy, surgical techniques, and postoperative management are required. Appropriate selection and referral of patients to specialist centers are also important criteria that affect clinical outcomes.

### **Ethical Issues**

The provision of nutritional support to people who are chronically sick, who have rapidly progressive disabling diseases, or who are terminally ill raises many ethical questions. Opinions about withholding or withdrawing artificial nutritional support vary from country to country because of different clinical, religious, and social beliefs and differences in national economies, some of which cannot support large-scale expensive long-term treatments. Thus, there is little home artificial nutrition in countries with poor economies. In more developed economies, the types of patients being fed may also vary considerably. For example, parenteral and enteral nutrition in patients with cancer are used more frequently in Italy than in the United Kingdom, suggesting that clinical attitudes to this type of nutritional support vary. The sanctity of human life is a belief that is strongly held by many religions, but when these conflict with medical judgment, public policies normally override personal religious beliefs. A common ethical controversy concerns the need to provide food and fluid to prolong life in severely disabled patients, such as those with severe neurological problems (e.g., cerebrovascular accident) or those approaching the ends of their lives. Although health professionals have a duty to prolong life, it seems inappropriate to prolong suffering. There has been controversy as to whether the provision of food and fluid by a feeding tube placed in the stomach or small intestine should be regarded as an essential part of care or medical treatment. The highest legal authorities in countries such as the United States and England have ruled that this is medical treatment. From an ethical perspective, there is no difference between withholding and withdrawing treatment, but in practice it is often more difficult to withdraw treatment once it has begun than to not initiate it. Joint discussions at the outset between mentally capable patients, family members, and health-care workers can do much to prevent future ethical dilemmas.

### **Conclusions**

Home nutritional support, including both oral and artificial (enteral and parenteral) methods of feeding, is an important modality of treatment that is being used for an increasing number of people with disease and disability who are managed in the community. The identification of individuals who are at increased risk of malnutrition and who may benefit from additional nutritional support is a vital first step, which can be undertaken using a validated screening tool (such as MUST; [Figure 1](#)). Oral nutritional support, including liquid multinutrient supplements, is of value in improving the nutritional intake and functional well-being of patients with malnutrition in the community. Without ETF, many patients with persistent swallowing difficulties would die; similarly,

without PN, many patients with persistent intestinal failure would not survive. Although these forms of home therapy can be life-saving, they may restrict normal lifestyle and lead to life-threatening complications. These complications can be prevented or treated by establishing an adequate organizational infrastructure. This should include education and training of both health workers and patients/caregivers as well as a management structure that allows all patients to be followed up and, when necessary, admitting patients to the hospital for more intensive investigations and therapy. Ethical difficulties about withholding or withdrawing artificial nutritional support are likely to continue and to vary with time and from country to country. Intestinal transplantation is becoming a potentially realistic option for a few patients with irreversible intestinal failure who cannot be adequately maintained on long-term PN, but it has not yet become part of routine clinical care in the same way as renal transplantation has become routine in patients with renal failure, who would otherwise receive a lifelong treatment with dialysis.

### Glossary

**Central venous lines or catheters (CVL)** Indwelling intravenous catheters, either silastic or polyurethane, placed with the tip in the superior vena cava to allow long-term provision of hypertonic dextrose solutions.

**Enteral nutrition (EN)** Nutrition through the gastrointestinal tract, either orally or through tube feedings.

**Essential fatty acids** Fatty acids which cannot be synthesized by humans and which are required in the diet, including linoleic, arachadonic, linolenic acids, docosahexanoic acid (DHA), and eicosapentanoic acid (EPA).

**Macronutrients** Carbohydrates, fats, or proteins required in large quantities in the diet, mainly for energy.

**Micronutrients** Vitamins or minerals essential in small quantities for normal physiologic functions but unable to be synthesized by humans and required in the diet.

**Multivitamin infusion (MVI)** A solution containing recommended requirements of essential vitamins and minerals.

**Parenteral nutrition (PN)** Nutrition delivered intravenously, not enterally.

### History and Introduction

From its beginnings in the late 1960s, PN has expanded rapidly to become available for many patients in the USA and in Europe, but its expense and complications preclude wide availability in many countries. Before the availability of parenteral nutrition, as many as 30–50% of hospitalized patients had unrecognized malnutrition from chronic diseases and would remain for weeks without adequate nutrition to maintain weight or lean body mass, making them susceptible to infections, poor wound healing, and other complications. Surprisingly, it has been difficult to demonstrate substantial reductions in morbidity or mortality with parenteral nutrition except in moderately or severely malnourished patients or those with long-term intestinal failure. It is difficult to estimate the exact impact, but an American registry, the Oley Foundation, enumerated 10 035 Medicare beneficiaries on home parenteral nutrition in 1992, giving a rough estimate of 40 000 patients on home parenteral nutrition in the USA. Approximately 15–20% of these patients were children.

One of the first attempts at parenteral nutrition was carried out by Sir Christopher Wren in 1656. He infused ale, opium, and beer intravenously into animals. Parenteral nutrition that we are most familiar with for patient support has been available for approximately 40 years. The research carried out by Dr Stanley Dudrick and others allowed the support of the first pediatric patient on intravenous nutrition. The provision of intravenous nutrition was challenged by the development of several factors, before its completed use in patient support, including catheter access, sterility of solutions, and the optimal form of each macro- and micronutrient.

## Indications for PN

There are many circumstances where PN is necessary and life sustaining. The indications for use have not changed dramatically over the years since the development of PN. Congenital malformation of the intestine, specifically small bowel atresia, was the diagnosis in the first cases PN was used in this age group. Congenital malformations of the gastrointestinal tract continue to be one of the leading reasons for its use as well as acquired diseases including necrotizing enterocolitis. Other indications include severe malabsorption, intestinal dysmotility, other congenital defects, and those with hematology–oncology diseases (Table 1).

## Dextrose

The primary source of energy during intravenous therapy is usually provided by dextrose (D-glucose). This is especially true in infants and children when higher energy requirements often necessitate glucose infusion rates of up to  $15 \text{ mg kg}^{-1} \text{ min}^{-1}$  or more. Not until 1945 did Zimmerman report the first attempt at infusing intravenous solutions through a catheter placed in the superior vena cava. Experiments performed by Dudrick in Beagle puppies advanced the glucose infusion solutions closer to what is utilized currently with hypertonic dextrose solutions. In current practice hypertonic solutions are infused through a catheter with its tip centrally located in the superior or inferior vena cava. It continues to be the major energy component of intravenous support.

Initial doses of glucose should be approximately  $5\text{--}7 \text{ mg carbohydrate kg}^{-1} \text{ min}^{-1}$  with incremental increases of  $2\text{--}5 \text{ mg kg}^{-1} \text{ min}^{-1}$ . Recommended maximum glucose infusion rate is  $12\text{--}14 \text{ mg carbohydrate kg}^{-1} \text{ min}^{-1}$  for infants. Frequent monitoring of blood glucose and urine for glucosuria are important parameters to follow to assess tolerance to increasing glucose infusion rates. It is important to avoid excessive carbohydrate intake to minimize complications from potential hyperglycemia with subsequent osmotic diuresis. In addition, hepatic steatosis can occur with overfeeding. Hyperglycemia may ensue even without excess carbohydrate infusion in certain clinical situations, such as sepsis, renal failure, and certain medication including corticosteroids. Glucose infusion rates should be decreased if hyperglycemia ensues; however, it may still be necessary to add insulin to control blood glucose to provide adequate support.

## Protein

Another vital macronutrient that needs to be provided is protein. Initial experiments from the 1930s were done with plasma as the protein source, where investigators achieved positive nitrogen balance. In the early 1900s research began into the development of protein hydrolysates and crystalline amino acids.

Vitrum, a company in Sweden, produced the first commercially available casein hydrolysate solution. It was developed by Arvid Wretling who hydrolyzed casein enzymatically then dialyzed the mixture to remove large polypeptides. Wretling went on to modify it further and eventually replaced the hydrolysates in the 1970s.

The development of amino acid solutions specifically for infants took place in the early 1980s. These solutions provided conditionally required amino acids for the immature organ systems of premature infants and newborns. They were formulated based on the postprandial plasma amino acid levels of breast fed infants. Special amino acid solutions for renal or liver failure are also available, which have increased amounts of branched chain amino acids. Studies with the solutions for liver failure have shown they may be beneficial in adult patients with encephalopathy. Glutamine is a much-researched amino acid that could not initially be added to PN solutions due to shelf instability in liquid form. If it is added as a dipeptide it has been found to be more stable. Not all studies have shown clear benefit to its addition in patients for gut adaptation or prevention of bacterial translocation.

Recommendations for initiation and advancement of protein is  $1\text{--}2 \text{ g kg}^{-1} \text{ day}^{-1}$  and advance by  $1 \text{ g kg}^{-1} \text{ day}^{-1}$  to goal (see Table 1 for protein requirements). Initiation at the higher dose is more common practice for premature infants based on more recent studies that have demonstrated good tolerance and optimal metabolic profiles with earlier and higher protein within the first

**Table 1** Conditions commonly requiring parenteral nutrition

Conditions	Examples/Comments
Surgical gastrointestinal disorders	Gastroschisis, omphalocele, tracheoesophageal fistula, intestinal atresias, meconium ileus, peritonitis, malrotation and volvulus, diaphragmatic hernia, prolonged postoperative ileus, Hirschsprung's disease, and intestinal dysmotility
Short bowel syndrome	
Prematurity	
Congenital heart disease	
Pancreatitis	
Gastrointestinal fistulas	
Bone marrow transplantation	
Acute intestinal disease	Antibiotic colitis, necrotizing enterocolitis, inflammatory bowel disease, chronic or secretory diarrhea
Hypermetabolic states	Burns, multiple trauma
Chronic idiopathic intestinal pseudoobstruction

24–48 h of life. Blood–urea nitrogen is monitored for tolerance to amino acid infusion. Prealbumin levels are helpful to monitor adequacy of protein intake.

### Lipid Emulsions

Glucose was the only nonprotein source of energy until intravenous lipids were developed between 1920 and the 1960s. The first emulsion available for clinical use was Lipomul, a cottonseed oil based formulation. Because there were many adverse effects from its use it was withdrawn from clinical use in the mid 1960s. Wretling, after extensive testing, developed Intralipid, a soybean-based emulsion, in 1961. It was well tolerated and is the most familiar intravenous fat emulsion currently available. It is available in 10%, 20%, and 30% solutions. The advantage of 20% and 30% over the 10% is the lower ratio of phospholipids to triglyceride, which minimizes the increase in plasma lipoprotein X levels. Lipid emulsions provide essential fatty acids, in addition to providing a concentrated energy source, particularly advantageous for patients requiring fluid restriction. Trials are underway for the use of emulsions that contain a blend of long chain fats with medium chain fats and those with fish oil blends. Also structured fat emulsions are being studied for clinical use. These specialized emulsions may have advantages in patients with liver disease and those with sepsis.

Lipid emulsions are usually initiated at  $1 \text{ g kg}^{-1} \text{ day}^{-1}$  and advanced to  $2\text{--}3 \text{ g kg}^{-1} \text{ day}^{-1}$  or 30–50% of total energy. More recent practice has been to limit to  $1 \text{ g fat kg}^{-1} \text{ day}^{-1}$  for patients who are anticipated to need PN for greater than two weeks as a hepato-protective measure. In addition, recent investigational use of a fish oil based emulsion has been found to be efficacious in reducing serum bilirubin levels in patients who have required long-term PN support. The mechanism is unclear, however a couple of proposed theories is less productions of inflammatory thromboxanes, prostaglandins, and leukotrienes and the absence of phytosterols. Serum TG levels are monitored for tolerance. Hypertriglyceridemia may occur in situations of stress, sepsis, and renal and liver insufficiency/failure. In addition, a number of medications can cause hypertriglyceridemia. In these situations a reduction in fat infusion is warranted, usually by infusing over 18–20 h instead of 24 h.

A minimum of 3–5% of total energy requirements is necessary to meet essential fatty acid requirements.

### Micronutrients

To provide complete nutritional support, micronutrients, electrolytes, and minerals also need to be included in the parenteral solution. Addition of adequate amounts of calcium and phosphate together in one solution may be particularly problematic without precipitation occurring. Solubility guidelines are available accounting for the brand and percentage of amino acids and other salts, which impact the pH of the solution. Compounding guidelines for the order of addition of calcium and phosphorus, amounts of other additives and the temperature of the solution are other factors to optimize the solubility. Filters in the delivery system also help in minimizing the risk of occlusion of the catheter if a solution should precipitate, especially with so-called ‘3-in-1’ solutions, where lipids are mixed with the glucose/amino acid solution. Further studies have evaluated the stability of the variety of nutrient components in these solutions.

Before the availability of vitamins and minerals, plasma levels of micronutrients fell rapidly while infusing only macronutrients. The only commercial preparation initially available was a trace element solution that had iron and iodide. The first commercial preparation of multivitamins for intravenous use was in the 1960s and lacked folic acid, vitamin B<sub>12</sub> and K, and biotin. It also had very high concentrations of vitamins A and D and thiamin. Because of the variability in practice, there was increased risk of toxicity to vitamins A and D and deficiencies of other vitamins. Recommendations were made for intravenous pediatric and adult intravenous preparations in 1975. By 1978 there was a commercial multivitamin preparation that met these recommendations. Current preparations available contain all vitamins for which there are Dietary Reference Intake values, with the exception of choline. A Food and Drug Administration mandate now requires the addition of vitamin K to all preparations. Differences between the pediatric and adult forms of multivitamins (MVI) include amounts of B vitamins and vitamin D (see Table 4). There is currently no multivitamin preparation designed specifically for the premature infant. Dosing recommendations of Pediatric MVI for this group are based on weight (1/3 vial for <500 g; 2/3 vial for 500–1000 g and full vial for over 1000 g).

Trace element deficiencies have been noted in patients receiving long-term parenteral-nutrition support. The first case of chromium depletion was reported in 1977; selenium deficiency in 1979 and molybdenum in 1981. There are now many trace element solutions available with a variety of combinations of minerals and range from solutions appropriate to meet the needs of premature infants through the adult population. They are also available as single elements to tailor a solution as necessary. Contamination of trace elements can occur in parenteral solutions. Aluminum is one element that has been under recent scrutiny with the Food and Drug Administration mandate to minimize the amount patients receive. It was initially found to be in high concentrations in the casein hydrolysates and continues to be found in high concentrations in a variety of intravenous preparations. Over time aluminum can deposit in the bone, interfering with bone calcium uptake and deposition in the brain may impair neurological development.

Parenteral iron supplementation is controversial due to its potential risk of anaphylaxis and possible effect of providing a nutrient source for bacteria during sepsis episodes. However, if the enteral route is contraindicated for prolonged course or malabsorption and blood transfusions are not being given, consideration for iron dextran supplementation is warranted (Table 2).

**Table 2** Pediatric parenteral nutritional requirements

	<2000 g	0–4 years	5–18 years
Energy (kcal kg <sup>-1</sup> d <sup>-1</sup> )	100	80–90	40–70

## Metabolic Complications

### Liver Disease

Although PN may be life-sustaining, long-term use may be detrimental to the liver. The severity of injury ranges from reversible transaminase elevations to severe cholestasis and cirrhosis, especially in infants with short bowel syndrome. It is still not clear whether this is due mainly to a nutrient deficiency, toxicity, or some physiological process missing because of the lack of enteral feeding. Prevention and treatment strategies continue to include minimizing or preventing episodes of sepsis, providing enteral feedings, moderating energy intake to provide adequate for growth, but not to overfeed, cycling parenteral nutrition infusion, reduction of copper and manganese, use of an amino acid solution developed for infants, treatment/prophylaxis for bacterial overgrowth and the use of ursodeoxycholic acid. Our common practice has been to reduce lipid exposure to 1 g kg<sup>-1</sup> day<sup>-1</sup> among infants likely to require long-term PN. Intravenous lipid emulsions are a rich source of linoleic acid, an omega-6 polyunsaturated fatty acid, and may enhance production of the proinflammatory cytokines. Increased leukotriene B<sub>4</sub> synthesis by the hepatic macrophages will draw additional polymorphonuclear leukocytes that intensify the inflammatory response to endotoxin by release of reactive oxygen species.

### Bone Disease

The development of osteopenia is another complication that is common with long-term parenteral-nutrition support. The reasons are multifactorial and include relative immobility, inability to provide adequate calcium and phosphorus with solubility limitations, and hypercalciuria. It has also been suggested that the dose of vitamin D in the multivitamin preparation may contribute to bone disease. Excessive vitamin D may suppress parathyroid hormone secretion and directly cause bone resorption. Although aluminum is still present in some intravenous solutions, including calcium gluconate, vitamins, trace elements, the amounts are much less than those seen with the casein hydrolysates and are not believed to be a significant contributor toward the development of metabolic bone disease. Prevention and treatment strategies include maximizing calcium and phosphorus in parenteral-nutrition solutions, especially in growing children, providing enteral supplementation of these minerals as feasible and provide weight bearing physical therapy as possible.

### Micronutrient Deficiency and Excess

If a patient is entirely parenteral-nutrition dependent, it is known that certain micronutrients need to be provided. Some parenteral-nutrition solutions require the addition of carnitine and selenium (if not provided in multi trace element solutions) and iron dextran (if the patient is not receiving transfusions or tolerating enteral iron). All serum levels should be monitored on a monthly basis or every 6–12 months if in the long-term phase of support. There may be other micronutrients not yet identified that may be deficient in the purified PN solution, hence another reason to begin enteral feedings as soon as feasible. Monitoring for excess losses is also important. For example, with increased stool/ostomy losses, the patient may require increased zinc in the parenteral-nutrition solution (Table 3).

Excess micronutrients can be caused by contamination, such as the case with aluminum, discussed earlier, or because of clearance. Copper and manganese can accumulate and become directly hepatotoxic because both elements depend on the biliary pathway for excretion. Therefore, in the presence of cholestasis, there will be increased intrahepatic accumulation. Manganese has also been reported to deposit in brain tissue, so copper and manganese levels should be monitored routinely.

**Table 3** Suggested monitoring schedule for inpatients receiving parenteral nutrition

<sup>a</sup>Weekly or more often as necessitated by clinical course.

### Catheter Complications

Complications with central venous catheters most frequently include obstructions, infections, and occasional leakage and perforation. Although parenteral nutrition can be temporarily provided through peripheral intravenous catheters, the high osmolarity of intravenous glucose-electrolyte solutions often cause phlebitis and loss of access. Therefore, long-term access has required placement of a central venous catheter, placed via the internal or external jugular vein or a subclavian vein. There is also increased placement of peripherally inserted catheters by a team of specially trained staff and by an interventional radiologist. Tip position in the superior vena cava or SVC-right atrial junction should be verified radiographically to reduce complications from venous thrombosis or rare perforations. Central placement allows rapid dilution of hypertonic solutions in a large-diameter vein to minimize obstruction or thrombosis. Catheters for central venous access have been made of polyvinyl chloride, polyurethane, and silastic, often with a Teflon cuff to anchor the catheter subcutaneously. However, formation of a fibrin sheath is common, often with a biofilm, which may harbor infectious organisms and prevent penetration of antibiotics. Central catheter obstructions can often be visualized by ultrasound or inserting radioopaque dye in the catheter. A thrombus can often be lysed with installation of a small bolus of tissue plasminogen activator. Long-term anticoagulation with coumadin, low-dose coumadin, or low molecular weight heparin has been advocated by some to avoid repeated catheter obstruction, venous thrombosis, superior vena cava obstruction, and potential pulmonary emboli.

Obstructions caused by precipitation of calcium-phosphate salts or medications may be susceptible to installation of a small amount of dilute acid, and those due to fatty material might be dissolved with dilute ethanol. For long-term home parenteral use, some patients have preferred use of implantable ports, which can be accessed through the skin daily with a special needle. Recently, peripherally inserted central catheters (PICC) have been used for longer periods up to a month or more without requiring a surgical procedure.

### Infections

Patients who require parenteral nutrition are often predisposed to infectious complications. The catheter hub is often the entry site with skin flora such as *Staphylococcus epidermidis*, *Staphylococcus aureus*, or *Candida* being the most common organisms, along with Gram negative enteric bacteria possibly from bacterial translocation. Antibiotic treatment through the central line is often successful without replacement of the catheter, using antibiotic combinations such as vancomycin and gentamicin, or with periodic indwelling infusions of a 70% ethanol lock (Table 4).

## Summary

Advancements in the technology, production and manufacturing of intravenous solutions have progressed over the past 40 years. Along with improvement in the solutions available for dextrose, amino acids and lipid emulsions, there has also been progress with the delivery systems, catheters, and improved sterile techniques for line and skin care to reduce overall complications.

Ongoing research and product development in areas associated with long-term PN support is vital for future patient management to be able to continue to provide optimal support with minimal risk for those patients for whom PN is life sustaining.

### Key points

- Childhood obesity has increased worldwide in epidemic proportions
- Children with obesity are at high risk for multiple comorbidities previously considered to be “adult” diseases.
- Lifestyle modifications including dietary changes aimed at decreasing total energy intake, increasing physical activity and decreasing sedentary time are crucial for weight management.
- Pharmacotherapy may have a role in the treatment of pediatric obesity, but evidence is limited.

- Bariatric surgery is effective in achieving weight loss and improving comorbidities in adolescents with severe obesity.
- Primary prevention and family-based lifestyle interventions for weight loss are recommended.

## Introduction

Childhood obesity has emerged as one of the most important medical and public health problems. The prevalence is unacceptably high, and the rate of increase in severe obesity continues to climb. The etiology of the disease is multifactorial and complex, assuming an interaction among genetic, biological and environmental factors. Childhood obesity is associated with several comorbidities that affect physical and mental health. The serious comorbidities associated with childhood obesity needs effective treatment options. A stratified approach to treatment is recommended. Epidemiology, clinical features, complications, management and prevention of childhood obesity are reviewed.

## Epidemiology

The prevalence of obesity has progressively increased during the past 30 years in all developed countries including the United States and most European countries, with these changes being more apparent in Mediterranean countries (with a prevalence between 20% and 40%) than in northern countries. Childhood obesity is also increasing in prevalence among the less developed countries.

In 2013–14, the worldwide number of children and adolescents (2–19 years of age) with obesity was estimated to be 110 million; this number has doubled since 1980. 22.8% of preschool children (age, 2–5 years), 34.2% of school-aged children (age, 6–11 years), and 34.5% of adolescents (age, 12–19 years) had overweight or obesity and 8.4% of preschool children (age, 2–5 years), 17.7% of school-aged children (age, 6–11 years), and 20.5% of adolescents (age, 12–19 years) had obesity (Ogden et al., 2014). Analyses of trends in overweight and obesity for both boys and girls (11–15 years of age) in North America and countries in Europe from 2002 to 2010 evidenced stabilization in overweight prevalence, but overall rates of overweight in many countries are high. In Spain, recent cross-sectional studies reports a joint prevalence of overweight and obesity of 44% in the population aged between 3 and 24 years (Aranceta-Bartrina et al., 2020).

Unfortunately, a high percentage of children with obesity carry their adiposity into adulthood. The tracking of obesity into adulthood is affected by age of the child, severity of obesity, and presence of parental obesity. Older age is associated with greater persistence of obesity into adulthood, and therefore most adolescents with obesity will continue to have obesity during the adult life (Kumar and Kelly, 2017).

## Assessment of overweight and obesity in childhood

The term obesity refers to body fat excess. Because of the unavailability and high cost of techniques that directly measure body fat, body mass index (BMI), derived from the body weight and height, has emerged as the accepted clinical standard measure of overweight and obesity for children 2 years and older. Body mass index is calculated by dividing the body weight in kilograms by the

height in meters squared. In general, BMI provides a reasonable estimate of adiposity in the healthy pediatric population. However, BMI may overestimate fatness in children who are short or who have relatively high muscle mass and may underestimate adiposity in a substantial proportion of children, such as those with reduced muscle mass due to low levels of physical activity. BMI should be viewed as a surrogate measure of adiposity and its strengths and limitations should be considered when used in clinical and research settings.

For children younger than 2 years, weight for length is the accepted measure of overweight and obesity. Because of normal growth and development during childhood, the absolute level of BMI in children vary with age and sex. In children and adolescents, standardized values of BMI as a function of age and sex for their reference population should be used. This has generated intense controversy regarding the establishment of “cutoff points” and the reference populations that should be used ([Martos-Moreno et al., 2014](#)). In terms of use for epidemiological studies and international comparisons, the International Obesity Task Force reference standards should be used. They have defined childhood overweight and obesity considering those cut-off points equivalent to BMI, 25 and 30 kg m<sup>2</sup>, in adults, for every sex and age value until 18 years ([Martos-Moreno et al., 2014](#)).

In clinical settings and according to local standards, the following BMI-based definitions are used for overweight and obesity for children and adolescents between 2 and 20 years of age:

- Overweight: BMI at or greater than 85th to less than 95th percentile for age and sex
- Obesity: BMI at or greater than 95th percentile for age and sex
- Severe obesity: BMI at or greater than 120% of the 95th percentile, or BMI at or above 35 kg/m<sup>2</sup> (whichever is lower). This corresponds to approximately the 99th percentile, or BMI z score at or above 2.3 above the mean ([Kumar and Kelly, 2017](#)).

There is also no consensus regarding the definition of morbid obesity in children and adolescents. Some authors suggest a BMI >3 SDS or 200% of the ideal body weight for height as possible cutoff points or BMI at or above 35 kg/m<sup>2</sup>.

The measurement of total body fat and its distribution is important because different adipose depots have distinct roles in the development of metabolic complications. However, access to techniques for directly measuring body fat content is limited in routine clinical practice. Indirect estimations of visceral adipose content can be made by performing waist measurements and by using international references that are classified according to ethnic group ([Martos-Moreno et al., 2014](#)).

Although consensus has not been reached regarding cutoff points for normal waist circumference measurements in childhood, high waist circumference seems to predispose to developing obesity-related comorbidities.

## Genetics factors

Heritable factors appear to be responsible for 30%–50% of the variation in adiposity. Large-scale genome-wide association studies (GWAS) that test the association of millions of common genetic variants without a prior hypothesis about their presumed role have identified >300 genetic loci for obesity traits. For example, variants in the primer intron of the gene coding for the fat mass and obesity-associated protein (FTO) have been associated with an elevation in BMI equivalent to approximately +0.4 kg/m<sup>2</sup> for each risk allele. This can explain, at least in part, the large heritable influences observed in obesity ([González-Muniesa et al., 2017](#)).

## Risk factors for childhood obesity

Childhood obesity is the consequence of an interaction among a complex set of factors that are related to, genetics, environment and ecological such as the family, school and community.

### Critical periods in the development of obesity

The first thousand days, from conception until the end of the second year of life, mark the first critical period in the development of obesity. Body mass index (BMI) usually increases until 7 months of age, when it reaches a temporary maximum (the so-called infant BMI peak). Between 5 and 7 years of age, the BMI reaches a minimum in children with adequate growth and development, after which it starts to rise again (that is, the adiposity rebound). During adolescence, BMI changes are substantially associated with puberty. Body weight at these critical periods is associated with later body composition. High maternal BMI, high gestational weight gain, rapid postnatal growth, early adiposity rebound, and early pubertal development are risk factors for childhood obesity ([Poskitt, 2013](#); [Rolland-Cachera et al., 2006](#)).

### Early feeding

Although there is no consistent evidence that breast feeding protects children from later obesity, the process of breast feeding may have positive influences on mothers' attitudes to child nurturing.

### Familial obesity

Hereditary factors have a strong effect on the development of obesity in children. There is evidence that obesity in one parent increases the risk of obesity in the child by 2- to 3-fold, and up to 15-fold if both parents have obesity (Poskitt, 2013).

### Socioeconomic and environmental deprivation

Deprived environments and families in which child care and nurture are deficient show the greatest predisposition to childhood obesity.

### Diet and dietary change

Eating behaviors in children and parental feeding styles have been shown to be associated with a high risk of childhood obesity. Several factors in the current “obesogenic” environment have resulted in increased energy consumption, such as increasing use of sugar sweetened beverages, sweet snacks, fast foods containing excess fat, large portion sizes, and high glycemic foods. Consumption of sugar-sweetened beverages (including fruit juices) has been postulated as an important contributor to the development of obesity in children. Consumption of fast food has also been purported to contribute to the increasing prevalence of obesity (Morano et al., 2010).

### Physical activity

The changes contributing to increased energy intake have been accompanied by factors predisposing to decreased energy expenditure such as reduced levels of physical activity and increasing time spent in sedentary activities such as use of television, computers, phones, and tablets. The amount of time spent watching television and the presence of a television in a child’s bedroom have been shown to be directly related to the prevalence of obesity in children and adolescents. This association can be explained by several potential mechanisms including displacement of physical activity and adverse effects on the quality and quantity of foods consumed. The use of electronic devices has also been associated with obesity during childhood (Seral-Cortés et al., 2021).

### Sleep

There is increasing evidence for an association between shortened sleep duration and/or poor sleep quality and obesity (Kumar and Kelly, 2017). Sleep may also have an association with decreased insulin sensitivity, independent of the association with adiposity.

### Clinical approaches to childhood obesity

Obesity in children has diverse causes, which can result in radically different pathologic entities. Although polygenic obesity is by far the most commonly observed, several single gene defects and syndromes associated with obesity have been identified. However, these account for less than 1% of childhood obesity (Table 1) (Martos-Moreno et al., 2014).

**Table 1** Clinical description of the main monogenic forms of obesity.

MC4R mutations	Severe early-onset obesity with hyperphagia Binge eating Tall stature and advanced bone age during childhood
Leptin deficiency	Severe early-onset obesity with low circulating leptin concentrations Hypogonadotrophic hypogonadism reversible after recombinant leptin administration
Leptin receptor mutations	Severe early-onset obesity Hypogonadotrophic hypogonadism, low TRH and GnRH concentrations
POMC deficiency	Severe early-onset obesity Low plasma cortisol concentrations Common impairment of skin and hair pigmentation
PCSK1 deficiency	Severe early-onset obesity Increased POMC and proinsulin and low insulin and cortisol concentrations Hypogonadism possible

GnRH, gonadotrophin-releasing hormone; MC4R, melanocortin receptor number 4; PCSK1, proprotein convertase type subtilisin/kexin 1; POMC, proopiomelanocortin; TRH, thyrotropin-releasing hormone.

### Common or polygenic obesity

Exogenous or “common” obesity is the most frequent form of obesity in children and adolescents. Hypercaloric nutrition and reduced physical activity coexist resulting in the accumulation of excess energy in the form of adipose tissue. Familial obesity is frequent. Unfortunately, this is also influenced by the individual’s socioeconomic situation. Prepubertal children with obesity are relatively tall for age. Advanced growth may be associated with advanced maturity of bones (advanced bone age) and early onset of puberty.

### Monogenic obesity

Monogenic obesity results from an alteration in a single gene and represents a minority of the total population of children with obesity. A common feature of these patients is severe early-onset obesity. The forms of monogenic obesity known to date can be classified into the following 3 categories:

1. *Genes involved in the adipocyte-hypothalamic system (leptin/melanocortin axis).* The most important genes included in this category are those coding for leptin (LEP), leptin receptor (LEPR), proopiomelanocortin (POMC), proconvertase 1 (PCSK1), proconvertase 2 (PCSK2), melanocortin receptor 4 (MC4R), and peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ). The most common single gene defect currently identified in children with obesity is mutations in the melanocortin 4 receptor. The clinical features of patients affected by these types of monogenic obesities are summarized in [Table 1](#) ([Kumar and Kelly, 2017](#); [Martos-Moreno et al., 2014](#)).

**Table 2** Secondary causes of childhood obesity.

ROHHAD, rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation; ROHHADNET, rapid-onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation with neural crest tumors.

2. *Genes associated with hypothalamic development.* Anomalies in at least 3 genes associated with hypothalamic development, including single-minded homolog 1 (SIM1), brain derived neurotrophic factor (BDNF), and neurotrophic tyrosine receptor kinase 2 (NTRK2), have been shown to correspond to obesity. To date, the reported number of cases involving these genes is small (Martos-Moreno et al., 2014).
3. *Obesity associated with syndromes.* There are a number of syndromes in which obesity is among the characteristic feature (Table 2). Children with genetic syndromes associated with obesity typically have early-onset obesity and characteristic features on physical examination, such as short stature, dysmorphic features, developmental delay, or intellectual disability (mental retardation), retinal changes, or deafness (Martos-Moreno et al., 2014).

Prader-Willi syndrome is the most common syndrome associated with obesity, and children have hypotonia and feeding difficulties during infancy (often with failure to thrive), followed by hyperphagia and subsequent development of obesity.

### Secondary obesity

Obesity can also be the consequence of a disease or its treatment. Endocrine diseases (Cushing syndrome) and pathologic processes or therapeutic protocols that affect the pituitary hypothalamic axis can promote weight gain. Likewise, some pharmacologic treatments, especially those with psychoactive ingredients, can result in obesity. The most frequent causes of secondary obesity are shown in Table 2.

### Complications of childhood obesity

Childhood obesity is associated with relevant comorbidities affecting almost every system in the body including, the cardiovascular, endocrine, pulmonary, gastrointestinal, and musculoskeletal systems. Many of the comorbidities encountered in youth with obesity, including type 2 diabetes mellitus (T2DM), dyslipidemia, obstructive sleep apnea (OSA), and steatohepatitis, used to be previously considered "adult" diseases.

#### Cardiometabolic and cardiovascular system

Children with obesity are at an increased risk of hyperinsulinemia, insulin resistance, prediabetes, and subsequently T2DM. The prevalence of prediabetes and T2DM varies with severity of obesity, race, ethnicity, and age of the child. Those who present with T2DM during adolescence appear to have more rapid deterioration of glycemic control and progression of diabetes-related complications such as microalbuminuria, dyslipidemia, and hypertension as compared with those who present it later in life. Children with obesity also have a high prevalence of other cardiometabolic risk factors including elevated blood pressure, low levels of high-density lipoprotein cholesterol, and elevated levels of triglycerides. Echocardiographic findings include left ventricular hypertrophy, increased left ventricular and left atrial diameter, and systolic and diastolic dysfunction (Kumar and Kelly, 2017; Styne et al., 2017).

#### Endocrine system

Obesity may be associated with early onset of sexual maturation in girls and with accelerated linear growth and advanced skeletal maturation. Adolescent girls are also at high risk of developing hyperandrogenism and polycystic ovary syndrome. Manifestations of polycystic ovary syndrome includes menstrual irregularities, acne, and hirsutism (Kumar and Kelly, 2017; Styne et al., 2017).

#### Respiratory system

Children with obesity have a considerably higher prevalence of OSA than do normal-weight children. The prevalence and severity of OSA increase with increasing BMI. Children with severe obesity may also have alveolar hypoventilation associated with severe oxygen desaturation. Childhood obesity has also been shown to be associated with asthma (Kumar and Kelly, 2017; Poskitt, 2013; Styne et al., 2017).

#### Gastrointestinal system

Nonalcoholic fatty liver disease (NAFLD) in children is strongly associated with obesity. The spectrum of NAFLD can range from simple steatosis to progressive steatohepatitis and cirrhosis. Nonalcoholic fatty liver disease is now the most common cause of liver disease in children. Although most patients with NAFLD are asymptomatic, laboratory abnormalities include elevations in levels of liver transaminases (alanine aminotransferase and aspartate aminotransferase), alkaline phosphatase, and gamma-glutamyl transpeptidase (Styne et al., 2017).

### Musculoskeletal involvement

Childhood obesity increases the risk of various musculoskeletal problems including impairment in mobility, increased prevalence of fractures, lower extremity joint pain, and lower extremity malalignment. Obesity is also a risk factor for unilateral or bilateral slipped capital femoral epiphysis and for tibia vara (Kumar and Kelly, 2017; Styne et al., 2017).

### Psychosocial aspects

Psychosocial consequences of childhood obesity are common and include poor self-esteem, anxiety, depression, and decreased health-related quality of life. Children with obesity are more likely to become victims of bullying and discrimination (Kumar and Kelly, 2017).

### Dermatologic alterations

Acanthosis nigricans, a marker of insulin resistance, is a common finding in children with obesity. Other skin abnormalities include intertrigo, hidradenitis suppurativa, furunculosis, and stretch marks (Kumar and Kelly, 2017).

### Neurological aspects

Childhood obesity is associated with a higher risk of idiopathic intracranial hypertension (pseudotumor cerebri). Clinical symptoms include headache, vomiting, retro-ocular eye pain, and visual loss (Styne et al., 2017).

### Long-term risks

Children whose obesity persists into adulthood have a significantly increased risk of T2DM, hypertension, dyslipidemia, and carotid-artery atherosclerosis than do adults who never had obesity. Higher BMI during childhood has also been associated with an increased risk of fatal and nonfatal cardiovascular events during adulthood in both men and women, though this may be partially mediated by the association between childhood obesity and adult obesity (Kumar and Kelly, 2017; Poskitt, 2013; Styne et al., 2017).

## Clinical evaluation of children with obesity

The clinical evaluation of children with obesity is directed at identifying the cause of obesity and its obesity-related comorbidities. The evaluation includes a complete history and physical examination.

Dietary history should consist of details of eating habits including frequency, content, and location of meals and snacks as well as intake of energy dense foods such as fruit juices and others. Physical activity assessment should include details of time spent in unstructured play, organized sports, school recess, and physical education as well as screen time (television, video games, mobile phones, and tablets). Medical history should include details about medications that may cause weight gain such as glucocorticoids, antipsychotic drugs, and antiepileptic drugs. A developmental history is important as developmental delay may point toward a chromosomal or genetic cause for obesity. A complete review of systems is helpful in determining an underlying etiology for the weight gain, such as Cushing syndrome or hypothalamic tumor.

The review of symptoms is also helpful in screening for obesity-related comorbidities such as OSA. Family history of obesity and obesity-related comorbidities is a predictor of persistence of obesity into adulthood. Performing a comprehensive psychosocial screening including collecting details related to depression, peer relationships, and disordered eating habits is crucial.

Physical examination should include measurement of height and assessment for dysmorphic features suggestive of a chromosomal or monogenic cause and for Cushingoid features.

Most children with exogenous obesity are tall, whereas children with genetic and endocrine causes of obesity tend to have short stature. Acceleration of bone age in respect to chronologic age, but adequate for the child's height, is frequent in obesity.

Blood pressure should be measured with an appropriate sized cuff (Styne et al., 2017).

There is lack of standardization and consensus on when to screen and the types of laboratory screening tests to perform in children with obesity. Most experts recommend that children with overweight, that is, BMI between the 85th and 95th percentiles, who are free from risk factors should have measurement of a fasting lipid profile (Styne et al., 2017). These children should also undergo measurement of fasting blood glucose or hemoglobin A1C and aspartate aminotransferase and alanine aminotransferase levels if they are 10 years and older and have 1 or more of the following risk factors: elevated blood pressure, elevated lipid levels, currently using tobacco, or having a family history of obesity-related diseases (Martos-Moreno et al., 2014; Styne et al., 2017).

Because the appearance of insulin resistance (IR) and subsequent alterations in carbohydrate and lipid metabolism is gradual, it is possible that hyperinsulinemia may exist in the absence of alterations in fasting glycemia. Thus, it could be necessary to analyze fasting insulinemia in children and adolescents with obesity and to calculate the HOMA index [fasting glucose (mmol/L) x insulin (mU/mL)/22.5] as an indicator of IR. When the patient belongs to an ethnic group with an elevated risk (Hispanic, African

American) or there are alterations in fasting glycemia ( $>100$  mg/dL) or insulinemia ( $>15$  mU/mL), dyslipidemia, hypertension, family history of T2DM, or conditions associated with IR such as acanthosis nigricans or symptoms of polycystic ovary syndrome, an oral glucose-tolerance test should be performed (Martos-Moreno et al., 2014).

A fasting lipid profile is recommended for all children with BMI  $>95$ th percentile even in the absence of risk factors. If the results of the fasting lipid profile are normal, repeated screening is recommended every 2 years (Kumar and Kelly, 2017; Styne et al., 2017).

Sodium and potassium concentrations can be altered in hypercortisolism, calcium and phosphorus in pseudohypoparathyroidism, and urea and creatinine with the presence of microalbuminuria in nephropathies. It is also recommended that a Vitamin D, hemogram and iron and ferritin concentrations be studied because of possible associated deficiencies (Styne et al., 2017).

Hormonal studies should be performed to rule out the possibility of hypothyroidism (free thyroxin (T4) and thyroid stimulating hormone) or hypercortisolism (24-h urinary cortisol concentrations). If growth hormone deficiency or insensitivity is suspected, serum insulin-like growth factor I (IGF-I) and insulin-like growth factor binding protein-3 (IGFBP-3) concentrations should be determined (Martos-Moreno et al., 2014).

Abdominal ultrasound is the technique of choice if non-alcoholic steatohepatitis or polycystic ovary syndrome is suspected (Styne et al., 2017). Imaging techniques may confirm the presence of fatty liver, indicated by increased echogenicity on ultrasonography, but liver biopsy is the only way to reliably distinguish between simple steatosis, steatohepatitis, and fibrosis and can also be helpful in excluding other causes of elevated levels of serum aminotransferases.

Children with signs and symptoms suggestive of a genetic or endocrine cause for the weight gain may need specific testing. In addition, children with signs and symptoms suggestive of comorbidity such as OSA may need specific testing such as an overnight polysomnogram (Styne et al., 2017).

## Treatment of childhood obesity

The treatment of obesity in children is based on the reorganization of dietary habits, increase physical activity, and behavioral modification. In this age group, the indications for pharmacologic or surgical treatment remain limited, and it is impossible to establish specific recommendations for their use (Kumar and Kelly, 2017; Styne et al., 2017). Treatment of the children with obesity should be supervised by an experienced professional with frequent visits, especially during the initial treatment period. It is recommended that treatment be individualized on the basis of the characteristics of the child and his or her family.

Weight loss goals should be determined by the child's age and severity of obesity and related comorbidities. Weight maintenance might be an appropriate goal for children who have mild obesity because BMI will decrease as children gain height. In contrast, weight loss is recommended in children with severe obesity and those with comorbidities. It has been suggested that a 500–1000 g weight loss per month is safe in children and adolescents with severe obesity and comorbidities (Kumar and Kelly, 2017; Styne et al., 2017).

### Dietary management

Nutritional intervention includes combined strategies aimed at achieving changes in lifestyle. It is impossible to establish specific recommendations regarding nutritional intervention in childhood obesity, because controlled studies with long-term follow-up are still required, including evaluation of diets with different degrees of energy restriction and changes in macronutrient composition (limitation of fats and carbohydrates or increases in fiber or proteins) or micronutrients (calcium). Diets with modified carbohydrate intake such as low glycemic index diets and low carbohydrate diets have been shown to be as effective as standard portion-controlled diets for weight management in children with obesity. However, adherence to the modified carbohydrate diets may be low and children may be unable to follow these types of regimens, particularly in the long term. Very low-energy diets have been used quite successfully for short-term weight reduction. However, such diets carry some risks for nutrition and growth, and are unacceptable to many children with obesity (Kumar and Kelly, 2017; Poskitt, 2013; Styne et al., 2017). There is no consistent evidence that reduction of any particular energy source is more effective than any other in promoting fat loss. Current recommendations are focused on programming intake and avoidance of energy excess, suggesting that children and adolescents with obesity consume a mixed and varied diet (balanced diet) with a moderate energy restriction, and decreasing portion size. It is recommended to encourage intake of five servings of fruits and vegetables daily, decrease intake of energy-dense foods such as saturated fats, salty snacks, and high glycemic foods such as candy, minimize intake of sugar-containing beverages, minimize eating outside home and fast food in particular, eat breakfast daily and avoid skipping meals (Moreno et al., 2010).

To support children understand these recommendations, programs such as the “traffic light” are useful. The “traffic light” format labels food as red, yellow, and green on the basis of the energy density of the foods (red foods being most calorie dense and green foods being least calorie dense). Children are encouraged to eat green foods more often and red foods rarely. Nutritional intervention strategies are strongly suggested to be combined (Poskitt, 2013).

### Physical activity

Children and adolescents with obesity perform less physical activity than their normal-weight peers. Reducing sedentary activities and increasing physical activity have positive effects on body composition and obesity-associated metabolic comorbidities (Poskitt, 2013; Styne et al., 2017) and are highly recommended in available clinical practice guides. Programming of collective family physical activities is also recommended (Styne et al., 2017). To achieve the first objective, the removal of the television and/or computer

from the child's room is recommended (Seral-Cortés et al., 2021; Styne et al., 2017). The time and type of sedentary activity should be limited and previously programmed with the parents. Walking to all destinations and avoiding the use of mechanical means are recommended when possible. The type of physical activity should be adapted to the child's age and be attractive and fun for him or her. In accordance with the acquisition of skills and improved physical condition, the duration and intensity of the activity can be gradually increased, including team activities.

It is recommended that children 6 years or older participate in 60 min or more of physical activity per day with a minimum of 20 min of moderate to vigorous physical activity daily (Kumar and Kelly, 2017; Styne et al., 2017).

Unstructured physical activity, including outdoor play, should be encouraged in younger children, whereas older children should be encouraged to participate in structured physical activity such as after-school sports. It is also recommended that "screen time" (other than homework) be limited to less than 2 h/d for children older than 2 years, whereas those younger than 2 years should avoid "screen time" altogether. Because of the increasing evidence for an association between shortened sleep duration and obesity, good sleep hygiene and adequate amount of sleep (10–13 h a night for preschoolers and 8–10 h a night for teenagers) should be recommended (Styne et al., 2017).

### Behavioral treatment strategies

Behavioral modification in lifestyle programs is an important part of weight loss programs. Behavioral strategies targeted at decreasing overall energy intake, decreasing sedentary time, and increasing physical activity are the objective of pediatric weight management. Parental participation has been shown to be effective in the treatment of childhood obesity and noted to give better results as compared with participation of the child alone.

Behavioral modification interventions include self-monitoring of food and physical activity as well as control of stimuli that contribute to or elicit unhealthy behaviors.

Unfortunately, behavioral interventions for treating overweight and obesity in children and youth are associated with a low to moderate treatment effect. The reported weight loss and BMI reductions have been modest, ranging from 1 to 3 kg/m<sup>2</sup> of BMI (Kumar and Kelly, 2017).

### Pharmacologic treatment

The role of pharmacological therapy in the treatment of obesity in children and adolescents is limited.

*Orlistat* has been the only medication currently approved for the treatment of obesity in adolescents (age >12 years). Orlistat is a lipase inhibitor that blocks absorption of

about one-third of the fat ingested in a meal. The recommended dose of orlistat is 120 mg, 3 times a day with meals. Orlistat is also available as an over-the-counter medication at a lower dose of 60 mg, 3 times a day. The efficacy of orlistat is modest: 1-year placebo-subtracted changes in BMI less than 1 kg/m<sup>2</sup> (4% of weight loss) (Kumar and Kelly, 2017; Styne et al., 2017). Adverse effects limiting the use of orlistat include diarrhea, abdominal pain, flatulence, and greasy stools. Orlistat blocks absorption of fat-soluble vitamins and therefore administration of a multivitamin is recommended.

*Metformin*, a drug approved for the treatment of T2DM in children 10 years and older, has been used off-label for weight loss in several trials but results in modest reductions in BMI only (placebo-subtracted BMI decrease of 1.1–1.4 kg/m<sup>2</sup>) (Kumar and Kelly, 2017; Styne et al., 2017).

*Liraglutide* was recently approved for the treatment of obesity in adolescents >12 years. Liraglutide is a glucagon-like receptor 1 agonist, which reduces food intake. In adults, treatment is associated with 6% of weight loss, 13% reduction in major adverse cardiovascular events and a 15% reduction in all-cause mortality (González-Muniesa et al., 2017).

Other medications that have been used off-label for the treatment of obesity in children include topiramate.

More trials are needed to better understand the efficacy and safety of these medications for the treatment of pediatric obesity.

### Surgical treatment

There are few available data regarding bariatric surgery in children and adolescents and they are limited to the publication of case studies and expert consensus statements, with no controlled studies or data regarding the long-term results. The retrospective series analyzed by the Collaborative Group for the Study of Pediatric Bariatric Surgery is based on gastric bypass surgery, the most used technique in the United States, whereas in Europe and Australia adjustable gastric banding has been more widely used. Thus, specific recommendations regarding its use in children and adolescents cannot be made, and it should be limited to extreme cases and performed only in highly specialized centers (Kumar and Kelly, 2017; Styne et al., 2017).

For an adolescent to be candidate for bariatric surgery, expert committees require that, in addition to the anthropometric requirements (BMI > 40 kg/m<sup>2</sup>) and the presence of severe associated comorbidities, the patient's maturity, both physical (estimated by bone maturation) and cognitive, as well as his/her capacity for decision making and the family structure should be evaluated to reduce possible adverse effects both during surgery and follow-up. An additional requirement includes previous failure of intense weight-loss programs during a minimum of 6 months (Styne et al., 2017). The percentage of children and adolescents who are candidates for bariatric surgery is very low.

## New treatments

The fact that the administration of recombinant leptin to patients with leptin deficiency reverses their clinical picture opens the door to the development of new treatments for specific conditions, such as the alteration of MC4R (Martos-Moreno et al., 2014). To date, clinical trials data are limited, with moderate secondary effects (flushing, nausea, vomiting, headache, insomnia, and alterations in taste) being reported. There are new drugs that have been extensively reviewed in recent publications (González-Muniesa et al., 2017; Martos-Moreno et al., 2014).

## Prevention of obesity during childhood

Although systematic reviews on the effectiveness of childhood obesity prevention programs have shown diverse and often conflicting results, some strategies were identified as useful; implementation of health education on nutrition, increased number of physical activity hours at school and the provision of healthy food at school. Limited evidence for the effectiveness of policies focusing on the child's environment and health information technologies focusing on children and parents is available. Performing interventions in primary care settings could improve parenting practices and promote healthy eating habits, but available studies showed only limited effect (Poskitt, 2013). The complexity of obesity requires multilevel and multicomponent interventions that take a systems approach. Multilevel approaches focus on changing health behaviors by acting on multiple frameworks: in practice, going from the individual, children or adolescents, schools or occupational environments and the communities. Multicomponent interventions incorporate more than one strategy to modify behaviors, within the same level. For the development of the interventions, health promotion models should consider information on the determinants, such as the target population and opportunities in the corresponding societies. Factors to be taken into account include maternal-child health, socioeconomic status, nutritional education and health literacy, parents' perceptions of healthy infant growth and development, peer pressure, family eating and physical activity behavior, and the role of food and built environments. Despite the many identified limitations of obesity prevention programs, policy efforts to prevent childhood obesity should continue.

## Conclusion

Childhood obesity remains an ongoing serious international health concern. Childhood obesity has its basis in genetic susceptibilities influenced by an obesogenic environment starting in utero and extending through childhood and adolescence. Endocrine etiologies for obesity are rare and usually are accompanied by attenuated growth patterns. Pediatric comorbidities are common and long-term health complications often result. The prevention of pediatric obesity by promoting healthy diets, physical activity, and school and residential environments should be a primary goal, in order to achieve effective results. Although some behavioral and pharmacotherapy studies reported modest success, additional research into accessible and effective methods for preventing and treating pediatric obesity is much needed. Stratified treatment is recommended, with initial management in primary care with focus on healthy eating habits and active lifestyle. Those with poor response to interventions in primary care and with significant health risks should be managed by a multidisciplinary team with expertise in childhood obesity. Pharmacotherapy and/or bariatric surgery should be considered in adolescence if there has been no response to structured weight management with a multidisciplinary team. Additional research is needed to evaluate the efficacy and safety of these treatments. The role of genetics, epigenetics, nutrigenomics or personalized nutrition remains to be better understood to improve obesity management.

### Glossary

**Adipokines** Cytokines present in adipose tissue.

**Adiposis dolorosa** Painful fat syndrome.

**Dyslipidemia** Abnormal blood fats.

**Hyperinsulinemia** High blood insulin.

**Visceral fat** Intraabdominal adipose tissue.

Obesity is a serious chronic disease associated with complications and comorbidities that involve most systems of the body (Table 1). The common factor in all obese people is the presence of excess adipose tissue stores and an increased percent body fat. Even in the absence of complications and comorbidities, obesity increases the risk of early mortality. The estimates of obesity-related excess deaths in the USA each year range from 125 000 to 400 000. In addition to the medical complications, obesity is associated with psychological and social problems that may overshadow the medical problems in the quality of life for many obese people. This article will discuss the role of distribution of body fat in the complications of obesity, then will summarize the major categories of complications and comorbidities.

### Role of Distribution of Body Fat in the Complications of Obesity

The distribution of excess adipose tissue contributes to many of the complications of obesity. Obese individuals may be divided into those whose excess fat predominantly is deposited in the upper body versus those with increased lower body obesity, or both upper and lower body obesity. Upper body obesity may be localized to the subcutaneous space versus the intraabdominal space (visceral fat). Waist circumference and the ratio of waist-to-hip circumferences correlate with the morbidity and mortality of obesity. Individuals with increased visceral fat, as measured by the cross-sectional area on computerized tomography (CT) or magnetic resonance imaging (MRI) scanning, are at greater risk for systemic complications of obesity compared to people with fat localized to abdominal subcutaneous depots or to the lower body. The mechanisms of these differences are not clear, but research has shown that visceral fat has a higher triglyceride turnover rate and releases greater amounts of fatty acids into the circulation than do other adipose tissue depots. Also, visceral fat has a higher concentration of adipokines (cytokines), substances that affect function of the immune system. Because blood vessels from the visceral fat drain into the portal vein, some investigators postulate that exposure of the liver to high levels of free fatty acids or these adipokines produces insulin resistance, which is known to be correlated with many of the complications of obesity described below. There are significant racial differences in deposition of visceral fat. Asians and Hispanics tend to selectively deposit fat in the abdominal cavity with excess energy intake whereas Blacks have less visceral fat than other groups.

### Metabolic and Organ System Complications of Obesity

Obesity is a syndrome that resembles premature aging. Multiple metabolic, hormonal, and organ system dysfunctions occur in aging. Similar changes occur in obesity, but at an earlier age. Below we will review generalized metabolic changes that occur with obesity, and then examine individual organ systems.

#### Metabolic Syndrome

The term 'metabolic syndrome' has been given to a cluster of abnormalities that classically includes insulin resistance, glucose intolerance, hypertension, and dyslipidemia. Several other abnormalities such as sleep apnea, gout, and pseudotumor cerebri have been associated with insulin resistance and the 'metabolic syndrome.' The classic abnormalities will be reviewed below and the other abnormalities later in the article.

#### Type 2 Diabetes

Type 2 diabetes mellitus (DM): a strong association of obesity with the prevalence of Type 2 DM is well documented. The risk of developing Type 2 DM increases with the degree and duration of obesity; as much as 50-fold with severe obesity. The US National Diabetes Commission reported that the risk of diabetes doubles for every 20% of excess body weight. The risk of Type 2 DM is greater with visceral obesity. Type 2 DM is frequently associated with other complications such as hypertension and dyslipidemia, resulting in additive risks for atherosclerosis and cardiovascular disease. Poor glycemic control in Type 2 DM may lead to severe microvascular complications, including nephropathy, retinopathy, and neuropathy. Weight loss is a very effective treatment for Type 2 DM and can prevent the onset of Type 2 DM in susceptible individuals. Type 2 DM, once extremely rare in children, has increased greatly in prevalence with the obesity epidemic.

### Insulin Resistance and Hyperinsulinemia

Insulin resistance refers to the phenomenon of insensitivity of the body cells to insulin's actions. Insulin resistance is usually associated with hyperinsulinemia. Different tissues may have differential insulin sensitivities. For example, adipose tissue may be more sensitive to insulin than muscle tissue, thus favoring the deposition of fatty acids in adipose tissue and diminished fatty acid

oxidation in muscle. There is a reduced efficiency of insulin to inhibit hepatic glucose production and stimulate glucose use in skeletal muscle and adipose tissue that leads to hyperglycemia.

Hyperinsulinemia is an independent marker that predicts the development of atherosclerosis. A causal relationship between hypertension and hyperinsulinemia has not yet been well established. Hypertension associated with hyperinsulinemia could be due to increased renal sodium retention, increased intracellular free calcium, increased sympathetic nervous system activity, or increased intraabdominal pressure because of increased visceral fat deposition.

The mechanisms of insulin resistance with increasing obesity are not clear, but increased production of cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6) are thought to play a role. Basal insulin levels increase with the degree of overweight, perhaps due to increased insulin secretion or reduced clearance by the liver. A reduced receptor number or post insulin-receptor defects may play a role in insulin resistance. Both basal hyperinsulinemia and insulin resistance decrease with weight reduction.

### Dyslipidemia

Obesity, particularly visceral obesity, is associated with increased serum levels of cholesterol, triglycerides, low-density lipoproteins (LDLs), very-low-density lipoproteins (VLDLs), apolipoprotein B, and reduced levels of high-density lipoprotein-cholesterol (HDL-c). There is a change in the composition of LDLs to increased small, dense LDLs, which are more atherogenic. The lower amounts of HDL-c compromise antiatherogenic function. Every 10% increase in relative bodyweight is associated with a 12 mg dl<sup>-1</sup> increase in serum cholesterol concentration. The correlation of serum cholesterol with body mass index (BMI=kg m<sup>-2</sup>) is greater for men than women. Increased serum triglycerides with weight gain may be due to increased intake of fats, hyperinsulinemia, and impaired removal of triglycerides into tissues because of low levels of lipoprotein lipase activity. Insulin resistance promotes lipolysis and increased circulating free fatty acids, which enhance the formation of VLDLs in the liver. Dyslipidemia contributes to increased atherosclerosis in obesity. Weight reduction usually reduces triglycerides, changes the composition of serum cholesterol to less small, dense LDLs, and increases HDL-c. These changes, if maintained over time, may reduce atherosclerosis.

### Gout

Serum uric acid and the prevalence of gout correlate positively with BMI. High serum uric acid levels correlate with insulin resistance and an increased risk of atherosclerotic cardiovascular disease in obesity. Serum uric acid levels may temporarily increase with acute weight loss, but usually decrease with large amounts of weight loss. The lower uric acid levels are maintained with continued weight loss.

### Abnormalities of Hormones and Other Circulating Factors

Multiple different hormones are altered in obesity. Below are a few that are felt to be important in altering the physiology and contributing to the complications of obesity.

#### Growth Hormone

Obesity is typically accompanied by a decrease in growth hormone (GH) levels and an increase in GH-binding protein (GHBP) levels. GH is released by the anterior pituitary and affects lipid, carbohydrate, and protein metabolism. An inverse relation exists between GH levels and percent fat mass. GH is lipolytic in adipose tissue. Animal studies show enhanced catecholamine-induced lipolysis and increased beta adrenoreceptors in adipocytes of GH-treated animals. The rises of GH after meals, with sleep, and in response to secretagogues such as arginine or levodopa are blunted in obese people. GH stimulates secretion of insulin-like growth factor-1 (IGF-1). However, IGF-1 is increased in obesity, suggesting a difference in sensitivity to GH. The defects in GH and IGF-1 are reversed by weight reduction.

#### The Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (HPA) axis may be abnormal in obesity, with similarities to patients with Cushing's syndrome such as insulin resistance, impaired glucose homeostasis, hypertension, and lipid abnormalities. High levels of emotional or physical stress are thought to increase cortisol secretion or turnover, and thereby increase visceral obesity. Another potential mechanism involves the peripheral metabolism of cortisol. The enzyme 11 beta-hydroxysteroid dehydrogenase-1 (11 beta-HSD-1), which converts steroid precursors to cortisol, is expressed in adipose tissue. With increasing obesity, more cortisol is derived from cortisone in adipose tissue due to the increased activity of this hormone. Urine studies in obesity also show an increase in the ratio of tetrahydrocortisol to tetrahydrocortisone, indicating a relative increase in the pathways leading to cortisol formation.

#### Adipokines (Cytokines)

Adipose tissue secretes a number of cytokines such as TNF- $\alpha$ , ILs, plasminogen activator inhibitor-1 (PAI-1), and retinol-binding protein 4 (RBP-4) that may play a role in fat metabolism and insulin resistance. Adipokine secretion is higher with obesity. TNF- $\alpha$  has been shown to alter basal and glucose-stimulated insulin secretion and produce insulin resistance in isolated cell lines. Adipocytes also produce IL-6, 10, and 11, which stimulate C-reactive protein, a systemic marker of inflammation. All of these ILs are

increased in obesity. IL-6 and PAI-1 have been postulated to play an etiologic role in the increased risk of thromboembolism observed in obese patients. Plasma IL-8 is increased in normoglycemic obese subjects, and is related to fat mass and TNF- $\alpha$  levels. Circulating IL-8 is also acutely up-regulated by hyperinsulinemia. An increase in circulating IL-8 may be one of the factors linking obesity with greater cardiovascular risk. Adiponectin is the only adipokine whose circulating concentration decreases with increased fat mass and, in line with this, is inversely correlated with the metabolic syndrome.

### **Renin–Angiotensin System**

Several components of the renin–angiotensin system are expressed by the adipose tissue. Angiotensinogen levels are increased and have been linked to hypertension and increased cardiovascular risk in obesity.

### **Leptin**

Leptin is a cytokine made predominantly in the adipose tissue. Leptin binds to receptors in the hypothalamus to signal the state of adipose tissue stores and act by inhibiting neuropeptide Y. Serum leptin levels correlate positively with body fat stores, and are higher in obese people, denoting leptin resistance in obesity. Females have higher serum leptin levels than males, but this association does not appear to be due to estrogen levels. Leptin is found in greater concentrations in abdominal subcutaneous fat compared to visceral fat, and some studies link leptin to regulation of energy expenditure.

### **Ghrelin and Obestatin**

Ghrelin and obestatin come from the same prohormone, preproghrelin. Ghrelin is a potent GH secretagogue that is produced mainly by the stomach and is present in several forms in serum. Administration of ghrelin increases food intake, and ghrelin levels increase with dieting and weight loss. However, serum ghrelin has a negative correlation with percent body fat, so levels in obese people are lower than in lean. Obestatin is thought by some to have an anorexic effect but its function and the interplay with ghrelin is not well understood.

## **Diseases of Organ Systems**

### **Atherosclerotic and Arteriosclerotic Vascular Diseases**

Diseases of the vascular system make the greatest contribution to the increased mortality associated with obesity. In both sexes, the excess mortality due to vascular disease increases linearly with BMIs greater than 25 kg m<sup>-2</sup>. The vascular complications of obesity can be categorized into four major groups:

1. Coronary heart disease (CHD)
2. Hypertension
3. Congestive heart failure
4. Cerebrovascular disease

### **Coronary Heart Disease**

Longitudinal studies show a positive correlation of BMI with CHD, and obesity is an independent predictor of CHD. However, in the presence of other risk factors such as hypertension, lipid abnormalities, and insulin resistance, all of which are increased by obesity, the risk of atherosclerotic CHD increases dramatically. Weight loss reduces all of these risk factors associated with cardiovascular disease, but there are only few long-term studies of changes in cardiovascular mortality due to weight loss. A very low-fat diet (10% of total calories as fat) has been shown to reduce the size of atherosclerotic plaques in coronary arteries.

### **Hypertension**

The prevalence of hypertension among overweight adults in the USA is 2.9 times higher than that of nonoverweight individuals. Every 10 kg increase in bodyweight is associated with increases of 3 and 2 mm Hg in systolic and diastolic blood pressures, respectively. Persistent hypertension can contribute to the development of left ventricular hypertrophy, coronary ischemia, and stroke.

The etiology of the association between hypertension and obesity is unclear. Some of the mechanisms offered to explain the association of obesity and hypertension are:

1. Hyperinsulinemia due to insulin resistance leading to increased renal reabsorption of sodium.
2. Sodium and fluid retention due to a decreased renal filtration rate, increased intraabdominal pressure, or increased plasma renin activity.
3. Increased sympathetic nervous system activity.
4. Increased cytokines and inflammation.

Except in long-standing cases, weight reduction is usually accompanied with a decrease in blood pressure. The reductions in blood pressure with weight loss are not dependent on decreases in salt intake. Many studies have shown that even modest weight losses, in the range of 5–10% of initial bodyweight, may produce reductions or even normalization of blood pressure in obese individuals.

***Congestive Heart Failure***

Total blood volume increases with excess body weight. Higher oxygen consumption in obesity and increased blood flow to the splanchnic bed and adipose tissue increase cardiac output. Also, the transverse diameter of heart, thickness of the posterior wall, and thickness of the interventricular septum increase with body weight. Left ventricular mass is a stronger predictor of morbidity and mortality than blood pressure. A combination of these factors may result in the congestive heart failure seen in severely obese people. The heart rate, stroke volume, blood volume, cardiac output, and left ventricular work return toward normal with weight reduction. One study that compared weight loss by dieting to treatment with antihypertensive drugs demonstrated a greater improvement in cardiac hypertrophy with weight loss, despite similar reductions in blood pressure.

***Cerebrovascular Disease***

Obesity-related atherosclerosis, arteriosclerosis, and hypertension increase the risk of cerebrovascular disease and strokes. Obesity is an independent risk factor for strokes, even in the absence of other comorbidities.

***Thromboembolic Disease***

The risks of venous stasis, deep vein thrombosis, and pulmonary embolism are increased in obesity, particularly in persons with abdominal obesity. Lower extremity venous disease may result from increased intraabdominal pressure, impaired fibrinolysis, and the increase in inflammatory mediators described above.

***Respiratory System***

Obesity is associated with reduced lung volume, altered respiratory patterns, and an overall reduction in the compliance of the respiratory system, including a diminished vital capacity and total lung capacity. More severe obesity is associated with the obesity–hypoventilation syndrome, which is characterized by excessive daytime sleepiness and hypoventilation. The increased work required to move the chest wall, a decrease in arterial oxygenation in the lungs, and a diminished sensitivity of the respiratory center to the stimulatory effect of carbon dioxide are postulated to contribute to the obesity–hypoventilation syndrome.

The obesity–hypoventilation syndrome may be associated with, or exacerbated by, obstructive sleep apnea, a syndrome characterized by repeated collapse of the upper airway and cessation of breathing with sleep. Obstructive sleep apnea occurs when the tongue obstructs the glottis and prevents entry of air into the trachea. Up to 50% of massively obese people have sleep apnea. The risk of arrhythmias and sudden death increases during apneic episodes. Weight reduction usually reduces the severity of sleep apnea, and massive weight reduction, such as that after gastric bypass surgery, eliminates the disease in most patients.

***Digestive System******Gallbladder Disease***

The risk of gallbladder disease, particularly gallstone formation, is increased in obesity, and occurs with greater frequency in women. The prevalence of gallbladder disease in obese individuals increases with age, bodyweight, and parity. The etiology of increased gallstones is unclear, but genetic factors play a role. Increased cholesterol production, which leads to increased excretion of cholesterol in bile, is known to occur in obesity and correlates with increases in body weight. Many obese people skip meals and the reduced number of meals may result in less frequent emptying of the gallbladder. The resulting bile stasis may contribute to gallstone formation. Although long-term weight loss and maintenance may reduce the occurrence of gallbladder disease, the risk of gallstone formation actually increases during the active weight loss phase. The etiology of this increase is thought to be the mobilization of cholesterol from adipose tissue during rapid weight loss. This increased load of cholesterol in the circulation produces supersaturation of the bile, leading to gallbladder sludge in approximately 25% of patients and to symptomatic disease in approximately 1–3%. Treatment with ursodeoxycholic acid reduces or eliminates the risk of gallstone formation during weight loss.

***Hepatic Disease***

Abnormalities in hepatic function are commonly reported in obese people. The frequency of fatty liver has been reported to be as high as 94% in very obese subjects, many of whom have elevated liver function tests. A small number of very obese subjects will develop micronodular cirrhosis. Weight loss results in disappearance of the excess fat and normalization of liver function tests.

***Reproductive System******Hormonal Complications: Males***

Obese men have elevated levels of plasma estrone and estradiol that correlate with the degree of obesity. Plasma total testosterone and free testosterone (the biologically active moiety) are reduced in obese men, and the reductions correlate negatively with the degree of obesity. The reduced levels of free and total testosterone are not generally accompanied by hypogonadism or a decrease in libido, potency, or sperm count in obese men. Free and total plasma testosterone levels normalize on significant weight reduction. Also, estrogen levels are normalized if the individuals attain normal weight, but not if the weight loss is modest and significant obesity persists.

***Hormonal Complications: Females***

Obese women have normal levels of total plasma estradiol, but reduced levels of sex hormone-binding globulins (SHBGs). Thus, free estradiol (the biological active moiety) is significantly elevated. The high levels of free estradiol are postulated to increase the risks of endometrial and breast cancer and to reduce fertility. Estrone, derived in adipose tissue from androgen precursors, is also increased in obesity. Obesity in women is associated with the polycystic ovary syndrome (PCOS), characterized by hyperestrogenism, hyperandrogenism, polycystic ovaries, oligomenorrhea or amenorrhea, hirsutism, and infertility. Women with PCOS also have insulin resistance and are at high risk for developing impaired glucose tolerance and DM. Weight loss usually normalizes SHBG and estradiol levels for individuals with simple obesity, but weight loss may not restore fertility to patients with severe PCOS.

***Obstetric Complications***

Obesity increases the risk of complications during pregnancy and childbirth. Increased bodyweight, hypertension, and fluid retention during pregnancy can lead to toxemia of pregnancy. Heavier women have a longer duration of labor and a greater frequency of abnormal labor and caesarian sections.

***Nervous System******Pseudotumor Cerebri***

This syndrome is characterized by increased intracranial pressure, headaches, blurred vision or loss of vision, and papilledema. It is most common in massively obese individuals and may be seen in association with sleep apnea or with the obesity-hypoventilation syndrome. It may be associated with retinal hemorrhage or loss of vision from severe papilledema. Some investigators believe that increased intraabdominal pressure with massive obesity is an etiologic factor for pseudotumor cerebri. Major weight loss, particularly after obesity surgery, results in dramatic improvement.

***Adiposis Dolorosa***

This is a syndrome of unknown etiology characterized by pain in subcutaneous adipose tissue. Adiposis dolorosa occurs predominantly in postmenopausal women (female to male ratio of approximately 30:1), and has been described over all areas of the body. The painful areas of fat may occur as subcutaneous lumps on physical examination, but more commonly there are no differences from normal adipose tissue. The disease usually begins gradually with mild pain and tenderness of the area involved, but may progress to severe pain, particularly with movement or exercise. Intravenous infusions of lidocaine are reported to relieve pain, short term or even permanently. The mechanism involved in the relief of pain from lidocaine is unknown.

***Alzheimer Disease***

Obesity has been linked to an increased prevalence of Alzheimer disease. The etiology of this increase is unknown.

***Immune System***

Animal studies have shown an increased rate of infection and mortality in obese dogs compared to lean animals experimentally infected with canine distemper virus. Cell-mediated immune response is impaired in obese individuals. Maturation of monocytes into macrophages after *in vitro* incubation is significantly less for obese compared to lean subjects. Impaired cell-mediated immune response in children was demonstrated to be due to subclinical deficiencies of zinc and copper. The impairment in the immune response was reversed after 4 weeks of zinc and copper supplements. As described above, there are changes in numerous cytokines with obesity. The role of these changes in immune function is not clear.

***Skin***

Obese people may have several disorders of the skin. The most common is stasis changes of the skin of the lower legs in massively obese people. The etiology of this finding is venous stasis, edema, and breakdown of the skin. Fragilitas cutis inguinalis is a condition of fragile skin in the inguinal area of obese people. This condition is diagnosed by stretching the skin of the inguinal area. A linear tear appears at right angles to an applied force that is insufficient to tear the skin of a normal person. This condition is unrelated to the sex and age of the person.

Acanthosis nigricans, seen occasionally in obesity, is characterized by darkening of the skin in the creases of the neck, axillary regions, and over the knuckles. An association between acanthosis nigricans and insulin resistance is reported in persons who have circulating antibodies to the insulin receptors. Because acanthosis nigricans also may be associated with highly malignant cancers such as intraabdominal adenocarcinomas, physicians should be alert to this possibility and not attribute the condition simply to the presence of obesity.

## Eye Disease

Obesity is associated with an increased prevalence of cataracts. Persons with abdominal obesity are at a greater risk than those with lower body obesity. Insulin resistance may be involved in the pathogenesis of cataract formation, and diabetes is a well-known risk factor.

## Cancer

Obesity increases the risk of many cancers, including breast, colon, prostate, endometrium, cervix, ovary, kidney, gallbladder, liver, pancreas, rectum, brain, esophagus, and non-Hodgkins lymphoma. **Table 2** shows the increased risk of selective cancers.

Although there are many theories about how obesity increases cancer risk, the exact mechanisms are not known. The mechanisms may be different for different types of cancer. Also, because obesity develops through a complex interaction of heredity and lifestyle factors, researchers may not be able to tell whether the obesity or other factors led to the development of cancer.

## Mechanical Complications of Obesity

### Arthritis

Obesity is frequently complicated by degenerative arthritis (DJD). Increased bodyweight leads to trauma of the weight-bearing joints and speeds the development of osteoarthritis in obesity. Knee and hip joints are particularly affected. However, obese patients have increased DJD of the hands, perhaps due to cytokines produced by adipose tissue, which may damage the cartilage in joints. Flattening of the arc of the planter surface of the feet (flat feet) occurs more frequently in obese people, presumably due to the stress of carrying excess body weight. Flat feet may lead to unsteady gait and aches and pains after walking. Increased fat deposition, particularly in the abdominal region, can change the natural curvature of the spine, causing lordosis and resulting in backache in obese people.

### Intraabdominal Pressure

In severely obese people, the excess visceral fat is thought to increase intraabdominal pressure. Animal research shows that experimentally induced acute increases in intraabdominal pressure to the levels seen in the abdomens of very obese people cause increases in pleural pressure, intracranial pressure, and central venous pressure. The investigators postulated that in humans, increased intraabdominal pressure may contribute to hypertension, insulin resistance and Type 2 DM, obesity–hypoventilation syndrome, pseudotumor cerebri, incisional hernia, and urinary incontinence. Massive weight loss following obesity surgery normalizes the increased intraabdominal pressure and reduces or eliminates all the symptoms listed above.

**Table 2** Deaths from cancer in women by BMI

Type of cancer	BMI ( $\text{kg m}^{-2}$ )					P for trend
	18.5–24.9	25.0–29.9	30.0–34.9	35.0–39.9	$\geq 40.0$

<sup>a</sup>Deaths per 100 000 women.

<sup>b</sup>RR, Relative risk of death compared to the reference group (BMI=18.5–24.9  $\text{kg m}^{-2}$ ).

## Surgical Complications

Obese patients are at an increased risk of surgical and perisurgical complications. These risks include an increased risk of complications and death from anesthesia, longer operating times, delayed wound healing, increased postoperative wound infections and pneumonia, and a higher frequency of incisional hernias after surgeries involving the abdominal wall. Many surgeons recommend weight reduction before elective surgery, but there are few data to document that acute weight reduction improves the outcome of surgery.

## Psychosocial Complications

### Psychological Complications

Obesity is associated with negative emotions, low self-esteem, decreased marital satisfaction, and body image disparagement. All of these conditions and beliefs show improvement with weight reduction.

Dieting efforts correlate positively with the prevalence of eating disorders, particularly binge eating. A correlation of eating disorders with abuse of drugs and alcohol has been shown. In strictly dieting female college freshmen who were not alcohol abusers at baseline, the frequency of alcohol abuse was reported to increase after a year compared to nondieters.

### Social Complications

Obesity carries a social stigma that dramatically affects the quality of life for obese individuals, particularly for women. Factors contributing to the social bias against obese people are beliefs that obesity is merely due to overeating and therefore obese people lack will power. Many members of the general public, and even health professionals, ignore the evidence for the medical and genetic contribution to obesity, believe that obese people are responsible for their own plight, and believe that they do not deserve sympathy for their disability. Despite similar intelligence (as judged by IQ values and the Scholastic Aptitude Test scores), a significantly lower number of obese females were admitted to certain colleges compared to nonobese females. The choice of mates is adversely affected by obesity. Obese individuals tend to marry mates with less education and from a lower socioeconomic class. It is more difficult for an obese person to find a job or to be promoted once hired, so lower earnings and a lower socioeconomic status are correlated with obesity. Obese employees are viewed as less competent, less productive, inactive, disorganized, and less successful by employers, regardless of actual productivity.

The bias against obesity has been shown to begin in early childhood. Obese children are considered lazy, stupid, slow, and self-indulgent by both children and adults. Because of these societal attitudes, many obese children and adolescents have lower levels of self-esteem than do their nonobese counterparts.

### Economic Impact

In the USA, the direct cost of obesity has been estimated at almost 150 billion dollars per year. The indirect costs of early retirement and increased risk for disability requiring financial support are also considerable. Because obese people have more health problems, health-care costs for the obese are higher than for lean individuals.

## Glossary

**Body composition** Relative proportion of tissue types within an individual. At its simplest level the body can be divided into the relative proportion of fat and fat-free mass.

**Body mass index (BMI)** Index of weight independent of height used as a proxy measure of body fatness; calculated as  $\text{weight(kg)}/\text{height(m)}^2$ .

**Metabolic syndrome** A cluster of risk factors (including abdominal obesity) associated with increased risk of cardiovascular disease and diabetes.

**Nutrition transition** Population-level shifts in diet and physical activity patterns often associated with modern lifestyles; in the latter stages characterized by high-fat/high-sugar/low-fibre diets and lower levels of activity.

**Obesity** Excess accumulation of body fat, which can be associated with a range of co-morbidities.

## Definition

Obesity is the excess accumulation of body fat or adiposity. It is commonly and most easily assessed by individuals' body weight independent of their height; the body mass index (BMI), calculated as  $\text{weight (kg)}/\text{height (m)}^2$ . The World Health Organization (WHO) classifies individuals with a BMI of 25–29.9  $\text{kg m}^{-2}$  as overweight and over 30  $\text{kg m}^{-2}$  as obese (Table 1). These classifications are themselves based on increased mortality and morbidity associated with excess body weight for height. Although the WHO recommends the use of these International Classification cut-offs for all countries there is evidence that the relationship between BMI and health may vary for different populations partly as a consequence of different associations with body fat and fat distribution. Lower BMI cut-offs for Asian populations have been suggested although the relationships are also not uniform across ethnic groups. Additional cut-off points are therefore suggested as a useful public health reference in certain settings (Table 1).

Women are predisposed to higher body weight for the purposes of reproduction and in all populations mean BMI is higher for females compared to males. Data from 2010 collated by the International Association for the Study of Obesity (IASO) indicate that globally more than 1 billion individuals were overweight and 475 million obese. Rapid increases in BMI and the prevalence of obesity have occurred across all world regions; data from 199 countries compiled by the Global Burden of Metabolic Risk Factors of Chronic Diseases Collaborating Group indicate that between 1980 and 2008, mean BMI increased by 0.4  $\text{kg m}^{-2}$  per decade for men and 0.5  $\text{kg m}^{-2}$  per decade for women worldwide. These figures mask large variations in rate of change; certain regions, such as Oceania, experienced rates of increase of over 2  $\text{kg m}^{-2}$  per decade during this time frame. The prevalence of overweight and obesity is now so high that the condition is increasingly recognized as a pandemic, with projections of further increases particularly within lower- and middle-income countries in the next decades. In children, overweight and obesity are assessed by age and sex specific cut-offs that predict adult BMI (Table 2). Globally, over 200 million school-aged children are classified as overweight and obese.

**Table 1** International classification of adult overweight and obesity according to body mass index (BMI)

Classification	BMI ( $\text{kg m}^{-2}$ )	
	Principal cut-off points	Additional cut-off points
Normal range	18.50–24.99	18.50–22.99 23.00–24.99
Overweight	25.00–29.99	25.00–27.49 27.50–29.99
Obese	$\geq 30.00$	
Obese class I	30.00–34.99	30.00–32.49 32.50–34.99
Obese class II	35.00–39.99	35.00–37.49 37.50–39.99
Obese class III	$\geq 40.00$

## Health Impacts

The WHO classifies overweight or obesity as the fifth leading risk factor for death, responsible for 7% of deaths globally. It is estimated that at 40 years of age, an obese person will live up to 7 years less than someone of normal weight. Obesity is associated with a range of comorbidities, many of which fall under the heading of the 'metabolic syndrome,' which is characterized by insulin resistance and dyslipidemia as well as by excess body weight and by increased body fat in the abdominal region. The risks of diabetes, hypertension, and dyslipidemia all increase with increasing body weight from a BMI as low as  $21 \text{ kg m}^{-2}$ . One of the closest associations between obesity and disease is with type II diabetes, where up to 90% of individuals with the condition are classified as overweight. Hypertension is up to five times higher in individuals who are overweight or obese. Excess body fatness is convincingly associated with a range of cancers and reducing obesity was one of the key recommendations of the 2007 World Cancer Research Fund report on cancer prevention. Other important comorbidities associated with body fatness include gall-bladder disease, non-alcoholic fatty liver disease, sleep apnea, and osteoarthritis. Increasingly, obesity is associated with psychological effects and stigma, which have important implications for quality of life. Owing to the wide range of associated morbidities, the direct and indirect costs of obesity are substantial and the health-care costs of treatment alone confer a massive burden on societies across the world. Middle- and lower-income countries are projected to experience the greatest rise in obesity rates but may lack the resources to cope with associated health costs.

## Etiology

Obesity is primarily caused by an imbalance between energy intake and expenditure, leading to weight gain. The components of the diet and the amount of energy expended are thus important determinants. From a substantial review of the evidence in 2007, the World Cancer Research Fund concluded that there was convincing or probable evidence that a sedentary lifestyle (including excess television viewing) and the consumption of energy-dense foods, sugary drinks, and fast foods were associated with increased risk of weight gain, overweight, and obesity.

There is increasing recognition of the role played by societal and environmental forces in influencing both sides of the energy balance equation and obesity is no longer viewed solely as preventable by the individual. The rapid rise in obesity rates across the globe has been attributed to correspondingly rapid changes in population demographics and dietary behavior. The so-called 'nutrition transition' from traditional forms of diet and activity to more 'Western' diets and lifestyles, characterized by increased energy density and high fat is likely to be a particularly important driver of obesity rates. Increasing urbanization is occurring across the globe, often with corresponding increases in obesity-inducing behavior such as a reduction in physical activity and access to highly processed urban food supplies.

Patterns of overweight and obesity are not uniform within populations and are strongly related to socioeconomic status. As countries become wealthier this pattern changes so that in the countries with the highest income, obesity rates are the highest amongst the poorest members of society whereas in lower-income countries the prevalence of obesity is highest amongst the highest socioeconomic class. This pattern reflects the changing distribution of obesity risk factors that occurs as countries progress through the nutrition transition.

The relative contributions of genetics and the environment to the etiology of obesity have been evaluated in several studies with inconsistent results and estimates of the inheritance of obesity range from 64% to 84%. Only very few individuals have genetically determined obesity relating to single-gene effects but complex gene-environment interactions are likely to predispose certain individuals to obesity within the context of particular diet and activity patterns. Investigation of the polymorphisms that underlie these interactions may help to understand the etiology of obesity and inform potential treatment and prevention strategies. However it is important to recognize that changes to the environment, rather than to genes, underlie the current worldwide obesity epidemic and addressing these environmental causes will be the most important component of effective prevention strategies.

## Assessment

One of the goals of assessment of overweight/obesity is to decide whom to treat. Three main issues must be evaluated: whether treatment is indicated, whether treatment is safe for the patient, and whether the patient is ready and motivated to lose weight. In addition, routine assessment of eating and activity patterns in adults as well as in children must be considered. Recognition of excessive weight gain relative to linear growth is essential throughout childhood. Motivation for weight loss in obese individuals is a key component of effective treatment but is often lacking partly because it depends on the acceptance and recognition that obesity is a medical disorder. Motivation for change may also be reduced if the obese individuals are yet to develop comorbidities and do not yet conceive that their health is compromised.

Proper identification and classification of obesity through body composition assessment are important steps to initiate before beginning weight-loss treatment. Dietary management, physical activity, surgery, pharmacotherapy, and psychosocial and familial support must be considered together as part of obesity assessment. Before beginning a weight-loss program, patients should be evaluated for the number and severity of cardiovascular risk factors, conditions that may require treatment in addition to weight-loss strategies.

## Measures of Body Fatness

Although BMI is a useful indicator of risk that is widely used at a population level, it is only a proxy measurement of body fatness and does not accurately reflect adiposity at an individual level. In addition, individuals with the same BMI may have very different body shapes depending on the distribution of fat; visceral fat in the abdominal region is associated with greater metabolic abnormalities. Many different techniques can be used to assess body fatness, each with its own advantages and disadvantages.

## Cadaver Analysis

The only direct measure of body fat but clearly not widely applicable. The main use of cadaver studies is to validate methods that can be used to study patients *in vivo*. All remaining techniques are indirect assessments that require certain assumptions to calculate body fatness.

## Imaging Techniques

Total adipose tissue and its distribution can be quantified using imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI). Both methods produce high-resolution cross-sectional images from signals resulting from exposure of the subject to an X-ray source (CT) or electromagnetic field (MRI). Total body fat volume, total fat mass, and percentage fat mass can be estimated and visceral fat depots can be measured with good accuracy. These techniques are very expensive and may be problematic for people with claustrophobia. Dual-energy X-ray absorptiometry (DXA) is a widely used imaging technique that utilizes the principle that transmitted X-rays at two energy levels are differentially attenuated by bone mass and soft tissue mass. It is possible to obtain abdominal fat estimates with DXA, although these cannot be separated into subcutaneous and visceral components.

## Densitometry

Total body fat can be assessed by measuring body density based on the Archimedes principles of water displacement, assuming two body compartments (fat and fat-free tissue) of distinct densities. Body density was traditionally measured using the technique of under-water weighing, which is both expensive and not widely acceptable to patients. Air displacement techniques are becoming more popular although these techniques also require a participant burden and may be problematic for individuals with claustrophobia.

## Bioimpedance Analysis

This predictive technique of assessing body fatness is becoming widely used for individuals and research studies. The measurement is based on the relative impedance of tissues to a small electric current that is passed through the body. The impedance is converted into an estimate of total body water, which is used to calculate fat-free mass and then fat mass by difference from body weight. Because the estimate of total body water is crude, the estimation of fat mass by this technique is relatively weak.

## Anthropometry

In addition to height and weight measurements for the calculation of BMI, other anthropometric assessments can provide useful predictions of body fatness and metabolic risk. Body fat can be estimated by measuring skinfold thickness directly using a caliper at different sites on the body. These often include the upper arm (biceps and triceps), under the scapular (subscapular), and above the iliac crest (suprailiac). The raw data provide a direct estimate of body fat, with an increasing number of measurement sites correcting for differences in fat distribution. Data can also be used to predict body density and thence fatness through prediction equations. These equations are population-specific however and may not be widely generalizable, suggesting that the raw skinfold thicknesses are often more useful.

Waist circumference, or the ratio of waist to hip circumference, has recently been recognized as a simple measure that has important risk prediction properties. Waist circumference is only minimally related to height and is a good predictor of visceral and total fat mass as well as disease risk. It is relatively easily measured within the primary care and research settings, which makes it a useful addition to the assessment of obesity by BMI. WHO guidelines specify that the circumference should be measured at the midpoint between the lower margin of the last rib and the top of the hip bone. Waist circumference cut-points associated with increased risk have not been fully defined as yet.

The health impact of obesity is considerable, and obesity impacts on both quality and length of life. Overweight and obesity are associated with a wide range of chronic conditions, such as diabetes, hypertension, cardiovascular disease (CVD), and certain cancers, as well as non-lifethreatening but painful conditions, such as arthritis, back pain, and breathlessness. Obesity also places enormous financial burdens on governments and individuals, and accounts for a significant proportion of total health care expenditure in developed countries. Analyses suggest that obesity is fast approaching cigarette smoking as the major preventable cause of mortality.

In recent years, our understanding of the epidemiology and causation of obesity has improved dramatically and there is an acceptance that urgent action is required to address the problem. There is also a limited, but growing, body of successful, large-scale obesity prevention initiatives from across the world. These experiences, together with understandings gained from smaller-scale obesity prevention initiatives and experiences from the management of other epidemics of noncommunicable diseases, provide useful guidance on effective planning and implementation of obesity prevention programs.

## Principles of Obesity Prevention

### Rationale for Obesity Prevention

There are a number of reasons why prevention is likely to be the only effective way of tackling the problem of overweight and obesity. First, obesity develops over time, and once it has done so, it is very difficult to treat. A number of analyses have identified the limited success of current obesity treatments (with the possible exception of surgical interventions) to achieve long-term weight loss. Second, the health consequences associated with obesity result from the cumulative metabolic and physical stress of excess weight over a long period of time and may not be fully reversible by weight loss. Third, the proportion of the population that is either overweight or obese in many countries is now so large that there are no longer sufficient health care resources to offer treatment to all. It can be argued, therefore, that the prevention of weight gain (or the reversal of small gains) and the maintenance of a healthy weight would be easier, less expensive, and potentially more effective than to treat obesity after it has fully developed.

## Objectives of Obesity Prevention

There remains a great deal of confusion regarding the appropriate objectives of an obesity prevention program. It is often assumed that to be effective, any intervention to address the problem of excess weight in the community should result in a reduction in the prevalence of overweight and obesity. However, such an objective is unrealistic and may be counterproductive. Most communities are experiencing significant increases in the average weight of the population as a result of a sizeable energy surplus resulting from reduced energy expenditure combined with an increased energy intake. This is leading to rapidly escalating rates of overweight and obesity. To reverse this trend will require not only the removal of this energy surplus but also the creation of a negative energy balance that will need to be maintained by the whole population for a significant period of time. Few (if any) interventions are capable of reducing energy intake, or increasing energy expenditure sufficiently, or are sustained long enough and with sufficient reach to achieve this effect. More appropriate objectives would relate to a reduction in the level of weight gain or the maintenance of weight stability in adults and the achievement of appropriate growth and development in children. The achievement of these objectives would result in a slowing in the rate of increase, followed by stabilization, and then an eventual decline in the level of overweight and obesity in the community.

However, even the goal of weight stability within a population may be difficult to achieve in the short term because it would require the maintenance or reestablishment of energy balance in a time of significant energy surplus. Therefore, it may be necessary to identify more sensitive short- and medium-term outcomes to evaluate obesity prevention programs. Such process outcomes may relate to the achievement of appropriate changes in energy intakes or outputs, food or physical activity behaviors, or changes to the environment that are significant enough to positively impact upon the achievement of energy balance.

## Importance of Weight Gain Prevention in Adults

There are a number of important reasons why it is preferable to focus on weight gain prevention as the key individual and population objective of obesity prevention initiatives in adults (**Box 1**). The association between elevated body mass index (BMI) and increased risk of ill health is clear and consistent. However, research has demonstrated that weight gain *per se* is also associated with increased health risk, and that this risk is independent of absolute BMI (provided a person is not underweight). A number of studies have shown strong relationships between weight gain and increasing levels of diabetes, hypertension, gall bladder disease, and coronary heart disease. Therefore, a large weight gain in a lean individual may carry equivalent risk in maintaining a stable but slightly elevated BMI in an overweight individual. The combination of an elevated BMI and ongoing weight gain, however, leads to greatly magnified levels of risk.

## Who Should Obesity Prevention Strategies Target?

Deciding where to invest limited time and resources in obesity prevention is a difficult task but finite health resources make this a necessity. WHO has identified three distinct but equally valid and complementary levels of obesity prevention (**Figure 1**). The specific 'targeted' approach directed at very high-risk individuals with existing weight problems is represented by the core of the figure, the 'selective' approach directed at individuals and groups with above average risk is represented by the middle layer, and the broader universal or populationwide prevention approach is represented by the outer layer. This replaces the more traditional classification of disease prevention (primary, secondary, and tertiary), which can be confusing when applied to a complex multifactorial condition such as obesity.

### Box 1 Why focus on weight gain prevention?

- Weight gain in adulthood carries an independent risk of ill health.
- Risk for chronic disease begins to increase from low BMI levels and significant weight gain can occur within normal limits.
- Extended periods of weight gain are difficult to reverse.
- Weight gain in adulthood is mostly fat gain.
- The relationship between absolute BMI and health risk varies with age and ethnicity, but no such variations occur in the relationship between weight gain and ill health.
- A focus on weight gain prevention avoids exacerbation of inappropriate dieting behaviors.
- Weight maintenance can serve as a first stage goal for weight treatment programs.
- The message is equally relevant to all sections of the adult population.
- It avoids further stigmatization of people with an existing weight problem.
- It avoids reference to poorly understood terms such as 'healthy weight.'

**Figure 1** Levels of obesity prevention intervention. Adapted from Gill TP (1997) Key issues in the prevention of obesity. *British Medical Bulletin* 53(2): 359–388, with permission from BMJ.

Universal prevention is the domain of public health, whereas selective and targeted prevention are predominantly dealt with in community and health care service settings. Community settings include schools, colleges, worksites, community centers, and shopping outlets.

### Whole Community

Overweight and obesity are public health problems of relevance to the whole community and require strategies that focus on populationwide change rather than attempting to address individuals or small groups in isolation of the community in which they live. An effective population strategy needs to both improve population knowledge about obesity and its management and reduce the exposure of the community to obesity-promoting factors in the environment. Action at a population level requires coordination at a central level and the investment of resources to be maintained over a long period of time to achieve population change.

### Family Focus

There are numerous reasons why children should be a major focus of any obesity prevention strategy. There is strong evidence that a high proportion of overweight or obese children will become obese adults. Childhood obesity also has immediate effects on health, and weight-related conditions are becoming more prevalent and their effect more pronounced as the rates of childhood obesity increase. However, children grow rapidly and increase the level of lean body mass as they age, and so reducing or keeping fat mass constant allows the normalization of weight over time. Thus, childhood (particularly younger children) is a period during which prevention efforts have a higher chance of success.

However, children also have little direct control over the environment in which they live. Parents and other caregivers mostly control decisions regarding the food available and the opportunities for activity. In addition, the behaviors of parents and other siblings have a profound effect on the diet and physical activity behaviors of children. For this reason, it is preferable to focus childhood obesity prevention efforts on the family environment rather than directly on children.

### High-Risk Groups

There are a number of groups that appear to be at higher risk of developing overweight and obesity ([Table 1](#)). These groups warrant special attention and include the following:

- Those with a family history of weight problems.
- Socially disadvantaged and isolated communities.
- Certain ethnic groups.
- Smokers who have recently quit smoking.
- Those who have recently lost weight.

**Table 1** Identifying at-risk groups for obesity

<i>Critical ages and life stages</i>	<i>Reason for increased risk</i>
Prenatal	There is strong evidence that <i>in utero</i> development has permanent effects on later growth and energy regulation.
Adiposity rebound (5–7 years)	BMI begins to increase rapidly after a period of reduced adiposity during preschool years. Food and activity patterns change as a result of exposure to other children and school. Early and rapid weight rebound often precedes the development of obesity.
Adolescence	Period of increased autonomy that is often associated with irregular meals, changed food habits, and periods of inactivity during leisure combined with physiological changes that promote increased fat deposition, particularly in females.
Early adulthood	Early adulthood usually correlates with a period of marked reduction in physical activity, increased alcohol consumption, and poor diets.
Pregnancy	Excessive weight gain during pregnancy often results in retention of weight after delivery, particularly with early cessation of breast feeding. Inappropriately large as well as inadequate weight gain may both contribute to weight problems for the developing child.
Menopause	In Western societies weight generally increases with age, but it is not certain why menopausal women are particularly prone to rapid weight gain. The loss of the menstrual cycle does affect food intake and reduce metabolic rate slightly.
<i>High-risk groups</i>	
Family history of weight problems	There is no longer any doubt that given the same environment some individuals are more prone to depositing fat. The basis of these differences in individual susceptibility to obesity is yet to be fully elucidated, but is believed to involve a number of physiological processes associated with fat deposition, oxidation, and involuntary energy expenditure.
Recent migrants and refugees	Recent migrants and refugees often find it difficult to maintain traditional diet and physical activity patterns and may replace them with inappropriate foods.
Socially or economically disadvantaged	In many developed countries, there is an inverse association between income and education level and obesity, which is most pronounced among women. It is argued that cheaper foodstuffs are usually high in fat and energy dense and those with less financial resources spend more time in sedentary activities such as watching TV.
Shift workers	Disrupted sleep patterns and altered daily routine have been associated with poorer quality diets, reduced opportunities to exercise and weight gain in those working night shifts.
Recent successful weight reducers	Successful weight reduction is usually followed by the regain of one-half to one-third of the weight loss over the following year. It is believed that biological and behavioral processes act to drive body weight back to baseline levels.
Recent past smokers	Smokers are usually thinner than nonsmokers because smoking tends to depress appetite, increase the basal metabolic rate, and, after each cigarette, induce a surge in heart and metabolic rate. The effect on metabolism of smoking 24 cigarettes per day has been estimated at approximately 200 kcal per day.

In addition, there are certain times in a person's life when the person is more prone to weight gain (**Table 1**). These age groups could be considered for selective prevention interventions. These times include the following:

- Prenatal
- Adiposity rebound (5–7 years)
- Adolescence
- Early adulthood
- Pregnancy
- Menopause

### Those with an Existing Weight Problem

In developing weight gain prevention strategies, it is important not to neglect those with an existing weight problem who could benefit from more intensive efforts to help prevent further weight gain.

### Key Elements of a Weight Gain Prevention Plan

Weight gain and obesity develop when the energy intake from food and drink exceeds energy expenditure from physical activity and other metabolic processes. It is often assumed that the prevention of weight gain should focus solely on attempting to alter these behaviors within individuals and communities. However, research has consistently shown that numerous and diverse factors,

**Table 2** Summary of the strengths of evidence of factors that may promote or protect against weight gain and obesity

<i>Evidence</i>	<i>Decreases risk</i>	<i>Increases risk</i>
Convincing	Regular physical activity High dietary fiber intake	High intake of energy-dense foods <sup>a</sup> Sedentary lifestyle
Probable	Home and school environments that support healthy food choices for children Promoting linear growth	Heavy marketing of energy-dense foods and fast food outlets Adverse social and economic conditions in developed countries (especially for women) Sugar-sweetened soft drinks and juices
Possible	Low glycemic index foods Breast feeding	Large portion sizes High proportion of food prepared outside of home Rigid restraint/periodic disinhibition eating patterns
Insufficient	Increased eating frequency	Alcohol

Source: Adapted with permission from World Health Organization (2003) *Joint WHO/FAO Expert Report on Diet, Nutrition and the Prevention of Chronic Disease*, WHO Technical Report Series 916. Geneva: WHO.

<sup>a</sup>Energy-dense foods are high in fat/sugar and energy-dilute foods are high in fiber and water, such as vegetables, fruits, legumes, and whole grain cereals.

including environmental and social factors, influence the behaviors that lead to excessive weight gain. Addressing aspects of the obesogenic (obesity-promoting) environment, as well as individuals' eating and physical activity patterns, is considered to be critical to the success of any obesity prevention program.

The 2003 WHO report on diet, nutrition, and the prevention of chronic disease undertook a detailed review of the literature and identified a range of key factors that either increase or decrease the risk of weight gain and the development of obesity (Table 2). These factors were rated on the quality of evidence available to support their contributory role. This analysis serves as a very useful guide as to the focus of weight gain prevention initiatives.

### Diet and Physical Activity Behaviors

The WHO analysis and subsequent reviews have identified a number of key dietary and physical activity behaviors, amenable to change, that could conceivably influence energy balance sufficiently to contribute to the prevention of weight gain and obesity. Behaviors that reduced the risk of obesity included regular physical activity, high dietary fiber intake, and possibly breast feeding, and low glycemic index diets. Behaviors that increased the risk of obesity included a high intake of energy-dense foods, a high intake of sugar-sweetened drinks and juices, time spent in sedentary behaviors, and possibly large portion sizes, a high intake of fast foods, and a restrained eating pattern.

The area of dietary and physical activity antecedents to weight gain and obesity is still incompletely understood and new research findings, which help clarify our understanding, are being presented on a regular basis. In addition, different behaviors are more prevalent or pronounced in different regions of the world. It is therefore difficult to give definitive recommendations on the most important and useful behaviors to target in obesity prevention strategies. However, strong evidence exists to support the inclusion of some key behaviors.

### Reducing Energy Intake

#### **Reducing the Intake of High Energy-Dense Foods (i.e., foods high in fat/sugar)**

There is a high level of agreement that the overconsumption of energy-dense foods is a major contributor to excess energy intake and weight gain and that the restriction of energy-dense food items is a useful strategy for the prevention of weight gain. However, discussion continues as to whether fat or refined carbohydrate is the major contributor to energy density in the modern diet and thus should be the target of programs to control weight. The debate is being fueled by dietary data from many developed countries showing that dietary fat intakes have leveled out or declined slightly and intakes of carbohydrates have increased dramatically. However, research has shown that dietary fat (along with water and fiber) is a major contributor to the energy density of foods and that *ad libitum* low-fat diet plans are an effective dietary approach to weight gain prevention or moderate weight loss. There is also strong evidence that excess refined carbohydrate, particularly high glycemic index carbohydrate, contributes to weight gain and its restriction aids weight loss and improves cardiovascular risk factor profiles.

#### **Increasing the Intake of High-Fiber, Energy-Dilute Foods (especially vegetables and fruits)**

There is less evidence on the effectiveness of increasing the intake of energy-dilute foods such as vegetables and some fruits in the diet. Such a strategy would assist weight gain prevention only if the inclusion of such foods leads to a reduction in the intake of more energy-dense alternatives and thus creates a reduction in energy intake. Few studies have addressed this issue in a comprehensive manner, but the additional health benefits of these foods make such a strategy low risk in nutritional terms.

### ***Reducing the Consumption of Sugar-Sweetened Soft Drinks and Juices***

Evidence is accumulating from a variety of studies that energy consumed as sweetened drinks is less well compensated for than energy consumed as solid food. Many, but not all, longitudinal studies have indicated that sweetened drinks (soft drinks or sodas) are associated with weight gain in both children and adults. Recent work has also demonstrated that the simple strategy of reducing the intake of sweetened drinks can be effective in preventing or limiting inappropriate weight gain.

### ***Reducing the Level of Food Prepared Outside Home***

The proportion of food purchased and consumed at food outlets outside home has increased dramatically in recent decades in both developed and developing nations. In the United States, approximately 40% of the household food budget is spent on food eaten away from home, and much of this is spent at fast food outlets. A number of analyses has linked increased consumption of fast food with increased risk of obesity. Although only a limited number of studies has evaluated the effect of reducing the consumption of fast food, it would seem to be a valuable strategy with few nutritional negatives.

### ***Reducing Portion Sizes***

The portion size of packaged foods and snacks, as well as restaurant serving sizes, has increased rapidly in recent times and has been identified as an important factor in the consumption of excess energy. Evidence suggests that people will consume the portion of food they are provided rather than respond to satiety signals to stop eating and leave food. Also, as the serving size increases, the ability of consumers to estimate accurately how much they have consumed decreases. Reducing portion sizes is a simple but immediately effective mechanism for reducing energy intake.

## **Increasing Energy Expenditure**

### ***Regular Physical Activity***

Although it is difficult to obtain accurate assessments of physical activity, there is little doubt that energy expenditure from activity has decreased in the past 50 years in most countries throughout the world. In contrast to popular belief, participation rates in organized leisure-time physical activity have not declined in recent times and may have increased in many countries. This supports the contention that the greatest contributor to this reduction in energy expenditure is associated with substantial changes in occupational and incidental physical activity. Changes in employment patterns and work practices together with a reliance on motorized transport and the removal of almost all manual labor from our daily lives have led to a dramatic reduction in daily physical exertion.

Studies that have examined the association between physical activity and weight gain and the impact of increasing physical activity on weight gain prevention have been limited by the ability to accurately measure physical activity across the whole day and to engage people in sufficient levels of physical activity to prevent weight gain. However, there is sufficient evidence to support an important role for increasing physical activity in any weight gain prevention strategy, although questions remain about how much exercise is necessary and what type of exercise is appropriate to promote. The issue of the amount of extra time that people should spend in moderate physical activity to prevent weight gain remains hotly debated, but it is clearly substantially more than the 30 min on 5 days or more each week recommended by experts to reduce CVD risk. The type of exercise that should be the focus of weight gain prevention strategies is also under review. It has been suggested that the most effective ways to include regular physical activity in daily living are through increased incidental activity, increased participation in active recreation, and increased use of active transport.

### ***Reduced Time Spent in Sedentary Behaviors (especially TV watching)***

Changes in societal structures and improvements in technology have allowed a reduction in time spent at work or on domestic chores, leaving a greater proportion of the day for leisure. At the same time, most of the entertainment options developed to fill this time, such as watching television, playing video games, and using computers, are sedentary activities that require very little energy expenditure. These forms of entertainment, which initially complemented other forms of leisure activity, are occupying more hours of the day and are displacing more active pursuits and games. As a consequence, a number of studies have identified clear links between time spent in this sedentary behavior and weight gain. However, it is important to make a distinction between a lack of physical activity and sedentary behavior because their mechanisms for impacting on body weight may be different and a person with a high level of physical activity can also have a high level of sedentary behavior. Although the precise pathway by which sedentariness influences weight gain is not known, it is believed to involve both a reduction in physical activity and physiological reductions in energy expenditure together with an increase in dietary energy intake through inappropriate food intake that is often stimulated by and accompanies sedentary activities.

Some studies in children have shown that programs that seek to reduce time spent in sedentary behaviors are more effective in controlling weight than programs that aim to increase physical activity alone. In some cases, a simple program to reduce the amount of time spent watching television was sufficient to significantly limit inappropriate weight gain in children.

## **Creating Supportive Environments**

The external physical, social, political, and economic environments in which people exist have a profound effect on their attitudes and behaviors. Each day, people interact with a wide range of services, systems, and pressures in settings such as schools, the

workplace, home, restaurants, and fast food outlets. In addition, laws, policies, economic imperatives, and the views of governments, industry, and society as a whole influence these settings. Each of the features of this complex system, which shapes the environment in which we live, has the capacity to inhibit or encourage appropriate dietary and physical activity patterns. The availability of open space, access to public transport, the design of suburbs, access to buildings, the perceived level of safety, provision of lighting, and many other factors influence our capacity and desire to be more physically active in our daily lives. Similarly, advertising pressures, access to appropriate food choices, school food policies, and nutrition information, and labeling all potentially influence food selection. Today, there is also a large commercial drive to promote obesogenic behaviors (cars and food are the two most advertised products on television). The Foresight Program of the UK Government Office for Science recently produced a complex conceptual model with 108 variables known as the obesity systems map to illustrate the complexity and interaction of the broad range of variables that drive the development of obesity.

Trying to motivate people to make healthy choices when the external environment works against such behaviors is a recipe for failure. **Figure 2** illustrates the role that the social environment plays in assisting or inhibiting personal behavior choices made by individuals, which ultimately has an impact on their health. Great success is likely to be achieved by creating a supportive environment and then promoting the healthy dietary and physical activity choices within such an environment.

### Identifying Effective Obesity Prevention Interventions

Identifying the most efficacious programs to prevent obesity from the published literature has proved problematic. A number of systematic reviews have assessed the current scientific literature of reported programs addressing the prevention of obesity in both children and adults and have identified only a limited number of evaluated programs to assess. Reviews of childhood obesity prevention initiatives indicated that certain approaches appear to be associated with greater success. An intensive intervention in small groups was a successful management strategy in children, as was involving all the family. Reducing levels of inactivity was successful at both treating and preventing weight gain. Some interventions which increased time spent in formal physical activity were successful in controlling weight gain but generally multicomponent programs which addressed a range of strategies were deemed to hold the most potential. The Ensemble Prévenons l'obésité des Enfants program is a multicomponent, community-based childhood obesity program which has been implemented in a number of local government regions in France and throughout Europe and has produced promising reduction in measured obesity rates.

However, most reviews conclude that there was simply too small a body of research conducted in a limited number of settings to provide firm guidance on consistently effective interventions. To address the limitation, some researchers have proposed a system that allows the integration of the available information from the literature together with other forms of evidence including experience from past public health and health promotion action to identify the target groups and settings most likely to have produced effective action on obesity. This is achieved by producing a classification system which is based on potential for change rather than demonstrated effectiveness. To achieve this, interventions are selected and assessed in terms of how 'promising' they may be in addressing population weight gain, using a health gain/risk framework. This allows the selection of interventions to be based on the best available evidence, while not excluding untried but promising strategies (see **Table 3**). The return or health gain can be defined in terms of demonstrated or modeled efficacy (from previous studies), potential population reach, and likely uptake (estimated). Uncertainty or risk can be defined in terms of the level of information or evidence to support the effectiveness of the intervention.

### Lessons from Other Prevention Efforts

Although the number of successful large-scale obesity prevention programs is limited, there is a wealth of information from past public health programs that can be used to address other chronic diseases and risk factors. The International Obesity Task Force identified 10 key principles on which efforts to prevent obesity at a population level should be based. These are presented in

**Figure 2** Influence of societal and environmental factors on development of obesity. Reproduced from House of Commons Health Committee (2004) *Obesity: Third Report of Sessions 2003–04. Volume 1. Report Together with Formal Minutes*. London: The Stationery Office Ltd.

**Table 3** Matrix for determining the 'promise' of an intervention

<i>Certainty of effectiveness* (Risk)</i>	<i>Potential population impact* (Return)</i>		
	<i>Low</i>	<i>Moderate</i>	<i>High</i>
Quite low	Least promising	Less promising	Promising
Medium	Less promising	Promising	Very promising
Quite high	Promising	Very promising	Most promising

### Box 2 IOTF principles for the development of population obesity prevention initiatives

1. Education alone is not sufficient to change weight-related behaviors. Environmental and societal intervention is also required to promote and support behavior change.
2. Action must be taken to integrate physical activity into daily life, not just to increase leisure time exercise.
3. Sustainability of programs is crucial to enable positive change in diet, activity, and obesity levels over time.
4. Political support, intersectoral collaboration, and community participation are essential for success.
5. Acting locally, even in national initiatives, allows programs to be tailored to meet real needs, expectations, and opportunities.
6. All parts of the community must be reached, not just the motivated healthy.
7. Programs must be adequately resourced.
8. Where appropriate, programs should be integrated into existing initiatives.
9. Programs should build on existing theory and evidence.
10. Programs should be properly monitored, evaluated, and documented. This is important for dissemination and transfer of experiences.

**Box 2** and are drawn from experiences addressing CVD, smoking, alcohol and drug problems, dental disease, road accidents, and other public health issues.

Although much has yet to be elucidated about the development of obesity and its effective management and prevention, there is a consensus that action to address the problem must not be delayed. Efforts to prevent weight gain need to be well designed, comprehensive, and appropriately resourced and evaluated so that the knowledge base improves with each new program.

## Key points

- Review the role of key nutrients, foods, and dietary patterns on risk of osteoporosis and fractures.
- Discuss the impact of modifiable and non-modifiable factors on bone health.
- Highlight novel interactions between nutritional health of other physiological systems and bone health.

## Glossary

**Dual energy x-ray absorptiometry (DXA)** This non-invasive test uses the degree to which x-rays are attenuated as they pass through the human body to evaluate bone mineral content and density of the entire skeleton or at selected sites (typically the lumbar spine, hip and cervical vertebrae)

**Osteocyte** Osteocytes comprise 95% of all bone cells and are derived from osteoblasts that have become imbedded in mineralized bone. These cells respond to mechanical forces and play an important role in the regulation of bone turnover

**Osteopenia** Osteopenia is a term used to denote low bone mass. It is diagnosed when the bone mineral density T Score (from a DXA test) is between  $-1.0$  and  $-2.5$

**Osteoporosis** A term used to denote a significant loss of bone. It is typically defined when the bone mineral density T Score (from a DXA test) is less than  $-2.5$

**Parathyroid Hormone (PTH)** Parathyroid hormone is secreted by the parathyroid glands in response to low serum ionized calcium. It functions to maintain circulating calcium concentrations within a narrow range

**Phosphatonin** Phosphatonins are compounds that regulate phosphorus metabolism using PTH-independent mechanisms

## Introduction

Optimal dietary intake is essential for bone health. During childhood and the pubertal growth spurt, nutrients are needed to fully consolidate skeletal mass and to insure the attainment of a peak bone mass consistent with one's genetic potential. After peak bone

mass is obtained, nutrition continues to play an essential role in skeletal health. If key nutrients are not consumed at required levels, mineral may be lost from bone or essential bone proteins may not be fully functional.

Osteoporosis and osteopenia are currently significant public health problems. Once a substantial amount of bone mineral and matrix is lost, bone becomes more susceptible to fracture. Osteopenia is defined when adult bone mineral density values are 1–2.5 SD below the mean peak value observed in a young adult. Osteoporosis is defined when adult bone mineral density falls 2.5 SD or more below that observed in a young adult. Recent estimates available from 2017 to 2018 suggest that more than 10 million adults over the age of 50 y in the United States have osteoporosis, and another 43 million have osteopenia and are at risk for osteoporosis and fracture (Sarafrazi et al., 2021). The increasing impact of low bone mass on public health can be demonstrated by the large increase in the age-specific rate of fractures (Rosengren et al., 2015). Recognition of this chronic disease is an increasing concern globally as the population ages and mean life span increases. Because bone loss is not fully reversible, the most effective strategies for treating osteoporosis should focus on prevention with nutrition playing a key role.

## Dietary intake and body mass

A balanced diet is important to promote health and to maintain an appropriate body weight. An individual's body weight is one of the strongest determinants of bone mass because of the skeleton's responsiveness to the load that is placed upon it. Individuals with small body frames or those that are excessively thin have an increased risk of osteoporosis due to a lower overall skeletal reserve to draw on for calcium needed to offset the annual loss of bone that occurs later in life. At the extreme end of this spectrum, individuals with anorexia nervosa are at risk of osteoporosis because of alterations in hormonal status and amenorrhea in addition to insufficient dietary intake of nutrients required for bone health.

Excess body weight is typically associated with a greater skeletal mass, but more recent evidence suggests that obesity may have negative effects on bone health. Excessive fat accumulation may adversely affect bone health by a variety of mechanisms including overall and adipocyte-specific hormonal dysregulation, and increased oxidative stress and inflammation, eventually compromising bone quality (Shapses et al., 2017). Insulin resistance has been proposed as a key mediator of the relationship between adiposity and bone mass (Kindler et al., 2019). Additionally, obesity has been associated with lower 25-hydroxyvitamin D (25OHD) and higher parathyroid hormone concentrations (Pereira-Santos et al., 2015). These changes are thought to occur in part due to sequestration of vitamin D in adipose tissue or volumetric dilution. Bariatric surgery as a treatment for severe obesity is becoming more common and leads to both a loss of body weight and bone mass. Available evidence from epidemiological studies suggests that the type of procedure (restrictive, malabsorptive, or mixed) plays a role in determining the risk of fractures, with mixed procedures such as Roux-en-Y gastric bypass being associated with the highest risk of fractures (Gagnon and Schafer, 2018). Overall, the observed negative effects of bariatric surgery on bone health are multifactorial, involving nutritional deficiencies, mechanical unloading, hormonal shifts, and changes to total body composition. At present, the long-term impact of this surgery on skeletal health has not been fully elucidated as fracture risk only begins to manifest 2–5 years post-surgery (Gagnon and Schafer, 2018).

While overall caloric intake impacts body weight, many individual nutrients and dietary components have been studied in relation to their impact on bone health (Table 1). Several of these key nutrients and components of the diet have key roles in bone health and skeletal homeostasis.

## Calcium

Calcium is the most abundant mineral found in bone and comprises approximately 33% of bone mineral. Optimal calcium intakes are essential across the lifecycle to meet the daily intrinsic requirements of calcium needed for skeletal growth and to offset urinary,

**Table 1** Nutritional, lifestyle, and physiological parameters that may influence bone health.

Minerals	Vitamins/hormones	Lifestyle and environmental factors	Dietary components	Interactions of the bone and other physiological systems
Calcium	Vitamin D	Body mass index	Protein	Muscle mass
Phosphorus	Vitamin K	Exercise	Soy/phytoestrogens	Gut microbiome
Magnesium	Vitamin A	Cigarette smoking	Fatty acids	Adipose tissue
Sodium	Vitamin C	Alcohol intake	Homocysteine	Immune function
Zinc	Vitamin B <sub>12</sub>	Sleep		
Copper	Vitamin B <sub>6</sub>			
Iron	Folate			
Boron				
Manganese				
Fluorine				
Potassium				
Silicon				

dermal and endogenous fecal calcium losses. When dietary intakes of calcium are not sufficient to maintain circulating calcium concentrations and/or when the losses of calcium from the body are excessive, bone calcium will be resorbed to maintain calcium homeostasis. Because calcium is essential for the structural integrity of bone, deficiencies or inadequate intakes of this mineral will have a detrimental impact on bone mass and quality (Weaver and Peacock, 2019).

Skeletal mass peaks at approximately age 20–30 years with the majority of this gain (nearly 50%) being accrued during the pubertal growth spurt (Baxter-Jones et al., 2011). Thus, this period of skeletal accretion can be viewed as a window of opportunity to maximize skeletal mass. Calcium supplementation studies in children found increased bone mass following supplementation, an effect that is most pronounced when implemented during the prepubertal period (Weaver et al., 2016b). However, supplementation appears to primarily impact the tempo at which peak bone mass is achieved because gains in bone mass are not typically maintained after supplementation ends and this does not appear to result in a net difference in peak bone mass. The data on the efficacy of calcium supplementation with or without vitamin D in reducing risk of fractures in adults are controversial. In 2013, the US Preventive Services Task Force (USPSTF) concluded that there was insufficient evidence to recommend daily vitamin D and calcium supplementation for the prevention of fractures in healthy adults (Moyer, 2013). In 2016, the National Osteoporosis Foundation (NOF) conducted a meta-analysis of randomized-controlled trials that supported the use of calcium and vitamin D supplementation as an intervention for fracture risk reduction in middle-aged to older adults (Weaver et al., 2016a). Subsequently, in 2018 the USPSTF published an updated review, which concluded that vitamin D and calcium supplementation or calcium supplementation alone is not associated with lower incidence of fractures in healthy adults, however, the quality of evidence was deemed to be low (Kahwati et al., 2018). In high-risk adults, calcium supplementation has been found to have mild beneficial effects on bone mass and reduced fracture risk (Harvey et al., 2017) and may have the greatest impact in individuals whose habitual dietary calcium intakes are below 400 mg (10 mmol) d<sup>-1</sup>.

In 2010 the National Academy of Medicine (NAM, previously known as the Institute of Medicine) updated the dietary recommendations for calcium and vitamin D (Table 2) (Ross et al., 2011). Using newly available data, the committee was able to set an RDA (recommended dietary allowance) for calcium and vitamin D for all age groups except infants. In infants during the 1st year of life available data were only sufficient to establish an adequate intake (AI). As in the previous recommendations, due to the importance of calcium in bone mineralization, the recommended daily allowance of calcium is highest (1300 mg (32.5 mmol) d<sup>-1</sup>) between the ages of 9–18 y. Because of the known decreased efficiency of intestinal absorption coupled with increased losses of calcium that occur in older women as they progress through menopause, calcium intakes were increased to 1200 mg (30 mmol) d<sup>-1</sup> in women ages 50 y and older but intakes for men remain at 1000 mg until the age of 70 y at which time they also increase to 1200 mg (30 mmol) d<sup>-1</sup>. Recent dietary intake data suggest most adults 19 y and older do not consume adequate amounts of calcium or vitamin D. The Dietary Guidelines for Americans (DGA) 2020–2025 highlighted both calcium and vitamin D as nutrients of public health concern for the general US population, including children and adults, as low intakes of these nutrients are associated with health concerns (USDA and USHHS, 2020). The DGA recommends all age groups over 2 y increasing consumption of nutrient-dense, calcium- and vitamin D-rich foods, such as low-fat dairy products or soy alternatives. This

**Table 2** 2010 Dietary reference intakes for Calcium and vitamin D.

Group	Ca RDA (mg)	Vitamin D RDA (IU)
Infants		
Birth–6 months	200 (AI)	400 (AI)
7 months–1 year	260 (AI)	400 (AI)
Children		
1–3 years	700	600
4–8 years	1000	600
Male adolescents/adults		
9–18 years	1300	600
19–70 years	1000	600
>70 years	1200	800
Female adolescents/adults		
9–18 years	1300	600
19–50 years	1000	600
51–70 years	1200	600
>70 years	1200	800
Pregnancy		
14–18 years	1300	600
≥19 years	1000	600
Lactation		
14–18 years	1300	600
≥19 years	1000	600

Only adequate intake (AI) recommendations are available for those under the age of 1 year.

recommendation is particularly important for adolescents during peak bone mass accrual, for adults during the time when peak bone mass accrual is still active, and in post-menopausal women and elderly adults.

Because the majority of dietary calcium is obtained from dairy products, those with low dairy intakes or with other factors such as lactose intolerance, dieting or altered appetite and food consumption patterns may need to rely more on fortified food products or calcium supplements. An increasing variety of calcium fortified food products are now also available. Individuals with lactose intolerance may improve intake of calcium by use of lactose-free dairy products or lactase pills. Whenever possible, increased calcium intake should be obtained from dietary vs. supplemental sources in order to obtain additional nutrients needed for bone health including protein, magnesium, zinc, phosphorus and vitamin D (Geiker et al., 2020).

Use of calcium supplements is currently common in the United States, particularly among older women. Several forms of calcium supplements are commercially available with calcium carbonate and citrate being the forms most commonly consumed. Existing supplemental forms differ slightly with respect to their relative calcium content per tablet and their absorbability; however the magnitude of these differences is minor and may not be biologically significant. Several calcium supplements now also contain additional nutrients required for bone health including vitamins D and K. Because the fraction of calcium absorbed decreases as calcium intake increases, little additional benefit per dose is achieved when taking supplemental calcium sources containing more than 500 mg (12.5 mmol) per dose (Heaney et al., 1975).

The increased availability of calcium-fortified food products may increase the likelihood of excessive intakes of calcium. The tolerable upper intake level (UL) for calcium ranges between 2000 and 3000 mg d<sup>-1</sup> depending on the age group in question. These limits for adults were based on data that found increased risk of kidney stones (mainly among postmenopausal women ingesting calcium supplements) (Ross et al., 2011).

## Vitamin D

Vitamin D is integral to bone health primarily due to the role it plays in calcium and phosphorus homeostasis. The active form of vitamin D, calcitriol, stimulates calcium and phosphorus absorption, and vitamin D along with parathyroid hormone (PTH) plays a regulatory role in renal calcium reabsorption and in calcium release from bone.

Vitamin D can be obtained either from the diet (as D<sub>2</sub> or D<sub>3</sub>) or is produced in the skin (as D<sub>3</sub>) following cutaneous exposure to sunlight. These two forms of vitamin D may have similar effects on target tissues at low doses, but some data suggest that high doses of D<sub>2</sub> may be less effective than D<sub>3</sub> for endocrine effects on target tissues while D<sub>2</sub> may be more available for autocrine/intracrine effects because of its lower affinity for vitamin D binding protein (Chun et al., 2019; Tripkovic et al., 2012). Circulating 25OHD is the best indicator of vitamin D status because this form is not tightly regulated, and its production is indicative of available D<sub>2</sub> and D<sub>3</sub>.

Lack of sufficient endogenous production of vitamin D in the skin is influenced by geographical location (northern latitudes have a shorter season over which the wavelength needed for vitamin D synthesis is available), increased use of sunscreen, and cosmetics and skin care products containing sunscreen (sunscreens when applied properly may limit the dermal production of vitamin D) and by lifestyle factors that decrease exposure to sunlight.

Calcium absorption is believed to be maximal when 25OHD concentrations are between 12 and 20 ng mL<sup>-1</sup> (30 and 50 nmol L<sup>-1</sup>) (Rosen et al., 2012). A serum 25OHD level of 16 ng mL<sup>-1</sup> (40 nmol L<sup>-1</sup>) was identified by the 2010 NAM committee as that desired for the population median and a concentration of 20 ng mL<sup>-1</sup> (50 nmol L<sup>-1</sup>) was identified as sufficient to meet the needs of "coverage" for the population (Ross et al., 2011). Recognizing the importance of vitamin D on skeletal health, the 2010 RDA for vitamin D was tripled over the earlier AI of 200 IU to the new RDA value of 600 IU for those between the ages of 1–70 y. In those over the age of 70 y this was raised to 800 IU to account for the increased concerns of bone health in this age group and for the variability in the physiology of aging that may impact renal function, cutaneous synthesis of vitamin D, altered body composition and increased PTH concentrations.

The UL for vitamin D was assessed using the indicators of hypercalcemia and related toxicity in adults and on retarded longitudinal growth in infants. Using these endpoints, the UL was set between 1000 and 3000 IU for infants and children through 8 y of age after which time it is set at 4000 IU over the remaining life course.

Achieving this level of vitamin D may be challenging from diet alone unless fortified food products are consumed. Vitamin D supplements may be useful in meeting requirements in those with low intake of dairy products. Several supplements are on the market containing various amounts of either D<sub>2</sub> or D<sub>3</sub>.

While both calcium and vitamin D have been found to have a positive impact on bone mass, their independent effect on bone is challenging to isolate because supplementation studies typically administer both calcium and vitamin D. It is important to note that the recent calcium and vitamin D dietary reference intakes (DRI), as are all DRI recommendations, are based on the needs of healthy populations and are not meant to displace medical recommendations targeted to those with diseases that impact bone health.

Practice guidelines from the Endocrine Society were developed in 2011 for individuals at high risk of vitamin D deficiency, including those with chronic diseases that affect vitamin D status as well as those taking medications that affect vitamin D homeostasis (Holick et al., 2011). The Endocrine Practice Guidelines Committee recommends routine screening for individuals at high risk of vitamin D deficiency, a higher daily intake for those at high risk of deficiency than that recommended by the NAM for the general healthy population, and a more aggressive supplementation regimen for individuals with a vitamin D deficiency, with all guidelines to be applied under medical supervision.

Because many nutrients are important in bone health and there is still much to be learned about individual nutrients and bone physiology, it is essential that a well-balanced diet, containing grains, fruits and vegetables, protein and calcium-rich products be consumed. Many nutrients, in addition to calcium and vitamin D, are particularly important for maintaining bone homeostasis as detailed below.

## Magnesium

More than half of the magnesium found in the body is located in bone. In addition to its presence in bone, magnesium is important in calcium metabolism and bone health because it is required for parathyroid hormone (PTH) secretion. Parathyroid hormone is integral to bone health because it increases the production of the active form of vitamin D (1,25-dihydroxyvitamin D) and plays a role in the tubular reabsorption of calcium and phosphorus.

Although magnesium deficiency is associated with abnormalities in vitamin D metabolism, hypocalcemia and impaired PTH secretion, epidemiological studies linking magnesium intakes to measures of skeletal health, such as incidence of fractures, have produced conflicting results. Observational studies have shown a positive association between magnesium intake and bone mineral density (Farsinejad-Marj et al., 2016). However, relationships between magnesium status and bone mass may be more challenging to elucidate due to the lack of a highly sensitive indicator of magnesium status (Razzaque, 2018).

Studies have indicated that typical magnesium intakes in healthy adolescents may not be sufficient to maintain magnesium balance (Abrams et al., 1997). Other groups, including older adults, those with gastrointestinal conditions, diabetes mellitus, alcoholism, or those being treated with diuretics are also at increased risk of magnesium deficiency (Razzaque, 2018). Because dietary intakes fall below recommended levels in several age groups and due to the known relationships between magnesium and hormones integral to bone health, increased attention should be focused on optimal magnesium intakes in relation to bone homeostasis particularly during the period of maximal bone acquisition.

## Zinc and copper

Zinc and copper play important roles in bone metabolism and bone health in part due to the roles they play as cofactors for various enzymes required for the synthesis or modification of bone matrix constituents. Zinc is a co-factor for many enzymes in the body, including alkaline phosphatase. Alkaline phosphatase is synthesized by osteoblasts and is essential for bone mineralization. Zinc also plays a role in the osteoblast via its involvement in aminoacyl-tRNA synthetase. Copper is a necessary co-factor for lysyl oxidase, an enzyme that is involved in collagen cross-linking. Both copper and zinc are found as components of superoxide dismutase and may protect bone from oxidative damage. Genetic defects that cause zinc deficiency (acrodermatitis enteropathica) or copper deficiency (Menkes disease) result in growth retardation, stunting and impaired bone growth.

## Vitamin K

Many proteins integral to bone health are dependent on vitamin K for the carboxylation of  $\gamma$ -carboxyglutamyl (Gla) residues. Osteocalcin, one such vitamin K dependent protein, is the most abundant non-collagenous protein in bone. Osteocalcin contains three Gla residues that require vitamin K for carboxylation. The ability of osteocalcin to bind to the hydroxyapatite fraction of bone is dependent on its degree of carboxylation. Deficiency of vitamin K increases the fraction of undercarboxylated osteocalcin in the circulation. In addition to osteocalcin, other vitamin K dependent proteins (including matrix Gla protein and protein S) are found in bone and cartilage. Continued research is needed to elucidate the impact of vitamin K deficiency on risk of osteoporosis and fracture. Although vitamin K status correlates with bone mineral density, a systematic review and meta-analysis of randomized controlled trials concluded that vitamin K supplementation appears to have little to no effect in the risk reduction of osteoporosis and fracture (Mott et al., 2019). However, because of the known relationship between vitamin K and several crucial bone proteins, optimal status of this vitamin should be achieved to promote skeletal health.

## Phosphorus

Phosphorus, like calcium, is an integral component of hydroxyapatite in bone. Bone contains 85% of the phosphorus found in the body, and together calcium and phosphorus comprise the major fraction of bone mineral. While sufficient phosphorus intake is necessary to support bone mineralization, phosphorus homeostasis can be maintained across a range of intakes and ratios of calcium to phosphorus in the diet. Diets high in phosphorus and low in calcium may be detrimental to bone health, as they have been associated with higher PTH levels and lower serum calcium concentrations in healthy individuals (Vorland et al., 2017).

Much attention has been focused recently on regulation of phosphorus homeostasis by PTH-independent mechanisms that are mediated via phosphatonins. To date, at least four phosphatonins have been identified. Of the phosphatonins identified to date, fibroblast growth factor 23 (FGF23) is the phosphatonin that contributes to phosphate homeostasis. Synthesis of FGF23 increases

in response to elevations in plasma phosphorus and calcitriol and FGF23 suppresses 1- $\alpha$  hydroxylase activity. These effects work in combination to reduce the body of excess phosphorus that is released during bone resorption. The role of FGF23 in bone physiology has opened up new possibilities for treatment of phosphorus related diseases that adversely impact bone mass (Pool and Wolf, 2017).

The phosphoric acid and phosphorus content of soda is often discussed in relation to bone health. The impact of these products on bone health is thought to be caused by their displacement of other more nutritive beverages (such as dairy products) from the diet. Phosphoric acid and other phosphorus containing-additives primarily present in sodas and processed foods are more readily absorbed than organic phosphorus naturally present in foods. Increased soda consumption may displace more nutritive beverages from the diet and may result in an unbalanced ratio of calcium to phosphorus in the diet, thus excessive soda intakes should be avoided (Vorland et al., 2017).

## Sodium and potassium

Some dietary components influence the retention of nutrients required for optimal bone health. Sodium is one of the strongest determinants of urinary calcium excretion. Increased dietary sodium concentrations elevate urinary calcium losses. Every 2300 mg (100 mmol) increase in dietary sodium increases the urinary excretion of calcium by roughly 40 mg (1 mmol) (Nordin et al., 1993). Thus, excessive intakes of sodium (such as those that may occur in individuals who consume large amounts of processed food, salt food heavily or consume foods high in sodium) increase the obligatory losses of calcium from the body. During the growth phase, this could potentially limit the amount of calcium that can be utilized for bone mineralization. The long-term impact of variation in sodium intake on bone mass and fracture risk has been difficult to quantify because of a lack of sufficient information on how dietary effects on urinary calcium loss are counterbalanced and because other dietary components may modify this response.

Dietary potassium may help buffer calcium losses in urine. Increased fruit and vegetable intake will assist in increasing dietary potassium intake while providing additional nutrients and antioxidants that have been linked to overall skeletal health.

## Protein

Protein is essential for the formation of the organic matrix of bone and optimal intakes are required for normal skeletal development, growth, and maintenance. Protein intakes are also needed to maintain muscle mass and help limit the involuntary loss of muscle (sarcopenia) that can occur as aging progresses. The importance of protein in bone health is well known, however, conflicting reports exist on the relative impact of extremes of protein intake on bone health. Many proteins are rich in sulfur amino acids. The resulting protein-induced acid load must be buffered before excretion from the body. Calcium is a positive cation and can be utilized to buffer increased dietary acid loads from high protein intakes. On average, for every 1 g increase in dietary protein intake, urinary calcium excretion increases by approximately 1 mg (Heaney and Layman, 2008).

Differences in habitual protein intakes have been related to bone mass and risk of fracture. Several recent systematic reviews and meta-analyses examining the relation between dietary protein intake and indices of bone health, such as bone mineral density and risk of fractures, have been published (Darling et al., 2009, 2019; Santesso et al., 2012; Shams-White et al., 2017, 2018; Wallace and Frankenfeld, 2017; Wu et al., 2015). Weak positive associations or no associations between total protein intake and bone health have been reported, and studies have found no overall adverse effects of higher protein intakes. Urinary calcium excretion increases in response to acute increases in protein intake, but intestinal calcium absorption also increases by an amount nearly comparable to that lost in urine. Insufficient intakes of protein can adversely impact muscle mass and function. In addition, low dietary protein intake has been associated with reductions in serum insulin-like growth factor 1 (IGF-1) concentrations. IGF-1 plays an essential role in skeletal health via its impact of osteoblast formation and bone growth. Evidence suggests that protein and calcium intake have a positive and synergistic effect on bone health, with higher intakes of protein coupled with higher intakes of calcium being associated with lower incidence of fractures and a slower rate of bone loss in adults (Dawson-Hughes and Harris, 2002; Sahni et al., 2010). Recent systematic reviews and meta-analyses reported that limited evidence showed no differences in the effect of plant vs. animal proteins on bone health (Darling et al., 2019; Shams-White et al., 2018; Wallace and Frankenfeld, 2017). More research is required to address the relative impact of the quantity and type of protein (animal vs. plant) on skeletal health.

## Phytoestrogens

Phytoestrogens are dietary components that have a chemical structure similar to that of endogenous estrogens. The primary phytoestrogens in the diet are obtained from soybean isoflavones (including genistein and daidzein). These compounds appear to be able to weakly mediate some of the genomic and non-genomic effects of estrogen and may function as agonists or antagonists depending on the tissue and type of estrogen receptor involved. To date, supplemental sources of these compounds have not been found to decrease fracture risk (Abdi et al., 2016; Lagari and Levis, 2013). Additional clinical data will assist in definition of the long-term impact of phytoestrogens on bone health and fracture risk.

## Homocysteine

For some time, it has been known that individuals with a genetic defect in homocysteine metabolism (homocystinuria) have an increased risk of early onset osteoporosis but less was known about the potential impact of circulating homocysteine concentrations on bone health among the general population. Much interest in this topic was generated by studies reporting significant relationships between serum homocysteine and lower bone mineral density in adults (Bailey et al., 2015; Enneman et al., 2014; Gerdhem et al., 2007; Zhang et al., 2014). The strength of the relationship observed is substantial and is comparable to the relationship found between serum homocysteine concentrations and cardiovascular disease. At present the mechanisms responsible for the impact of homocysteine concentrations on fracture risk are not known. Increased homocysteine concentrations could possibly interfere with normal collagen production and other effects of elevated homocysteine concentrations on bone health may be indirect. Further research will assist in identifying the mechanisms and relationships between homocysteine and bone health and the degree to which this relationship is influenced by nutritional status (particularly folate, vitamin B<sub>12</sub> and vitamin B<sub>6</sub>), sex, age, and ethnicity.

## Other lifestyle factors

Lifestyle choices such as smoking, alcohol abuse, physical activity and sleep also impact overall bone health. Excessive alcohol intake is a risk factor for low bone mass (Cheraghi et al., 2019; Maurel et al., 2012). This finding may be a consequence of poor dietary quality in chronic alcoholics and may also be related to adverse effects of excessive alcohol intake on osteoblast function. Cigarette smoking also adversely impacts bone health (Yoon et al., 2012). Smokers may be leaner, and female smokers may experience an earlier menopause and have lower post-menopausal estrogen levels. Smoking may also have adverse effects on bone cells themselves either directly or indirectly through an increase in oxidative stress.

Exercise is known to positively influence bone mass (Kemmler et al., 2020). During exercise the strain placed on bone stimulates the osteocyte to positively influence the balance in bone remodeling. Many studies have found positive associations between exercise and bone mass at several sites, especially the hip and the spine. The impact of exercise on bone mass is related to the intensity of the exercise and is associated with the degree to which it increases the habitual physical activity level of the individual. The impact of exercise on bone mass is also influenced by diet and may be most efficacious when calcium intake is optimal (Daly et al., 2014). Exercise not only impacts bone mass but also influences muscle strength, muscle mass, balance and coordination. These improvements in muscle strength may also lead to improvements in posture, balance, flexibility, coordination and gait stability that influence the risk of falls. Robust evidence exists on the importance of physical activity in children and adolescents, particularly during peak bone mass accrual. Currently, only one-half of youth meet the recommendations for daily 60 min of moderate to vigorous intensity physical activity. Efforts should be directed to promoting physical activity during this crucial time of bone development (Weaver et al., 2016b).

A growing body of literature suggests that sleep may also have an impact on bone health (Moradi et al., 2017; Wang et al., 2018). Observational studies have shown a U-shaped association between sleep duration and risk of osteoporosis, with short (<8 h) or long (>8–9 h) sleep durations being associated with a higher risk of osteoporosis in adults. Currently, the mechanisms by which sleep affects bone health are unknown. One potential mechanism is the alteration of normal circadian rhythmicity in bone cells, as both osteoclasts and osteocytes express clock-controlled genes (Swanson et al., 2018). More research is needed to understand the relationship between sleep and bone health as it may be mediated by factors such as physical inactivity and hormonal imbalances.

## Targeting groups at risk

The World Health Organization has evaluated risk factors for fracture using global epidemiology data. Using these data, an electronic web-based program called FRAX<sup>®</sup> has been developed that allows individuals to calculate their 10-y risk of major osteoporotic fracture using their individualized risk factors and other attributes that have been linked to osteoporotic fracture. Many of these factors are identified in Table 3.

## Nutrient/gene interactions

Optimal nutrition is needed to supply the necessary substrates for bone but an individual's ability to utilize a given nutrient is influenced by their genetic makeup as a substantial amount of bone mineral acquisition (up to 80%) is genetically determined.

Many candidate genes have been associated or linked with the risk of osteoporosis or fracture, including genes coding for hormones (parathyroid hormone), receptors (including the parathyroid hormone, vitamin D, estrogen, glucocorticoid and calcitonin receptors), cytokines and growth factors (including the insulin-like growth factor 1, transforming growth factor B, epidermal growth factor, interleukin 4 and interleukin 6) and bone matrix proteins (such as osteocalcin, collagen type I ( $\alpha 1$  and  $\alpha 2$ ) and collagen type II ( $\alpha 1$ )). While many of these genes have obvious roles in bone metabolism, other candidate genes (such as those coding for apolipoprotein E and methylenetetrahydrofolate reductase) have less obvious relationships to bone mass (Yuan et al., 2019).

**Table 3** Factors that have been associated with risk of osteoporotic fracture.**Nonmodifiable risk factors**

## Height

Shorter stature is associated with a lower net bone mass

## Age

Risk of osteoporotic fracture in women doubles every 7–8 years after the age of 50

## Sex

Women are at greater risk from lower peak bone mass and loss that occurs during menopause

## Low femoral neck BMD

A 1 SD decrease in BMD increases fracture risk by approximately 1.5–2.6 fold

## Prior fragility fracture

Is associated with a nearly two-fold increased risk of subsequent fracture

## Parental history of fracture

Up to 80% of the variability in bone mass is due to genetic factors

**Modifiable risk factors**

## Weight

Low weight (<127 lb or BMI <21 kg m<sup>-2</sup>) is a risk factor for low bone mass

## Current tobacco smoking

Smoking is associated with leanness, earlier menopause and may be toxic to bone cells

## Alcohol

Alcohol intake greater than two units per day

## Physical activity

Sedentary behavior and lack of weight bearing activity

## Dietary intake

Low intake of Ca and vitamin D and a poorly balanced diet low in fruits/vegetables and protein and high in sodium

**Disease-related risk factors**

## Medication use

Oral glucocorticoids, GnRH agonists, depot medroxyprogesterone acetate (MPS), aromatase inhibitors, heparin, anticonvulsants (phenytoin)

## Diseases

Rheumatoid arthritis, lupus, hyperthyroidism, type 1 diabetes, ankylosing spondylitis, Cushing's, renal failure, total gastrectomy, gastrointestinal diseases (IBD and celiac), diseases that reduce mobility (stroke, Parkinson's, multiple sclerosis), organ transplant

## Other clinical factors

History of fainting, falls, or dizziness

## Muscle weakness

## Neuropathy of the lower extremities

## Impaired vision

Diet may influence interactions between genotype and environmental factors. For instance, the impact of exercise on bone can be influenced by the habitual dietary calcium intake and the individuals' genotype (such as the vitamin D receptor genotype). Further research into the genetic control of bone mineral acquisition and loss will be invaluable in targeting groups at risk for low bone mass and may eventually be useful in setting genotype-specific intakes of bone-related nutrients to maximize skeletal health throughout the lifecycle. Newer work is utilizing genome wide association studies (GWAS) to identify genes associated with bone mass in various pathways such as those involved in vitamin D metabolism. Currently, ~30 GWAS studies that have been conducted have identified over 100 independent loci that are associated with bone mineral density (Estrada et al., 2012; Sabik and Farber, 2017). This trait has a complex genetic architecture, and more research is needed to identify which loci harbor variants that possess a causative role on the risk of osteoporosis and associated fractures. These studies will shed new light on genetic determinants of bone with the long-term goal of identifying those at risk so interventions and nutritional recommendations can be initiated prior to the development of osteoporosis.

**Interactions of the bone and other physiological systems**

Bone health is integrally related to other physiological systems, and perturbations in these systems that are caused by under- or over-nutrition may also impact bone health. Excess adiposity, insufficient muscle mass, a dysbiotic gut microbiome, altered gut barrier function, or impaired immune system, can all have a negative impact on bone mass and/or quality. Excess adiposity adversely affects bone health by a variety of mechanisms involving adipose-derived endocrine factors, such as the adipokines leptin and adiponectin, and obesity-induced inflammation and oxidative stress (Shapses et al., 2017). Substantial crosstalk between bone and muscle occurs with various factors, such as genes, nutrition, mechanical pressure, inflammation, and endocrine factors affecting both bone and skeletal muscle simultaneously. Additionally, the muscle secretes a panel of myokines that act on the bone in an endocrine fashion. Myokines, such as myostatin, transforming-growth factor- $\beta$  (TGF- $\beta$ ), and IL-6 negatively affect bone formation,

while IGF-1, FGF-2 and irisin promote bone formation (Kaji, 2016). Key nutrients, such as vitamin D, may play a key role in mediating the relationship between muscle and bone. Vitamin D inhibits myostatin production in muscle tissue and decreased myostatin results in greater bone mass (Gunton et al., 2015). Coordinated regulation of bone and muscle by neuronal pathways has also been explored (Houweling et al., 2015). Identifying unifying factors mediating these relationships may be an important avenue toward understanding and treating both osteoporosis and sarcopenia.

Increasing evidence obtained from studies using germ-free mice has demonstrated a connection between gut microbiota and bone homeostasis (Lu et al., 2021). Although the mechanisms underlying this relationship are not fully elucidated, the gut-microbiome/bone relationship may be mediated by the gut-microbiome's effect on the immune system. More research is needed to fully understand the overall impact of nutritional status and individual nutrients on the health of other physiological systems that are also integral to skeletal health.

## Key points

- Define pediatric feeding disorder using current guidelines
- Be familiar with normal feeding and digestion physiology
- Understand the multidisciplinary approach to evaluation and management of pediatric feeding disorders
- Identify medical comorbidities common with pediatric feeding disorders
- Appreciate psychosocial contributors to successful evaluation and treatment

## Introduction

Feeding is the process by which children accept and digest food in amounts adequate to meet their nutritional needs for proper growth. Though seemingly a simple instinctive act, feeding children is actually a complex process requiring a combination of successful caregiver interaction, the child's oral-motor skills, and intact gastrointestinal motility and absorption. Feeding disorders have traditionally escaped recognition by primary providers due to a "normal" growth curve or an assumption that feeding disorders are a normal, transient occurrence in childhood which impedes the opportunity for early intervention.

The term "feeding disorder" is used when young children are unable to eat enough to maintain their nutritional needs. Feeding disorders are surprisingly common in children, and it has been reported that 25–35% of typically developing children will have mild feeding disorders, and up to 75% of children with disabilities, including Autism Spectrum Disorder, will have more severe feeding problems. Clinical manifestations include food refusal/selectivity, gagging, vomiting, swallowing difficulty, poor weight gain, or failure to thrive. Conventionally, these disorders have been grouped into medical, oral-motor, and behavioral categories with most children exhibiting overlapping problems. Therefore, it is more accurate to think of these disorders as a continuum from strictly physiologic defects to primarily behavioral, with the vast majority of these disorders as a combination of many etiologies.

## Classification of feeding disorders in children

Given the complexity of feeding disorders and various etiologies, numerous attempts at classifying feeding disorders have been made based on apparent etiology, physical condition, or associated behaviors. Currently, there are two primary definitions using slightly different frameworks. The first, *Pediatric Feeding Disorder (PFD)* is based on the framework of the International Classification of Functioning, Disability, and Health, and defined as “impaired oral intake that is not age-appropriate, and is associated with medical, nutritional, feeding skill, and/or psychological dysfunction.” The second, *Avoidant/Restrictive Food Intake Disorder (ARFID)* based on Diagnostic and Statistical Manual of Mental Disorders—Fifth Edition (DSM-V) is defined as “an eating or feeding disturbance (e.g., apparent lack of interest in eating or food; avoidance based on sensory characteristics of food; concern about aversive consequences of eating) as manifested by persistent failure to meet appropriate nutrition and/or energy needs associated with one (or more) of the following: (1) significant weight loss (or failure to achieve expected weight gain or faltering growth in children); (2) significant nutritional deficiency; (3) dependence on enteral feeding or oral nutritional supplements; (4) marked interference with psychological functioning.” In addition, the disturbance cannot be attributed solely to a medical condition or other mental disorder, lack of available food, and there is no evidence of concern with how the individual experiences body weight or shape. Though there are two frameworks with which to view feeding disorders under, they both have an emphasis on functioning and consider medical, nutritional, oral-motor skill, and psychological factors.

## Feeding and swallowing physiology

Understanding the mechanisms involved in feeding is useful in understanding why a child refuses to eat. The swallowing process is conventionally divided into three phases: oral, pharyngeal, and esophageal. The oral phase includes the oral preparatory phase and the oral phase of the swallow. The oral preparatory phase occurs when food is manipulated in the mouth and masticated if necessary, reducing it to a consistency ready for swallowing. This phase of swallowing includes the transit of the bolus over the tongue posteriorly until the pharyngeal swallow is triggered. In the newborn and young infant, all phases are driven reflexively by typical rooting and sucking behavior. The pharyngeal phase begins when swallowing is triggered and the bolus is moved through the pharynx into the esophagus. The esophageal phase begins with the opening of the upper esophageal sphincter, and then peristalsis then carries the bolus into the stomach. After passing the lower esophageal sphincter, food enters the stomach, beginning the gastrointestinal and absorptive phase of feeding. Food is emptied from the stomach into the small intestine based on the volume, nutrient composition, and caloric density of the meal. Most nutrient absorption then occurs in the small intestine, while the large intestine generally resorbs fluids that are ingested and secreted during normal digestion.

Poor coordination, timing, or motor dysfunction during any phase of swallowing may lead to aspiration or other feeding difficulties, and medical conditions affecting any portion of the GI tract may lead to discomfort either during or after feeding which may also contribute to feeding difficulties. To understand feeding and swallowing disorders, one must recognize that there are dynamically changing developmental skills and social abilities in the growing child. Progression through the normal stages of feeding (see **Table 1**) requires the attainment of physical abilities such as postural stability, oral–motor coordination, and sensory awareness. In addition, factors such as emerging cognitive skills play an important role in an effective caregiver–child feeding interaction.

It is also important to understand that as very young children age, the oral phase of sucking, chewing, and managing food comes under more voluntary control, requiring cortical integration of sensory/motor input to coordinate the complex patterns of jaw, tongue, and oral movements, which is why some feeding difficulties may not present until after the newborn period.

## Evaluation and treatment of pediatric feeding disorders

Due to the diverse and complex factors that contribute to feeding disorders, literature supports the use of a multidisciplinary team for evaluation and treatment of pediatric feeding disorders whenever possible. This team ideally would include a variety of pediatric specialists, including physicians (e.g., general pediatricians, developmental pediatricians, pediatric gastroenterologists, allergists, and otolaryngologists), nurse practitioners, dietitians, feeding specialists (e.g., speech and language pathologists, occupational therapists etc.) psychologists, and social workers.

## Evaluation

An appropriate evaluation is the critical first step in initiating treatment for a feeding disorder. The assembled team must begin its approach to diagnosis and therapy with a comprehensive assessment completed by all disciplines. These include a careful prenatal, birth, and neonatal history. Assessment of nutrition and medical status of the child should be accompanied by an appropriate psychological and/or developmental evaluation.

**Table 1** Developmental progression of feeding summary.

<i>Age</i>	<i>Developmental skill</i>	<i>Progression of textures</i>	<i>Behavioral expectations</i>
Birth to 4 months	Needs to be fully supported Suck-swallow-breath Rooting and sucking	Bottle/breastfeeding/formula—liquids only	Eats every few hours Volume increases from ~1/2 oz to 4–5 oz
4–6 months	Supported sitting Hand to mouth Holds own bottle Sucking Gag reflux starts to decrease	Liquids only appropriate Closer to 6 months—smooth state 1 or 2 baby pureed foods (by spoon)	Volume increases from 4 oz to 8 oz
6–8 months (after holding head up)	Can sit upright with support Unilateral hand to mouth Vertical munching of easily dissolvable solids	Homemade purees (smooth) Hard teething foods (with supervision) Finger foods may be introduced May start baby-led weaning, but should be cautious as skills may not be present	8 oz every 4–5 h Touching and exploring food is important Placed in high chair 1–2/day
8–9 months (after hand to mouth)	Needs sitting support Introducing cup and straw drinking Grasps small items Rotary jaw movements emerging	Dissolvable solids *Breastmilk/formula still primary source of nutrition	Palming foods Meals are MESSY Distractible Might not want to sit in high chair
10–12 months	Minimal assistance for sitting Mostly bottle, but cup drinks Teething started Self-feeding and assisted feeding	Beginning table foods/soft mashable foods	Accidental dropping foods, though sometimes intentional Bottle refusal common
12–18 months	Sits upright without support Self-feeding with spoon emerging Chewing	Intermediate soft table foods (some mixed textures)	Sits in high chair ~10–15 min Intentional throwing behaviors emerge
18–24 months	Mostly self-feeding Grasp and pinch present Cup drinking Efficient chewing Most teeth in	Broad range of table foods Difficult, tough, and chewy foods	Expresses preferences (can be strong expressions)
2–4 years	2: intense preferences Circulatory jaw rotations Holds cup with 1 hand Self-feeds with fork 3–4: individuation, toilet training	High risk choking foods still monitored	15–20 min meals (max 30 min) 5–6 “mini meals” a day Tantrums (during meals and other times) Lots of “no” statements
School age	Reasoning, negotiating Still concrete thinking		20–30 min meals Starts to understand behavior/consequences
High school	Individuation Personal identity Social autonomy		Exploring foods outside of family/culture Increased eating outside of home setting Skipping meals, increasing snacking Dietary restrictions

## Physicians

Medical issues (i.e., gastroesophageal reflux, milk protein allergy, cleft palate, etc.) that occur very early in infancy may be the initial cause for food refusal. Consequently, for the majority of children with a feeding disorder, an early food avoidance pattern is common. The early food avoidance pattern may significantly impact the caregiver–child interaction surrounding feeding and meals. For example, because of severe gastroesophageal reflux, the child may learn to associate eating with pain. Consequently, when the caregivers attempt to feed the child, they will encounter food refusal behavior, which leads most caregivers to terminate the meal prematurely, or can lead to coercive feeding practices, both of which are detrimental. Thus, even when the medical condition is medically managed, the child will still have the learned history of pain associated with eating, but now also has the new history of having refusal behaviors to escape the meal, or, further negative association with eating due to coercive feeding practices. Due to this connection, certain groups may be at a higher risk for feeding difficulties. For example, children with food allergies, gastroesophageal reflux, eosinophilic gastroenteropathy, and motility disorders may demonstrate increased food refusal. A variety of medical conditions such as cardiopulmonary, genetic, and metabolic disorders can also lead to poor appetite and slow weight gain.

The most important role for the physician is to assess for any of these conditions that could contribute to feeding difficulties as an initial cause, as well as identify any disorder that would require treatment before the implementation of a therapeutic treatment program for feeding refusal (see [Table 2](#) for comorbid conditions). A complete history, including past medical history, family

history, social history, and medical review of systems may provide clues to any of these conditions. Physical examination of the child includes a general survey examination for the determination of any underlying medical disorders that may preclude safe feeding. It should include an assessment of nutrition status, evaluation of tongue and jaw movement, dentition, airway sounds, speech, and oral cavity assessment as well as a complete cardiac, pulmonary, and abdominal exam. For children with severely limited intake, an assessment of hydration status should also be made.

A full laboratory evaluation should be considered in children with feeding disorders to conduct a nutrition assessment as well as identify possible comorbid conditions. A blood count, iron panel and 25-hydroxy vitamin D can help identify dietary deficiencies in these nutrients. Based on a diet recall, other micronutrient levels may be needed, and the physician should work with the dietitian to identify these. Inflammatory markers, electrolytes, liver function tests, celiac serologies, thyroid function tests, and urinalysis may each be helpful to identify a possible co-morbid disorder. Infants may require a stool guaiac to assess cow's milk protein intolerance, and further stool analysis may be required if malabsorption is suspected.

Based on the history, physical exam and direct clinical feeding observation, diagnostic evaluations may be warranted to better assess swallowing and anatomy (see [Table 3](#)). The decision to obtain further study of swallowing function is often the result of a collaborative discussion between a physician and feeding specialist. The modified barium swallow (MBS) study is the most widely used procedure to assess oral, pharyngeal, and upper esophageal phases of swallowing. Positioning, food texture, bolus size, rate, and the amount of food presented can be manipulated during the performance of the MBS study to determine the safest and most efficient method of feeding. Clinical evaluation before the MBS is essential so that the food textures, liquid consistencies, and treatment techniques can be included at the time of the study. Changes in head and neck position, such as chin tuck, should be tried before the actual study to better correlate clinical and radiologic findings. The child's level of cooperation should also be assessed before the MBS.

Additionally, a standard upper gastrointestinal contrast series utilizing barium may be required for assessment of anatomy of the gastrointestinal tract ([Fig. 1](#)). Children with food allergies, repetitive vomiting, or abdominal pain may also need endoscopic evaluation, and some children will also need colonoscopy to rule out the possibility of underlying inflammatory disease such as eosinophilic gastroenteropathy. Gastroenterology consultation can help determine the utility of these studies. Depending on symptomatology and physical exam, some children may need cranial imaging to look for evidence of intracranial mass lesions, hydrocephaly, or posterior fossa anomalies, such as the Chiari malformation. If allergic disease is suspected, consultation with a pediatric allergist is recommended.

**Table 3** Possible diagnostic evaluations for patients with feeding disorders.

## Feeding specialists

Oral–motor and swallowing problems are commonly seen in children with congenital and acquired neurologic conditions such as cerebral palsy, structural abnormalities, or traumatic brain injury. Premature and medically fragile infants may miss sensitive periods of oral–motor development resulting in delayed acquisition of feeding skills. This early interruption of feeding skill development and lack of experience can lead to oral aversion or more serious feeding disorders such as food refusal.

The feeding specialist refers to the team member whose responsibilities include assessing and treating oral–motor and swallowing dysfunction and performing instrumental evaluations of swallowing when warranted. The exact credentials of a feeding specialist may vary by location and institution, but often include speech and language pathologists, occupational therapists, and developmental specialists. Occupational therapists may also evaluate fine motor, sensorimotor, and visual motor function as well as positioning and the need for adaptive equipment. Speech/language pathologists may also evaluate and make recommendations for communication skills when necessary.

As part of the initial evaluation, an observation of a feeding session between the child and the primary caregiver will often offer insight into the feeding problem, especially from an oral–motor/sensory and behavioral perspective. Clinical signs of oral–motor dysfunction, length of meals, and nature of the caregiver–child interaction are noted. Observation of the muscle tone, posture and positioning, as well as special seating systems and feeding devices are routine, as these can give insight into the child's overall neurologic functioning.

After a clinical feeding observation, a feeding specialist may decide that further evaluation of swallowing anatomy and function is warranted. A modified barium swallow (MBS) may be recommended and can be obtained with collaboration between the patient's feeding therapist and physician. A feeding specialist may also pursue fiberoptic endoscopic evaluation of swallowing (FEES) which allows for direct visualization of the nasal, pharyngeal, and laryngeal structures. This procedure enables evaluation of events occurring immediately before and after the pharyngeal phase of swallow. FEES allows for visualization of any residue in the epiglottic valleculae and pyriform sinuses, and at times, it may be possible to see aspirated materials below the level of the true vocal folds. This procedure does not provide information on the oral phase of swallowing. FEES may also be combined with sensory testing (FEESST). Pulses of air are directed at mechano-receptors within the larynx and reactions are observed that show potential sites of impairment. In older children, this could guide different swallowing techniques to prevent coughing, choking, or aspiration.

## Dietitians

Dietitians dedicated to pediatric care are also essential members of the diagnostic team. The dietitian's assessment of the current nutritional status, anticipated growth, and recommended energy intake (that is both age and diagnosis appropriate) is an essential

part of the diagnostic and therapeutic process. Children with feeding disorders are less likely to take in the recommended amounts of vitamins and minerals, so careful diet recalls including precise foods and estimated amounts are important to identify risks for nutrient deficiency, and adequacy of caloric intake. Obtaining a list of preferred foods and beverages can be helpful when making recommendations for more calorie or nutrient dense meal and snack options. Assessing accurate volumes of fluid intake are equally important to identify risk for dehydration. A dietitian's assessment of nutrition status is crucial to determining the acuity of a patient's feeding disorder and identification of protein-calorie malnutrition is important as these patients may be at risk for refeeding syndrome if energy intake is increased significantly and suddenly.

It is also important to consider potential comorbid medical conditions that may increase energy needs. For example, children with cystic fibrosis or other pulmonary disorders may require an increased energy intake which can further exacerbate feeding difficulties if families are already struggling with the child accepting even their standard energy needs. The dietitian is instrumental in predicting energy and macronutrient requirements in these patients, and monitoring growth trends.

## **Behavioral psychologists**

Behavioral difficulties such as food refusal or selectivity are not isolated problems and are often multifactorial in nature. Oftentimes a medical illness may adversely affect feeding patterns, making mealtimes unenjoyable for children and impacting child-caregiver interactions as families struggle to improve feeding behaviors. When there are concerns for failure to thrive or malnutrition, immediate solutions (e.g., highly caloric supplemental beverages), or supplemental enteral feeds (via nasogastric or gastrostomy tube), may exacerbate feeding difficulties. These strategies, though necessary medically, can adversely impact hunger, feeding experience, endurance during mealtimes, and inadvertently reinforce escape behaviors around feeding.

Within the setting of pediatric feeding disorders, behavioral psychologists, assess for emotional and behavioral patterns to feeding. They may complete detailed behavioral observations, extensive interviews focusing on antecedents and consequences of behaviors, developmental screenings and assessments, and psychiatric review of systems to assess for comorbid conditions (behavioral and psychiatric) as a part of the assessment process. As a part of the functional behavioral assessment, psychologists assess for which behaviors are potentially reinforced by escape from negative physical experiences associated with medical or skill-based concerns; associated behaviors may have been inadvertently reinforced by social responses. In many cases challenging feeding behaviors are reinforced by both medical/skill-based and social factors.

Given the context of pediatric feeding difficulties, assessments by behavioral psychologists are often completed from the perspective of family systems approaches to help identify a variety of individual and family factors which may contribute to feeding challenges. As the child demonstrates increased distress around food and mealtime, caregivers may engage in a variety of accommodation strategies (modifying routines, offering preferred foods, limiting going elsewhere for meals). Though these strategies are understandable and in response to the child's behavior and the strategies may reduce distress in the short-term, the child does not learn new strategies to cope with the feeding difficulties and the symptoms continue. One of the behavioral psychologists' goals in the initial evaluation is to begin to understand this accommodation cycle.

Many children with pediatric feeding disorders also have comorbid developmental, behavioral, or psychiatric disorders which can exacerbate feeding difficulties. As a part of the developmental screening and/or assessment as well as the psychiatric review of systems, the behavioral psychologists assess for whether additional neurodevelopmental or neuropsychological assessment may provide diagnostic clarification. In addition, they can assess for whether additional in-home or outpatient therapy is required to address comorbid conditions which can impact feeding, such as broader anxiety disorders, Attention Deficit Hyperactivity Disorder or if there are concerns regarding body image disturbances.

## **Social workers**

Since medical issues, behavioral needs, and family psychodynamics all play a central role in the development of the abnormal feeding patterns, a clinical social work evaluation is necessary for assessment and intervention of underlying familial interactions and support systems. Caring for children with feeding disorders negatively impacts caregivers quality of life and pediatric feeding disorders are associated with increased caregiver-related distress, which can also impact adherence to medical recommendations as seen in other pediatric populations. Social workers can assess for caregiver distress and help guide the medical team to develop family-centered treatment plans. They can then help provide additional support and resources to the family as needed to enact these plans. This approach can help to ensure continued success once the child has returned to the home environment.

Additionally, assessment of food and housing security is needed to ensure that the reason for selective eating is not due to lack of availability of food, or inability to store food. Globally, the number of undernourished individuals was decreasing up until 2014, but has been increasing since. In the United States, prior to the COVID-19 pandemic, food insecurity continued to decrease but over 11% of the population still experienced food insecurity. Since the COVID-19 pandemic, food insecurity concerns have risen drastically around the globe, particularly for women and those with lower socioeconomic status. Social workers can meet with families to help assess whether there are concerns for food insecurity. In addition, social workers' familiarity with local resources in the region allows them to help families obtain support from community, state, and federal resources.

Specific resources and interventions to address food insecurity may vary based on location. In high income countries, insecurity is often a sign of unequal distribution of resources. For these families, community and federal resources such as WIC, SNAP, and food banks are often recommended by social workers, in addition to school-based feeding programs. Often in lower income countries, food insecurity is a result of lack of access to food resources and addressing strategies for families and communities to be prepared for natural disasters is important for prevention. When there are already concerns for access or in response to natural disasters, income assistance, provision of tools, cash transfers, or emergency aid are important interventions.

The role of social workers extends beyond working with individual families. Social workers can also help the medical team collaborate with community members. In places such as the United States this may include collaborating with Early Intervention, Head Start, private daycares, and schools and as children get older. Social workers are paramount to ensuring consistency in plan across all environments. In other countries, social workers may work on developing community education, peer support groups, conducting home visits, and engaging in advocacy work.

### Cultural considerations within evaluations

All specialties should be aware of cultural considerations throughout the evaluation. Meals are inherently social activities and food has significant cultural implications within family structures. Not only are there differences in acceptable foods across cultures, but there are differences in timing, location, and mealtime expectations based on cultural preferences. Within pediatric feeding disorders, perception of weight concerns and concern with picky feeding are another area in which culture plays an important role. Food and feeding are such important aspects of culture that there are also differences in the role of food across cultures. It is important for providers to ask questions to help understand each family's values, culture around feeding, and to understand caregiver perceptions and concerns about weight and food intake.

## Treatment of feeding disorders

### Multidisciplinary approach

Throughout the treatment process, a multidisciplinary approach is paramount. The initial and perhaps most important part of any therapeutic approach to introducing or increasing oral food intake is to establish the safety of eating as well as the types and textures of food the child can consume most efficiently. The physician, dietician, feeding specialist, behavioral psychologist, and social worker work together to identify potential safety concerns and discuss barriers to treatment, including feeding skill deficits, behavioral, developmental, or psychological comorbidities, and family risk and protective factors.

### Medical intervention

The goal of all therapy is directed toward allowing caregivers to safely feed their children in a developmentally appropriate manner. The physician in the treatment team must ensure that all appropriate diagnostic studies have been performed to determine whether an underlying medical condition has predisposed a child to developing an unusual feeding pattern. This includes appropriate utilization of consultants and diagnostic modalities (Table 3). Once these studies have been performed, the physician must coordinate all the resources and direct care so that feeding therapy may proceed with minimal risk to the patient, keeping the child safe from aspiration and other complications.

### Nutritional support

Throughout the intervention process, dietitians monitor concerns for malnutrition, micronutrient deficiencies, and dehydration. They may make recommendations regarding necessary volume and types of food intake required to maintain appropriate nutritional status. In addition, they can help families identify strategies to increase caloric intake, whether through supplementing current diet with foods found in the grocery store or through use of high calorie supplemental beverages. Dietitians can help caregivers identify acceptable sources of nutrients using store-bought foods or over-the-counter supplements for patients with nutrient deficiencies.

In the case where there are urgent concerns regarding malnutrition, dangerous micronutrient deficiencies, or significant safety concerns with the act of feeding, providers may decide that enteral feeding support through the use of a nasogastric or gastrostomy tube is needed, for which hospital admission may be necessary to expedite this process. The feeding tube allows for safe delivery of nutrients while the patient and family work with the care team on implementation of the treatment plan, with the eventual goal of tube removal and full oral feeding.

### Feeding skill development

If there are safety concerns with chewing skills or the child has not been cleared for PO intake, feeding specialists may use more nonnutritive approaches. These may include oral stimulation, which is performed to reduce hypersensitivity, facilitate management

of secretions, establish or retrain the swallowing mechanism, and maintain coordination of breathing and swallowing. As the child's skills improve or they are cleared for oral intake by medical providers, the feeding specialist may gradually transition to nutritive approaches.

Oral-motor techniques and positioning to improve muscle strength and postural control as a foundation for feeding and swallowing are largely based on a neurodevelopmental framework. The use of adaptive seating systems is a key component to feeding a child with physical disabilities that require external devices to provide head, neck, and trunk support. Attention must be paid as to how positioning affects the feeding process, as a change in head and neck posture and oral-motor structures may affect oral-motor control.

Once airway safety, sensitivity, and positioning have been assessed and a management plan has been implemented, a variety of treatment approaches have been suggested for children with feeding disorders. Goals often include advancing accepted food textures and flavors (including increasing volume of nonpreferred food), and improvement in self-feeding, including utensil use.

### **Behavioral interventions**

Feeding specialists and the behavioral psychologist work together to develop and implement a behavioral plan. Behavioral interventions for pediatric feeding disorders are the most common modality of therapy and are often included within a multidisciplinary team approach that also addresses physiology, oral-motor functioning, caregiver-child interactions, and community or social support.

In general, behavioral strategies are presented in a sequence beginning with the use of the most positive and least intensive strategies that have a reasonable expectation of being effective. These less intensive strategies have the advantage of minimizing deviations from the norm in mealtimes for most families. More intensive behavioral strategies are utilized as needed. Although these more intensive strategies do require significant deviations from the norm of typical family meals and can be a burden on caregivers, these procedures can usually be faded over time.

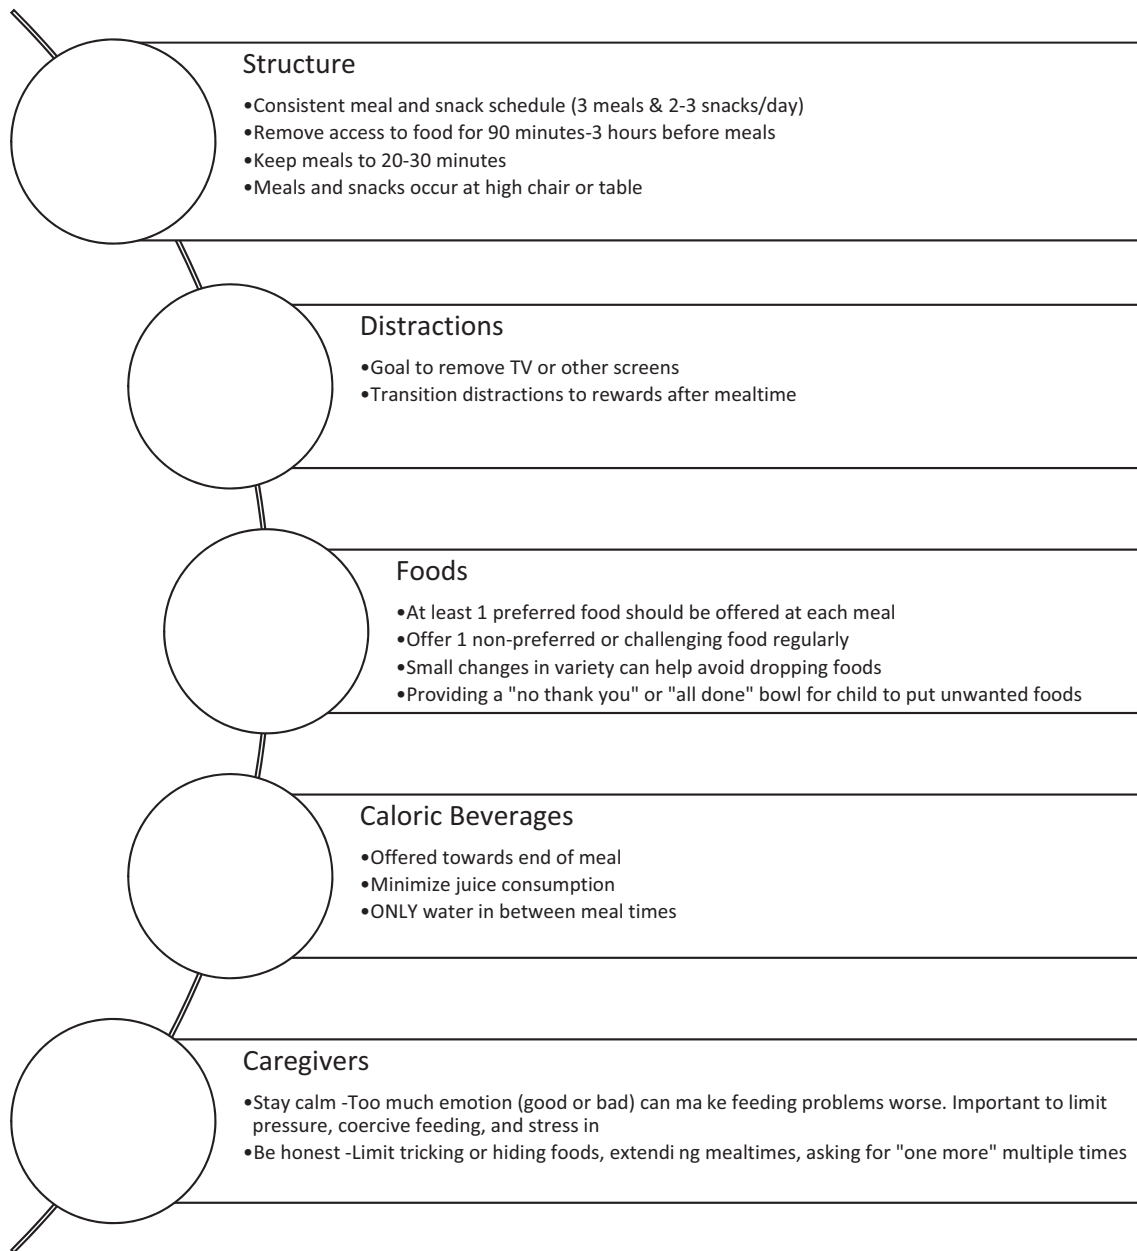

Many of the less intensive strategies involve mealtime "hygiene" strategies (see Fig. 2). These include the establishment of mealtime structure (same time and place for meals, minimizing snacking or grazing in between meals) and minimizing distracted mealtimes (transitioning screens/electronics to after the meal). Other strategies include the types of foods offered (modifying textures of food offered), including at least 1 preferred food at each meal with 1 nonpreferred or a challenge food offered regularly. If children engage in escape behaviors, such as throwing food, identifying a more acceptable behavior to communicate their preferences can be helpful. To expand variety of accepted foods, interventions often focus on opportunities for the child to engage with new or nonpreferred foods in positive or neutral settings.

Creating a neutral or positive mealtime environment can be challenging as both child and caregivers have experienced potentially thousands of negative mealtimes. It is important to work with caregiver to stay calm during mealtimes. Increased pressure, emotion (positive or negative), and stress can make mealtimes less enjoyable for both child and caregiver, thus worsening feeding difficulties. Many families understandably engage in behaviors which may increase accepted bites in the short-term, but inadvertently reinforce feeding difficulties in the long-term, such as hiding nonpreferred foods in preferred foods, extending mealtimes, or continuing to ask for additional bites during a meal. However, these behaviors can lead to increased mistrust by the child and can make behavioral interventions more challenging later on.

As feeding behaviors become more challenging, or if children need additional behavioral support, intensive behavioral interventions often include a combination of exposure and reinforcement principles. Exposure based interventions may be conducted by behavioral psychologist, feeding specialist, or a combination and include graduated exposures to more challenging foods. Exposures are often paired with reinforcement-based interventions including rewarding appropriate eating behavior (i.e., positive reinforcement), ignoring food refusal behavior (i.e., escape extinction), or removing positive reinforcement in response to food refusal behavior (i.e., response cost). Thus, if a child accepted a bite, he or she would be rewarded with attention or a concrete reinforcer, such as a preferred toy, music, or video. If the child engaged in food refusal behavior, such as batting at the spoon or turning their head away from the food, potential attentional reinforcers would be limited through withdrawal of attention or limiting access to a toy. As the behavioral psychologist and feeding specialist work with the child and caregivers through these trials and interventions, they continue engage in data collection, observation, and assessment to update their conceptualization and then modify exposures and reinforcers to increase chance of success for the child.

### **Caregiver involvement**

It is critical that caregivers are involved throughout all of the treatment process, but especially with behavioral approaches to feeding interventions. The behavioral psychologist and social worker can work together to identify what caregiver's abilities are to implement behavioral interventions based on caregiver factors, family structure, family work structure, and which caregivers are involved in mealtimes. Solely providing didactic information to caregivers regarding which strategies to use, is not as effective as skill-based caregiver training which involves step-by-step criteria-based training. When possible, caregiver training, including instruction, discussion, handouts, role-playing, feedback, and the practice of techniques and videotape with a trained clinician can result in increased caregiver treatment integrity.

**Fig. 2** Abnormal esophagus secondary to esophageal stricture following repair of esophageal atresia.

It is also important to work with caregivers from a stance of cultural awareness and sensitivity. Whether associated with cultural or individual family preferences, reinforcement systems can be a topic met with hesitancy by caregivers. Working with the family to understand their beliefs and caregiver values and providing psychoeducation and/or modifying interventions to meet the family's value systems is important for maintaining caregiver engagement.

## Treatment settings

The above-mentioned strategies may be implemented in a variety of settings, depending on illness severity, geographic location, comorbid medical conditions, and psychosocial needs of the family. Across the United States, multidisciplinary programs generally fall into the following categories: inpatient, partial-inpatient, outpatient intensive, or outpatient consultative, with the inpatient program being the most intensive. While many patients would benefit from an inpatient program, the availability of these programs

is limited, and waiting lists are often long. Outpatient programs may not offer the initial intensity of an inpatient program, but do offer long-term continuity of care. Ultimately, the choice in care setting should be approached using the family-centered model of a multidisciplinary team.

## Conclusion

Children who can't or won't eat require a systematic diagnostic and therapeutic approach by a team of dedicated professionals from many specialties. Proper evaluation for underlying medical conditions, deficits in feeding skills, and behavioral contributions are necessary for successful treatment. There is an important psychosocial domain that must be addressed and treatment plans must be family-centered. The goal of safe oral feeding is attainable in most children when those involved in the care of children understand the complexity of eating and the associated medical and psychological conditions that comprise a feeding disorder. Helping these children to eat will allow independence from artificial sources of nutrition such as gastrostomy feeds and parenteral nutrition, and ultimately reduce family mealtime stress.

## Key points

- The most possible mechanism for sarcopenia is the defect of protein degradation through autophagy-lysosome signaling.
- Milder CR (15–25%) would also be effective for age-related muscle atrophy in humans.
- Many supplemental candidates for possible combating sarcopenia is needed systematic and fundamental research using rodent models of sarcopenia.

## Introduction

The contraction of skeletal muscle is the driving force behind the body's movement and plays an important role in maintaining homeostasis. The skeletal muscle makes up almost half of the human body. Therefore, a decline in the metabolic and contractile properties of skeletal muscle can have very serious consequences for human health. Sarcopenia occurs as a result of age-related loss of muscle strength, quality, and quantity. It often refers to cellular processes (denervation, inflammation, mitochondrial dysfunction) and the resulting loss of muscle strength, function, and mobility and increased risk of falls. Sarcopenia is considered "primary" (or age-related) when there is no apparent cause other than aging (Cruz-Jentoft et al., 2010), especially when it is associated with decreased physical activity or work inactivity. Secondary sarcopenia usually occurs in the presence of several causes. This condition would be plausible for acute or chronic diseases that are common in the elderly, such as stroke, hip fracture, diabetes mellitus, chronic heart failure, and chronic obstructive pulmonary disease (von Haehling et al., 2010). Muscle mass loss is more pronounced in the lower extremity muscle groups, and at the myofiber level, it is characterized by atrophy and fibronecrosis of certain type II muscle fibers. Sarcopenia is characterized by atrophy and fibrous necrosis of specific type II muscle fibers at the muscle fiber level.

The mechanism of age-related muscle atrophy is thought to be influenced by multiple factors simultaneously, including inadequate nutritional intake, hormonal changes, poor muscle regeneration, and increased oxidative stress. Although the specific contribution of these factors is still not elucidated, it has been reported that the regulatory factors of muscle hypertrophy decrease reactively and quantitatively with aging, and that autophagy dysfunction becomes apparent (Sakuma and Yamaguchi, 2010; Wohlgemuth et al., 2010). On the other hand, no apparent enhancement of negative regulators [calpain, NF-κB (nuclear factor-κB), atrophy gene-1 (atrogin-1)] is observed in aging mammalian muscles (Sakuma et al., 2017). It is widely accepted that strategies such as nutritional supplementation and physical training (both aerobic and resistance exercise) are important interventions for

maintaining skeletal muscle mass. In particular, resistance training combining with amino acid supplementation is known to be the most effective in reducing the progression of sarcopenia (Sakuma and Yamaguchi, 2018). On the other hand, sarcopenia has been found to be most attenuated by mild caloric restriction (CR) in all mammals. Recent studies have also pointed to the potential application of new supplements (soy isoflavones, ursolic acid, etc.) in the prevention of muscle atrophy. In this article, we outline the molecular mechanisms of sarcopenia and detail recent nutritional approaches to inhibit this.

## **Molecular mechanism regulating sarcopenia**

### **No significant change of ubiquitin-proteasome system (UPS) in sarcopenic muscle**

UPS is essential for the control of proteolysis, as (1) substrates are covalently bound by multiple ubiquitin molecules and (2) proteins tagged by the 26S proteasome complex are degraded and released. Three enzymes regulate the ubiquitination of protein: ubiquitin activating enzyme (E1), ubiquitin binding enzyme (E2), and ubiquitin ligase (E3). Most famous E3 ubiquitin ligases (MuRF1 and atrogin-1) are increased in various skeletal muscle atrophy models (in vivo) such as cancer, diabetes, renal failure, denervation, and glucocorticoid administration (Bodine et al., 2001). These ubiquitin ligases are particularly important in muscle atrophy because loss of atrogin-1 or MuRF1 in mice inhibits fasting, denervation, and dexamethasone-induced muscle atrophy (Baehr et al., 2011; Cong et al., 2011).

Numerous studies in a variety of mammalian muscles have not yielded a concordant view of atrogin-1 or MuRF1 mRNA and protein changes associated with aging (Sakuma et al., 2017; Edström et al., 2006). A marked upregulation of phosphorylated Akt and forkhead box O (FOXO) 4 appears to occur in the gastrocnemius muscle of aging female rats. In addition, Léger et al. (2008) showed a decrease in nuclear FOXO1 and FOXO3a in 70-year-old humans, despite the absence of obvious age-related changes in these atrogen's mRNA. Sandri et al. (2013) demonstrated that mice with null mutation of atrogin-1 have a greater loss of muscle mass with aging (Sandri et al., 2013). In addition, although muscle mass is at least partially maintained in MuRF1-deficient mice, the age-related decline in muscle strength is more pronounced than in control mice (Hwee et al., 2014). As Sandri et al. (2013) showed, chronic inhibition of these atrogens exacerbates the decline rather than preventing it. As Sandri et al. (2013) have shown, chronic attenuation of these atrogens can't be considered an effective therapeutic target to combat sarcopenia, as it exacerbates decline rather than preventing muscle weakness.

### **Adaptation of autophagy-linked signaling in muscle with age**

Using the lysosomal-dependent pathway, macroautophagy (autophagy) is a catabolic process that extensively degrades cytoplasmic components. This process is characterized by the incorporation of a portion of the cytoplasm into autophagosomes. The autophagosome then fuses with the lysosome to form an autophagolysosome, where the material in the cytoplasm is degraded and the degradation products are recycled.

Autophagy was thought to be a crude and non-selective degradation system. However, autophagy is an extremely precise way to recover altered organelles and abnormal protein aggregates. Autophagy is selective for specific cargo receptors such as Nix (Bnip3L), Nbr1, p62/SQSTM1, and optineurin (Neel et al., 2013). Three molecular complexes regulate the autophagosome formation at least. These are the microtubule-binding protein 1 light chain 3 (LC3)-coupled system and the regulatory complexes governed by beclin-1 and unc51-like kinase-1. The LC3-binding system is composed of various proteins encoded by autophagy-related genes (Atg).

In invertebrates and higher organisms, autophagy declines with normal aging. In *Drosophila* skeletal muscle, the proteolytic function of the autophagy/lysosome system has been shown to decline with age (Demontis and Perrimon, 2010), suggesting a gradual accumulation of polyubiquitin protein aggregates in aging *Drosophila* muscle. Interestingly, overexpression of FOXO increases the expression of many autophagy molecules and inhibits the accumulation of polyubiquitin protein aggregates in sarcopenic *Drosophila* muscle (Demontis and Perrimon, 2010). There are multiple reports on age-related autophagic changes in mammalian skeletal muscle (Wohlgemuth et al., 2010; Gaugler et al., 2011; Wenz et al., 2009). The amount of Beclin-1 was significantly increased in plantar muscles than young Fischer 344 rats (Wohlgemuth et al., 2010). Using immunofluorescence microscopy and Western blotting of fractionated homogenates, we found that p62/SQSTM1 and Beclin-1 selectively accumulated in the cytoplasm of myofibers in sarcopenic mice (Sakuma et al., 2016) (Fig. 1).

On the other hand, the amount of Atg7 and Atg9 proteins was not modulated in aged rat plantaris muscles (Wohlgemuth et al., 2010). Furthermore, Wohlgemuth et al. (2010) suggested a significant increase in the amount of LC3 in muscle with aging, but failed to detect a significant increase with age in the ratio of LC3-II to LC3-I, a more suitable marker for assessing autophagy progression. On the other hand, Wenz et al. (2009) pointed out that the ratio of LC3-II to LC3-I increased significantly with age in the biceps femoris of wild-type mice. The transcriptional levels of autophagy-linked molecules did not show a significant increase with age (Wohlgemuth et al., 2010; Gaugler et al., 2011). Not all of the substances involved in autophagy signaling are similarly altered in aging skeletal muscle at both the mRNA and protein levels. Interestingly, human studies (Carnio et al., 2014) using muscle samples clearly demonstrated age-dependent autophagy defects in older human volunteers, including reduced amounts of Atg7 protein and LC3-II/LC3-I protein ratios. Therefore, sarcopenia would be involved in a marked impairment of autophagy signaling, but more detailed investigation is needed in this area. Fig. 2 is a hypothetical illustration of the autophagic dysfunctional situation in sarcopenic muscle fibers.

**Fig. 1** Serial cryosections of the quadriceps muscle of 3- and 24-month-old mice. p62/SQSTM1 and LC3 immunoreactivity. In young quadriceps muscle, immunofluorescence labeling showed that p62/SQSTM1 was present in the membrane and at a low level in the cytosol of several muscle fibers (A). Marked increases of p62/SQSTM1 immunoreactivity were observed in the membrane and the cytosol of aged muscle fibers (D). No apparent difference in LC3 immunoreactivity was observed in the muscle between 3- and 24-month-old mice (B and E). White arrows denote the muscle fibers possessing p62/SQSTM1. Bar = 50  $\mu$ m. Data from [Sakuma et al. \(2016\)](#).

## Supplementation with protein and amino acids

### Amino acids

Dietary protein provides amino acids necessary for muscle protein synthesis and, as an anabolic stimulus, acts directly on protein synthesis. Studies of young adults fed dietary protein suggest that more than half of the amino acids derived from protein are available for circulation within 5 h after a meal, and that  $\sim 11\%$  of these amino acids are incorporated into muscle proteins ([Groen et al., 2015](#)). The slowing of the anabolic response to protein intake in the elderly is a problem, suggesting that more protein may be needed to prevent loss of muscle strength and muscle mass ([Wolfe et al., 2008](#)). Epidemiological studies suggest that there is a positive correlation between maintaining muscle mass and protein intake. A number of reviews suggest that nutritional interventions such as high protein intake and intake of leucine, a branched-chain amino acid, combined with resistance training would be effective in reducing muscle fiber atrophy in sarcopenia ([Dickinson et al., 2017](#); [Timmerman and Volpi, 2008](#)). In particular, leucine is considered to be an amino acid with unique characteristics and has been the most studied in recent years. In particular, leucine has been the most studied in recent years and plays a variety of roles, including nitrogen donation for alanine and glutamine synthesis in muscle, glucose homeostasis, and translational regulation of protein synthesis.

Amino acid supplementation after acute resistance exercise has a synergistic effect on contraction-induced escalation of muscle protein synthesis ([Walker et al., 2011](#)). In human studies, amino acids have been shown to phosphorylate eukaryotic initiation factors 4F and p70S6K via mTOR. Resistance training and amino acid supplementation have been shown to result in additive hypertrophy ([Esmarck et al., 2005](#)). In fact, a study of frail elderly men and women showed that lean body mass increased in the protein supplementation group (in addition to resistance-type exercise training), but did not change in the placebo (exercise only) group ([Tieland et al., 2012](#)). Furthermore, the administration of multiple essential amino acids also increases muscle mass and protein synthesis, even under normal conditions without resistance training. ([Nicastro et al., 2011](#)). On the other hand, some reports have failed to prove the synergistic effects of long-term supplementation of several amino acids and carbohydrates with resistance training ([Godard et al., 2002](#)). Although the combination of both resistance training and amino acid supplementation has been recommended for the prevention of sarcopenia ([Sakuma and Yamaguchi, 2018](#); [Wakabayashi and Sakuma, 2014](#)), recent systematic reviews ([Beaudart et al., 2017](#); [Thomas et al., 2016](#)) often deny the positive effects of amino acid supplementation. [Beaudart et al. \(2017\)](#) found that the additional effect of nutritional interventions on [Beaudart et al. \(2017\)](#) noted that the additional effect of nutritional interventions on muscle mass was only found in 8 (23.5%) high quality RCTs. Exercise interventions in the elderly increased muscle strength in almost all studies (29/25 RCTs), while nutritional supplements had no beneficial effect in the majority of studies (8/35 RCTs, 22.8%). Therefore, the effects of amino acid supplementation on muscle mass, strength, and body performance may only be seen in elderly people with low nutrition and sarcopenia.

**Fig. 2** The hypothesis of the cytosol condition of sarcopenic muscle fibers (autophagic defect). In the cytoplasm of sarcopenic muscle fibers, the normal autophagy-dependent system does not work and large amounts of degenerated proteins and nonfunctional mitochondria accumulate. The denatured proteins can penetrate inside normal mitochondria and become entangled with normal proteins. Some dysfunctional mitochondria left in cells would release substances that are toxic to muscle cells.

## HMB

HMB is a metabolite of the branched-chain amino acid (BCAA) leucine. The initial reaction of HMB synthesized in the body is the transamination of leucine to  $\alpha$ -ketoisocaproic acid (KIC) by BCAA aminotransferases, which occurs primarily in skeletal muscle. HMB has been shown to stimulate protein synthesis via mTOR, a central regulator of mRNA translation efficiency (Wilkinson et al., 2013), reduce proteasome expression and enzyme activity, and decrease apoptosis in myonuclei (Gerlinger-Romero et al., 2011; Hao et al., 2011). He et al. (2016) have demonstrated that HMB supplementation increases mitochondrial biosynthesis and fat oxidation. Indeed, mitochondrial dysfunction and oxidative stress-induced anabolic resistance are observed in the muscles of the elderly (Holecek, 2017).

There are also a certain number of papers on the effects of HMB supplementation in humans, Deutz et al. (2013) used 3 g of HMB during 10 days of bed rest and obtained interesting results. Their results showed that compared to a control group, HMB reduced muscle weakness during bed rest and maintained muscle strength during the rehabilitation period. This was a well-designed study, as the amount of HMB supplementation was comparable to that frequently used in academic research, and the diet of the subjects was controlled. On the other hand, Hsieh et al. (2010) demonstrated that HMB supplementation had a positive effect during a 2–4 week intervention period. The authors found a decrease in blood urea and urinary urea excretion, suggesting a decrease in proteolysis, although the difference in anthropometric parameters was not significant. However, this study has some limitations, including a short supplementation period. On the other hand, a meta-analysis of several randomized controlled trials found that HMB supplementation can prevent loss of lean body mass in older adults without changing fat mass (Wu et al., 2015). HMB supplementation may be maximized when combined with other substances such as arginine and lysine. For example, Flakoll et al. (2004) demonstrated that consumption of an HMB/Arg/Lys mixture (2/5/1.5 g per day) for 12 weeks increased limb circumference, leg and hand grip strength, and whole body protein synthesis. Since neither group showed any improvement in muscle strength, they ruled out an effect of HMB supplementation on muscle strength. One systematic review of high quality supported that there was no difference between HMB and placebo on muscle strength (Wu et al., 2015). However, this meta-analysis presented many evidence to support HMB supplementation on muscle mass (Wu et al., 2015). Taken together, these data suggest that HMB supplementation in the elderly has a positive effect on muscle mass, but no clear effect on physical performance and muscle strength. Two reviews with somewhat insufficient evidence also found that it is not possible to determine whether HMB alone is effective in improving muscle strength, physical performance, and/or mass (Wu et al., 2015; Malafarina et al., 2013), and more research on the effects of HMB supplementation on reducing sarcopenia is needed.

Although it is not clearly elucidated whether HMB alone attenuate sarcopenic symptom, HMB plus vibration improve significantly this. Whole body vibration and local vibration have been implemented as treatment for muscle weakness in the elderly. One RCT using sarcopenic men (mean age 88.6 years) indicated that 8-week vibration (12–16 Hz, 3–5 mm) significantly improved muscle strength and physical performance (gait speed, five-times-sit-to-stand test, and timed-up-and-go test) (Zhu et al., 2019). Although systematic reviews and meta-analyses have shown that vibration therapy may be a positive strategy for improving physical

performance and muscle strength in sarcopenia, caution is needed in interpreting the data due to the limited number of relevant studies (Wu et al., 2020). Very intriguingly, Wang et al. (2020) recently showed that combined low-magnitude high-frequency vibration (LMHFV) and HMB intervention markedly enhanced muscle strength (twitch and tetanic force) and decreased intramuscular fat infiltration (lower oil red O area) in aging SAMP8 mice. Although this study uses an aging mouse model, I feel that the combination of LMHFV and HMB for sarcopenia patients is a very interesting approach.

## Polyphenol

Among the natural compounds, polyphenols appear to be of interest to modulate mitochondrial function and protect against metabolic disease by activating mitochondrial biogenesis through SIRT1 and PGC-1 $\alpha$ .

### Catechin

Tea (*Camellia sinensis*), especially green tea whose main active ingredient is catechins, contains many phenolic hydroxyl groups (-OH). There are four monomers of catechins: epigallocatechin gallate (EGCG), epicatechin (EC), epigallocatechin (EGC), and epicatechin gallate (ECG). Recently, it has been shown that green tea catechins have the potential to modulate skeletal muscle cell homeostasis and inhibit muscle mass loss. In fact, ECs have enhanced mitochondrial capacity in animal and human studies on cardiac, skeletal muscle, and neuronal cells (Daussin et al., 2021). 8 weeks of EGCG (5 mg/kg, 4x/week) appears to reduce fibrosis and necrotic myofibers in muscular dystrophy mice (Nakae et al., 2008). EGCG supplementation also decreases protein carbonyl content, a marker of oxidative stress, in aged (34 months) male Wistar rats (Senthil Kumaran et al., 2008). Furthermore, in vitro and in rodent model studies, EGCG supplementation leads to increases in myonuclear number, myotube formation, cross-sectional area, and muscle mass (Luk et al., 2020). On the other hand, some results show that the effects of catechin supplementation on muscle adaptation are disparate; Si et al. (2019) conducted an experiment in which 20-month-old male C57/BL mice were fed EC or EGCG (0.25% w/v in drinking water) and a standard diet. The results showed that the survival rate significantly increased from 39% to 69% after 37 weeks of EC intake, whereas no significant effect was observed with EGCG. In addition, EC improved physical activity, slowed skeletal muscle degeneration, reversed age-related mRNA and protein expression of the extracellular matrix and growth factor-activated receptor pathways in skeletal muscle, and reversed age-related decreases in the nicotinic acid and nicotinamide pathways in both serum and skeletal muscle. Thus, the effects of EC on skeletal muscle have been demonstrated. Thus, the effect of EC on skeletal muscle was more pronounced than that of EGCG.

That Oligonol, a lychee extract rich in flavanols consisting of phenolic compounds such as catechins and procyanidins, prevents obesity caused by a high-fat diet and kidney damage caused by diabetes (Liu et al., 2016). Feeding 32-week-old senescence-accelerated mouse prone 8 mice (SAMP8) with a chow diet containing 200 mg Kg<sup>-1</sup> oligonol for 8 weeks showed that oligonol prevented high-fat diet-induced obesity and diabetes-induced renal damage. Addition of oligonol resulted in decreased expression of mitochondrial biosynthetic genes (PGC-1 $\alpha$  etc.) and mitochondrial fusion genes (Mfn2 etc.), increased expression of Atg13, LC3-II and p62, and abundant accumulation of autophagosomes and lysosomes (Chang et al., 2019). Although much has been demonstrated about the effects of supplementation with green tea extracts (EC, EGCG, oligonols, etc.) on mitochondria and myofibers, almost all studies have been conducted using rodent models. In order to apply the results of animal studies to humans, it is necessary to examine the safety, bioavailability, and efficacy of green tea in sarcopenia patients. Most clinical studies on the effects of green tea extract on sarcopenia patients are not randomized controlled clinical trials, and the current limited human studies do not provide sufficient evidence to confirm a beneficial effect on sarcopenia patients.

### Soy isoflavone

Isoflavones, a type of flavonoid found in soybeans, are one of the most naturally occurring organic compounds. Structurally similar to estrogen, they bind to estrogen receptors and exert physiological functions (such as antioxidant effects). Estrogen receptors (ERs) include ER $\alpha$  and ER $\beta$ , and daidzein, a type of soy isoflavone, acts on ER $\beta$  rather than ER $\alpha$ . For example, when isoflavones were added to a high-fat diet for 12 weeks, muscle mass increased in mice after ovariectomy (Beekmann et al., 2015). On the other hand, when isoflavones were fed for as long as 120 days, fat accumulation in skeletal muscle of male mice was suppressed (Kurrat et al., 2015). Thus, it was suggested that isoflavones affect muscle mass and function not only in females but also in male mice. Unfortunately, many researchers have investigated the effects of isoflavone supplementation by assessing only muscle mass, not muscle fiber size (Aoyama et al., 2016; Ogawa et al., 2017). This method of assessment is likely incorrect when large amounts of fat and connective tissue accumulate in atrophied tissues (Wall et al., 2015). In other words, the muscle mass maintenance effect of isoflavones, as assessed by these muscle mass alone, may not accurately reflect changes in muscle fiber size. Abe et al. (2013) examined the effect of isoflavone administration on muscle atrophy by assessing muscle fiber size. The results showed that isoflavone (20% of the diet) administration significantly suppressed fibroatrophy in the tibialis anterior muscle 4 days after denervation. At this time, the expression of IRS-1 and p-Akt1 proteins was significantly increased in the muscles of denervated mice after isoflavone supplementation. Hirasaka et al. (2014) also found that isoflavone inhibited the damage to acetylcholine receptors caused by denervation, suggesting that isoflavone intake may have a protective effect on the neuromuscular junction. Furthermore, an in vitro

study using cells reported that isoflavones suppressed the transcriptional activity of MuRF-1 and inhibited TNF- $\alpha$ -induced myotube atrophy (Hirasaka et al., 2013).

Many experiments on isoflavone supplementation in vivo have utilized amounts exceeding 1% of the dietary intake (Beekmann et al., 2015; Kurat et al., 2015). Because it is very difficult for humans to consume such amounts of isoflavones at every meal, the supplemental data of Abe et al. (2013) are not realistic for determining the effect of isoflavones on muscle atrophy. Our group (Tabata et al., 2018) demonstrated that administration of 0.6% isoflavone (AglyMax) modulates the degree of denervation-induced muscle fiber atrophy in mice. AglyMax is an isoflavone aglycone that is a mixture of daidzein, genistein, and glycitein in a 7:1:2 ratio, and in humans it has been noted to have a higher absorption rate and quantity than glucosides. This effect is thought to be due to reduced signaling in an apoptosis-dependent system, rather than an atrophy gene-1 (atrophy gene-1)-dependent system.

Daidzein is thought to be effective in older women. 8-Prenylnaringenin, which has estrogenic effects similar to daidzein, is thought to inhibit denervation-induced atrophy of skeletal muscle by promoting phosphorylation of Akt (Mukai et al., 2012). In addition, quercetin, a type of flavonoid found in fruits and vegetables, scavenges ROS. This effect of quercetin is noteworthy because ROS activates NF $\kappa$ B pathway and Foxo pathway and induces the expression of E3 ubiquitin ligase. In addition, in a hindlimb unloading model, quercetin administration to the gastrocnemius muscle decreased the expression of atrogin-1 and MuRF-1 and prevented the loss of skeletal muscle mass (Mukai et al., 2010). Whether daidzein, quercetin, and AglyMax inhibit age-related muscle atrophy needs to be tested, but it seems likely.

### Resveratrol

Resveratrol (3,5,4'-trihydroxystilbene), which is found in grape skin, seeds, and peanuts, is a polyphenolic phytoalexin produced by plant species. When young female mice were immobilized on one limb for 7 days, resveratrol prevented loss of muscle mass, muscle fiber CSA, and muscle strength, while simultaneously increasing satellite cell content during the 7-day recovery period (Bennett et al., 2013). In different atrophy model, we (Asami et al., 2018) demonstrated that 0.5% resveratrol diet for young mice significantly prevented decreases in muscle weight and fiber atrophy as well as the increase in atrogin-1 and p62 immunoreactivity after 2 weeks of denervation. Administration of resveratrol causes activation of SIRT1-AMPK $\alpha$ -PGC-1 $\alpha$  signaling, which induces a variety of biological responses important for healthy aging (Gülçin, 2010). In fact, four weeks of resveratrol supplementation induced the increase of mitochondrial mass and function, suppression of lipid peroxide, and increases in activity of catalase and superoxide dismutase, causing increased physical endurance in mice (Muhammad and Allam, 2018); however, the effects of resveratrol on sarcopenia have not yielded stable results. Low to moderate daily intake of resveratrol for 6–7 weeks has no effect on muscle strength and function in older mice (Baumann et al., 2014; Zhou et al., 2019). Similarly, long-term consumption (10 months) of low to moderate resveratrol has no beneficial effects on muscle function and mass in aging mice. Overall, resveratrol appears to have a protective effect against sarcopenia. However, more detailed studies are needed, especially in humans, since these effects are contradicted by the age of the experimental species and the variation of dose and duration with the supplementation.

### Creatine supplementation

Creatine is a guanidine compound produced endogenously in the liver, kidney and pancreas from arginine, glycine and methionine. Creatine monohydrate (CrM) is one of the most widely used and researched supplements. At the cellular level, CrM has been suggested to reduce oxidative stress, prevent motor neuron shedding, and enhance mitochondrial function. Since phosphocreatine plays an important role in supporting metabolism during high-intensity exercise, this metabolic disturbance is thought to inhibit muscle performance and reduce muscle mass. It is still unclear whether creatine levels change with age, and several studies have failed to show a beneficial effect of CrM supplementation during resistance training in older adults (Bermon et al., 1998; Rawson et al., 1999). On the other hand, CrM supplementation during resistance training in the elderly has been reported to increase muscle mass and strength, endurance, and power (Rawson et al., 1999; Brose et al., 2003). Administration of CrM in a 2-month resistance exercise program (67–80 years old) did not affect the increase in total volume or muscle strength from training (Bermon et al., 1998). On the other hand, longer term (>4 months) studies have demonstrated the beneficial effects of CrM supplementation to further increase muscle strength and muscle mass after resistance training (Rawson et al., 1999; Brose et al., 2003). Some previous studies have shown little benefit of CrM supplementation without resistance training in older adults (Rawson et al., 1999; Parise et al., 2001). More recently, two other systematic reviews of low to moderate quality found some evidence supporting no difference between CrM supplementation combined with progressive resistance training and exercise alone with respect to physical performance, but with respect to muscle mass and strength, some evidence supporting the combined. However, for muscle mass and strength, there was some evidence to support the combined intervention (Wu et al., 2015; Denison et al., 2015).

## Vitamin D

Vitamin D has traditionally been considered an important regulator of bone metabolism and phosphorus and calcium homeostasis. Muscle mass loss and vitamin D deficiency often occur together; the prevalence of low vitamin D levels in persons 65 years of age and older is estimated to be about 50%. (Wicherts et al., 2007). The mechanisms by which vitamin D affects muscle function and strength is not fully understood, but is probably vitamin D receptor (VDR)-mediated. Interestingly, the expression of vitamin D receptors in skeletal muscle is also known to decrease with age (Snijder et al., 2006). Long-term vitamin D deficiency causes severe muscle weakness, which improves with vitamin D supplementation.

There is considerable clinical and epidemiological evidence linking vitamin D status to differences in muscle strength and function in the elderly; Annweiler et al. (2009) found that vitamin D supplementation improved muscle strength and performance in a double-blind study of elderly people living in areas with low vitamin D levels and nursing home residents. They found that vitamin D supplementation improved muscle strength and performance. In a double-blind study of older adults and nursing home residents living in areas with low vitamin D levels (Annweiler et al., 2009), found that vitamin D supplementation improved muscle strength and performance and reduced the risk of falls. In a double-blind study, they found that vitamin D supplementation improved muscle strength and performance and reduced the risk of falls. Consistent with this observation, a number of epidemiological studies have shown reduced lower extremity function, including longer walking times and sit-to-stand times, in older adults with hypovitaminosis D status (Wicherts et al., 2007; Bischoff-Ferrari et al., 2004). However, the relationship between vitamin D and muscle mass and composition is less clear in comparison to the large body of evidence on the benefits of high vitamin D status on skeletal muscle function. A more comprehensive understanding of the effects of vitamin D on skeletal muscle function, muscle strength, and muscle mass may be a very effective means of preventing muscle atrophy (sarcopenia) in the elderly. However, many studies have shown negative results of treatment with vitamin D in elderly patients without vitamin D deficiency. In the absence of vitamin D deficiency in elderly patients, vitamin D is unlikely to be effective in controlling sarcopenia. In fact, a very recent meta-analysis (Prokopidis et al., 2022) reported that vitamin D intake does not attenuate sarcopenia in community-dwelling older adults.

## Ursolic acid

Ursolic acid (UA), found in plants and fruits such as apples, is a natural pentacyclic triterpenoid carboxylic acid; UA has anticarcinogenic, antioxidant, anti-inflammatory, and anti-obesity properties (Prokopidis et al., 2022), and besides, UA has confirmed beneficial effects in animal models of hyperlipidemia and diabetes (Katashima et al., 2017). Supplementation with UA was reported to increase skeletal muscle and muscle strength in a mouse model (Wang et al., 2009). A systematic review, including animal studies, concluded that UA supplementation increases physical fitness (ex. muscle strength) and muscle mass by increasing sirtuin 1 expression and muscle satellite cells and activating the mTOR pathway in muscle. Indeed, Kunkel et al. (2012) found that ursolic acid reduced two different types of muscle atrophy, fasting and muscle atrophy-induced stress, by decreasing the mRNA levels of the muscle atrophy genes atrogin-1 and MuRF1. In addition, UA supplementation increased Akt phosphorylation in skeletal muscle in vivo. Intriguingly, ursolic acid may not have a direct effect on skeletal muscle, because UA alone was not sufficient to promote activation of IGF-I and insulin receptors. More recently, Yu et al. (Kunkel et al., 2011) experimented with long-term (21 days) administration of UA (orally 100 mg/kg) in a chronic kidney disease (CKD) mouse model. They found that administration of ursolic acid significantly inhibited CKD-induced muscle atrophy (tibialis anterior) by decreasing the expression of inflammatory cytokines (IL-6, TNF- $\alpha$ , etc.) and ubiquitin E3 ligases (MuRF-1, atrogin-1, MUSA1, etc.). They found that the decrease in the phosphorylation levels of NF- $\kappa$ B (p65), STAT3, and p38 were significantly inhibited by UA in CKD-induced atrophic muscle.

The hypertrophic effects of UA in humans are less clear. For example, in healthy adults, UA supplementation (50 mg/day provided by ingesting 500 mg of loquat leaf extract) did not improve muscle mass and strength compared to placebo ingestion (Yu et al., 2017). Furthermore, UA (3 g) for resistance-trained men did not modify activation of anabolic signaling pathways after one RT (Cho et al., 2016). Eight weeks of UA supplementation (450 mg/day) combined with RT increased IGF-I levels and muscle strength compared to RT alone, however the authors did not observe a substantial increase in LBM (Church et al., 2016). In summary, UA supplementation may have anabolic effects, but these effects have not been consistently confirmed in humans (Bang et al., 2014). Therefore, further studies are needed to determine the effects of UA supplementation on sarcopenia in humans.

## omega-3 PUFAs

The major omega-3 PUFAs are alpha-linolenic acid (ALA), eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA). In order to ensure structural cell function, the concentration of EPA and DHA in cell membranes is important. Major dietary sources of EPA and DHA are fatty fish (e.g., mackerel) and seafood. ALA is found in plant foods such as chia seeds, vegetable oils, and nuts. Although about 500 mg of EPA and DHA per day is recommended, most adults in the United States do not achieve the recommended intake of DHA and EPA (Lobo et al., 2021).

Supplementation with omega-3 PUFAs provides an interesting alternative opportunity because of low risk of adverse events and anti-inflammatory properties. Supplementation with omega-3 PUFAs may be beneficial for a variety of aging processes, including

bone and eye health, and cognition. Omega-3 PUFAs have also been suggested to have multiple beneficial effects in muscle such as increased muscle fiber size and improved mitochondria function (Vannice and Rasmussen, 2014). In addition, previous randomized controlled trials (RCTs) demonstrated that muscle protein synthesis in the elderly is promoted by omega-3 PUFA supplementation (Gray and Mittendorfer, 2018). When resistance training was combined with omega-3 PUFA supplementation, the improvement in muscle quality and function obtained from resistance training was also significantly enhanced (Smith et al., 2015). Cross-sectional studies have also been conducted on the association between dietary intake of omega-3 fatty acids and physical performance. The association between grip strength and dietary intake was investigated in 2893 men and women aged (59–73 years) included in the Hertfordshire Cohort study. This study indicated that each additional serving of fatty fish was associated with an increase in grip strength of men (0.43 kg) and women (0.48 kg) (Da Boit et al., 2017).

It is generally accepted for the anti-inflammatory effects of omega-3 PUFAs. Supplementation with omega-3 PUFAs have decreased in CRP and IL-6 in middle-aged and elderly people (Robinson et al., 2008). A recent RCT also investigated the effects of DHA and EPA treatment (8 weeks) in the elderly and found significant reductions in levels of IL-6, IL-1 $\beta$ , and TNF $\alpha$  (Custodero et al., 2018). Since chronic low-level inflammation may be involved in the development of sarcopenia, this suppression of inflammation by omega-3 PUFA may be one mechanism to combat sarcopenia. On the other hand, it has also been reported that omega-3 PUFA supplementation does not affect inflammatory markers (Tan et al., 2018), and further studies in sarcopenic older adults are needed.

The mTOR pathway plays an important role in skeletal muscle generation and muscle protein synthesis. Sakuma found increased activation of the mTOR-p70s6k signaling pathway in response to increased amino acid and insulin supply after 8 weeks of omega-3 PUFAs supplementation compared to the placebo group (Tan et al., 2018). It has also been suggested that supplementation with omega-3 PUFAs decreases the expression of inhibitory pathways to mTOR and causes important changes in gene expression that favor skeletal muscle anabolism (Smith et al., 2011). Therefore, omega-3 PUFAs have the potential to overcome age-related anabolic resistance through activation of mTOR signaling.

### Caloric restriction (CR)

CR has been recognized as the most powerful intervention to extend lifespan by slowing both primary aging (natural decline associated with aging) and secondary aging (accelerated aging due to disease or negative lifestyle factors) in many species. It has been recognized as the most powerful intervention to extend life by slowing both primary aging (natural decline associated with aging) and secondary aging (accelerated aging due to disease and negative lifestyle factors). It has been recognized as the most powerful intervention to extend lifespan by slowing both primary aging (natural decline associated with aging) and secondary aging (accelerated aging due to disease or negative lifestyle factors). The protective effects of CR, which is recognized as the most potent intervention to extend lifespan in many species, may be attributed to its ability to reduce the occurrence of mitochondrial abnormalities and attenuate oxidative stress. CR reduces the total amount of muscle protein synthesis and the fractional synthesis rate of individual proteins in rodents, but not the age-related CR was shown to have no effect on the decrease in mitochondrial density (Smith et al., 2015). These findings suggest that CR does not increase mitochondrial biosynthesis, but rather maintains mitochondrial function by protecting existing cellular components (Smith et al., 2015). Furthermore, CRs are resistant to increased apoptotic signaling in skeletal muscle with aging (Lanza et al., 2012). Notably, CR regulates most of the apoptotic pathways that occur in aging muscle, including mitochondria, cytokines/receptors, and Ca<sup>2+</sup>/ER stress-mediated signals (Lanza et al., 2012).

How does CR regulate sarcopenia, independent of mitochondrial function and apoptosis? CR increases PGC-1 $\alpha$  in various organs such as brain, heart, liver, and visceral adipose tissue. PGC-1 $\alpha$  plays a variety of roles, including enhancement of mitochondrial biosynthesis, fatty acid oxidation, autophagy activation, neuromuscular junction gene induction, and myokine secretion. Indeed, Valdez et al. (Dirks and Leeuwenburgh, 2004) showed that lifelong CR in mice significantly suppressed abnormalities at the synapse due to age-related loss protection of motoneurons by PGC-1 $\alpha$ . It is known that autophagy in skeletal muscle decreases with age (Wohlgemuth et al., 2010), and normal function of autophagy by CR may inhibit age-related atrophy of muscle fibers.

A large study of CR in primates was conducted and showed favorable results for both all-cause and age-related mortality (Valdez et al., 2010). On the other hand, another study failed to find any significant difference by CR in either all-cause mortality or age-related mortality (Colman et al., 2014). The inhibitory effect of CR on sarcopenia in mice, rats and rhesus monkeys is well known (Mattison et al., 2012; McKiernan et al., 2011). We would like to clarify whether CR suppresses sarcopenia in humans and to what extent dietary restriction is possible.

Fig. 3 represents an overview of nutritional intervention for sarcopenia.

### Conclusion

The recent advances in our understanding of muscle biology have led to possible candidate for molecular mechanism and nutritional treatment of sarcopenia. The most possible mechanism for sarcopenia is the defect of protein degradation through autophagy-lysosome signaling. Although resistance training combined with amino acid-containing supplementation is usually recommended to prevent age-related muscle wasting and weakness (Sakuma and Yamaguchi, 2018), supplementation with proteins (amino acids) only did not influence sarcopenic symptoms. Milder CR (15–25%) would also be effective for age-related muscle

**Fig. 3** Nutritional interventions affect different mediators in sarcopenic muscle. Recent findings suggest that the myostatin-Smad pathway inhibits protein synthesis probably due to blocking the functional role of Akt. Treatment with an ursolic acid upregulates the amount of IGF-I and then stimulates protein synthesis by activating the Akt/mTORC1/p70S6K pathway. Administration of omega-3 PUFA or HMB may work to prevent sarcopenia by activating mTORC1. Sarcopenic muscle exhibits a marked defect of autophagy-dependent signaling, which is effectively ameliorated by caloric restriction and oligonol supplementation. ALK activin receptor-like kinase, ActRIIB activin receptor IIB, IGF-I insulin-like growth factor I, TSC tuberosus sclerosis complex, TORC1 component of TOR signaling complex 1, Rheb Ras homolog enriched in brain, mTORC1 mammalian target of rapamycin complex 1, eIF4E eukaryotic initiation factor 4E, FOXO forkhead box O, LC3 microtubule-associated protein light chain 3, Bnip BCL2/adenovirus E1B 19 kd-interacting protein, Atg autophagy-related genes.

atrophy in humans, although some evidence-based modification is necessary. Many candidates such as catechins, soy isoflavones, and ursolic acid may combat sarcopenia, although systematic and fundamental research on this treatment has not been conducted, even in rodent models of sarcopenia (McKiernan et al., 2012).

### Key points

- Metabolic homeostasis relies on a complex and integrated system to adapt to changes in nutrient provision and utilization.
- Most cells use glucose for ATP synthesis and energy supply however other fuels (e.g., fatty acids, amino acids and ketone bodies) have an important energy supply role in metabolic adaptation in response to prolonged fasting or starvation.
- Thyroid hormones are known as potent hypothalamic regulators of whole-body energy homeostasis.
- AMP-activated protein kinase (AMPK) and the evolutionary-conserved NAD<sup>+</sup>-dependent histone deacetylase SIRT1 axis integrates multiple hormonal and nutritional signals (e.g., glucagon, leptin, adiponectin, glycogen, and free fatty acids) to regulate cellular and whole body energy homeostasis during starvation

### Glossary

**Adapted starvation** Relates to the state of steady fat store depletion and minimal proteolysis beyond three weeks of fast during which ketone bodies and fatty acids are the main energy substrates

**AMPK** The AMP-activated protein kinase is an important sensor of nutrient supply to cells and intracellular energy status. Under conditions of low intracellular energy charge, AMP and ATP are bound in a competitive manner and activation of AMPK leads to downregulation of anabolic and upregulation of catabolic enzymatic pathways with the aim to increase intracellular ATP availability

**Cori cycle** The metabolic pathway in which lactate—generated through anaerobic glycolysis in the muscle—is used for hepatic glucose synthesis, which then is transported back to the muscle as an energy substrate

**FOXO** Forkhead box O is a family of transcription factors. FOXOs are elemental regulators of metabolism, upregulate key enzymes of hepatic gluconeogenesis during early starvation, interfere with adipocyte differentiation and increase protein catabolism

**Intermediate phase** This relates to the necessary transcriptional transition to ketogenesis and ketolysis as well as fatty acid oxidation during two to three weeks after initiation of fasting

**Kwashiorkor** Kwashiorkor is one of the major clinical syndromes of severe childhood malnutrition (SCM, see also *Marasmus*). While wasting is characteristic for all syndromes of SCM, Kwashiorkor has additional clinical features of protein energy malnutrition such as hypoalbuminemia, generalized edema, skin changes (dermatitis, hypopigmentation). The underlying etiology in comparison to marasmus is still unclear, additional stressors such as infections and environmental toxins might be involved. The overall mortality is high

**Marasmus** Marasmus is one of the major clinical syndromes of severe childhood malnutrition (SCM, see also *kwashiorkor*) characterized by non-edematous slow weight loss and wasting of muscle protein compartment through months and years. The serum albumin is normal and associated overall mortality is low following reintroductions of adequate nutrition

**mTOR** Mammalian target of rapamycin is a serine/threonine protein kinase with pleiotropic intracellular anabolic effects and functions. mTOR is involved in regulation of protein synthesis, cell proliferation, cell survival and inflammatory reactions. Upstream activators are insulin and insulin-like growth factors (IGF-1), inhibition is mediated through the AMPK-FOXO pathway

**PGC1 $\alpha$**  PPAR $\gamma$  coactivator-1 $\alpha$  is a transcriptional coactivator involved in mitochondrial metabolism. It is accepted as the central node in starvation-induced transcriptional co-activation and regulates large clusters of genes involved in oxidative phosphorylation and fatty acid metabolism

**PPAR** Peroxisome proliferator-activated receptor is a family of ligand-activated transcription factors involving three main subclasses, PPAR $\alpha$ ,  $\beta$  and  $\gamma$ . PPAR $\alpha$  acts as an intracellular fatty acid sensor and is one of the master regulators of cellular fatty acid oxidation and ketone body production

**SIRT1** An evolutionary-conserved NAD<sup>+</sup>-dependent histone deacetylase which is an important element of metabolic homeostasis and energy conservation during fed-fasted-refed transitions

## Introduction

Human metabolism and body function rely on the essential provision and effective utilization of energy at a cellular level. However, on a daily basis, there are numerous fluctuations in nutrient intake and changes in metabolic demand such as variations in physical activity and environmental factors. A highly integrated system allows the human body to adapt to these changes in daily life and maintain a state of homeostasis.

Critical illness, chronic disease and other environmental factors may lead to periods of prolonged fasting (total absence of nutrient intake) and starvation (prolonged period of inadequate food intake) that challenge homeostatic mechanisms and result in depletion of preexisting fuel stores. In response, a complex interplay of regulatory factors and systems is required to stimulate a sequence of further changes, called metabolic adaptation and provide ongoing energy supply to the body's organs.

This article provides a review of normal metabolic processes and responses in the feeding-fasting cycle and the biochemical adaptations that occur in response to prolonged fasting and starvation in humans.

## The feeding/fasting cycle

### Energy requirements and metabolism

Energy is essential for many important body functions, including the maintenance of cellular integrity and function, new tissue synthesis and growth, thermoregulation and adaption to physical activity and other metabolic stressors. The energy requirements of an individual vary with age, sex, body composition, physical activity, and stress. In the normal adult at basal state, approximately 75% of energy requirements reflect the energy needs of major organs (brain ~20%, skeletal muscle 18–22%, abdominal organs ~25%, and heart ~11%). In children, up to 50% of resting metabolic energy is expended by the brain. During normal daily activity, the total energy requirement and the proportion of energy needed by different tissues may vary considerably.

### Energy production

Adequate availability of metabolic fuels for energy production has to be maintained in both the fed and the fasting states. The body derives energy from combustion of carbohydrate, fat, and protein provided exogenously in the fed state with the surplus being stored as glycogen in liver and muscle and as triacylglycerol in adipose tissue. These stores help to endogenously buffer periods of low-energy intake such as the post absorptive and fasting state. A mixture of metabolic fuels including glucose, triacylglycerols, ketone bodies, non-esterified fatty acids, and amino acids is present in the circulation. The proportion of these energy substrates in the blood at any one time depends on the fed or fasting state of the individual, the extent of fuel stores, and recent or current metabolic demand and stressors. Many of these are interconvertible and thus allow easier adaptation to situations of changing exogenous energy supply. In a normal, non-obese 70 kg adult, there are approximately 500 MJ (120,000 kcal) contained in adipose tissue, 100 MJ (24,000 kcal) stored in muscle and visceral proteins, and 8 MJ (2000 kcal) stored as liver and muscle glycogen. During

a normal day, half of the total energy requirement is met by carbohydrate metabolism. At this rate, glycogen stores would be exhausted after 1–2 days of fasting. However, glycogen stores are maintained for a longer period owing to the production of glucose from gluconeogenesis (Fig. 1). Gluconeogenic substrates such as lactate, amino acids (alanine, glutamine), glycerol, and  $\beta$ -hydroxybutyrate are shuttled from muscle and adipose tissue toward liver and kidney where they act as core substrates for gluconeogenesis. During prolonged fasting, the liver will account for approximately 80% of total body glucose production, whereas the remaining 20% is made by the kidney.

### Carbohydrate metabolism

Glucose plays a key role in body metabolism. It is the preferred source of energy for the majority of tissues and is particularly important for the retina and the brain where it is the main energy substrate. Owing to a lack of mitochondria, red blood cells and the renal medulla are completely reliant on glucose as the sole metabolic fuel at all times. Therefore, the metabolic changes that occur during fasting and starvation target the necessity to spare blood glucose and liver glycogen for use by brain and other glucose-dependent tissues by providing alternative fuels to other tissues (Table 1).

Glucose enters the bloodstream through absorption from the intestine, the breakdown of liver glycogen, and hepatic gluconeogenesis from glucogenic precursors (e.g., lactate, alanine). To produce energy from glucose, three metabolic pathways are involved (Fig. 2). Glucose is first oxidized to form pyruvate via the glycolytic pathway. Pyruvate then enters the Krebs cycle and is completely oxidized to form  $\text{NADH} + \text{H}$ ,  $\text{FADH}_2$ , and carbon dioxide. The  $\text{NADH} + \text{H}$  transports hydrogen to the respiratory chain where it is used to reduce oxygen to water through oxidative phosphorylation. The net yield of energy from the metabolism of 1 molecule of glucose is 38 molecules of ATP. As the combustion of glucose within the human body is coupled to the energy-consuming synthesis of ATP, the overall efficiency of energy extraction from glucose within the cell is only approximately 50%.

Of all energy substrates, blood glucose concentration is the most constant. Because of the strict glucose requirements of the brain, the circulating blood glucose pool is tightly controlled at approximately 16 g or 5 mmol  $\text{L}^{-1}$ . Three important mechanisms are responsible for this regulation.

1. Insulin, as an anabolic hormone, enhances glucose uptake into muscle and fat and stimulates glycogen synthesis. It also inhibits lipolysis, glycogenolysis, and gluconeogenesis. High insulin levels will decrease blood glucose levels. Conversely, low insulin levels will cause a rise in blood glucose by decreased inhibition of glycogenolysis and reduced peripheral uptake of glucose.
2. Glucagon, a 29-amino acid peptide released from pancreatic  $\alpha$ -cells, counteracts the insulin effect and increases liver glycogen breakdown, gluconeogenesis, and ketogenesis from fatty acids. It also stimulates lipolysis from adipocytes in extrahepatic tissue.

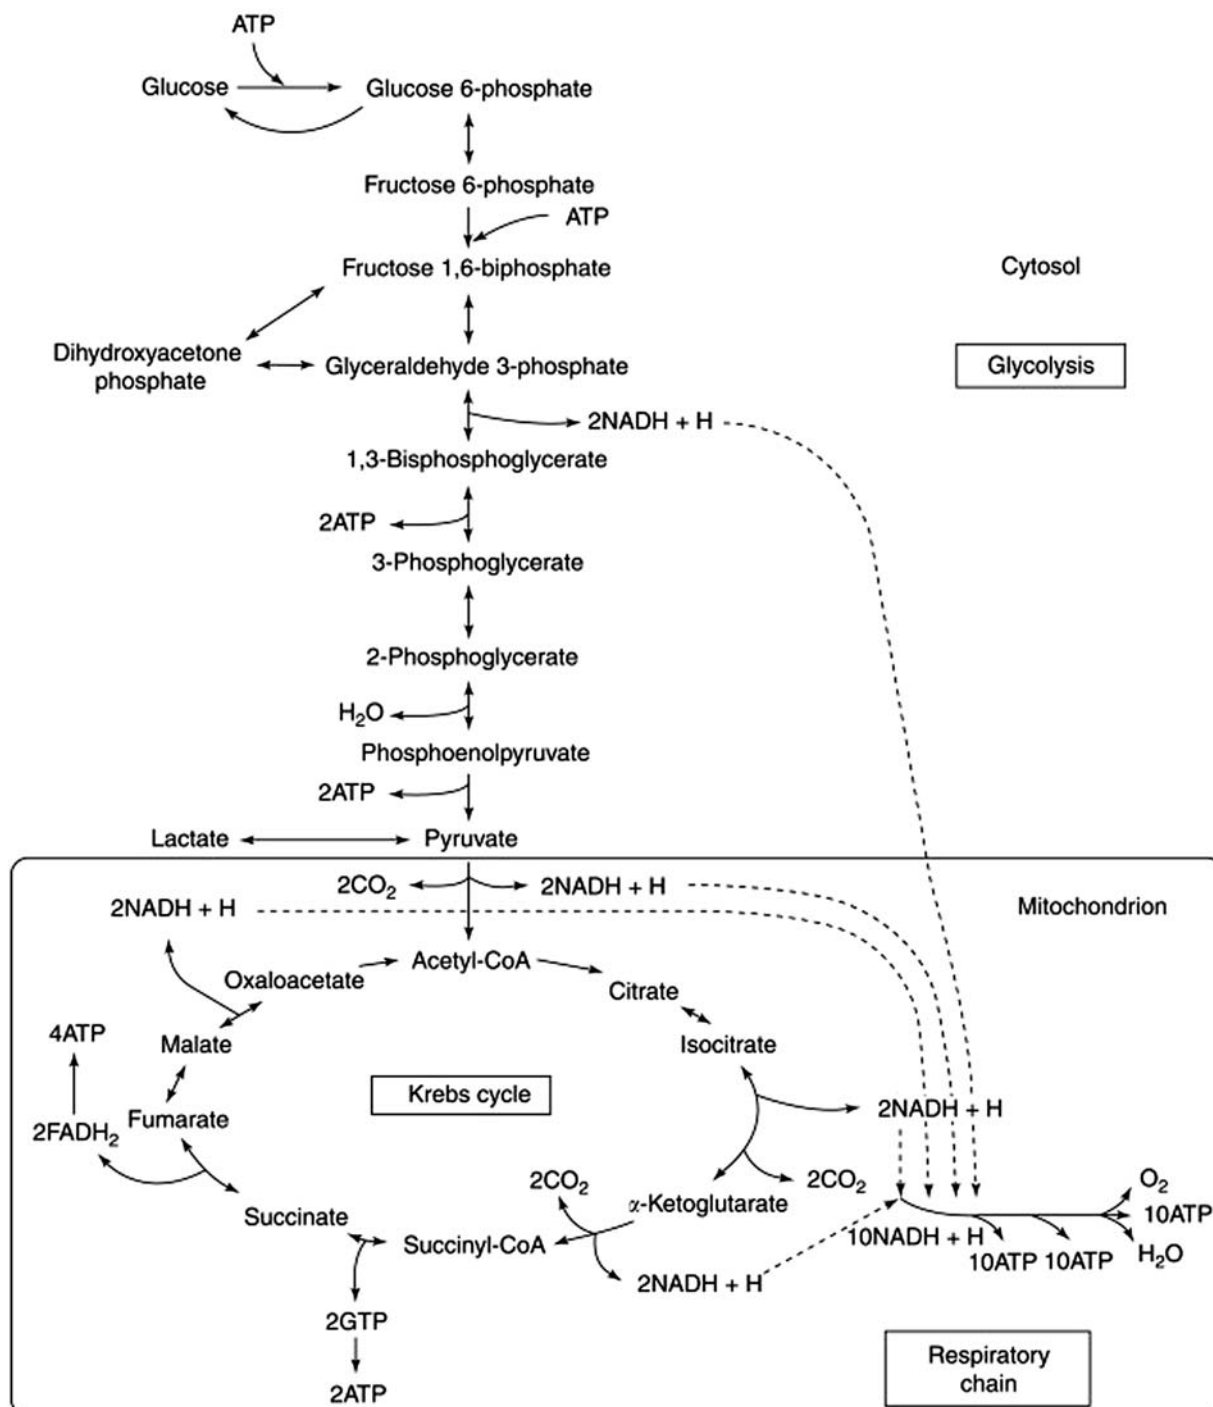

**Fig. 1** The metabolism of energy substrates to maintain glucose homeostasis.

**Table 1** Energy sources of different parts of the human body.

Organ	Preferred energy sources (well-fed state)	Alternative energy sources (starvation state)
Liver	Glucose, fatty acids	Fatty acids
Skeletal muscle	Glucose, fatty acids (resting muscle)	Fatty acids, ketone bodies
Cardiac muscle	Fatty acids	Fatty acids, amino acids and ketone bodies
Adipose tissue	Glucose	Fatty acids
Kidney	Glucose, fatty acids	Fatty acids
Brain <sup>a</sup>	Glucose	Glucose, later ketone bodies
Red blood cells <sup>a</sup>	Glucose	Glucose
Outer retina and lens <sup>a</sup>	Glucose	Glucose

<sup>a</sup>Glucose-dependent tissues.**Fig. 2** The production of energy from glucose via the glycolytic pathway, the Krebs cycle, and the respiratory chain.

The net result of glucagon activity is an increase in blood glucose concentration, which helps to maintain blood glucose levels despite the effect of insulin.

3. Neuroendocrine counter regulatory responses to glucose deprivation in the brain with sympathoadrenal upregulation and release of cortisol, catecholamines, and growth hormone act to rapidly normalize blood glucose by increasing hepatic gluconeogenesis and glycogenolysis and curtailing peripheral tissue glucose uptake and utilization.

The fed state is characterized by increased blood concentrations of glucose, amino acids, and fat. Insulin secretion is stimulated while glucagon levels remain unchanged or are decreased resulting in increased glucose uptake into tissues and enhanced glycogen, protein, and triacylglycerol syntheses. Glucagon balances this effect by stimulating glycogen breakdown to maintain blood glucose levels. By this mechanism, blood glucose levels are regulated during periods of surplus carbohydrate ingestion and excess glucose is stored as glycogen or fat.

Glycogen is a complex, hydrated gel-like polymer of glucose arranged in a highly branched spherical form. It allows glucose to be stored in large amounts and a relatively small volume without causing osmotic shifts and acts as a rapidly available short-term energy buffer in the post absorptive and fasting state. The terminal glucose molecules within this branching structure are accessible to the enzymes mediating glycogen breakdown to allow the rapid release of glucose in times of stress. The glycogen molecule expands in size after a carbohydrate-rich meal to approximately 40 nm in diameter and shrinks to 10 nm in diameter or less between meals. An adult man receiving a normal carbohydrate-containing diet has approximately 70 g of liver glycogen and 200 g of muscle glycogen. The final enzymatic step required to complete glycogen breakdown to glucose, glucose-6-phosphatase, is present only in the liver. Muscle glycogen is metabolized by anaerobic glycolysis to form pyruvate and lactate. Lactate is then transported to the liver where it acts as a precursor for gluconeogenesis ("Cori cycle") (Fig. 3). The Cori cycle contributes to approximately 40% of the normal plasma glucose turnover. It has the advantage of providing energy (net 3 molecules of ATP) without the loss of glucose molecules. The energy required for the resynthesis of glucose in the liver is derived from fatty acid oxidation. The total body glycogen stores can meet the energy needs of the brain for approximately 3 days, after which, alternative sources of metabolic fuel must be found.

### Protein metabolism

Body nitrogen resides in two main compartments. Approximately half of the body's nitrogen is contained in extracellular tissues such as collagen. The nitrogen present within these tissues is relatively fixed and does not change significantly with starvation. The nitrogen turnover within this compartment can be assessed by the measurement of hydroxyproline excretion. The remaining nitrogen is present in the lean muscle mass, comprising skeletal and visceral muscles. The proteins within these tissues are constantly being broken down and resynthesized at a rate of between 3 and 3.5 g kg<sup>-1</sup> day<sup>-1</sup> in a young adult. Measurement of urinary 3-methylhistidine and creatinine excretion can be used to estimate the fractional catabolic rate of skeletal muscle. Similar to fatty acids and glucose, amino acids can be completely oxidized. However, the body's protein compartments—contrary to liver glycogen or adipose tissue—are not primarily energy stores. Although amino acids serve as important energy substrates in gluconeogenesis and Krebs cycle oxidation during times of inadequate energy intake, the loss of functional body protein is the life-limiting factor in prolonged fasting, with associated clinical sequelae.

In the fed state, amino acids digested and absorbed in excess of the body's immediate requirements for incorporation into proteins or other molecules are either oxidized for energy or metabolized to glycogen or fat. Protein provides approximately 17 kJ g<sup>-1</sup> (4 kcal g<sup>-1</sup>) of energy when metabolized as an energy source.

Prolonged fasting results in depletion of liver and muscle glycogen stores. In this clinical setting, the conversion of amino acids to glucose in liver and kidney contributes to the glucose requirements of the brain. The transition to metabolism of amino acids as

**Fig. 3** The metabolism of muscle glycogen and protein to form glucose, involving the Cori cycle (lactic acid cycle) and the Cahill cycle (glucose-alanine cycle).

an energy source is mediated by an alteration in the balance of insulin and glucagon. The breakdown of tissue protein to provide glucose results in a sustained loss of body nitrogen of approximately  $12 \text{ g day}^{-1}$ . Experimentally, this loss of body nitrogen can be prevented by the administration of glucose. As a result of muscle protein breakdown, amino acids—predominantly alanine and glutamine—are released into the circulation. However, the amount of alanine released exceeds the alanine content of the muscle protein. This is because approximately one-third of the alanine released from muscle originates directly from the muscle protein, whereas the remaining two-thirds is derived from pyruvate. Pyruvate is formed by the metabolism of muscle glycogen or by the transamination of other amino acids contained within the muscle protein. Alanine is then transported to the liver where it is rapidly taken up and converted to glucose: this is known as the Cahill or glucose–alanine cycle (Fig. 3). Despite the increased release of alanine from muscle, plasma alanine levels fall in early fasting. This results from the rapid uptake and conversion of alanine by the liver to glucose. Similar to the glucose–alanine cycle between muscle and liver, there is a steady exchange of glutamine and glucose between muscle and kidney: glutamine released from muscle tissue acts as one of the main renal gluconeogenic precursors besides lactate in prolonged fasting.

Two major metabolic pathways accomplish regulated protein catabolism in prolonged fasting: the ubiquitin–proteasome system (UPS) and the autophagy–lysosomal system. The calcium-dependent calpain–calpastatin system and the caspase–proteolytic system is less well described but likely also play a role. The UPS acts through a cascade of enzymes that conjugate polyubiquitin chains with the target protein that are thereby marked for further degradation by the so-called “proteasome.” The ubiquitinated proteins are bound by two 19S-regulatory proteins, unfolded and transported to the proteolytic centers of the 20S proteasomal core. The UPS serves as the primary route for degradation of short-lived proteins with high selectivity, allowing fine-tuning of the steady state of many regulatory and rate-limiting enzymes and degrading defective proteins. UPS-mediated catabolism is an important adaptation mechanism during acute starvation to maintain intracellular amino acid pools as a substrate source for gluconeogenesis. The enzyme complex is activated by a number of metabolic changes seen in fasting and starvation such as the decrease in insulin and other anabolic hormones, an increased concentration of intracellular reactive oxygen species, a decrease in intracellular amino acid concentration, and a reduction in AMP/ATP ratio.

Autophagy describes a catabolic process in which cell constituents (organelles, proteins) are engulfed by a phagophore and delivered to the lysosomal compartment for further degradation. It is primarily responsible for the degradation of long-lived proteins and those too large for other surveillance pathways and proceeds at a basal rate in nearly all eukaryotic cells in a “housekeeping role”. Autophagy also plays a significant role in response to conditions of chronic nutrient starvation by inactivation of mTOR in response to metabolic changes (e.g., increased energetic or oxidative intracellular stress or a decrease in intracytoplasmic amino acids) leading to generation of amino acids able to be recycled for essential cellular functions. The UPS and autophagy systems are closely interrelated, share activating trigger factors and intracellular signaling pathways, as well as protein substrates, and can compensate for the compromise of the other system.

### **Fat metabolism**

Fat is an efficient store of energy providing approximately  $38 \text{ kJ g}^{-1}$  ( $9 \text{ kcal g}^{-1}$ ). Fat is predominantly stored as triacylglycerols within adipocytes. Contrary to carbohydrate metabolism with blood glucose concentrations being tightly regulated, the concentrations of triacylglycerols and nonesterified fatty acids are much more variable between individuals related to variation in fat stores and gender. In the fed state, insulin stimulates triacylglycerol synthesis by allowing acyl-CoA from excess carbohydrates, protein, or fat being stored as adipose tissue. During fasting, triacylglycerol is converted to fatty acids and glycerol (Fig. 4). Within days, glycerol and palmitate release increases by two to three times fed levels, regulated by hormone-sensitive lipase. Owing to the absence of glycerol kinase in white adipose tissue, glycerol cannot be completely metabolized within the adipocytes and is transported to the liver where it is converted into glucose by gluconeogenesis. Fatty acids released from adipocytes are either delivered to the liver to be oxidized or re-esterified with glycerol-3-phosphate to re-enter the cycle to form triacylglycerol (Fig. 4). The energy cost of re-esterification of fatty acids in starvation may account for 2–3% of the resting energy expenditure.

Fatty acid oxidation is stimulated by activation of carnitine/acyl carnitine translocase acyltransferase, which influences the transport of long-chain fatty acids into the mitochondria. Most of the acetyl-CoA produced from fatty acid oxidation is metabolized to acetoacetate, which, in turn, may be converted to  $\beta$ -hydroxybutyrate and acetone. These products are known as “ketone bodies” and are water-soluble intermediates. In the fed state, ketone bodies are only produced in small quantities, are generally metabolized by the liver, and are not released into the circulation. During fasting, the rate of production of acetoacetate and  $\beta$ -hydroxybutyrate significantly increases to allow them to be used by the brain and other tissues as an alternative energy source.

## **Metabolic consequences of fasting and starvation**

### **Overview**

The transition from the post absorptive state and the early phases of adaptation to the steady state of adapted starvation can take up to 3 weeks (Table 2).

The length of survival (Fig. 5) will finally be determined by the total endogenous caloric reserve (calories per kilogram of bodyweight) that is the magnitude of preexisting stores of fat and protein, as well as the rate at which the endogenous substrates are utilized in the fasting state defined by the total energy expenditure (calories per kilogram of bodyweight per day). Owing to a different body composition with a much higher percentage of total body water and smaller subcutaneous fat stores, the neonatal

**Fig. 4** The triacylglycerol/fatty acid cycle.

**Table 2** Time course of the adaptive metabolic response to starvation.

<i>Metabolic adaptation</i>	<i>Duration</i>	<i>Pathway</i>	<i>Effect</i>
Post absorptive state	12 h	Glycogenolysis	Carbohydrate mobilization
Early starvation	2–3 days	Gluconeogenesis	Glycogenic AA mobilization
Intermediate phase	2–3 weeks	Ketogenesis/fatty acid oxidation	Transcriptional transition to fatty acid metabolism
Adapted starvation	>3 weeks	Ketogenesis/fatty acid oxidation	Steady fat store depletion economized proteolysis

overall caloric reserve is significantly lower compared with that of the adult. The neonate is further disadvantaged in its ability to tolerate starvation by its higher energy expenditure that is negatively related to the gestational age. Thermal stress, as a consequence of a 2.5–3 times higher surface area to bodyweight ratio in comparison to an adult, and the limited insulating capacity from subcutaneous fat are important determinants of increased neonatal energy expenditure and thus susceptibility to starvation.

### Metabolic adaptation in the post absorptive state

The post absorptive state commences when the last nutrient is absorbed from the previous meal and continues until the next meal or for approximately 12 h during a normal overnight fast. Decrease in the insulin/glycogen ratio prompts metabolic transition from exogenous energy consumption to reliance on endogenous energy sources/breakdown of liver glycogen. It is, therefore, called the glycogenolytic phase of starvation. The hepatic release of approximately 200–250 g of glucose per day or  $8\text{--}10\text{ g h}^{-1}$  balances the rate of glucose utilization of the brain and other tissues. A minor part of glucose formation derives from non-carbohydrate sources including glycerol (from triacylglycerols) and pyruvate and lactate (from muscle).

### Metabolic adaptation in prolonged fasting

Fasting beyond 12 h will lead to the gluconeogenic phase of starvation represented by the transition from glycogen to metabolism of glucogenic amino acids as the main source of energy. This is mediated by a further decrease in the insulin/glucagon ratio. As a result, blood levels of the branched-chain amino acids, alanine, and glutamine double after 3–5 days of fasting. The glucose–alanine cycle provides glucose to the muscle in exchange for alanine provided to the liver as a precursor for gluconeogenesis (see Fig. 3). The intestine preferentially takes up glutamine released from the muscle during fasting where it is used as an energy source, and by the kidney where it is also used for renal ammonia production. Although the metabolism of amino acids to glucose is a very important step of metabolic adaptation to fasting, it only provides approximately 45 g glucose per day. This amount alone

**Fig. 5** Duration of survival in different age groups expected in starvation (solid line) and semi starvation (dashed line). Reproduced from Heird et al. (1972).

is insufficient to meet the glucose requirements of the brain and must be supplemented by energy produced from fat metabolism. Gluconeogenesis occurs at the expense of the functional protein compartment and provides energy substrates until the lipolytic and ketogenic machinery has fully adapted. Increased efficiency of the adaptive metabolic switch to fat and ketone body utilization is reflected by a fall in plasma amino acids if fasting is prolonged.

### Metabolic adaptation in starvation

During periods of prolonged inadequate nutrient intake, the human body needs to mobilize preexisting stores of nutrients for continued functioning. This is done through down-regulation of anabolic energy consuming processes (fatty acid/triglyceride synthesis, glycogenesis) and activation of catabolic reactions (glycolysis, fatty acid oxidation, and proteolysis). The process of metabolic adaptation to starvation involves three main principles:

1. Replacement of glucose by fat as the main source of energy.
2. Promotion of ketone bodies as a fuel alternative in glycolytic tissues.
3. Maintenance of minimum of glucose supply by gluconeogenesis from glucogenic amino acids and glycerol, and by the shut-down of irreversible glucose oxidation in the citric acid cycle.

The mobilization of triacylglycerol stores to provide energy during starvation is regulated by a number of factors as outlined in the section below. Non-esterified fatty acids are released into the circulation and free fatty acid concentrations increase from 0.5–0.8 to 1.2–1.6 mmol L<sup>-1</sup> within the first few days of fasting. Fatty acids circulate bound to albumin and can be oxidized in the liver or other tissues to produce energy. The switch to using ketone bodies as an energy source by the brain appears to be primarily controlled by the blood concentration of ketone bodies rather than a hormonal effect. Ketone body production by the liver peaks after 3–4 days of fasting. However, blood ketone body levels continue to rise rapidly for the first 7–10 days before stabilizing at approximately 6–8 mM at 2–3 weeks. The continued rise in blood ketone body levels despite achieving maximal liver production early in fasting is due to decreased renal excretion of ketone bodies and increasing muscle fatty acid oxidation (Fig. 6).

As fatty acid oxidation and ketone body formation increase, there is a reduction in glucose production and oxidation mediated by downregulation of the pyruvate dehydrogenase complex activity. After a 3-week fast, a marked reduction in glucose metabolism throughout the brain is observed using positron emission tomography. Glucose uptake of the brain is more than halved after a fast of 5 weeks.

After a period of fasting longer than 3 weeks, the process of metabolic adaptation to starvation is complete. Gluconeogenesis and glycolysis have been minimized paralleled by increase in hepatic ketone body production. The kidney becomes the major gluconeogenic organ and produces half of the body's glucose requirements. Glutamine is the predominant substrate for kidney gluconeogenesis, and the nitrogen product of this process provides the ammonia needed to buffer ketoacids in the urine. This saves energy compared to the energy-intensive ammonia disposal through the hepatic urea cycle. As a result, urinary nitrogen losses decrease to 4–6 g day<sup>-1</sup>. Two-thirds of brain fuel consumption consists of ketone bodies, thereby markedly diminishing the need for muscle proteolysis to provide gluconeogenic precursors. With prolonged fasting, muscles change from ketone body production to fatty acid oxidation.

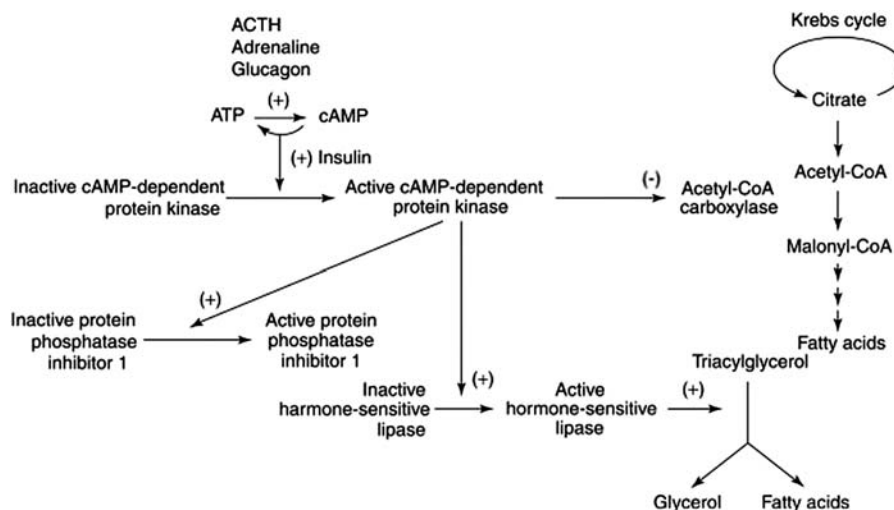

At completion of adaption, there is slow and ongoing depletion of the protein compartment and breakdown of the adipose tissue. Death will occur when there is a failure to replenish fuel stores through refeeding and insufficient available energy to maintain essential bodily functions. As fat is the predominant source of energy, the time until death in uncomplicated fasting will depend on the size of the prefasting fat stores. In a normal adult, fat stores will be sufficient to sustain life for approximately 60–70 days. The extent of protein loss is also linked to survival, and a loss of more than half of the lean body mass compartment (approximately half of total body protein) is predictive of death.

### Regulation of adaptation in starvation

Metabolic regulation in starvation involves a complex interplay of nutrient sensing mechanisms and neural/endocrine adaptive processes on a tissue and cellular level, leading to structural, biochemical, and functional modifications.

#### Neural and endocrine regulation

The hypothalamus, in particular the arcuate nucleus (ARC), is acknowledged as a major center for integrating nutritionally relevant information from peripheral organs into an energy code setting the level of whole-body energy expenditure. Reduction in resting energy expenditure during fasting cannot be solely explained by decrease in lean body mass, and coordination of hormonal changes on the hypothalamic level plays an additional important role. Catecholamine secretion and turnover are decreased in uncomplicated starvation (Table 3). This is clinically recognized as a reduction of core temperature, heart rate, and blood pressure during starvation.

**Fig. 6** Lipolysis is stimulated by the action of glucagon, ACTH, and adrenaline. This effect is mediated by cyclic AMP-dependent protein kinase.

**Table 3** Effects of the major hormones in the steady (fed) state, during fasting and starvation.

Hormonal change and metabolic consequences		Steady (fed) state Exogenous energy consumption	Fasting state Transition to endogenous energy sources	Starvation Metabolic adaptation: use of alternative endogenous energy sources; reduction in energy utilization and expenditure
Hormone	Insulin	↑	↓	↓
	Glucagon	↓ Or unchanged	↑	↑
	Cortisol	Normal diurnal variation	↑	↑
	Growth hormone	Normal diurnal variation	↑	↑†
	Epinephrine	Normal variation in response to stressors	↑	↑/↓
	Thyroid hormones	Normal range	↓	↓
Metabolic consequences	Increased glucose uptake		Reduced peripheral glucose uptake/usage	Reduced peripheral glucose uptake/usage
	Glycogenesis*		Glycogenolysis* gluconeogenesis	Gluconeogenesis*#
	Lipogenesis		Ketogenesis	Ketogenesis*
	Protein synthesis		Lipolysis	Lipolysis
			Proteolysis	Proteolysis
				Glycogenolysis

†Loss of IGF-1 mediated anabolic effect.

\*Predominant metabolic process.

#During early starvation.

During late starvation.

Thyroid hormones are known as potent hypothalamic regulators of whole-body energy homeostasis. Fasting results in marked suppression of diencephalic thyroid-stimulating hormone (TSH) secretion as a consequence of a fall in leptin (an adipocyte-derived hormone, which induces biosynthesis and release of hypothalamic TRH under non-fasting conditions through an increased hypothalamic type 2 de-iodinase-dependent triiodothyronine ( $T_3$ ) production). Decreased activity of 5'-monodeiodinase in the liver and peripheral tissues resulting in a reduction in the conversion of thyroxine ( $T_4$ ) to the metabolically active form  $T_3$ , has been observed within hours to days in patients on a starvation diet. However, the mechanism linking low-circulating  $T_3$  levels to decreased resting energy expenditure in starvation is not well understood yet.

Glucagon plays a crucial role in the early phase of adaptation to starvation (Table 2) and stimulates hepatic glucose output by increasing hepatic glycogenolysis and gluconeogenesis through its canonical cAMP/PKA pathway, facilitating phosphorylation and allosteric change of key metabolic enzymes and nuclear factors (e.g., CREB, cAMP response element-binding protein).

In prolonged starvation, cortisol increases hormone-sensitive lipase synthesis. Insulin levels fall by 35% within 24 h of fasting. This is associated with a 50–80% increase in the rate of lipolysis. Low-circulating insulin levels cause a reduction in the uptake of glucose into adipocytes by altering the function of the GLUT4 glucose transporter (Fig. 4). Adequate amounts of glycerol-3-phosphate are therefore unavailable for the re-esterification of fatty acids produced from triacylglycerol breakdown.

### Nutrient sensing mechanisms

The coupling of the body's metabolic environment to the energy status of the cell is crucial for its adaptive response to starvation. Cells have sensors detecting limitation of nutrient availability during starvation, initiating homeostatic mechanisms in order to tailor their metabolic needs to nutrient fluctuations and aiming to restrict overall energy expenditure. The AMP-activated protein kinase (AMPK) and the evolutionary-conserved  $NAD^+$ -dependent histone deacetylase SIRT1 axis integrates multiple hormonal and nutritional signals (e.g., glucagon, leptin, adiponectin, glycogen, and free fatty acids) to regulate cellular and whole body energy homeostasis during starvation (Table 4).

AMPK is a heterotrimeric complex composed of a catalytic  $\alpha$ -subunit and two regulatory ( $\beta$  and  $\gamma$ ) subunits with multiple isomers. Different subunit compositions (AMPK complexes) may have specific roles and respond to different types of stress stimuli. AMPK is activated under conditions of low-energy charge by the binding of AMP (and less so, ADP) to the  $\gamma$ -subunit leading to: (1) possible stimulation of Thr172 phosphorylation (on the  $\alpha$ -subunit) by an upstream kinase (LKB1); (2) inhibition of dephosphorylation of Thr172 by protecting it from phosphatases; and (3) allosteric activation of AMPK already phosphorylated on Thr172. Thr172 may also be directly phosphorylated by increased intracellular calcium through the calcium-sensitive kinase CAMKK2. Recent studies identified AMPK is localized in distinct compartmentalized pools with different targets and in lysosomes, is activated by an AMP-independent mechanism in response to low glucose levels, when aldolase binding fructose-1,6-biphosphate regulates AMPK-axin binding, resulting in co-regulation of AMPK and mTOR. Activated AMPK has essential roles in mitochondrial regulation, directing metabolism toward increased catabolism (increased energy production) and decreased anabolism (reduced energy usage) (Table 4).

mTOR, mammalian target of rapamycin; FOXO, forkhead box protein O; SREBP1, sterol regulatory element-binding protein 1; ChREBP, carbohydrate-responsive element-binding protein; HNF4 $\alpha$ , hepatocyte nuclear factor 4 $\alpha$ ; STAT, signal transducer and activator of transcription; PFKFB3, 6-phosphofructo-2-kinase/fructose-2, 6-biphosphatase 3.

SIRT1 is induced and activated by intracellular NAD<sup>+</sup> levels (nicotinamide adenine dinucleotide) that increase similar to AMP with fasting and nutrient restriction leading to restitution of intracellular energy balance by switching off energy-intensive biosynthetic pathways (such as protein synthesis, glycogen synthesis, fatty acid, and sterol synthesis) and favoring ATP production (through, e.g., lipolysis, fatty acid oxidation, and mitochondrial biogenesis). Further, deacetylation of lysine residues helps SIRT1 to increase the degree of chromatin compaction, leading to direct repression of transcriptional activity. On a structural level, this translates into the observed muscular plasticity during starvation, with a switch from fast-twitching glycolytic type II fibers to slow-twitching oxidative type I fibers.

The Forkhead box O (FOXO) transcription factor family has received considerable attention as elemental regulators of metabolism. FOXOs play a crucial role in transcriptional upregulation of key enzymes of hepatic gluconeogenesis in early starvation (G6Pase, PEPCCK), blockage of adipocyte differentiation, decrease in protein synthesis, and increase in protein degradation (through UPS and autophagy; see above). Its activity and cellular localization are controlled and increased by its acetylation (through SIRT1) and phosphorylation (through AMPK) states.

The peroxisome proliferator-activated receptors (PPARs) are another family of important ligand-activated transcription factors. PPAR $\alpha$ , for example, acts as an intracellular fatty acid sensor which is one of the master regulators of cellular fatty acid oxidation and regulates ketogenesis. The estrogen receptor-related receptor (ERR) family ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) represents a further important downstream target of AMPK. Activation is associated with increased expression of fatty acid oxidation genes and enzymes of the oxidative phosphorylation cascade (OXPHOS). It also enhances pyruvate dehydrogenase kinase 4 (PDK4), the crucial enzyme involved in the starvation-induced shutdown of the pyruvate dehydrogenase complex. Although these nuclear transcription factors confer a first level of specificity to transcriptional adaptive processes during times of energy deficit, coregulators are required for the transcriptional machinery to become fully activated, significantly increasing the diversity of interacting partners and thus the complexity of this regulatory process. The PPAR $\gamma$  coactivator-1 $\alpha$  (PGC-1 $\alpha$ ) is generally accepted as the central node in starvation-induced transcriptional coactivation and is involved in the regulation of large clusters of genes controlling oxidative phosphorylation and fatty acid metabolism. It drives, for example, the switch from glycolytic to oxidative muscle fibers. It exerts its effect in conjunction with the transcription factors FOXO, PPAR, and ERR. PGC-1 $\alpha$  is controlled by the AMPK-SIRT1 axis and activated—similar to FOXO—by deacetylation and phosphorylation.

Fibroblast growth factor 21 (FGF21) is a fasting induced hormone produced primarily in the liver as well as other tissues including skeletal muscle. It is thought to contribute to the late stages of adaptive starvation by regulating fuel derived from tissue breakdown although data is conflicting and mostly generated from mice, with its exact role in humans to be defined.

## Conclusion

Metabolic adaptation is a complex and coordinated process which stimulates ongoing provision of energy in situations of adverse energy supply such as prolonged fasting and starvation. It includes a highly evolved and integrated network of energy sensing

mechanisms, neural and endocrine regulatory factors and modifications to human energy utilization pathways within the body to preserve the function of critical organs.

## Glossary

**Aphasia** Acquired language disorder; may include difficulty in producing or comprehending spoken or written language. Originally aphasia referred to total inability to communicate, dysphasia to partial impairment; over time, aphasia has come to mean either both partial and total language impairment in common use.

**Apraxia** Loss of the ability to execute or carry out learned purposeful movements, despite the desire and physical ability to do so. It is a disorder of motor planning, not caused by inco-ordination, sensory loss, or failure to comprehend. The activity may be performed as a conditioned response (e.g., if handed a cup, the patient may take it and drink, although may not be able to do this to command).

**Dysphagia** Difficulty in swallowing, can be neurological, structural, or functional in origin. This article refers only to neurological dysphagia. Although classified under 'signs and symptoms' of the ICD-10 classification, it is often discussed as a disease-state *per se*.

**Naso-Gastric Tube** A means to deliver liquid feed directly into the stomach for people who are unable or unsafe to take food orally. A fine-bore, usually silicone or polyurethane feeding tube with a guidewire to aid placement through the nose, the esophagus, and into the stomach. After checking its position, the guidewire is removed. The tube may be retained in place using adhesive tape applied to the nose, a clip attached to the tube may be secured to the face, or a nasal bridle may be used: a device that secures the tube in place by tapes that hold the tube in the nasopharynx and exit through both nostrils. Most often used for short-term feeding, but may be used longer-term.

**Percutaneous Endoscopic Gastrostomy (PEG)** A means to deliver liquid feed directly into the stomach for people who are unable or unsafe to take food orally. A feeding tube placed into the stomach through the abdominal wall, usually using a combination of local anesthetic infiltration into the abdominal wall and intravenous sedation. During the procedure an endoscope is passed through the mouth to help locate the trans-abdominal puncture and placement of the feeding tube. Once the tract is established, most PEG tubes need only their retaining devices (flanges or balloons that are part of the tubing) to maintain position. May be retained in place for long periods.

## Introduction

Stroke is a common and devastating event, the incidence rising with age. Approximately 125 000 and 500 000 new or recurrent strokes affect individuals each year in the UK and the US, respectively, creating a significant burden of long-term disability in survivors. Stroke is a syndrome that is sudden in onset, featuring signs of cerebral dysfunction that are vascular in origin. In first strokes, thrombo-embolic infarction is the underlying pathophysiological event in approximately 80% of cases, with 10% attributed to primary intracerebral hemorrhage and 10% to other/uncertain types. Resulting neurological and functional impairments vary in range, combination, and severity. These can include altered consciousness, motor and somato-sensory, auditory, visual, smell and taste disturbance, and loss. Impairments of memory, speech, language, continence, and higher-order cognitive functioning such as planning and decision-making also occur. Overall, the impairments and disabilities that result from stroke can exert a variable, negative impact on eating, mobility, mood, ability to selfmanage and selfcare, social role-function, and quality of life.

The challenge of nutritional management is apparent in the scope and complexity of issues presented. These include the physical, psychological, and social impact of stroke on appetite and eating, as well as prestroke nutritional status. Potential effects of metabolic injury responses, immobilization, and infective complications on energy, nitrogen, and micronutrient requirements must be considered. In individuals in whom oral feeding cannot be established, parenteral hydration and artificial nutritional support may be necessary, by the enteral route if possible, utilizing nasogastric tubes (NGT) or percutaneous endoscopic gastrostomy (PEG).

Effective nutritional management of stroke requires the integrated skills and knowledge of a multidisciplinary team. Complex situations entailing ethical and legal issues relating to hydration and nutritional support can arise, and involvement of patient and carers in all aspects of planning is vital.

## Risks of Protein-Energy Malnutrition

The reported frequency of malnutrition after acute stroke has ranged from 6% to 62%, measured via multiple assessment methods, some of which have been previously validated (e.g., Subjective Global Assessment and Mini Nutritional Assessment). This is important because the presence of under-nutrition shortly after admission has been independently associated with significantly greater mortality and likelihood of developing pneumonia, infections, pressure sores and gastrointestinal bleeds in hospital, with increased risk of death or dependency poststroke.

A number of factors may interact to impair the nutritional status of stroke patients. These include factors that led to deterioration in prestroke nutritional status, direct physical and psychosocial effects of stroke on the consumption of food and fluids following hospital admission, and organizational factors that can hinder efficient, effective meal delivery and consumption in institutional and residential settings.

## Prestroke Nutritional Status

Risk factors for malnutrition identified at the time of hospital admission have included increasing age, living alone, dementia, and inadequate dental status. Findings are consistent with those from surveys of elderly populations, where a wide range of personal characteristics and social and environmental features have been linked with poorer appetite and nutritional status (see related articles) The presence of malnutrition in older adults may be associated with impaired immune responses, increasing vulnerability to pneumonia and sepsis. The significance of a low serum albumin concentration in predicting clinical outcomes has been noted in stroke and older populations, where it may be more a reflection of disease severity than an indicator of nutritional status.

## Poststroke Eating Problems

Neurological and functional impairments can result in eating problems following stroke, which can lead to an increased risk of protein-energy malnutrition. During the acute phase of recovery, eating disability has been associated with inadequate consumption of food and fluids and deterioration in body mass index, triceps skin fold thickness, mid-arm muscle circumference, and serum protein concentrations. Four months poststroke weight loss >3 kg (mean 6.6 kg) was found in 24% patients, and in 26% (mean loss 8.3 kg) at 1 year. Eating difficulties and low prealbumin values were associated with weight loss at both time points; at six months poststroke 66% of survivors were found with some degree of enduring disablement that affected eating. Specific eating problems include impaired lip closure leading to oral leakage of food and fluids, dysphagia, inability to manipulate utensils linked to loss of motor skills in eating, and difficulties in maintaining an upright posture at mealtimes. Visual field or perceptual deficits can result in inability to see or perceive the contents of a meal tray, whereas aphasia and dysarthria can hinder or prevent expression of dietary needs and preferences. Loss of concentration, short-term memory and cognitive impairments such as apraxias are common sequelae to stroke and can make it difficult for individuals to sustain the sequence of activities necessary to complete a meal, or even to remember to eat and drink (Table 1). Taste and smell dysfunctions have been reported but impact on eating has not been investigated. A number of assessment instruments have been developed to enable health professionals to identify the extent of eating disability and the nature of support needed.

**Table 1** Eating disabilities of a cohort of acute stroke admissions to a South London hospital, March 1998–December 1999

<i>Eating disabilities<sup>a</sup> at hospital</i>	<i>3–5 days after admission to</i>	<i>Number (%)</i>
Posture control	No functional impairment	325 (56)
	Mild–moderate impairment	219 (37)
	Severe impairment	43 (7)
Arm movement	No functional impairment	159 (27)
	Mild–moderate impairment	295 (50)
	Severe	133 (23)
Lip closure	No functional impairment	449 (76)
	Partial impairment	109 (19)
	Severe impairment	29 (5)
Chewing	No functional impairment	369 (63)
	Partial impairment	172 (29)
	Severe impairment	46 (8)
Swallowing	No functional impairment	341 (58)
	Partial: Cannot tolerate 1 of 3 textures	66 (11)
	Severe: Cannot tolerate 2 of 3 textures	64 (11)
	Aspiration/high risk; nil orally	116 (20)
Communication	No functional impairment	276 (47)
	Partial impairment	149 (25)
	Severe impairment	162 (28)
Attention and praxis	No functional impairment	417 (71)
	Partial impairment	130 (22)
	Severe impairment	39 (7)
Visual field/ perceptual loss/ neglect	No functional impairment	428 (73)
	Partial impairment	132 (23)
	Severe impairment	25 (4)

<sup>a</sup>Total 670 stroke patients, of whom 587 (586 for attention and praxis; 585 for visual fields) were able to be assessed.

### Organizational Factors

Organizational factors can hinder dietary provision and consumption in institutional settings. These include an inadequate meal-time environment, marked by poor lighting, noise, distractions (e.g., television, consultant ward rounds), unpleasant smells, temperature extremes, and lack of facilities or facilities that deter social eating. Lack of adequate assistance for dietary selection, meal delivery, and supervision may result in a meal that is inappropriate in relation to texture, portion size, patient preference and swallowing ability, or, with around half needing help to eat in the early stages poststroke, which the patient is unable to eat without help, which may not be available.

## Management of Stroke-related Psychosocial and Physical Problems Impairing Food Consumption

### Evidence-based Guideline Recommendations

The provision of effective nutritional care requires a concerted approach by health professionals in developing locally tailored evidence-based standards and guidelines for nutritional screening, assessment, and dietary support. These should be linked to national standards and guidelines (where they exist), clinical audit and processes for practice development. Recognition of the need for such guidance has led to the development and dissemination of evidence-based guidelines by interprofessional expert groups, designed to inform professional judgment and bench-mark care within wider stroke management. Implementation of guidelines can best be achieved by multifaceted strategies, for example, combining education of health professionals with leadership and sensitive change management approaches.

Following acute stroke, guideline recommendations emphasize the need for screening and assessment for nutritional risk to be undertaken on admission to hospital and repeated at regular intervals (e.g., weekly for hospital inpatients) using a valid, reliable instrument by appropriately trained personnel. Individuals who are malnourished at the point of admission, or likely to become so, can then be referred to dietitians for further assessment and prompt initiation of nutritional support. Early identification of

individuals whose swallow function may be unsafe with oral food and fluids is vital, as well as referral for specialist swallow assessment, usually by a speech pathologist. Screening of swallowing function should be undertaken using a validated and reliable method by appropriately trained personnel, initially as soon as the patient is able to be assessed poststroke or on admission to hospital, before patients are given food or drink. Following detailed assessment, modification of dietary textures may be advised to ensure safe eating in those with some degree of swallowing impairment. In others, artificial nutritional support using enteral routes may be necessary, owing to the severity of dysphagia or cognitive impairments. In individuals who are capable of taking food orally, the provision of support for physical, functional, and psychosocial problems is an essential aspect of nutritional management. To achieve this, appropriate specialist assessment should be requested, e.g., occupational therapy, physiotherapy, and psychology.

### **Psychosocial Problems**

In the acute phase following stroke, approximately 30% of patients develop clinical signs of depression, 30% are anxious, and a similar proportion report loss of confidence as a major psychological problem. However, mood dysfunction may occur at any time, from immediately after stroke onset to many months later. Depression may result from an interaction of factors, including a direct result of the stroke lesion. Despite extensive investigation, there is no robust evidence that depressed mood after stroke is caused by a lesion in any particular area or side of the brain. Depression is more common amongst people with chronic disease than matched otherwise healthy groups, and associated with reactions to physical loss, altered lives and sense of identity. Comparatively little is known of interactions between depression, anorexia, and nutritional status in the early stages of recovery following stroke in individuals with and without physical eating problems. However, at 6 months patterns of behavioral disturbance characterized by depressed mood, anorexia, and insomnia have been identified and associated with weight loss. Anxiety-evoking experiences relating to being fed, or choking in the presence of dysphagia, may also result in avoidance or withdrawal from eating. General approaches to the treatment of poststroke depression are not different to the nonstroke population, and include antidepressant drugs, and behavioral and psychotherapeutic techniques. Use of therapeutic skills in communication, eating assistance, and provision of emotional support are vital in alleviating mealtime anxiety and increasing interest in food.

The enjoyment of eating as a social activity can be affected adversely by impairments of speech, lip closure, chewing and swallowing, and manual dexterity. Severely disabled individuals who are relearning eating and swallowing skills initially require privacy and a quiet environment. As rehabilitation progresses, social integration at mealtimes can be achieved.

### **Communication Problems**

Whilst dysphasia refers to difficulty, and aphasia to inability to communicate verbally, aphasia is often used as a relative term. It affects 20–38% of acute stroke patients with possibly as many as 40% affected by dysarthria (speech difficulties due to oromotor dysfunction), resulting in variable difficulty or inability to express thoughts in language (expressive aphasia) or to comprehend language (receptive aphasia). Expressive aphasia, also known as Broca's aphasia, results from strokes affecting the prefrontal gyrus, whereas Wernicke's receptive aphasia results from lesions of the central sulcus. Dysarthria results from neurological damage affecting neuromuscular systems that control speech production; because these systems are also concerned with swallowing, dysarthria often coexists with difficulty swallowing (dysphagia).

Communication problems can result in inability/difficulties in expressing hunger, thirst, meal preferences (aphasia), reading a menu, or writing preferences (aphasia can occur alongside dyslexia and dysgraphia). Receptive aphasia can impair comprehension of instructions at mealtimes and thus affects response to information and rehabilitative advice. If paralysis and visual field and perceptual deficits are combined with expressive communication deficits, nonverbal communication can also be limited, affecting ability to signal assent or dissent by nodding the head or to use gestures or point to food items/utensils. Early involvement of speech pathologists is vital to enable individuals to regain lost functions in speech and language. In selected patients, visual material, e.g., pictures and symbols, can be helpful. Use of short sentences with single topics, simple terms, no jargon, normal volume speech, a clear light with a good view of the speaker's face and appropriate gestures, and patience in allowing individuals time to respond are helpful in general communication.

### **Impairments of Arm Movement and Posture**

Stroke can affect any of the neural mechanisms controlling voluntary movement and posture. These include the motor and sensory cortex and associated pathways, cerebellum, basal ganglia, and brain stem. The impact on eating skills can be considerable, because weakness or paralysis affecting the arm occurs in 80% of strokes. Loss of coordination, spatial awareness, abnormal muscle tone, and sensory loss may also occur. Common problems resulting from this are difficulties manipulating cutlery, lifting/loading food onto utensils, cutting food, inserting food in the mouth, drinking from a cup, or discerning the spatial relationships between objects.

If one arm is unaffected, then some degree of compensation is possible, particularly if this is dominant (unless this has been intentionally immobilized: Constraint Induced Therapy). Use of the unaffected hand is important in detecting temperatures of food and liquids where sensation is impaired. An occupational therapy assessment is necessary to identify specific deficits,

rehabilitation techniques, and appropriate aids to eating. Lightweight plastic cups and cutlery with molded or built-up handles, plate-guards and nonslip mats can be provided. Where upper limb impairment is severe, individuals may require assistance or to be fed.

Postural impairment following stroke can result in inability to maintain an upright sitting position, required for safe and effective food preparation, eating and swallowing. A physiotherapy assessment can identify the most effective techniques for rehabilitation of muscle weakness and to counteract abnormal muscle tone (spasticity). Appropriate aids to seated balance can include molded seating and supports.

### Visual Field Loss and Visual Neglect

Between 30% and 60% of individuals who sustain an acute stroke suffer from visual field loss due to partial or complete hemianopia. Neurological damage affecting the parietal or temporal lobes and involving the sensory pathway between the optic chiasma and visual cortex underlies this problem. The impact of loss in up to half the visual field is that food items on a meal tray may not be seen and therefore may remain uneaten. Compensatory interventions include instruction in scanning the visual field, or placing items within it for those who are unable to do this. Consistent placement of items on a meal tray and verbal identification of contents using a clock system is also helpful.

Neurological damage affecting the visual cortex of the occipital lobe, often following right hemisphere strokes, can result in neglect of half the visual space. A classic feature is failure to eat food on the left side of a plate. Affected individuals need reminding to focus on food items in the neglected space; placing a colored marker on one side of the plate can be helpful. This problem may occur in conjunction with visual field loss.

### Attention Span, Short-Term Memory

Impairment of attention span and short-term memory of a few minutes duration are common following acute stroke. Attention deficits result in an inability either to focus on immediate events or to establish a new focus unless a current stimulus is removed. As a consequence, an activity that requires a sequence of steps, such as eating a meal with two or three courses, may not be completed unaided. Lack of concentration also deters relearning eating patterns. Removing or minimizing distractions at mealtimes, simplifying the complexity of information necessary to regain eating skills, and providing verbal, written, or auditory alarms as reminders to eat are important in overcoming this problem.

## Swallowing Difficulties

### Screening and Assessment

Dysphagia affects approximately 45–60% of people with acute stroke. Variable in severity, it is characterized by sensory or motor loss affecting one or more of the stages of swallowing, i.e., oral preparation, oral transport, pharyngeal transport, and reflex swallowing (Table 2). The effects of stroke on esophageal peristalsis have been little examined. It has been estimated that approximately 50% of dysphagic patients either die or recover their swallow spontaneously within the first 2 weeks of stroke onset. For most of the others, at least some degree of functional swallowing can be restored with time. Approximately 10–20% will still be affected by 6 months; a small number never recover swallow function, although for some, recovery may take years. Swallowing impairment that prohibits eating normal texture food can exert a negative impact on functional recovery and quality of life.

Typical clinical features of dysphagia include delayed oral and pharyngeal transit times, retention of food in the cheek cavities, uncontrolled leakage of food/fluids out through the lips or onwards into the pharynx, causing choking and regurgitation of food/fluids through the nose and mouth. Tongue coordination may be poor, triggering of swallow and laryngeal cartilage elevation may be delayed or absent, gag may be abnormal. After swallow there may be a wet, 'gurgly' voice or coughing. Alternatively, the patient may aspirate silently, with no overt signs. Complications resulting from dysphagia can be life threatening, i.e., aspiration of food/fluid into the respiratory tract resulting in pulmonary infection, and dehydration. Longer hospital stay, strong inverse correlations with functional capacity, and an increased mortality have been associated with dysphagia. Early identification of the problem is vital, encompassing screening as soon as possible after admission, clinical bedside assessment (CBA), and, if necessary, instrumental assessment using, for example, videofluoroscopic swallowing studies (VSS) or fiberoptic endoscopic examination of swallowing (FEES).

Screening is a procedure intended to identify patients with potential swallowing problems, who can then be referred for more detailed assessment of phases of swallowing, together with judgment of extent of dysfunction and risk of aspiration. Systematic reviews have identified a number of screening methods of varying validity and reliability, which combine identification of clinical features of dysphagia with or without swallowing water. Prescreen assessment of conscious level, oromotor and laryngeal function, signs of existing respiratory aspiration and the extent to which the patient can safely cooperate with the examination are necessary. Aspiration of food or fluid into the respiratory tract may be accompanied by choking, indicated by voice changes (wet, hoarse, gurgling) or breathlessness, or it may be silent. Loss of swallowing and protective gag reflexes or the presence of features of dysphagia or aspiration when attempting to swallow water at an initial screen are indications that nil should be given by mouth. Detailed investigation is then necessary. During the acute phase of stroke the patient's condition may not be stable, and even if there

**Table 2** Stages of swallowing: effects of stroke

<i>Stage</i>	<i>Effects of stroke</i>
(1) Oral preparation Duration variable Lip closure forms anterior seal Chewing of food by mandibular and maxillary teeth Salivation evoked by parasympathetic nervous system Bolus formation controlled by tongue Sensory feedback from oral mucosa on volume & consistency determine timing of bolus ejection	Inadequate lip seal causes leakage of food/fluid chewing slower, food impacts in oral sulci Hyposecretion of saliva Paralysis of tongue impairs bolus formation Sensory loss leads to impaired bolus lateralization
(2) Oral transport Duration 1 s Bolus of 5–15 cm <sup>3</sup> separated, moved to tongue midline Oral cavity sealed, mandible raised, pressure exerted by tongue against palate propels bolus to posterior oral cavity	Slowed transport Bolus localization, separation and formation impaired; can lead to food retention in oral cavity Lack of fine motor coordination may lead to loss of liquid bolus control; risk of aspiration Abnormal positioning of bolus; diminished tongue elevation; inadequate bolus propulsion
(3) Pharyngeal transport/reflex swallowing Duration 0.5–0.6 s Bolus impacts on sensory receptors in tissues of soft palate, pharynx, tongue, fauces Swallowing reflex stimulated; elevation/closure of velopharyngeal mechanism, elevation of larynx, closure of vocal cords, pharyngeal peristalsis, relaxation of esophageal sphincter Respiration transiently ceases as bolus enters esophagus; breathing resumed; soft palate returned to resting position	Events may occur in abnormal sequence/timing Impaired sensation, delay/absent swallowing reflex Velopharyngeal closure impaired; food regurgitated through nose/mouth Incomplete laryngeal elevation/vocal cord adduction Swallowing reflex delay/absence leading to coughing, aspiration
(4) Esophageal transport Duration 8–20 s Peristalsis moves bolus to stomach	Effects of stroke little investigated Aging results in slight impairment of peristaltic amplitude

is no initial indication of problems, a high index of suspicion should be maintained and screening repeated if the patient's condition deteriorates.

There is no standardized format for clinical bedside assessment (CBA) but speech pathologists and other specially trained health professionals generally employ a combination of methods with demonstrated validity and reliability. These encompass the medical history relating to onset of swallowing problems; oral sensory and motor testing; laryngeal and pharyngeal assessment; presence/absence of swallowing, cough, and gag reflexes; cognitive and language function; alertness, attention span, and ability to follow instructions. Swallow function is usually assessed by observing the patient and feeling for swallow/laryngeal elevation with a graded sequence of foods and fluid consistencies. Adjunct assessments may be used, such as concurrent pulse oximetry to monitor oxygen saturation during swallowing, cervical auscultation to assess swallow function from swallow sounds, or assessment of muscle activity by cervical surface electromyography.

CBA provides limited detail of swallowing and functions poorly in relation to subtle signs of dysphagia and silent aspiration of food, fluids, or saliva into the respiratory tract: more invasive assessment may be required. VSS, using a modified barium swallow procedure, provides a detailed radiological assessment of the oral, pharyngeal, and upper esophageal phases of swallowing; can detect functional impairments resulting in aspiration, evaluate optimal head/neck positioning during swallowing, and determine the impact of food textures on the process. Limitations include its labor-intensive nature, exposure to radiation, problems transporting disabled stroke patients to radiology departments, variable protocol standardization with respect to volumes, consistencies, or textures of food and fluids and screening positions adopted. Further, views represent a snapshot of swallowing under ideal, rather than normal, circumstances, and variability in the reliability of reporting has been identified between and within raters of VSS outcomes. FEES entails passage of a flexible endoscope nasally, over the velum and into the pharynx. Its advantages lie in observation of bolus transit through the hypopharynx and identification of laryngeal penetration and aspiration; being portable it can be performed in a range of settings, overcoming the transport problems of VSS. However, it cannot investigate the oral stage of swallowing. The clinical utility of other methods are being explored, such as assessment of breathing patterns, to detect respiratory phases in relationship to swallows, and abnormal breathing patterns, such as swallow apnea followed by inspiration rather than expiration; impedance pharyngography, based on changes in the electrical impedance of the neck during swallowing.

**Table 3** Standardized classifications of texture modified foods and fluids

Modified foods	Au texture A – Soft/UK Texture E	Au texture B – Minced and Moist/UK Texture D	Au texture C – Smooth Pureed/UK Texture C
Description	May be naturally soft (e.g., ripe banana), or may be cooked or cut to alter its texture	Soft and moist, may have some variation in texture, should easily form into a ball	Smooth and lump-free; may have a grainy quality, but no lumps
Characteristics	Soft foods can be chewed but should not need to be bitten. Minimal cutting required – easily broken up with a fork. Food should be moist or served with a sauce or gravy to increase moisture content	Easily mashed with a fork. May be presented as a thick puree with obvious lumps, but lumps are soft and rounded, not hard or sharp. Small lumps can be broken by the tongue	Moist and cohesive enough to hold its shape on a spoon (i.e., when placed side by side on a plate these consistencies maintain their position without ‘bleeding’ into one another). Can be molded, layered, piped. Au Runny puree/UK Textures A/B: Smooth, uniform consistency, will ‘bleed’ into one another; may be poured (A only); cannot be molded, layered, piped
Modified Fluids	Au Mildly thick/UK Stage 1	Au Moderately thick/UK Stage 2	Au Extremely thick/UK Stage 3
Description	Thicker than naturally thick fluids such as fruit nectars and commercial sip feeds.	Similar to room temperature pouring honey or a thickshake	Similar to pudding or mousse
Flow rate	Steady, fast flow; runs fast through the prongs of a fork, but leaves a mild coating on the prongs.	Slow flow; slowly drips in dollops through the prongs of a fork.	No flow; sits on and does not flow through the prongs of a fork.
Characteristics	Pours quickly from a cup but slower than regular fluids. May leave a coating in the cup/on the back of a spoon after being poured. Can be drunk from a cup, or a standard-bore straw with effort.	Cohesive, pours slowly. Can be drunk from a cup although flows very slowly/difficult or impossible to drink using a straw, even a wide bore straw	Cohesive and holds its shape on a spoon. Cannot pour from a cup; needs to be taken by spoon. Too thick if the spoon is able to stand upright in it.

### Nutritional Management and Treatment

Use of modified food textures and fluid consistencies aims to reduce the level of challenge posed in terms of manipulation of the food bolus (i.e., by reducing the numbers of different textures presented and increasing the viscosity) and to alter the rate at which it passes through the pharynx, to maximize patient control of swallowing and reduce the risk of aspiration. National professional groups world-wide have developed classification systems for modification in the texture and consistency of foods and fluids. These usually cite approximately three grades, e.g., soft, minced, and pureed foods; mildly, moderately, and extremely thickened fluids (Tables 3–7).

It is commonly the responsibility of the speech pathologist to recommend the most appropriate food textures and maneuvers to promote safe eating for a dysphagic stroke patient (Tables 4 and 8). Dietitians ensure that texture-modified meals are adequate to meet nutrient requirements, offer choice, and are palatable. Skilled nursing assistance and interventions at mealtimes can also aid eating and mealtime processes. Impaired oral preparation may be compensated for by positioning food on, and tilting the head

**Table 4** Australian standardised terminology and definitions for texture modified fluids 2007

	Mildly thick	Moderately thick	Extremely thick
Description	Thicker than naturally thick fluids such as fruit nectars, but for example, not as thick as a thickshake	Similar to the thickness of room temperature honey or a thickshake	Similar to the thickness of pudding or mousse
Flow rate	Steady, fast flow	Slow flow	No flow
Characteristics	Pours quickly from a cup but slower than regular, unmodified fluids. May leave a coating film of residue in the cup after being poured. Drink this fluid thickness from a cup. Effort required to take this thickness via a standard bore straw	Cohesive and pours slowly. Possible to drink directly from a cup although fluid flows very slowly. Difficult to drink using a straw, even if using a wide-bore straw	Cohesive and holds its shape on a spoon. It is not possible to pour this type of fluid from a cup into the mouth. Spoon is the optimal method for taking this type of fluid. This fluid is too thick if the spoon is able to stand upright in it
Testing Information	Subjectively, fluids at this thickness run fast through the prongs of a fork, but leave a mild coating on the prongs <sup>a</sup>	Subjectively, fluids at this thickness slowly drip in dollops through the prongs of a fork	Subjectively, fluids at this thickness sit on and do not flow through the prongs of a fork

<sup>a</sup>Testing scales for viscosity exist but are not formalised or standardised, and therefore are not included.

**Table 5** Texture A—Soft: Australian standardised terminology and definitions for texture modified foods and fluids 2007

<i>Food type</i>	<i>Recommend</i>	<i>Avoid</i>
Bread, cereals, rice, pasta, noodles	<ul style="list-style-type: none"> <li>• Soft sandwiches(a) with very moist fillings, for example egg and mayonnaise, hummus (remove crusts and avoid breads with seeds and grains)</li> <li>• Breakfast cereals well moistened with milk(b)</li> <li>• Soft pasta(a) and noodles</li> <li>• Rice (well cooked)</li> <li>• Soft pastry, for example quiche with a pastry base</li> <li>• Other, soft, cooked grains</li> </ul>	<ul style="list-style-type: none"> <li>• Dry or crusty breads, breads with hard seeds or grains, hard pasta, pizza</li> <li>• Sandwiches that are not thoroughly moist</li> <li>• Course or hard breakfast cereals that do not moisten easily, for example toasted muesli, bran cereals</li> <li>• Cereals with nuts, seeds and dried fruit</li> </ul>
Vegetables, legumes	<ul style="list-style-type: none"> <li>• Well cooked vegetables (a) served in small pieces or soft enough to be mashed or broken up with a fork</li> <li>• Soft canned vegetables, for example peas</li> <li>• Well cooked legumes (the outer skin must be soft), for example baked beans</li> </ul>	<ul style="list-style-type: none"> <li>• All raw vegetables (including chopped and shredded)</li> <li>• Hard, fibrous or stringy vegetables and legumes, for example sweet corn, broccoli stalks</li> </ul>
Fruit	<ul style="list-style-type: none"> <li>• Fresh fruit pieces that are naturally soft, for example banana, well-ripened pawpaw</li> <li>• Stewed and canned fruits in small pieces</li> <li>• Pureed fruit</li> </ul>	<ul style="list-style-type: none"> <li>• Large/round fruit pieces that pose a choking risk, for example whole grapes, cherries</li> <li>• Dried fruit, seeds and fruit peel</li> <li>• Fibrous fruits, for example pineapple</li> </ul>
Milk, yoghurt, cheese	<ul style="list-style-type: none"> <li>• Milk, milkshakes, smoothies (b)</li> <li>• Yoghurt (may contain soft fruit)(b)</li> <li>• Soft cheeses, (a) for example Camembert, ricotta</li> </ul>	<ul style="list-style-type: none"> <li>• Yoghurt with seeds, nuts, muesli or hard pieces of fruit</li> <li>• Hard cheeses, for example cheddar and hardened/crispy cooked cheese</li> </ul>
Meat, fish, poultry, eggs, nuts, legumes	<ul style="list-style-type: none"> <li>• Casseroles with small pieces of tender meat(a)</li> <li>• Moist fish (easily broken up with the edge of a fork)</li> <li>• Eggs (a) (all types except fried)</li> <li>• Well cooked legumes (the outer skin must be soft), for example baked beans</li> <li>• Soft tofu, for example small pieces, crumbled</li> </ul>	<ul style="list-style-type: none"> <li>• Dry, tough, chewy, or crispy meats</li> <li>• Meat with gristle</li> <li>• Fried eggs</li> <li>• Hard or fibrous legumes</li> <li>• Pizza</li> </ul>
Desserts	<ul style="list-style-type: none"> <li>• Puddings, dairy desserts, (b) custards, (b) yoghurt (b) and ice-cream (b) (may have pieces of soft fruit)</li> <li>• Moist cakes (extra moisture, e.g., custard may be required)</li> <li>• Soft fruit-based desserts without hard bases, crumbly or flaky pastry or coconut, for example apple crumble</li> <li>• Creamed rice, moist bread and butter pudding</li> </ul>	<ul style="list-style-type: none"> <li>• Dry cakes, pastry, nuts, seeds, coconut, dried fruit, pineapple</li> </ul>
Miscellaneous	<ul style="list-style-type: none"> <li>• Soup (b) – (may contain small soft lumps, e.g., pasta)</li> <li>• Soft fruit jellies or nonchewy lollies(a)</li> <li>• Soft, smooth, chocolate</li> <li>• Jams and condiments without seeds or dried fruit</li> </ul>	<ul style="list-style-type: none"> <li>• Soups with large pieces of meats or vegetables, corn, or rice</li> <li>• Sticky or chewy foods, for example toffee</li> <li>• Popcorn, chips, biscuits, crackers, nuts, edible seeds</li> </ul>

(a) These foods require case-by-case consideration.

(b) These foods may need modification for individuals requiring thickened fluids.

towards, the unaffected side; posterior positioning of food on the tongue may promote oral transport. If pharyngeal transport/reflex swallowing is impaired, it is important to ensure upright posture, head stable in the midline with a slight forward flexion to protect the airway; prompting of synchronization of the sequence of inspiration, breath-holding, swallowing, possibly repeatedly, expiration, and coughing on expiration to clear food debris may be helpful. Maintaining an upright posture for at least 30 min after meals minimizes risk of regurgitation/aspiration.

Many nondietary, therapeutic approaches to manage dysphagia have been identified including: oral electrical, thermal and chemical pharyngeal stimulation; high-intensity swallowing therapy; exercises to improve laryngeal closure, labial/mandibular closure, tongue elevation, and lateralization; use of palatal training devices and prostheses to assist triggering of the swallowing reflex or lower the palatal vault to improve bolus formation; drug therapy (nifedipine); use of biofeedback involving mirrors and VSS. Although benefits have been described for many of these interventions, lack of randomized, controlled clinical trials with adequate power limits conclusions on effectiveness.

**Table 6** Texture B—Minced and Moist: Australian standardised terminology and definitions for texture modified foods and fluids 2007

<i>Food type</i>	<i>Recommend</i>	<i>Avoid (in addition to the Foods to Avoid listed for Texture A – Soft)</i>
Bread, cereals, rice, pasta, noodles	<ul style="list-style-type: none"> <li>• Breakfast cereal with small moist lumps, for example porridge or wheat flake biscuits soaked in milk</li> <li>• Gelled bread</li> <li>• Small, moist pieces of soft pasta, for example moist macaroni cheese (some pasta dishes may require blending or mashing)</li> </ul>	<ul style="list-style-type: none"> <li>• All breads, sandwiches, pastries, crackers, and dry biscuits</li> <li>• Gelled breads that are not soaked through the entire food portion</li> <li>• Rice that does not hold together, for example parboiled, long-grain, basmati</li> <li>• Crispy or dry pasta, for example edges of a pasta bake or lasagne</li> </ul>
Vegetables, legumes	<ul style="list-style-type: none"> <li>• Tender cooked vegetables that are easily mashed with a fork</li> <li>• Well cooked legumes (partially mashed or blended)</li> </ul>	<ul style="list-style-type: none"> <li>• Vegetable pieces larger than 0.5 cm or too hard to be mashed with a fork</li> <li>• Fibrous vegetables that require chewing, for example peas</li> </ul>
Fruit	<ul style="list-style-type: none"> <li>• Mashed soft fresh fruits, for example banana, mango</li> <li>• Finely diced soft pieces of canned or stewed fruit</li> <li>• Pureed fruit</li> <li>• Fruit juice(a)</li> </ul>	<ul style="list-style-type: none"> <li>• Fruit pieces larger than 0.5 cm</li> <li>• Fruit that is too hard to be mashed with a fork</li> </ul>
Milk, yoghurt, cheese	<ul style="list-style-type: none"> <li>• Milk, milkshakes, smoothies(a)</li> <li>• Yoghurt(a) (may have small soft fruit pieces)</li> <li>• Very soft cheeses with small lumps, for example cottage cheese</li> </ul>	<ul style="list-style-type: none"> <li>• Soft cheese that is sticky or chewy, for example Camembert</li> </ul>
Meat, fish, poultry, eggs, nuts, legumes	<ul style="list-style-type: none"> <li>• Coarsely minced, tender, meats with a sauce.</li> <li>• Casseroles dishes may be blended to reduce the particle size</li> <li>• Coarsely blended or mashed fish with a sauce</li> <li>• Very soft and moist egg dishes, for example scrambled eggs, soft quiches</li> <li>• Well cooked legumes (partially mashed or blended)</li> <li>• Soft tofu, for example small soft pieces or crumbled</li> </ul>	<ul style="list-style-type: none"> <li>• Casserole or mince dishes with hard or fibrous particles, for example peas, onion</li> <li>• Dry, tough, chewy, or crispy egg dishes or those that cannot be easily mashed</li> </ul>
Desserts	<ul style="list-style-type: none"> <li>• Smooth puddings, dairy desserts,(a) custards,(a) yoghurt(a) and ice-cream(a) (may have small pieces of soft fruit)</li> <li>• Soft moist sponge cake desserts with lots of custard, cream or ice-cream, for example trifle, tiramisu</li> <li>• Soft fruit-based desserts without hard bases, crumbly or flaky pastry or coconut, for example apple crumble with custard</li> <li>• Creamed rice</li> </ul>	<ul style="list-style-type: none"> <li>• Desserts with large, hard or fibrous fruit particles (e.g., sultanas), seeds or coconut</li> <li>• Pastry and hard crumble</li> <li>• Bread-based puddings</li> </ul>
Miscellaneous	<ul style="list-style-type: none"> <li>• Soup(a) – (may contain small soft lumps, e.g., pasta)</li> <li>• Plain biscuits dunked in hot tea or coffee and completely saturated</li> <li>• Salsa's, sauces and dips with small soft lumps</li> <li>• Very soft, smooth, chocolate</li> <li>• Jams and condiments without seeds or dried fruit</li> </ul>	<ul style="list-style-type: none"> <li>• Soups with large pieces of meats or vegetables, corn, or rice</li> <li>• Sweets and lollies including fruit jellies and marshmallow</li> </ul>

(a) These foods may require modification for individuals requiring thickened fluids.

## Nutrient Requirements

Diabetes mellitus, hypertension, and renal failure are common in the stroke population; their disease-related dietary management requirements need to be borne in mind for affected stroke patients. Many different approaches can be used to estimate energy requirements. Resting energy expenditure can be estimated on the basis of body weight, height, age, and sex, with modifications to accommodate activity and injury factors, and supplemental values to replenish malnourished individuals. Estimation of resting energy expenditure by indirect calorimetry using a portable metabolic monitor provides more accurate estimates derived from the respiratory quotient. Values do not consider periods of activity, pyrexia, pain, or energy increments necessary for nutritional repletion, so further corrections are necessary.

Following stroke a number of factors may affect energy requirements. Inactivity caused by paralysis reduces energy expenditure, but muscular paresis increases the relative energy cost of activity. Infections, which commonly complicate stroke, will increase

**Table 7** Texture C—Smooth Pureed: Australian standardised terminology and definitions for texture modified foods and fluids 2007

<i>Food type</i>	<i>Recommend</i>	<i>Avoid (in addition to the Foods to Avoid listed for Texture B – Minced and moist)</i>
Bread, cereals, rice, pasta, noodles	<ul style="list-style-type: none"> <li>• Smooth lump-free breakfast cereals, for example semolina, pureed porridge</li> <li>• Gelled bread</li> <li>• Pureed pasta or noodles</li> <li>• Pureed rice</li> </ul>	<ul style="list-style-type: none"> <li>• Cereals with course lumps or fibrous particles, for example all dry cereals, porridge</li> <li>• Gelled breads that are not soaked through the entire food portion</li> </ul>
Vegetables, legumes	<ul style="list-style-type: none"> <li>• Pureed vegetables</li> <li>• Mashed potato</li> <li>• Pureed legumes, for example baked beans (ensuring no husks in final puree)</li> <li>• Vegetable soups that have been blended or strained to remove lumps(a)</li> </ul>	<ul style="list-style-type: none"> <li>• Coarsely mashed vegetables</li> <li>• Particles of vegetable fiber or hard skin</li> </ul>
Fruit	<ul style="list-style-type: none"> <li>• Pureed fruits, for example commercial pureed fruits, vitamised fresh fruits</li> <li>• Well mashed banana</li> <li>• Fruit Juice(a) without pulp</li> </ul>	<ul style="list-style-type: none"> <li>• Pureed fruit with visible lumps</li> </ul>
Milk, yoghurt, cheese	<ul style="list-style-type: none"> <li>• Milk, milkshakes, smoothies(a)</li> <li>• Yoghurt(a) (lump-free), for example plain or vanilla</li> <li>• Smooth cheese pastes, for example smooth ricotta</li> <li>• Cheese and milk-based sauces(a)</li> </ul>	<ul style="list-style-type: none"> <li>• All solid and semisolid cheese including cottage cheese</li> </ul>
Meat, fish, poultry, eggs, nuts, legumes	<ul style="list-style-type: none"> <li>• Pureed meat/fish (pureed with sauce/gravy to achieve a thick moist texture)</li> <li>• Soufflés and mousses, for example salmon mousse</li> <li>• Pureed legumes, hummus</li> <li>• Soft silken tofu</li> <li>• Pureed scrambled eggs</li> </ul>	<ul style="list-style-type: none"> <li>• Minced or partially pureed meats</li> <li>• Scrambled eggs that have not been pureed</li> <li>• Sticky or very cohesive foods, for example peanut butter</li> </ul>
Desserts	<ul style="list-style-type: none"> <li>• Smooth puddings, dairy desserts,(a) custards,(a) yoghurt(a) and ice-cream(a)</li> <li>• Gelled cakes or cake slurry, for example fine sponge cake saturated with jelly</li> <li>• Soft meringue</li> <li>• Cream(a), sirup dessert toppings(a)</li> </ul>	<ul style="list-style-type: none"> <li>• Desserts with fruit pieces, seeds, nuts, crumble, pastry or nonpureed garnishes</li> <li>• Gelled cakes or cake slurries that are not soaked through the entire food portion</li> </ul>
Miscellaneous	<ul style="list-style-type: none"> <li>• Soup(a) – vitamised or strained to remove lumps</li> <li>• Smooth jams, condiments and sauces</li> </ul>	<ul style="list-style-type: none"> <li>• Soup with lumps</li> <li>• Jams and condiments with seeds, pulps or lumps</li> </ul>

(a) These foods may require modification for individuals requiring thickened fluids.

Source: Reproduced with permission from Australian Standardised Terminology and Definitions for Texture modified foods and fluids (2007) *Nutrition & Dietetics* 64 (Suppl. 2): S53–S76.

energy expenditure, with each 1 °C rise in core temperature raising it by 13%. The impact of the cerebral injury on poststroke metabolism, i.e., resting energy expenditure at different levels of stroke severity, has not been fully investigated. Evidence for metabolic injury responses based on hormonal profiles and changes in blood glucose concentration in the acute phase is limited. Hyperglycemia is common following stroke and has been associated with increased morbidity and mortality. Hyperglycemia can be attributed to overt or latent diabetes mellitus, stress responses, and effects of glucose intolerance in elderly subjects. Elevated plasma cortisol and catecholamine concentrations representing a transient stress response have been reported in the first 72 h following stroke. Nitrogen requirements following stroke can be estimated using reference ranges based on body weight, or using nitrogen balance studies.

Studies of nutritional supplementation of stroke patients have not conclusively demonstrated improved outcomes. One major international trial clearly showed no benefit from isocaloric supplements for unselected stroke populations, but early indications are that targeted protein-rich supplementation may be useful.

Fluid balance requirements require careful attention, because dehydration is a serious risk in individuals with dysphagia and physical disabilities that impair drinking, with potential to compromise already impaired cerebral circulation. Oral intake of fluid is contraindicated where the swallowing and gag reflex are lost or swallowing and level of consciousness are impaired. Parenteral (intravenous or other routes) fluid replacement therapy is then necessary, usually short term. Fluid requirements can be calculated on the basis of 35 ml per kg body weight daily in adults, but sepsis and fever can increase needs. Fluid intake and output in conjunction with insensible losses should be monitored on a daily basis together with the symptoms of dehydration, i.e., urine specific gravity, thirst, dry mucous membranes, and loss of skin turgor.

**Table 8** Compensatory strategies and restorative therapies for dysphagia

Stage of swallow	Swallow disorder	Compensatory strategy	Restorative/rehabilitative exercises/therapy
Oral preparatory	Poor lip seal	Supported lip and jaw closure	Lip exercises
Oral preparatory	Poor cheek tone	Intra-oral prosthesis, cheek hold technique (apply pressure to weak side), tilt head towards unaffected side	Cheek tone exercises
Oral preparatory	Poor sensation in oral cavity	Increase bolus taste, volume, density, temperature, carbonated drinks	Sensory awareness program
Oral preparatory	Poor tongue movement	Modify consistency of bolus, pace rate of bolus presentation, avoid mixed consistencies, remove residue from oral cavity post swallow	Tongue lateralization exercises
Oral preparatory	Poor chewing/ jaw closure	Jaw support, diet modification	Chewing exercises
Pharyngeal	Delayed swallow	Adapted cutlery and crockery to assist in self feeding, chin tuck posture, increase bolus taste, volume, density, temperature, fizzy drinks	Thermal stimulation, PNF to the fauceal arches
Pharyngeal	Reduced base of tongue movement	Chin tuck, clearing swallows, effortful swallow, decrease bolus size, increase bolus consistency	Tongue hold technique, gargle & yawn exercises, supersupraglottic swallow
Pharyngeal	Unilateral pharyngeal paresis	Head rotation to damaged side, head tilt to unaffected side, back or side lying, clearing swallows, liquid wash down	
Pharyngeal	Unilateral tongue and pharyngeal paresis	Head tilt to unaffected side, clearing swallows	
Pharyngeal	Reduced laryngeal closure	Chin tuck, head rotation to damaged side, supraglottic swallow, supersupraglottic swallow, alter bolus consistency	Supraglottic swallow, supersupraglottic swallow, breath hold maneuver, push-pull voicing
Pharyngeal	Reduced laryngeal elevation	Chin tuck & lie on side/back, supersupraglottic swallow, Mendelssohn maneuver, clearing swallows	Falsetto voicing, Mendelssohn maneuver, Shaker technique, surface electromyography
Pharyngeal	Cricopharyngeal dysfunction/reduced anterior movement of hyolaryngeal structure	Head rotation, avoid mixed consistencies	Shaker technique
Fatigue		Nutritional supplements, decrease meal size, increase frequency of meals	

PNF: proprioceptive neuromuscular facilitation.

### Artificial Nutritional Support

The presence of severe dysphagia and cognitive and complex physical impairments may render oral feeding unsafe or insufficient for nutritional requirements. If the gastrointestinal tract is functional, the options for delivering enteral nutritional support are either a fine-bore NGT or a PEG or radiologically inserted gastrostomy.

Decisions concerning choice of route are influenced by the anticipated duration of dysphagia and benefits versus risks. Impact on nutritional status, rehabilitation, quality of life, safety, tolerance, flexibility, ease of use, costs of insertion, removal, and maintenance are all important considerations. In the majority of cases dysphagia resolves within the acute phase of stroke, i.e., approximately 2–3 weeks. For relatively short time periods, enteral feeding by fine-bore NGT is recommended, and a major international trial of early insertion of PEG has not shown benefit. Advantages of NGT are the technical simplicity of intubation, maintenance and removal, low cost and ease of use. Accidental displacement and repeated removal by confused or cognitively impaired patients are not uncommon; nasal bridles to maintain secure positioning are showing promise. Placement positioning difficulties and malposition, discomfort, and risks of aspiration are potential complications, with aspiration occurring in up to 10% of patients.

For feeding over longer periods, a PEG inserted under local anesthetic and sedation offers greater comfort, toleration, ease of use, and reported improvements in nutritional status. However, costs are greater and this more invasive procedure carries a 1–2% technique-related fatality, often more for delayed insertion in malnourished patients. Minor complications include stomal sepsis, leakage, and blockage. Peritonitis, perforation, gastrointestinal bleeding, and intestinal obstruction can rarely occur. Most enterostomy catheters are made from nonacid-hardening polyurethane or silicone and can be left *in situ* for 6 months and longer.

No consensus exists concerning the time period within which gastrostomy feeding should be initiated following stroke, but it should be considered where dysphagia persists beyond 14 days, or the patient cannot tolerate a NGT. Rarely, enteral nutrition may be contraindicated following stroke owing to gastrointestinal bleeding resulting from severe stress ulceration; nonstroke-related contraindications may also be present, e.g., ascites, bleeding disorders. Parenteral nutrition should then be considered.

Issues relating to the optimum timing of commencement of artificial feeding can be challenging for a patient group that may experience sudden and major cognitive and physical impairments with uncertain recovery potential. Nutritional deterioration can be rapid in acutely ill patients unable to take food orally. Decision-making can be difficult and stressful, and require extensive and sensitive communication between healthcare team members, patient (where possible) and families (where available). Failure to establish timely agreed nutritional care planning for patients who have eaten little or nothing for more than 5 days and are likely to eat little or nothing for the next 5 days or longer, who are unable to take in nutrients properly, or who have increased nutritional needs is unacceptable.

### Evaluation of Nutritional Support

It is vital that nutritional status is monitored in the acute phase of recovery and that dietary intakes are readjusted accordingly. Appropriate dietary, anthropometric, and clinical assessments, which can be performed on a weekly basis, are discussed. Other important components of monitoring include recovery of physical functions related to independence in eating, including swallowing capacity, and observing for complications of enteral support techniques. Effective nutritional management following stroke requires coordination of the professional skills of doctor, nurse, speech pathologist, dietitian, occupational therapist, and physiotherapist, ideally within the context of a nutrition support team. Dynamic leadership, referral policies, clear accountability and lines of communication are essential for the team to deliver effective support. Follow-up services in the community are also necessary to prevent deterioration in nutritional status in the later stages of rehabilitation.

## Introduction

Inflammatory bowel disease (IBD) may cause significant symptoms and morbidity if left untreated, including malnutrition in the form of macro and micronutrient deficiencies. Current standard of care includes therapies designed to suppress the immune response, with inherent risk of infection and undesired side effects. In addition, IBD is often diagnosed in childhood and early adulthood, and the disease, as well as therapies used to manage it need to be balanced during this important period of growth and fertility. A

treatment approach that focuses on dietary management is appealing to patients due to the favorable risk and side effect profile. In this article we will explore the associations between of diet and nutrition and the risk of developing IBD, the influence diet has on disease activity, common nutritional deficiencies and how these can be identified and managed. Lastly, proposed methods to manipulate the diet to manage active disease are discussed.

## Inflammatory bowel disease (IBD) background

The Inflammatory Bowel Diseases (IBD), Ulcerative Colitis (UC) and Crohn's disease (CD), result in chronic relapsing and remitting inflammation of the gastrointestinal tract (Lamb et al., 2019). These diseases are thought to be caused by the interplay between genetic susceptibility, environmental factors, and intestinal microflora, resulting in an abnormal mucosal immune response and a compromised gut epithelial barrier function (Guan, 2019).

CD can affect all segments of the bowel, the most common being the terminal ileum and colon (Torres et al., 2017). The inflammation is typically segmental, asymmetrical, and transmural. UC, in contrast, results in inflammation limited to the mucosal layer, starting at the rectum and extending in a continuous fashion to proximal segments of the colon (Ungaro et al., 2017).

The clinical presentation of IBD relates to the areas of the gastrointestinal (GI) tract that are affected; but commonly includes abdominal pain, chronic diarrhea, and weight loss. Extraintestinal manifestations (EIM) including arthritis, skin rashes, eye disease such as episcleritis and anterior uveitis and metabolic bone disease; are not uncommon, with 50% of patients with IBD experiencing at least one EIM throughout the course of their illness. The EIM appears before the diagnosis of IBD 25% of the time (Harbord et al., 2015; Vavrika et al., 2015). The onset of IBD can occur at any age, but is most common between the ages of 10–40 years (Torres et al., 2017; Ungaro et al., 2017).

The diagnosis of IBD requires endoscopy and biopsy with characteristic histological features in a patient with suggestive clinical symptoms and where alternate diagnosis such as infection have been excluded. Due to the risk of significant complications and absence of a cure, appropriate long-term management to achieve and then maintain remission is necessary (Ungaro et al., 2017; Torres et al., 2017).

Current standard of medical care in IBD is determined by subtype, severity, and location in the gastrointestinal tract. In mild to moderate UC, Aminosaliclates are the first line standard treatment option, with immunosuppressants and biological agents reserved for those who do not respond, those who present with severe disease or those with a diagnosis of CD (Ungaro et al., 2017; Torres et al., 2017; Lamb et al., 2019; Raine et al., 2021). Immunosuppressive agents used as part of the standard treatment algorithm include anti-metabolites (Thiopurines and Methotrexate), anti-tumor necrosis factor alpha (anti TNF- $\alpha$  e.g., Infliximab, Adalimumab),  $\alpha$ 4 $\beta$ 7 ligand blocker Vedolizumab, the Interleukin (IL)-12 and IL-23 blocker Ustekinumab and Janus Kinase (JAK) inhibitors (Tofacitinib) (Raine et al., 2021; Torres et al., 2019). Aside from Aminosaliclates, the unifying mechanism of action of these medications is immune suppression, with inherent increased risk of infection as well as many other potential risks and side effects that are medication specific.

Surgery may be required in the setting of disease-related complications such as fistulae, perforation, or medically refractory disease. In CD most patients present with an inflammatory phenotype at diagnosis but, over time complications such as strictures, fistulae and abscesses may develop and up to half of patients require surgery at some point in the course of their disease. Surgery is less commonly required in UC, with a 10-year risk of 15.6%, but when required almost universally necessitates a total colectomy (Frolkis et al., 2013).

The pathogenesis of IBD is complex and associated with genetic susceptibility of the host, intestinal microbial dysbiosis and immunological abnormalities as well as other environmental triggering factors such as the diet (Guan, 2019).

This article will give an overview of the factors contributing to the pathogenesis of IBD before outlining the important aspects of nutrition in more detail. Specific to diet and IBD we will outline:

1. The proposed mechanisms of diet-microbial-immune system interactions that occur with important dietary components in the pathogenesis of IBD.
2. Established associations between elements of the diet and the development of IBD
3. Proposed assessment tools for malnutrition as well as micro and macro nutrient deficiencies
4. Dietary recommendations in the management of IBD for maintenance of remission and treatment of active disease.

An in-depth review of food supplements, probiotics and nutraceuticals is beyond the scope of this article.

## Pathogenic factors in IBD

### Genetic factors in IBD

At a genetic level, genome wide association studies (GWAS) have identified over 240 genetic risk loci for IBD (Park, 2019). Many of these genes play important roles in maintaining intestinal mucosal homeostasis, particularly involved in bacterial handling. Others code for epithelial barrier function, innate mucosal defense, immune regulation, cell migration, autophagy, and adaptive immunity. Examples of genes implicated in the development of IBD are NOD2, which codes for a protein involved in the innate immune response to bacterial peptidoglycan, ATG16L1, a gene that codes for a protein responsible for autophagy and bacterial clearance

and IL-23 Receptor (IL-23R) gene which is involved in the activation of adaptive immune responses. It should be noted that these are at-risk loci and only a small proportion of those who carry these genes develop IBD (Guan, 2019). Furthermore, twin studies demonstrate modest concordance rates in IBD, even among monozygotic twins, with rates in CD of 2.0–55.0% and 6.3–17.0% in UC (Gordon et al., 2015). Thus, while genetics play a role in the predisposition of a person to IBD, other environmental factors are needed for the development of clinical disease.

### Microbiome in IBD

The microbiome, defined as the collection of microorganisms and their genes found in the host has become integral to our understanding of health and disease (Valdes et al., 2018). Dysbiosis, defined as an imbalance in the composition of the gut microbiome, is a hallmark of IBD. Evidence to support the role of the gut microbiota in IBD include the predisposition of inflammation for anatomical regions with relative fecal stasis (terminal ileum and rectum) and the effectiveness of fecal diversion as treatment for CD (Ni et al., 2017). The dysbiosis observed in IBD is characterized by loss of microbial diversity, particularly a loss of favorable species involved in the production of short chain fatty acids (SCFA), such as *Faecalibacterium prausnitzii* and *Bacteroides*, as well as an increase in invasive and adherent pathogenic species such as *Escherichia coli* (Zuo and Ng, 2018). Further studies have also demonstrated that there are differences in function of the gut microbes, as measured by characterizing metabolomic products of the microbiome; and these functional differences may be even more pronounced and influential than the changes in the microbial community structure (Franzosa et al., 2019; Santoru et al., 2017).

### Immunological abnormalities

The immunological dysregulation that occurs in IBD encompasses abnormalities in both the innate and adaptive immune responses (Guan, 2019; Porter et al., 2020). It is characterized by epithelial damage, including abnormal mucus production and defective repair, expansion of inflammation driven by intestinal flora, and large numbers of inflammatory cells infiltrating the lamina propria of the gut mucosa. There is failure of immune regulation to control the inflammatory response and the activated lamina propria cells produce high levels of proinflammatory cytokines including TNF, IL-1 $\beta$ , IFN- $\gamma$  and cytokines in the IL-23/Th17 pathway. This increase in proinflammatory cytokines is coupled with reduced tolerogenic responses, which results in the initiation and perpetuation of the inflammatory response.

It is postulated that the combination of dysbiosis, altered mucosal function and impaired mucosal barrier function found in IBD, results in mucosal inflammation.

### Environmental influences

Epidemiological studies suggest a significant role of environmental factors in the pathogenesis of IBD. IBD is more prevalent in developed nations; however incidence rates are accelerating in more recently westernized countries such as Brazil and Taiwan (Ng et al., 2017). There is also a higher risk in first-generation immigrants from developing countries who have relocated to developed nations, suggesting that the typical western lifestyle, including diet and other environmental factors, may contribute to the development of IBD (M'Koma, 2013).

Environmental factors that have been identified as risk factors for the development of IBD include smoking, antibiotic use (particularly in childhood), vitamin D deficiency and oral contraceptive use (Piovani et al., 2019; Ungaro et al., 2014; Mahid et al., 2006; Cornish et al., 2008).

Physical activity, breastfeeding, high plasma vitamin D were found to be associated with a decreased risk in the development of IBD in a large umbrella meta-analysis (Piovani et al., 2019). Diet is another modifiable environmental factor that has an established association with the risk of developing IBD. It has gained particular interest due to its modifiable nature.

### Nutrition, diet and IBD pathogenesis

Due to the risks associated with the current medical and surgical treatment options for IBD as well as the need for long term medical therapy there is substantial interest in the role of diet as a disease management strategy, but there is a variable quality of evidence to support clear recommendations (Sasson et al., 2021). Patient survey data demonstrates that implementation of a restrictive diet and avoidance of specific foods in the belief that it could prevent relapse was utilized by 68% of individuals with IBD; whilst in another study 89% of IBD patients felt that dietary guidance in disease management was important. Only 16% of participants, however, felt they received adequate information on the recommended diet (Limdi et al., 2016; Wong et al., 2012).

Large epidemiological studies have established multiple dietary associations with the development of IBD (Ananthakrishnan et al., 2013, 2015; Shoda et al., 1996; John et al., 2010; Jantchou et al., 2010; Dong et al., 2020). Mechanistically, diet can impact IBD in several ways, including changing the structure of the microbiome; modifying gut microbial defenses; and directly modulating inflammatory responses. We further outline these interactions on an individual nutrient level (See Table 1) and a summary of the proposed positive and negative impacts are outlined in Figs. 1 and 2.

**Table 1** Associations between dietary components and risk of developing IBD and proposed mechanisms.

Dietary component	Mechanism	Risk of IBD development	
		CD	UC
Breastfeeding	<ul style="list-style-type: none"> <li>- Modulates microbiome (Azad et al., 2013)</li> <li>- Reduces infant infection and antibiotic use (IBD risk factor) (Parigi et al., 2015; Piovani et al., 2019)</li> <li>- Contains secretory IgA: strengthens mucosal barrier function (Rogier et al., 2014)</li> </ul>	Reduced risk of developing IBD, dose response, with greatest reduction >12 months of breast feeding (Xu et al., 2017)	Reduced risk of developing IBD, dose response, with greatest reduction >12 months of breastfeeding (Xu et al., 2017)
Fiber	Fermented to SCFA by colonic bacteria, downstream effects include: <ul style="list-style-type: none"> <li>- Primary energy source for colonocytes</li> <li>- Maintain integrity of protective mucus barrier</li> <li>- Inhibiting recruitment and activation of pro inflammatory cells</li> <li>- Increasing the number and activity of regulatory T cells (Prada Venegas et al., 2019; Goncalves et al., 2018)</li> </ul>	Fiber, especially fruit derived decreased the risk of CD (Ananthakrishnan, et al., 2013, 2015; Andersen et al., 2018; Li, F. et al., 2015; Amre et al., 2007)	Fruit and vegetable consumption associated with reduced UC risk (Li et al., 2015a,b) Other studies have not shown a relationship with fiber intake and development of UC (Wang et al., 2017; Ananthakrishnan, et al., 2013, 2015)
Sugar	<ul style="list-style-type: none"> <li>- Decreased thickness of colonic mucus layer</li> <li>- Increased gut permeability</li> <li>- Decreased microbial diversity</li> <li>- Decreased fecal SCFA (Laffin et al., 2019; Montrose et al., 2021)</li> </ul>	Soft drink and refined sugar intake increase CD risk (Narula et al., 2021) Sugar intake had no impact on CD risk (Racine et al., 2015)	Soft drink and refined sugar intake increase UC risk (Narula et al., 2021) Sugar and soft drink intake as well as sucrose intake are associated with increased risk (Racine et al., 2015; Wang et al., 2017)
Fat	<ul style="list-style-type: none"> <li>- Diet high in saturated fat increases sulphite-reducing pathogens (Devkota et al., 2012)</li> <li>- Diet high in animal fat (as well as sugar) resulted in dysbiosis (increased pro inflammatory organisms) and decreased favorable SCFA (Agus et al., 2015)</li> <li>- High animal fat diet decreased secretory IgA (Muhomah et al., 2019)</li> </ul>	<ul style="list-style-type: none"> <li>- Associations between total fat, animal fat and n-6 PUFA and incidence of CD (Shoda et al., 1996)</li> <li>- High n-3 PUFA and n-3:n-6 PUFA ratio associated with lower risk of CD (Amre et al., 2007)</li> </ul>	<ul style="list-style-type: none"> <li>- Consumption of the n-3 PUFA, DHA associated with reduced risk of UC (John et al., 2010)</li> <li>- Linoleic acid (a n-6 PUFA) associated with an increased risk of UC (Tjonneland et al., 2009)</li> <li>- Recent meta-analysis showed no association between fat total or subtype intake and disease risk (Wang et al., 2016)</li> </ul>
Red meat	<ul style="list-style-type: none"> <li>- Altered microbiome</li> <li>- Increased intestinal permeability (Li et al., 2021)</li> </ul>	Higher animal protein and red & processed meat intake associated with increased risk of IBD (Narula et al., 2018; Jantchou et al., 2010; Ge et al., 2015)	Higher animal protein and red & processed meat intake associated with increased risk of IBD (Jantchou et al., 2010; Dong et al., 2020; Ge et al., 2015; Narula et al., 2021)
Emulsifiers and nanoparticles	<ul style="list-style-type: none"> <li>- Reduce microbial diversity</li> <li>- Reduce mucus thickness</li> <li>- Increase bacterial encroachment on the epithelium</li> <li>- Increasing intestinal permeability (Bancil et al., 2021; Ruiz et al., 2017)</li> </ul>	Association between emulsifiers and ultra-processed food intake and development of CD (Narula et al., 2021; Roberts et al., 2013)	Association between ultra-processed food intake and development of UC (Narula et al., 2021)

CD: Crohn's Disease, DHA: Docosahexaenoic Acid, IBD: Inflammatory Bowel Disease, IgA: Immunoglobulin-A, n-3: Describes the position of the double bond on carbon 3, counting the methyl carbon as carbon number 1, n-6: Describes the position of the double bond on carbon 6, counting the methyl carbon as carbon 1, SCFAs: Short Chain Fatty Acids, UC: Ulcerative Colitis.

## Breastfeeding

Environmental exposures during the first few years of life may influence the risk of disease development, particularly that of allergy and asthma (Cole and Ownby, 2017). This is hypothesized to be due to alteration in the gut microbiota of children, which is important for the development of immune regulatory responses, so called “microbial-immune” cross talk. Stable microbial structure is reached by age 3–4 years, and breastfeeding is the most significant factor associated with microbiome structure (Stewart et al., 2018). Breastfeeding exerts a strong influence on intestinal microbial composition of the infant, with different abundances of taxa, particularly lower in pathogens such as *Clostridium difficile* and *Escherichia-Shigella* identified in breastfed infants when compared to those who were formula fed (Azad et al., 2013).

Breastmilk contains multiple immune modulating compounds, including secretory IgA which strengthens the intestinal barrier and regulates the commensal gut microbiota, promoting a healthy balance between pro and anti-inflammatory gene expression later in life (Rogier et al., 2014; M'Rabet et al., 2008). This protects the infant from the first external pathogenic insults, which is important to reduce neonatal infection and subsequent antibiotic use, which is an established risk factor for IBD. In addition, breastmilk promotes immune tolerance to commensal bacteria, which can avoid undesired inflammatory responses against these innocuous antigens. This regulatory response is missing in IBD and manifests in dysregulated immune responses (Parigi et al., 2015; Piovani et al., 2019).

A large meta-analysis has established the association between breastfeeding and lower risk of development of both UC and CD across many ethnic groups. Breastfeeding duration has a dose-dependent association, with the greatest reduction in risk observed in infants who were breastfed for at least 12-months (Xu et al., 2017). See Table 1 for summary of proposed mechanisms of influence of dietary components on gastrointestinal inflammation and epidemiological studies to support associations with IBD risk.

## Dietary fiber

Dietary fiber provides a substrate for the bacteria that inhabit the distal gut, and these bacteria are integral to its handling. While human intestinal epithelial cells produce approximately 17 enzymes to digest fiber, bacteria produce thousands of complementary enzymes to depolymerize and ferment dietary polysaccharides to form host absorbable SCFAs such as butyrate, propionate and acetate. These SCFAs have an array of functions that are significant to the maintenance of gastrointestinal health, including provision of the primary energy source for colonocytes; inhibiting recruitment and pro-inflammatory activity of neutrophils, macrophages, dendritic cells and effector T-cells; and increasing the number and activity of regulatory T-cells (Prada Venegas et al., 2019; Goncalves et al., 2018). In IBD, bacteria that possess this capability from the Firmicutes phylum, such as *Faecalibacterium prausnitzii*, are less abundant, leading to lower stool SCFA concentration compared with healthy controls, which may contribute to increased intestinal inflammation (Sokol et al., 2009; Takaishi et al., 2008).

Studies in animal models have demonstrated the protective effect of fiber when given before the development of colitis (Silveira et al., 2017). In the absence of fiber, the intestinal microbiota in mice resorted to consuming the mucus layer glycoproteins as a nutrient source, leading to erosion of this barrier of defense against enteric pathogens (Desai et al., 2016). It is therefore plausible

**Fig. 1** Schematic representation of proposed mechanism of favorable diet-gut-immune interactions that may protect from the development of IBD and improve disease activity. (Created with BioRender). PUFA: Polyunsaturated Fatty Acid, SCFA: short-chain fatty acid, IBD: Inflammatory Bowel Disease, Ig: Immunoglobulin. Reproduced from original article: [Wark et al. \(2021\)](#).

that fiber might help to prevent IBD, or once inflammation is established it may help to restore, and then maintain, intestinal integrity ([Gill et al., 2021](#)).

Large cohort studies and several systematic reviews have explored the relationship between the consumption of fiber, including the source of fiber, and the risk of developing IBD. The Nurses' Health Study prospectively followed up 170,776 women for 26 years and demonstrated that women with an intake of fruit-derived fiber in the highest quartile (median 24.3 g/day) was associated with a 40% reduction in risk of CD (multivariate HR 0.59, CI 0.39–0.90) compared with women in the lowest quartile of fiber consumption (median 11.6 g/day). This apparent risk reduction appeared greatest for fiber derived from fruits, whereas fiber from cereals, whole grains or legumes did not modify the risk. In contrast, neither total intake of dietary fiber nor intake of fiber from specific sources modified the risk of UC ([Ananthakrishnan et al., 2013](#)).

**Fig. 2** Schematic representation of proposed mechanisms of pathological diet-immune interactions that may contribute to IBD risk and disease activity (Created with BioRender). PUFA: Polyunsaturated Fatty Acid, SCFA: short-chain fatty acid, IBD: Inflammatory Bowel Disease, Ig: Immunoglobulin. Reproduced from original article: [Wark et al. \(2021\)](#).

A large subgroup ( $n = 39,511$ ) of women from this cohort who also completed a retrospective validated food frequency questionnaire (FFQ) recalling intake from their high school years was examined. A trend for women in the highest quartile of fiber intake to be less likely to develop CD than women in the lowest quartile (26.2 vs. 16.8 g fiber per day,  $p = 0.06$ ) was identified. When combined with a diet high in vegetables and fish in addition to fiber (quantified by a “prudent” diet score), these women had a significantly lower risk of incident CD (HR 0.47, 95% CI 0.23–0.98,  $p = 0.04$ ) ([Ananthakrishnan et al., 2015](#)). Again, this association was not found for UC, nor was it found in a more recent systematic review of nine studies examining the risk of UC in 240,327 people ([Wang et al., 2017](#)).

A large European prospective cohort study ( $n = 401,326$ ) showed an inverse relationship between cereal fiber intake and the development of CD in non-smokers but no associations between other sources of fiber and the development of CD or UC

(Andersen et al., 2018). It should be noted that the median age of this cohort was middle age (median age at recruitment 49.6 years), which is older than the median incident age for IBD, suggesting that earlier exposures may be the most critical in modulating disease risk (Torres et al., 2017; Ungaro et al., 2017).

A meta-analysis of 14 case-control studies focusing on fruit and vegetable intake alone, demonstrated that a higher consumption of fruit was associated with a lower risk of development of both UC (OR = 0.69, 95% CI 0.49–0.96) and CD (OR = 0.57, 95% CI 0.44–0.74), whereas a higher consumption of vegetables was associated with a reduced risk of UC (OR 0.71, 95% CI 0.58–0.88) but not CD (OR 0.66, 95% CI 0.4–1.09) (Li, F. et al., 2015). Similar associations between higher fruit and vegetable intake and lower risk of CD were demonstrated in a smaller case control study performed in a pediatric population (Amre et al., 2007).

Several small clinical trials have reported a favorable effect of the use of fiber on disease outcomes in IBD patients but overall, the benefit of fiber demonstrated in clinical trials has been modest. One study (n = 102) reported that dietary fiber in the form of *Plantago ovata* seed was equivalent to mesalazine at maintaining remission at 12-months (40% vs. 35%, respectively) (Fernandez-Banares et al., 1999), and another small (n = 31) open label trial demonstrated that the addition of fiber to mesalazine resulted in reduced rate of relapse at 12-months when compared to mesalazine alone (Copaci et al., 2000).

A systematic review examined six randomized controlled trials in patients with CD prescribed high fiber diets or fiber supplements. They found there was no benefit in the use of dietary fiber in active disease nor in the maintenance of remission (Wedlake et al., 2014).

In the setting of pouchitis following an ileal pouch-anal anastomosis (IPAA), a small well-designed cross over double blind placebo controlled study of 20 patients, reported a positive outcome, with improvement in both clinical and endoscopic parameters following a 3-week fiber supplemented diet (Welters et al., 2002). Table 2 summarizes the dietary factors proposed to influence IBD disease activity. Fig. 3 summarizes the dietary management approaches used across the phases of IBD disease activity.

In summary, current data supports the association between fiber intake and the development of IBD, however the data to support its use as a specific IBD therapy is much weaker. Despite this, clinicians should recommend adequate dietary fiber intake due to the many other proven benefits, such as the positive association between fiber intake and a reduced risk of cardiovascular disease, stroke, rectal cancer and diabetes (Gill et al., 2021). The exception to this is in the setting of a patient with known intestinal strictures, where excessive fiber may lead to intestinal obstruction.

## Sugar

Animal data support an association between sugar intake and IBD. Mice fed diets high in sucrose and fructose have demonstrated proinflammatory changes consistent with IBD. They were shown to have a decrease in the thickness and quality of colonic mucus, an increase in serum lipopolysaccharide (LPS), which is a bacterial endotoxin and a driver of inflammation, as well as decreased microbial diversity and fecal SCFA content (Laffin et al., 2019; Montrose et al., 2021).

Findings in human studies are less conclusive. In a large nested matched case-control study among 366,351 participants where incident IBD cases were matched to controls, the authors reviewed the association between consumption of a diet high in sugar and soft drinks with risk of a subsequent diagnosis of IBD. The study found a small but significant increased UC risk in the group of patients with a high intake of sugar and soft drinks (Incidence Rate Ratio (IRR) of sugar intake in the fifth vs. the first quintile 1.68, 95% CI 1.00–2.82,  $P = -0.02$ ) (Racine et al., 2015). This risk was apparent only in those with a concurrent vegetable intake below the population median. No significant associations were found in the development of CD.

A systematic review examined the contribution of carbohydrate and sugar consumption to the risk of a person developing UC. The only sugar associated with a small but statistically significant increased risk of UC was sucrose, with a Relative Risk (RR) per 10 g increment/day of 1.098 (95% CI 1.024–1.177). The same relationship was not found with total sugar intake or other sugar types including fructose, other disaccharides and starch (Wang et al., 2017). A more recent prospective cohort study which included 116,087 patients across seven geographic regions identified associations between the consumption of soft drinks (HR 1.94,  $p = 0.001$ , CI 1.42–2.66) and refined, sweetened foods (HR 2.58,  $p = 0.003$ , CI 1.44–4.62) and the risk of IBD (Narula et al., 2021).

Studies specifically addressing the impact of sugar intake on active disease and maintenance of remission are lacking, though restricting sugar intake is a component of the Autoimmune protocol diet (AIP), IBD-Anti Inflammatory Diet (IBD-AID) and Specific Carbohydrate Diet (SCD). These diets will be discussed in further detail in following sections.

## FODMAPs, wheat and gluten

Consumption of fermentable oligo-, di-, and monosaccharides, and polyols, collectively known as FODMAPs leads to increased GI water secretion, increased fermentation in the colon, and increased gas production. This can lead to luminal distension and can trigger meal-related symptoms in patients with Irritable Bowel Syndrome (IBS) (Lacy et al., 2021). Gluten is a protein found in wheat, and many wheat-based foods are also high in FODMAPs (Rhys-Jones, 2021).

Mouse models have demonstrated that chow and enteral nutrition fortified with gluten compared with gluten-free diets resulted in an increased incidence and severity of terminal ileitis. Polymerase chain reaction (PCR) analysis of distal ileal tissues they found increased expression of the genes coding for the proinflammatory cytokines TNF and Interferon gamma (IFN-gamma) in mice consuming gluten containing chow (Wagner et al., 2013).

Diets low in FODMAPs have been used with success in improving symptoms in patients in IBS and as such are part of international guidelines as an evidence-based management strategy (Altobelli et al., 2017; Lacy et al., 2021; Vasant et al., 2021). There is

**Table 2** Dietary components in the management of IBD.

Dietary component	Active disease		Maintenance of remission	
	CD	UC	CD	UC
Fiber	No benefit of addition to the diet: No avoid in stricturing disease (Bischoff et al., 2020)	No evidence of benefit, but no evidence of harm in active UC Pouchitis: Improved clinical and endoscopic parameters with 3 weeks of inulin (Welters et al., 2002)	No impact on risk of relapse (Wedlake et al., 2014)	Equivalent to mesalazine in maintenance of remission at 12-months. Added to mesalazine improved rates of remission at 12 months vs. mesalazine alone (Copaci et al., 2000; Wedlake et al., 2014, Fernandez-Banares et al., 1999)
Sugar	Small trials suggest improvement with restriction/avoidance as part of broader restrictive diets such as SCD/AIP/IBD-AID: see below		No data	
FODMAPs and gluten	Restriction associated with improved symptoms and lead to reduction in fecal calprotectin in patients with mildly active disease (Bodini et al., 2019)		In patients with quiescent disease and ongoing functional symptoms low FODMAPs diet improved symptom scores (Cox et al., 2020; Prince et al., 2016; Herfarth et al., 2014)	
Fat	Not reported	Not reported	A diet with a ratio of n-3:n-6 PUFA of >0.65 associated with reduced flare risk (Uchiyama et al., 2010)	Myristic acid associated with increased risk of disease flare (Barnes et al., 2017) A diet with a ratio of n-3:n-6 PUFA of >0.65 associated with reduced flare risk (Uchiyama et al., 2010)
Red meat			Restricting red meat to fortnightly decreased rate of relapse at 2 years 94% SVD vs. 33% omnivorous (Chiba et al., 2010) Larger study did not show a difference in relapse between meat $\geq 2$ /week vs. $\leq 1$ /month (Albenberg et al., 2019)	Meat, in particular red and processed meat increased risk of relapse (Jowett et al., 2004)
Emulsifiers and nanoparticles	Positive results in a 4 month pilot study (n = 20) excluding microparticles in addition to steroid treatment, not replicated in larger study (n = 88) (Lomer et al., 2001, 2005) EEN which is efficacious in active CD contains multiple food additives including a variety of emulsifiers (such as polysorbate 80 used in animal trials) and is associated with positive clinical outcomes (Logan et al., 2020)	Increased titanium dioxide nanoparticles in serum of patients with active UC (Ruiz et al., 2017)	Not reported	Not reported

AIP: Autoimmune Protocol Diet, CD: Crohn's Disease, EEN: Exclusive Enteral Diet, FODMAPs: Fermentable, Oligosaccharides, Disaccharides, Monosaccharides and Polyols, IBD: Inflammatory Bowel Disease, IBD-AID: Inflammatory Bowel Disease- Autoimmune Diet; n: Number, n-3: Describes the position of the double bond on carbon 3, counting the methyl carbon as carbon number 1, n-6: Describes the position of the double bond on carbon 6, counting the methyl carbon as carbon 1. PUFA: Polyunsaturated Fatty Acid, SCD: Specific Carbohydrate Diet, SVD: Semi-Vegetarian Diet, UC: Ulcerative Colitis.

evidence that this approach has a place for patients with quiescent IBD and concurrent functional symptoms consistent with IBS. The prevalence of self-reported non-coeliac gluten sensitivity (NCGS) is 23.6–27.8% in IBD, with NCGS being more common in patients with stricturing disease and those with recent self-reported flares (Aziz et al., 2015) (Limketkai et al., 2018).

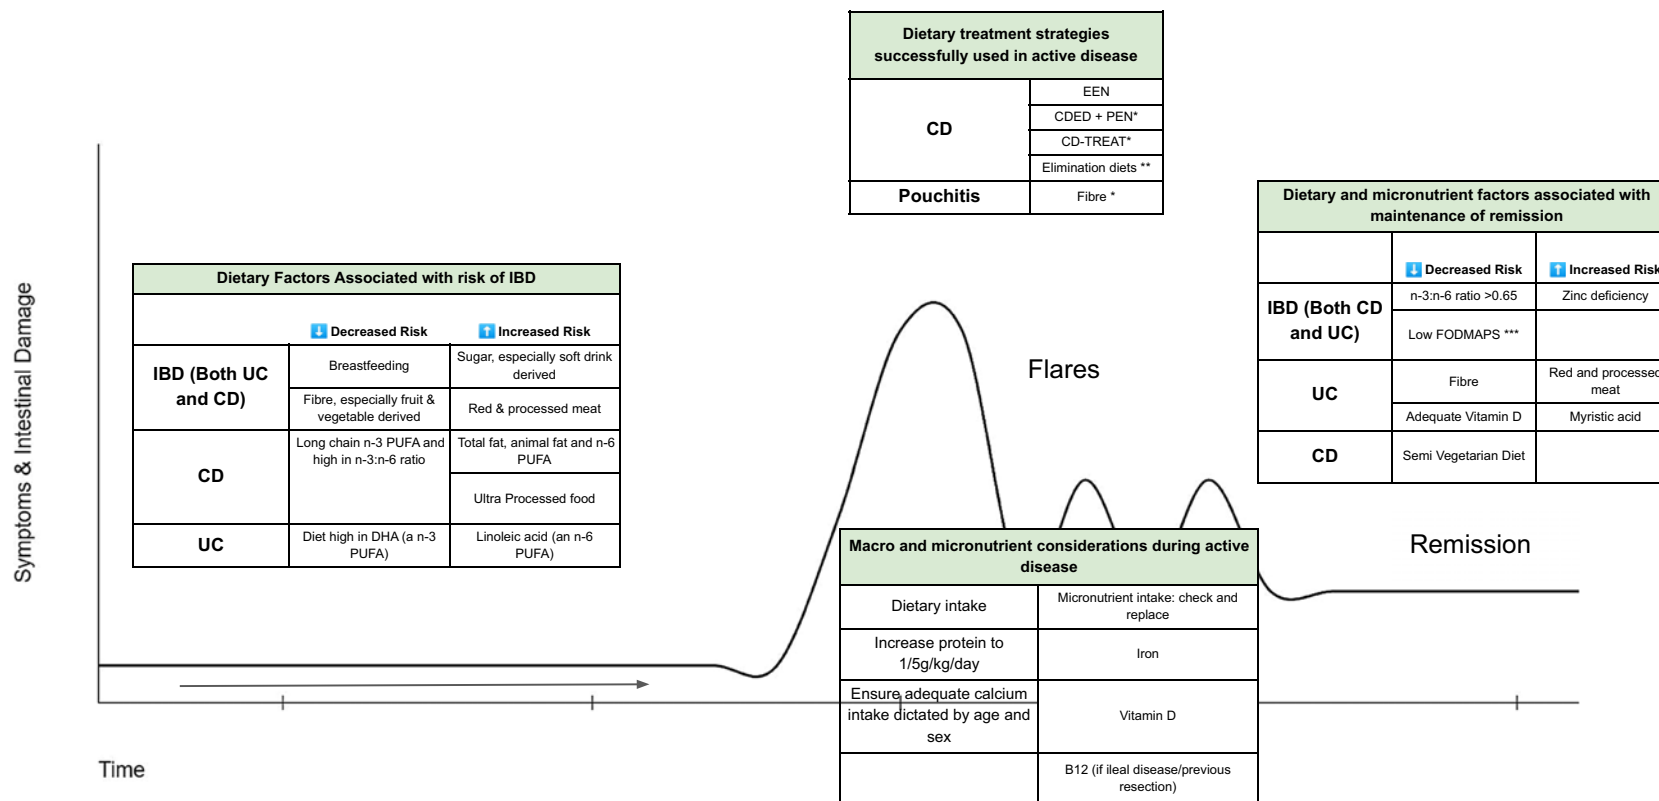

A randomized, double blind, placebo-controlled study demonstrated higher symptoms scores for pain, bloating and urgency in 32 patients with quiescent IBD and concurrent IBS challenged with FODMAPs (Cox et al., 2017). Several trials of patients with quiescent IBD following a low FODMAP approach have demonstrated an improvement in symptom severity scores, reduced fatigue, less self-reported flares and a higher quality of life without objective change in markers of inflammation (Cox et al., 2020; Prince et al., 2016; Herfarth et al., 2014). Interestingly, one study performed in 55 patients with IBD which included patients in remission or with mild disease activity on a stable medication regimen were commenced on a low FODMAP diet. In some patients there was a slight reduction in the fecal calprotectin, though the clinical significance of this is uncertain and these findings have not yet been replicated (Bodini et al., 2019).

## Fat

Triglycerides (TG)s make up the largest proportion of dietary fat in the human diet. A TG is composed of a glycerol backbone and three fatty acids (FA)s esterified to the glycerol. The FAs in the human diet vary in the carbon chain length and in the number and position of the double bonds along the hydrocarbon chain. Most dietary oils contain TGs with FA containing 4–26 carbons. The type of dietary fat is defined by the saturation, the position of the first double bond relative to the methyl end (marked with “n” or “omega”) in the carbon chain and the isomerization of the double bond (cis vs. trans). These characteristics determine the physical properties of the fats, for example, whether they are solid or liquid at room temperature (Ross, 2014).

1. Monounsaturated FAs (MUFAs): At least 12 carbon atoms long, typically with a double bond at the n-9 or n-7 position. Most common in the diet is oleic acid (C18:1, n-9 cis), found in olive oil
2. Polyunsaturated FAs (PUFA): Contains 2–6 double bonds between carbons within the fatty acid chain (the number of double bonds is indicated by a number to the right of the number of carbon atoms, e.g., C22:6 is a FA with 22 carbon atoms and 6 double bonds in the molecule). The position of the first double bond would be at the n-3, n-6 or n-9 if longer than 18 carbons in length and located at the n-7 position for a 16-carbon atom FA. FAs with double bonds at the n-3 and n-6 position are essential in the diet since the human biosynthetic enzymes cannot form double bonds at any position closer to the methyl end other than n-9. Example of a common n-6 PUFA in the diet is linoleic acid (C18:2, n-6,9 all cis) found in seed oils and n-3 includes alpha-linolenic acid (C18:3, n-3,6,9 all cis) found in vegetable oils, nuts and docosahexaenoic acid (C22:6, n-3,6,9,12,15,18 all cis) found in fish.
3. Saturated FAs have no double bonds and are found in animal food sources such as meat, dairy, palm oil and pastries (due to the use of butter or margarine).
4. Trans FAs are found in small quantities naturally in animal source fat, but can also be produced by partial hydrogenation of polyunsaturated oils by the food industry.

Healthy eating guidelines recommend limiting foods high in saturated and trans-fat due to the link with metabolic disease, cancer and even poorer mental health outcomes (NHMRC, 2013, Forouhi et al., 2018). Animal models have supported the role saturated fat may have in promoting bowel inflammation. Mouse models have demonstrated that a diet high in saturated fat, but not PUFA, increased the proinflammatory T-cell responses, as well as the incidence of colitis. This was thought to be due to the fat promoted taurine conjugation of bile acids facilitating an increased availability of sulfur to sulphite-reducing microorganisms such as *Bifidobacterium wadsworthii*, which is associated with intestinal inflammation (Devkota et al., 2012). Furthermore, mice fed a high fat-high sugar diet developed gastrointestinal dysbiosis characterized by increased proinflammatory microorganisms and decreased favorable SCFA that made them more susceptible to chemically-induced colitis (Agus et al., 2015). In another study, mice fed high fat diets had a reduced level of secretory immunoglobulin A coating the gut microbiota, which is an important component of gut barrier function (Muhomah et al., 2019).

\*Trials with small numbers, \*\* Autoimmune Protocol Diet, Specific Carbohydrate Diet and Mediterranean Diet show symptomatic benefit, but no objective improvement in inflammatory activity, \*\*\* Indicated in the management of IBD patients with concurrent functional symptoms during remission

**Fig. 3** Dietary influences on the risks of a person developing IBD, dietary measures used in its treatment and for the maintenance of remission. CD: Crohn's Disease, CDED: Crohn's Disease Exclusion Diet, CD-TREAT: Crohn's Disease Treatment-with EATING diet; a solid food-based diet designed to replicate the nutrients and food ingredients composition of Exclusive Enteral Nutrition, DHA: Docosahexaenoic Acid, EEN: Exclusive Enteral Nutrition, FODMAPs: Fermentable Oligosaccharides, Disaccharides Monosaccharides and Polyols, IBD: Inflammatory Bowel Disease, n-3: Describes the position of the double bond on carbon 3, counting the methyl carbon as carbon number 1, n-6: Describes the position of the double bond on carbon 6, counting the methyl carbon as carbon 1, PEN: Partial Enteral Nutrition, PN: Parental Nutrition, PUFA: Polyunsaturated Fatty Acid, UC: Ulcerative Colitis, Ultra processed foods: Formulations of ingredients made by a series of industrial steps that require sophisticated equipment and technology. They are aimed at making the final product hyperpalatable and with a long shelf life.

N-3 PUFAs typically from fish have anti-inflammatory functions. They are precursors to anti-inflammatory cytokines and suppress inflammatory T-cell responses (Chapkin et al., 2007). In contrast, it has been suggested that n-6 PUFA found in edible seed oils such as sunflower oil, serve as precursors to pro-inflammatory signaling molecules such as cytokines, prostaglandins and leukotrienes (Patterson et al., 2012) (Gonzalez-Becerra et al., 2019).

The data on the effect of fat intake on incidence of IBD are variable. Dietary intake of n-3 PUFA, n-6 PUFA and the ratio between them appears to be important in both IBD risk and disease control. Shoda et al. correlated the incidence of CD with population daily average nutrient intake in a Japanese population with minimal migration, and therefore stable genetics (Shoda et al., 1996). They found that the incidence of CD strongly correlated with the average daily intake of total fat, animal fat and n-6 PUFA (Shoda et al., 1996).

A case-control study in children found that a higher consumption of long chain n-3 FA and a higher ratio of dietary n-3:n-6 FAs was associated with a lower risk of CD (Amre et al., 2007). A nested case-control study within the EPIC cohort of 203,193 adults demonstrated an association between the consumption of dietary linoleic acid (C18:2, n-6) and an increased risk of UC, with an Odds Ratio (OR) of consumption in the highest vs. lowest quartile of 2.49 (95% CI 1.23–5.07,  $p = 0.01$ ) (Tjonneland et al., 2009).

With regards to UC, a prospective cohort study of 25,639 participants in the UK demonstrated that there was a protective effect of higher consumption of the n-3 PUFA docosahexaenoic acid (C22:6) and incidence of UC (John et al., 2010). A more recent meta-analysis of nine studies including 172,555 participants however, failed to demonstrate an association between fat intake or fat categories and UC risk (Wang et al., 2016).

Fat intake may modulate the risk of disease flare in those with established IBD. In a prospective study of 412 patients in remission from UC on Aminosalicilate, higher intake of the saturated FA myristic acid (C14:0, commonly found in coconut oil, palm oil and dairy products) was associated with an increased risk of a UC flare (OR 3.01, 95% CI 1.17–7.74) (Barnes et al., 2017). In a dietary intervention, 230 IBD patients who had been induced into remission via conventional pharmacotherapy were commenced on a dietary regimen that targeted a dietary fat intake with a n-3/n-6 ratio of 1. This was achieved through restricting the consumption of dietary sources of n-6 PUFA (in particular food rich in vegetable oil, e.g., mayonnaise and fried foods) and promoting the consumption of foods high in n-3 PUFA (such as salmon and sardines) (Uchiyama et al., 2010). Objective assessment of the n-3/n-6 ratio was achieved by analyzing the ratio between n-3 and n-6 FA in the erythrocyte membrane (an objective measure reflecting the ratio between these FAs in the diet). They found that those who maintained remission for at least 12 months had a significantly higher n-3/n-6 FA ratio than those who relapsed.

Studies examining dietary cholesterol consumption have not been conducted, though due to its presence in similar food groups, levels of consumption tend to mirror saturated FA intake, and as a result the stand-alone effect of cholesterol intake difficult to assess (Xu et al., 2018). No studies have specifically examined dietary intake of fat in the setting of active disease.

## Red meat

Red, but more significantly, processed meat consumption has been suggested to have proinflammatory effects in the gastrointestinal tract. Proposed mechanisms are the generation of DNA damaging amines in the cooking process, as well as the fermentation of meat derived protein by the gut microbiota to produce DNA damaging toxic substances such as ammonia, amines and nitrous compounds (Le Leu and Young, 2007; Sugimura et al., 2004; Lewin et al., 2006). Another contributing factor is the concurrent presence of saturated fat, emulsifiers and food additives in processed meats; with their established deleterious effects (Ge et al., 2015; Bancil et al., 2021; Narula et al., 2021).

Unprocessed red meat also showed evidence of harm in animal models. Li and colleagues reported that mice fed the diet highest in unprocessed red meat developed an altered microbiome in addition to increased intestinal permeability; they also suffered more severe colitis than mice fed a diet containing less red meat (Li et al., 2021).

A recent large prospective cohort study of 116,087 participants found that a processed meat intake of  $\geq 1$  serving (55 g) per day was associated with a higher risk of development of CD than an intake of  $\leq 1$  serve per week (HR 2.07, 95% CI 1.14–3.76) (Narula et al., 2021). No significant associations were found with the intake of unprocessed red or white meat intake and IBD risk. Another study that examined dietary factors in a cohort of 67,581 French women reported an association between a high animal protein intake, in the form of meat or fish rather than eggs or dairy, and an increased risk of IBD (third vs. first tertile of intake HR 3.31, 95% CI 1.45–6.34) (Jantchou et al., 2010).

The EPIC-IBD Cohort found that protein intake from an animal source, and meat consumption were associated with a higher risk of IBD, whereas protein intake from a vegetable source was not (Ge et al., 2015). This finding could be confounded by the protective effect of dietary fiber that accompanies the intake of vegetable based protein (Dong et al., 2020). Finally, a meta-analysis of nine studies investigating the associations between meat consumption and IBD risk found that red meat consumption was associated with an increased risk of IBD (RR 2.37, 95% CI 1.4–3.99), while white meat consumption was not (Ge et al., 2015).

Jowett and colleagues performed a prospective cohort study of 191 patients to determine dietary risk factors for relapse in UC (Jowett et al., 2004). They identified that the consumption of meat (OR 3.2, 95% CI 1.3–7.8), particularly red and processed meat (OR 5.19, 95% CI 2.1–12.9), was associated with an increased risk of relapse at 12 -months. A recent interventional study which randomized CD patients in remission ( $n = 214$ ) to consume a high meat ( $\geq 2$  serves per week) or a low meat ( $\leq 1$  serve/month) diet for 49 weeks revealed that relapse occurred in 62% of the participants in the high meat intake group and 42% in the low meat intake group, with the difference in relapse not reaching statistical significance between the groups ( $p = 0.61$ ) (Albenberg et al., 2019).

From a broader health perspective, the consumption of processed, and to a lesser extent, unprocessed red meat has been associated with detrimental health outcomes such as multiple forms of cancer, cardiovascular disease and dementia (Vernooij et al., 2019; Zhang et al., 2021; Huang et al., 2021). Conversely, the consumption of a vegetarian diet results in positive alterations to the gut microbiome compared with an omnivorous diet and has been associated with health benefits including reduced risk of ischemic heart disease and multiple types of cancer (Dinu et al., 2017). Semi vegetarian diets (SVD), which include infrequent consumption of meat, have been associated with similar health benefits, which may improve long term adherence (Derbyshire, 2016; Aykan, 2015).

There is promising data on the use of low meat, semi-vegetarian diets in maintenance therapy after medically or surgically induced remission in CD. Adherence to these diets are postulated to increase beneficial bacteria through the provision of fiber and prebiotic food (Chiba et al., 2015). The semi-vegetarian diet proposed includes red meat every 2 weeks, fish once a week and encourages daily consumption of brown rice, green tea, fermented foods, eggs, dairy products and vegetables. A pilot study of 22 patients reported an impressive 2-year clinical remission rate of 92% and diet adherence rate of 72% (Chiba et al., 2010). Studies in larger cohorts are necessary to verify this finding.

## Food additives

### Emulsifiers

Emulsifiers are over 60 different food additives that are used to stabilize the consistency of food products and prevent unappetizing separation of oil and water in the product (Bancil et al., 2021). Emulsifiers lengthen the shelf life and optimize the appearance and texture of food and have become an integral part of the “Western” diet which is rich in heavily processed food. Examples include lecithin found in chocolate, xanthan gum found in mayonnaise, carrageenan found in flavored milks and polysorbates found in ice cream (McClements, 2016; Cox et al., 2021).

An eloquent review by (Bancil et al., 2021) and colleagues summarized the many studies in animal models that have demonstrated the impact of emulsifiers on intestinal inflammation, which include: decreasing microbial diversity, reducing mucus thickness, increasing bacterial encroachment on the epithelium, increasing intestinal permeability and inducing the production of pro inflammatory mediators in the gut. The addition of emulsifiers such as carrageenan and methylcellulose to the diet have also been found to increase risk and severity of colitis in animal models. It should be acknowledged that the experimental doses of emulsifiers used in these animal models can be much higher than average human consumption, although this limitation may be mitigated by the fact that studies in animal models test the acute effect of emulsifiers, whereas the intake in humans is over many years and therefore the cumulative dose in the human diet is likely to exceed the doses tested in animals, although not directly comparable.

An in vitro model which stimulated the lumen-associated and mucus associated human intestinal microbial ecosystems, termed the “mucosal simulator of the human intestinal microbial ecosystem” (M-SHIME) was generated. Its design utilized a series of pH and temperature-controlled vessels that were inoculated with human fecal suspension and maintained to mimic conditions of the human GI tract. When polysorbate 80 (P80) was added to this model there was a 50% decrease in microbial species diversity and an increase in microbial genes coded for flagellin expression which is a marker of bacterial adhesion and invasion that can directly activate an inflammatory response. Transfer of the emulsifier treated M-SHIME microbiota into a germ-free mouse host increased IL-6 (a pro inflammatory cytokine) expression suggesting that host-microbial interactions may be responsible for driving intestinal inflammation (Chassaing et al., 2017).

In a study of patients with CD vs. healthy controls it was found that patients with CD demonstrated an increased expression of malX gene (essential for maltodextrin metabolism), which has been associated with E Coli adhesion and postulated to be a driver of inflammation (Nickerson and McDonald, 2012). This suggests a mechanism by which Western diets and the consumption of food additives may promote dysbiosis and contribute to the initiation and perpetuation of disease in susceptible populations.

A large prospective cohort study of 116,087 participants, spanning seven geographical regions examined the association between the consumption of a diet rich in ultra-processed food and incident CD. Ultra-processed food includes all types of packaged and formulated foods that contain emulsifiers, flavorings, colors and thickeners used in processed meat, sauces, mass produced biscuits and pastries, see glossary for formal definition (Monteiro et al., 2019). They found that the consumption of  $\geq 5$  serves of ultra-processed food per day was associated with an increased risk of CD with a HR of 1.83 (95% CI 1.22–2.72) (Narula et al., 2021). Roberts and colleagues also demonstrated a positive correlation between emulsifier consumption and incidence of CD (Roberts et al., 2013).

A double blind randomized controlled study was conducted in 12 patients in remission from their UC (Bhattacharyya et al., 2017). For 12 months all participants were instructed to follow a “no-carrageenan diet,” while 5 were randomized to receive 200 mg/day carrageenan capsules, the other 7 were randomized to a placebo dextrose tablet. Three of the 5 patients receiving the carrageenan capsules relapsed vs. none of the 7 randomized to receive the placebo capsules ( $p = 0.046$ ). The carrageenan group also had a significant increase in circulating IL-6 levels and fecal calprotectin between the beginning and the end of the study, while the placebo group did not. This is a very small study that supports the notion that carrageenan may impact the risk of disease relapse.

On the other hand, while food additive consumption in the context of whole foods common in Western diet may increase the incidence of IBD, formulas used in Exclusive Enteral Nutrition (EEN), an effective treatment for CD outlined in further detail below, all contain food additives such as modified food starch, inorganic phosphates, maltodextrin and carrageenan, yet have positive clinical efficacy in active disease (Logan et al., 2020). This challenges the perception that these ingredients are universally harmful.

### Nanoparticles

Titanium dioxide nanoparticles are widely used as food additives and in pharmaceutical products. Ruiz and colleagues demonstrated in a mouse model as well as ex vivo that administered titanium dioxide nanoparticles accumulated in intestinal epithelial cells (IECs) and resulted in increased intestinal permeability and worsened acute colitis through a mechanism involving the NLRP3 inflammasome (Ruiz et al., 2017). An increased titanium level was found in the blood of patients with active UC. A pilot study of 20 patients with active ileal or ileocolonic CD were treated with standard corticosteroids at the clinicians' discretion. Patients were randomized to two groups, the first group was given advice to exclude food and pharmaceuticals that contained nanoparticles in addition to recommendation to avoid fibrous fruit and vegetables, which was part of standard dietary advice for CD at the time. The control group were given standard dietary advice alone. At 4 months there was a significant improvement in the Crohn's Disease Activity Index (CDAI) in the treatment group. (Lomer et al., 2001). A larger study including 88 IBD patients did not replicate these findings (Lomer et al., 2005).

### Malnutrition assessment and management considerations in IBD

Malnutrition is more common in IBD patients than in the general population, with an adjusted OR of 5.57 (Nguyen et al., 2008). When compared to the Australian Nutrient reference values, the most significantly deficient macro and micro nutrients consumed in people with IBD include total energy, fiber, folate, calcium; in particular consumption from the food groups of breads, cereals, legumes, fruit, vegetables and dairy (Lambert et al., 2021). As outlined in the European Society for Clinical Nutrition and Metabolism (ESPEN) guidelines on clinical nutrition in IBD (Bischoff et al., 2020), malnutrition presents as a more common issue in CD than UC given its ability to affect any part of the gastrointestinal tract, whereas UC is limited to the colon and has fewer direct malabsorptive effects. Malnutrition is most prevalent in active disease and is associated with a worse prognosis when present; with increased rates of hospitalization, surgery, and mortality (Nguyen et al., 2008; Gajendran et al., 2016; Wallaert et al., 2012). Assessment of energy, macro- and micro-nutrient intake requires screening, assessment and management to prevent inadequate intake, which can lead to sequelae such as loss of muscle mass, osteoporosis and, in the setting of the pediatric population, sub optimal growth and development.

### Macronutrient deficiencies

For malnutrition to be managed, it first must be recognized. There are two malnutrition screening tools (NST) that have been designed for use in the IBD population. Several NSTs designed for use in broader population groups have been validated in IBD populations, where associations with clinical outcomes such as flares, hospitalization and need for surgery have been identified, see Table 3 for NSTs and their components (Russell et al., 2022; Li et al., 2019; Elia, 2003; Haskey et al., 2018; Kondrup et al., 2003; Jansen et al., 2016; Sumi et al., 2016). The Malnutrition Universal Screening Tool (MUST) is one such screening score, which considers Body Mass Index (BMI), weight loss, patient overall wellbeing and food intake and has been shown to be an accurate patient administered screening tool and can be carried out prior to their clinic review, which increases its ease of utilization (Sandhu et al., 2016). Once a patient is identified as being at risk, a more detailed and time consuming nutrition assessment tools (NAT), such as the Subjective Global Assessment (SGA) can be utilized for more detailed objective measurement (Detsky et al., 1987; Garry and Vellas, 1999). Limited data has shown that the scores obtained from the briefer nutrition screening tools associated well with a diagnosis of malnutrition compared with the more resource heavy and time consuming assessment tools (Li et al., 2019).

When protein calorie malnutrition is detected, oral nutritional support in the form of supplements or EEN are the preferred options in the setting of macronutrient deficiency and active disease. During active disease there is a proteolytic and catabolic response, as such there is a recommendation for an increase in daily protein intake from 1 g/kg/day to 1.2–1.5 g/kg/day (Bischoff et al., 2020). Outside of this setting, broad energy requirements and dietary recommendations are similar to those of the healthy population; i.e., there is no such thing as an “oral IBD diet” that can generally be recommended to promote remission, however, some of the approaches trialed and supporting data are outlined in following sections (Bischoff et al., 2020).

Under nutrition can negatively impact surgical outcomes. It is therefore recommended that patients with severe nutritional risk, defined as a weight loss >10–15 kg in the last 5 months, BMI <18.5 kg/m<sup>2</sup> and/or albumin <30 g/L, should receive nutritional therapy prior to surgery to optimize outcomes (Bischoff et al., 2020).

A large study conducted in the USA found that even after adjusting for confounding factors such as malnutrition, surgery, age and comorbidity; the use of Parenteral Nutrition (PN) had a 2.5- fold higher odds of death and a twofold increase in length of hospital stay compared to enteral nutrition (Nguyen et al., 2007). Consequently, PN is reserved for those who have the most complicated disease, such as those who have decreased gut absorptive capacity (short gut), specific surgical cases of bowel obstruction, those who have attempted, but are intolerant to or cannot meet their nutritional requirements with Enteral Nutrition (EN) alone (Bischoff et al., 2020).

### Micronutrient deficiencies

Micronutrient deficiencies can present with a vast array of signs and symptoms which can be screened for via taking a patient history, however, the most accurate way to assess for most deficiencies is via a blood test to quantify the serum level of the micronutrients

**Table 3** Nutrition screening tools and nutritional assessment tools used in assessment of patients with IBD.

Name	History	Examination	Investigations	Comment
Malnutrition Universal Screening Tool (MUST) (Elia, 2003; Sandhu et al., 2016)	<ul style="list-style-type: none"> <li>Unintentional weight loss last 6 months as (% of initial body weight)</li> <li>Acute illness</li> <li>Adequacy of food intake over last 5 days</li> </ul>	Height Weight BMI		<ul style="list-style-type: none"> <li>Designed for IBD cohort</li> <li>Recommended for the ambulatory care setting</li> <li>Has been validated as a patient collected pre clinic screening tool to improve efficiency (Sandhu et al., 2016)</li> <li>Designed for IBD cohort</li> <li>Omits BMI: Felt to be a poor marker of malnutrition risk</li> </ul>
Saskatchewan IBD-Nutrition Risk Tool (SK-IBD) (Haskey et al., 2018)	Questionnaire: <ul style="list-style-type: none"> <li>Experienced GI symptoms for &gt;2 weeks</li> <li>Unintentional weight loss in last month</li> <li>Eating poorly due to decreased appetite</li> <li>Restriction of food groups</li> </ul>			
Nutritional Risk Screening 2002 (NRS-2002) (Kondrup et al., 2003)	<ul style="list-style-type: none"> <li>Food intake as a % of normal in last week</li> <li>Severity of disease: (mild, moderate, severe)</li> </ul>	Height Weight BMI		Correlates with clinical outcomes in IBD (Li et al., 2019)

that are present in the vascular compartment. When interpreting blood results of micronutrients and trace elements it is important to consider that serum values may be increased or decreased by a change in inflammatory activity and this can impact the interpretation of results in this context (Dingnass et al., 2015; Bischoff et al., 2020). For summary of important micronutrients and suggested indications for testing see Table 4.

### Iron

Iron deficiency anemia is a common form of anemia in IBD patients with active disease and can be caused by blood loss from mucosal inflammation, malnutrition with reduced iron intake or impaired uptake through the duodeno-jejunal mucosa (Dingnass et al., 2015). It should be screened for at least every 3-months with a ferritin level during periods of active disease (Bischoff et al., 2020). In the presence of inflammation, a serum ferritin of <100 µg/L may be considered indicative of iron deficiency and supplementation is warranted. ECCO guidelines recommend IV replacement due to its superior speed of replacement and tolerability compared to oral iron (Dingnass et al., 2015). Oral iron can be considered in those with clinically inactive disease, mild deficiency and those who have not been intolerant to oral iron (See Table 3).

### Vitamin B12

A systematic review of the literature has demonstrated that the primary risk factor for Vitamin B12 deficiency in IBD is ileal resection or areas of small intestinal disease >20 cm (Duerksen et al., 2006). UC does not predispose to deficiency with the possible exception of deficiency following restorative proctocolectomy (Battat et al., 2014). Patients with risk factors for B12 deficiency should be screened annually.

Administration of vitamin B12 via the intramuscular route to replace and maintain vitamin B12 levels is the current standard of care, however delivery via the oral and sublingual route is being increasingly explored and practice may change in the coming years (Bischoff et al., 2020; Gomollon et al., 2017). If vitamin B12 levels are low in patients without these IBD specific risk factors for deficiency then an alternative explanation such as autoimmune gastritis should be sought (Battat et al., 2014).

### Folate

Folate is present in animal and plant foods and fortification in food is now common practice in bread and breakfast cereal (NHMRC, 2006; Zealand, 2016). Folate is absorbed in the proximal small intestine which is a less common site of CD related inflammation, but deficiency can be contributed to by therapeutic agents such as sulfasalazine and methotrexate. A study of 257 patients with IBD vs. healthy controls demonstrated that patients with CD, in particular with disease duration of >5 years had lower folate levels than those patients with UC and healthy controls (Huang et al., 2017). A meta-analysis also demonstrated that serum folate concentrations were lower in IBD patients, interestingly, this was more marked in patients with UC in this study (Pan et al., 2017).

No guidelines surrounding routine testing are available, however, it would be logical to test in patients with risk factors for deficiency or patients who would face significant complications of deficiency such as those on sulfasalazine or Methotrexate, patients with malnutrition and pregnant patients with IBD.

### Calcium

It is clear from large population based studies that IBD is associated with an increased risk of osteoporosis and osteopenia, resulting in an elevated incidence of low trauma fractures (Etzel et al., 2011; van Staa et al., 2003). Fracture propensity is increased by chronic inflammation, corticosteroid use, vitamin D deficiency and low dietary calcium intake (Vernia et al., 2013).

Serum calcium concentrations are kept at a tight set point via hormonal pathways, including parathyroid hormone, vitamin D and fibroblast growth factor 23. These mechanisms result in mobilization of skeletal calcium and resorption of calcium from the distal nephron of the kidney to maintain consistent serum calcium levels. As such, serum calcium measurements are not helpful in assessing the adequacy of a patient's calcium status (Houillier et al., 2005).

The minimum recommended daily calcium intake is 1000 mg for men and pre-menopausal women and 1300 mg for post-menopausal women and men >60 years (NHMRC, 2006). There are helpful online calculators such as the tool available from the International Osteoporosis Foundation that can assist in assessing sufficiency of dietary calcium intake (International Osteoporosis Foundation, 2022). A large study assessing calcium intake in patients with IBD compared with healthy controls found the intake of calcium was significantly lower in the IBD group and below minimum dietary recommendations in one-third of patients (Vernia et al., 2013). Self-reported lactose intolerance leading to dietary restriction was a major contributing factor. Low calcium intake represents a reversible risk factor for osteoporosis. Corticosteroids can also reduce calcium absorption from the gut and increase urinary losses leading to secondary hyperparathyroidism with a resultant increased bone resorption (Lamb et al., 2019).

Oral calcium supplementation should be taken with caution following a long-term cohort study that demonstrated that a calcium intake of >1400 mg daily was associated with an increase in all-cause mortality, in particular cardiovascular disease and ischemic heart disease (Michaelsson et al., 2013). This was most marked in people with a high dietary calcium intake plus oral supplementation rather than a high dietary calcium intake alone. As such, long term calcium supplementation is not recommended unless dietary calcium intake is <800 mg/day (Lamb et al., 2019). The suggested dose of daily oral calcium supplement in IBD patients with insufficient dietary intake is 500–1000 mg/day (Harbord et al., 2015).

**Table 4** Key points in assessment and management of micronutrient deficiencies.

Vitamin/minerals	Blood test frequency in active disease	Blood test frequency in remission	Route of replacement	Comment
Iron	3 monthly 3-monthly during pregnancy, even in IBD remission (Bischoff et al., 2020)	6–12 monthly	Oral if: - Clinically inactive disease - Mild deficiency - Tolerate oral IV if: - Active IBD - Intolerant to oral - Hb <100 g/L (Dingnass et al., 2015)	Ensure bloods are interpreted in the context of disease activity: In active disease: Ferritin <100 µg/L considered deficient In remission: Ferritin <30 µg/L considered deficient
B12	If clinical symptoms suggestive of deficiency or anemia	Annually if risk factors present	If deficient: 1000 µg intramuscularly second daily for 2 weeks then monthly indefinitely If >20 cm small bowel resection: 1000 µg intramuscularly monthly indefinitely (Bischoff et al., 2020) High dose oral therapy and sublingual routes of delivery being explored (National Institutes of Health, 2022)	Patients at increased risk of deficiency: - Ileal resection or active disease >20 cm sbnd UC with restorative proctocolectomy (Duerksen et al., 2006; Battat et al., 2014) in patients with low levels and no risk factors, alternative causes such as AI gastritis should be considered
Folate	No guidelines but consider in those with risk factors: - Malnutrition - Sulfasalazine or Methotrexate therapy - Disease duration >5 years - Pregnancy (Bischoff et al., 2020)	No guidelines, annual test alongside B12 or if a patient develops anemia or symptoms suggestive of deficiency	Oral	Monitor and supplement in women contemplating pregnancy and breastfeeding. In particular, supplement those taking Sulfasalazine
Vitamin D	3 monthly	Annually	Oral replacement, dose guided by degree of deficiency	
Calcium	Guided by dietary assessment rather than bloods (Houillier et al., 2005) Helpful assessment tool: (International Osteoporosis Foundation, 2022)	Serum calcium level does not reflect stores and does not fluctuate with changes in calcium intake	Diet: minimum recommended daily calcium intake is 1000 mg for men and pre-menopausal women and 1200–1500 mg for post-menopausal women and men >60 (NHMRC, 2006) Oral supplementation if dietary calcium intake is <800 mg/day, max dose 1000 mg/day. (Harbord et al., 2015)	
Zinc	3 monthly (Siva et al., 2017)	Annually	Dietary replacement Consider oral supplementation if deficient and unable to meet dietary requirements	Limited evidence, based on clinical experience

### Vitamin D

The National Osteoporosis Society (UK) and ESPEN guidelines recommend that vitamin D be checked and replaced according to standard clinical cut offs in those with malabsorptive conditions such as IBD, in order to optimize bone health. This is particularly pertinent in those with additional risk factors for low Bone Mineral Density (BMD) and fracture risk such as female gender, Asian ethnicity and significant cumulative corticosteroid use (Francis et al., 2015; Bischoff et al., 2020).

Vitamin D is also thought to have immunomodulatory properties including antibacterial and anti-inflammatory actions on cells from the innate and adaptive immune system that modulate gastrointestinal inflammation as well as having a role in the maintenance of gastrointestinal mucosal barrier function (Fletcher et al., 2019). It is postulated that deficiency may contribute to increased IBD disease activity (Ham et al., 2014). This proposition was supported in a study of 70 UC patients in remission which demonstrated that those who had vitamin D levels lower than a cut off of 35 nmol/L were at a higher risk of flaring within the following 12-months than in patients with a level above this threshold (Gubatan et al., 2017). In practice, monitoring of Vitamin D on an at least annual basis for those in remission and 3-monthly in individuals who are at risk of deficiency is logical, with replacement therapy initiated as appropriate (Ananthakrishnan, 2016; Pirotta et al., 2019).

### Zinc

Zinc is an essential trace element which is absorbed predominately in the proximal small intestine and is proposed to have immunoregulatory properties as well as decreasing the severity of colitis in animal models (Maares and Haase, 2020). There is evidence from a prospective registry of 996 patients with IBD that there is an association between zinc deficiency and disease related complications such as hospitalization and surgery and those who normalized their zinc over serial measurements had improved outcomes (Siva et al., 2017). Patients with CD, even in remission consume diets lower in zinc, with a prevalence of deficiency ranging from 15 to 40% (Taylor et al., 2018; Siva et al., 2017).

The question of causation vs. association remains, however, to replace deficiencies, if found, seems appropriate. There are no guidelines around testing for zinc deficiency in active disease nor remission.

Malnutrition in IBD key points:

- More common in CD than UC and relates to extent of disease
- Most prevalent in active disease
- A result of anorexia, reduced small bowel absorption
- Confers a poorer prognosis
- Screen at diagnosis and during periods of increased disease activity
- Broad macronutrient nutritional recommendations are the same for IBD as the general population however protein requirements are increased to 1.2–1.5 g/kg/d in active disease
- Oral nutrition, be it by food or EN formulas is preferred, PN should be reserved as last resort
- Consider micronutrient deficiencies: see Table 3 for further detail.

## Diet as therapy for active disease in IBD

There are several prescriptive dietary approaches that have been studied for use in clinical practice to manage IBD flares (See Table 5 for summary of approaches, key inclusions and exclusions and relevant trial data). Due to the restrictive nature of these dietary regimens, they are largely reserved for the most unwell patients or those wanting to avoid the use of steroid-based medications, particularly children in whom steroids can impact growth trajectory (Ajebab et al., 2017).

### Exclusive Enteral Nutrition (EEN)

EEN is a treatment strategy which has been shown to be effective in patients with CD, with sparse data in UC. EEN involves the use of a complete liquid formula that provides all the patient's nutritional requirements as the sole source of food. EEN can be given orally or via a nasogastric tube (NGT) (Mitreva et al., 2021; van Rheenen et al., 2020; Fardet et al., 2012). The proposed mechanism by which EEN improves outcomes in CD includes: improved nutritional parameters; modification of the gut microbiome with reduced antigenic stimulus driving inflammation; and increased expression of tight junction proteins between epithelial cells reversing the increased permeability to intestinal bacteria, which is seen in patients with CD (Mitreva et al., 2021).

The use of EEN in place of corticosteroids avoids the deleterious impacts of steroids, such as increased infection risk, decreased bone mineral density, hypothalamic-pituitary-adrenal axis suppression, mood and cognitive changes, altered glycemic control and acne (Patschan et al., 2001; Prantera and Marconi, 2013; Narula et al., 2018). EEN is usually given for 6–8 weeks during an acute flare of CD, with the aim of inducing remission. EEN may also be considered in the preoperative setting or in the context of fistulizing or stricturing disease as an alternative to corticosteroids which have been shown to increase the risk of perioperative infection and anastomotic break down with a higher doses conferring a greater risk of these complications (Subramanian et al., 2008).

The role of EEN in the treatment algorithm for IBD is influenced by the age of the patient, with significantly more data to support its use available in the paediatric population.

**Table 5** Elimination diets proposed for use in the treatment of active CD.

<i>Diet name</i>	<i>Components excluded</i>	<i>Components allowed</i>	<i>Key study findings</i>
Autoimmune protocol (AIP)	Refined sugars, gluten, grains, legumes, nightshades (e.g., potato, tomato, capsicum, eggplant), dairy, eggs, coffee, alcohol, nuts, seeds, oils, food additives (Konijeti et al., 2017) 6-week elimination 5-week maintenance Staged re introduction	Fresh foods, bone broth, fermented food (Konijeti et al., 2017)	Prospective active disease, CD and UC N = 15 Concurrent medication use No control arm Outcomes: clinical parameters: improved biochemical and endoscopic assessments: trends to improvement did not reach statistical significance Adverse events: increase symptoms and SBO in patients with known small bowel strictures (Konijeti et al., 2017)
Anti-inflammatory Diet (IBD-AID)	Refined sugar, gluten containing grains, lactose, saturated fat (Olendzki et al., 2014)	Pre biotic and pro biotic foods including soluble fiber (e.g., encouraged: Leeks, onions, fermented foods, banana, oats, flaxseed meal, legume flour lean meat, poultry, fish) Textures altered according to symptoms and advanced as tolerated (Olendzki et al., 2014)	Retrospective case series N = 27 No control arm UC and CD active disease 4 weeks of intervention 24 out of 27 had a clinical response All patients able to discontinue at least one IBD medication and clinical parameters were improved No biochemical or endoscopic measures assessed (Olendzki et al., 2014)
Specific Carbohydrate Diet (SCD)	Complex carbohydrates, lactose Sucrose (e.g., table sugar), Maltose (e.g., wheat and grains) Grains Potato Soy Preservatives and processed foods (Cohen et al., 2014)	Monosaccharides e.g., honey Homemade fermented (lactose free) yogurt Low lactose dairy Most fresh fruits Most non starchy vegetables Eggs Oil (Cohen et al., 2014)	Patient surveys, retrospective case series and case reports in patients with UC and CD demonstrate improvement in clinical parameters of up to 42% at 12 months (Kakodkar et al., 2015; Suskind et al., 2016) Prospective pediatric cohort with active CD N = 9 Lead to improvement in clinical scores as well as capsule endoscopy activity scores at 12 and 52 weeks (Cohen et al., 2014) Adverse impacts: below recommended calcium intake (Kakodkar and Mutlu, 2017; Sasson et al., 2021)
Mediterranean Diet (MD)	Moderate consumption of: diary Alcohol: wine, with meals Low consumption of: Meat Saturated fat (Lewis et al., 2021; Hoevenaar-Blom et al., 2012)	Fresh fruit Vegetables Legumes Nuts Fish Wholegrains Olive oil predominant fat source (Lewis et al., 2021; Hoevenaar-Blom et al., 2012)	Equivalent to the more restrictive SCD in symptomatic improvement measured by CDAI (Lewis et al., 2021)

CD: Crohn's Disease, CDAI: Chron's Disease Activity Index, IBD: Inflammatory Bowel Disease, n: number, SBO: Small Bowel Obstruction, UC: Ulcerative Colitis.

Sci. 61, 3255–3260.

### ***Pediatric cohort***

In pediatric patients EEN is first-line standard of care for induction of remission of CD and the effectiveness of EEN has been examined in several large meta-analyses (Swaminath et al., 2017; Narula et al., 2018; van Rheenen et al., 2020; Yu et al., 2019). EEN was found to be at least as equivalent to corticosteroids in achieving clinical remission and normalizing of biomarkers C-reactive protein (CRP) and Fecal Calprotectin but more effective at achieving mucosal healing and histological remission than corticosteroids. The use of EEN also avoids the additional pediatric specific corticosteroid side effects of slowed growth trajectory and development (Lo et al., 2020; Ajebab et al., 2017).

It should be noted that despite its clinical benefits, patients on EEN were more likely to withdraw from allocated treatment than those on corticosteroids (23% vs. 6%). The reasons cited include: unpalatable formulations, poor acceptance of NGT and side effects such as diarrhea and vomiting (Narula et al., 2018). There is some evidence that EEN is more effective in treating newly diagnosed CD rather than patients with established disease (Frivolt et al., 2014). A case review of 27 Australian children with CD managed with EEN reported 12/15 (80%) of newly diagnosed CD patients entering clinical remission after 8 weeks of EEN, compared with 7/12 (58%) of children with longstanding disease (Day et al., 2006).

### ***Adult cohort***

The data supporting the use of EEN in the adult population is more contentious (Sasson et al., 2021; Wall et al., 2013). A systematic review found that corticosteroids were more effective than EEN in induction of clinical remission (73% vs. 45%), though the evidence was low quality (Narula et al., 2018). Another older but relatively large (n = 107) multi-center study of adult patients with active Crohn's showed lower rates of clinical remission in the EEN group compared with corticosteroid plus sulfasalazine, (53% vs. 79%,  $p < 0.001$ ) and the median time to remission was substantially longer with dietary therapy than steroids (30.7 days with EEN vs. 8.2 days with medical therapy) (Lochs et al., 1991). Further research with larger cohorts is required, particularly given the nature of the intervention, where blinding is not possible.

### ***Complicated CD: fistulizing and stricturing disease***

Several small, largely observational studies have demonstrated the benefit of EEN in fistulizing and stricturing disease. In patients with both luminal and enterocutaneous fistulae the delivery of EEN has been shown to induce both symptomatic and radiologic remission and even result in cutaneous fistula closure in up to 62% of patients (Yan et al., 2014; Hu et al., 2014; Yang et al., 2017). As a preoperative intervention EEN has been shown to decrease surgical time, length of hospital stay and risk of post-operative complications as well as reduce the risk of endoscopically detectable post-operative recurrence at 6 months (Li, G. et al., 2014; Li, Y. et al., 2015; Ge et al., 2019). A study examining the effectiveness of EEN prescribed for preoperative optimization in patients with stricturing or penetrating disease found it was so effective that up to 25% of patients no longer required surgical intervention and were able to remain controlled with medical management (Heerasing et al., 2017).

### ***Use of EEN in UC***

Early publications discounted the role of EEN in UC and as a result the literature has largely focused on its use in CD (Shaoul et al., 2018). Studies in pediatric populations have indicated that the clinical EEN response rates were no worse in patients with a colonic distribution of CD, giving promise to its use in UC, which has a solely colonic distribution (Buchanan et al., 2009; Shaoul et al., 2018). With this in mind, a recent single center open label randomized controlled trial (n = 62) looking at the use of EEN in addition to standard of care (SOC) in patients with Acute Severe Ulcerative Colitis (ASUC) was designed (Sahu et al., 2021). SOC was consistent with the ECCO guidelines and included intravenous corticosteroids and initiation of rescue therapy on day 5 (Infliximab or Ciclosporin) if Oxford criteria were met (Harbord et al., 2017). Decision and timing of colectomy followed a joint patient-medical-surgical team assessment. It was found that compared to SOC, the EEN group had a higher response rate to corticosteroid therapy that reached statistical significance on per protocol analysis (per protocol analysis corticosteroid failure in EEN group 19% vs. SOC 43%,  $p = 0.04$ ). Response rates to rescue therapy rate of colectomy index admission were equivalent. Rates of subsequent hospitalization or colectomy at 6 months were lower in the EEN group (EEN 16%, SOC 39%,  $p = 0.045$ ). This gives promise to the use of EEN in UC patients with ASUC, but more research in this group of patients is warranted.

### ***Differences between EN formulas***

Enteral nutrition has been used in various forms, all preparations contain protein, fat and carbohydrate, but are classified based on the protein constituent of the formula; primarily elemental, semi-elemental and polymeric (Limketkai et al., 2019). In addition to their carbohydrate and fat components, elemental formulas are a mixture of single amino acids that are broken down to their simplest form, theoretically making them easier to digest and entirely antigen free. Semi-elemental formulas are made with protein hydrolyzates and have a mean peptide chain length of 4–5 amino acids, which are partially predigested and too short for antigen recognition. Polymeric formulas contain whole protein from sources such as milk, egg and soy that do require digestion and have antigenic potential (Narula et al., 2018). Polymeric formulas are considered more palatable and cost effective (Mitreva et al., 2021). A meta-analysis of 11 trials including 378 patients (both adult and pediatric) demonstrated no significant differences between elemental and non-elemental (semi-elemental and polymeric) diets for active Crohn's disease in remission rates (64% vs. 62%) or adverse event rates (17% in both groups) (Narula et al., 2018). A study which examined the compositional analysis and evidence of efficacy of 61 formulas demonstrated that despite their significant variability in composition, they produced similar rates of

remission (Logan et al., 2020). This suggests that no specific formula type is superior to another, and formula selection should be based on local availability, cost and palatability.

### EEN key points

- There is good evidence to show that EEN is superior to corticosteroids in treatment of active CD in children, as supported by the current guidelines.
- Minimal data for use in UC but further trials warranted
- It may be more effective in the earlier stages of the disease
- In adults, EEN does not appear to be superior to corticosteroids but its side effect profile is favorable and maybe considered in those who have contraindications to corticosteroids.
- EEN also appears to be beneficial in stricturing and fistulizing CD in the preoperative setting
- There does not appear to be a difference in clinical benefit between the type of EEN and the focus should be on the palatability to improve adherence to the regimen.

### Partial Enteral Nutrition (PEN)

The limited tolerability of EEN led to the trial of approaches to improve adherence to therapy. Partial Enteral Nutrition (PEN) is a diet that combines EEN with an unrestricted oral diet. Unfortunately, PEN does not seem to be as effective in treating active disease as EEN. In an observational study of 90 children with active CD who were allocated to PEN with unrestricted diet, EEN or anti-TNF at the clinician's discretion, fecal calprotectin reductions to  $<250 \mu\text{g/g}$  and rates of clinical response were measured by Pediatric disease indices. A fecal calprotectin level of  $250 \mu\text{g/g}$  was selected as an appropriate cutoff as this has previously been shown to correlate well with endoscopic remission in CD (D'Haens et al., 2012). The improvements in these parameters were less in the PEN group compared to those receiving EEN and anti-TNF therapy (FC to  $<250 \mu\text{g/g}$  PEN 14%, EEN 45%, anti-TNF 62%,  $p < 0.001$ , clinical response PEN 64%, EEN 88%, anti-TNF 84%,  $p = 0.08$ ) (Lee et al., 2015). In a randomized trial of 50 children with active CD, EEN was compared to PEN. The remission rates, were significantly lower in the PEN group (15% vs. 42%  $p = 0.035$ ) and only the EEN group demonstrated improvements in biochemical indices of hemoglobin, ESR and albumin (Johnson et al., 2006).

Despite the lack of efficacy of PEN in active CD, it does show promise as an adjunct to medical therapy in both induction and maintenance phases of disease management. In a retrospective study of 47 children who were in remission after EEN, those who continued nocturnal supplementary PEN feeds in addition to an unrestricted daytime diet were compared to those who ceased the PEN feeds. The relapse rate at 12-months was significantly higher in the group that were on normal diet alone compared to the children who continued supplemental overnight feeds (79% vs. 42%,  $p < 0.02$ ) (Wilschanski et al., 1996). It should be noted that this was in an era prior to the widespread availability of maintenance therapy. A randomized controlled study of 51 Japanese adults with CD in remission on maintenance therapy with mesalazine with or without azathioprine was conducted. One group were instructed to consume half their daily estimated calories via elemental diet, with the remainder via an unrestricted diet; while the control group continued unrestricted diet alone. They observed a lower relapse rate in the patients on PEN vs. standard diet (34.6% vs. 64.0% HR 0.4, 95% CI 0.16–0.98) (Takagi et al., 2006). In another prospective study of 39 adult patients with CD in remission and on PEN of 35–50% of their daily estimated energy intake plus standard medical therapy (5-ASA  $\pm$  Azathioprine and Prednisone) for CD demonstrated a higher clinical remission rate at 12 months compared with patients on standard therapy in the intention to treat analysis 48% vs. 22% ( $p = 0.0003$ ) (Verma et al., 2000).

A meta-analysis of four studies in Japanese patients with active CD ( $n = 342$ ) compared treatment using PEN (at least 600 kcal/day of formula) in addition to Infliximab induction therapy vs. Infliximab monotherapy without dietary restrictions. It found that the addition of PEN to Infliximab monotherapy resulted in a higher rate of clinical remission (69.4% vs. 45.4%,  $p < 0.01$ ) which was sustained at the 1 year follow up (75.4% vs. 49.2%,  $p < 0.01$ ) (Nguyen et al., 2015). These studies need to be confirmed in a broader patient cohort to determine the generalizability of this strategy.

### PEN with restricted diet- Crohn's disease exclusion diet (CDED)

It was postulated that the unrestricted nature of the whole food diet component of the PEN approach may have contributed to its failure as a treatment strategy to induce remission, suggesting that the mechanism of EEN depends on the exclusion of specific components of a free diet as opposed to the sole beneficial effect of the enteral nutrition alone. To address this, the Crohn's disease exclusion diet (CDED) was designed. It aimed to exclude dietary components that are hypothesized to degrade the mucus layer and increase intestinal permeability. Excluded foods include foods containing animal fats, gluten, maltodextrin, emulsifiers, sulfites and certain monosaccharides. A CDED also mandates the consumption of certain fruits (e.g., bananas and peeled apple) and animal source protein as well as food containing resistant starch (e.g., peeled fresh potatoes) (Sigall-Boneh et al., 2014).

A CDED has shown promise in a difficult to treat patient cohort, many of whom had undergone previous resections and despite co therapy and dose escalation had failed biologic therapy. In a retrospective cohort of 21 adult and pediatric patients treated with combined enteral nutrition and CDED, at the end of 6-week treatment regimen 61.9% of patients were in clinical remission and biochemical parameters had also improved (Sigall Boneh et al., 2017). A follow up study in 74 pediatric patients with CD that looked at two groups over two phases was performed. The first group had CDED with 50% EN for 6-weeks followed by CDED

with 25% EN for 6 weeks. The second group had EEN for 6 weeks followed by an unrestricted diet and 25% EN for 6 weeks. The CDED group had improved treatment tolerability (97.5% vs. 73.6%,  $p = 0.002$ ). At week 6 the response rates in both groups were 75%. At week 12 the CDED group had a remission rate of 75% and a sustained reduction in CRP and fecal calprotectin, whereas the group where free diet had been re-introduced had a remission rate of 45.1% (Levine et al., 2019). These studies are small but do give promise to the concept that PEN plus a more select diet may be a plausible treatment strategy in patients with CD.

### PEN key points

- Unrestricted Diet with PEN is not as effective as EEN in induction of remission
- Unrestricted Diet with PEN is an effective adjuvant to standard therapy in improving response rates to biological therapy and in maintenance of remission
- The use of CDED in conjunction with PEN may improve the efficacy of this approach in active disease

### Targeted CDED

Although EEN is successful at achieving mucosal healing, its patient acceptability is limited which can reduce its utility in the real-world setting. Using PEN with an unrestricted diet to induce remission does not seem as effective as EEN and the need to continue supplement drinks for an extended period may impact upon adherence and therefore efficacy of therapy.

To bridge this gap, Salvos and colleagues designed a prescriptive and personalized diet that recreates EEN by the exclusion of certain dietary components, such as gluten, lactose and alcohol, and matches others as close as possible to ordinary food, termed CD-TREAT (Svolos et al., 2019). They demonstrated in a group of healthy controls that when CD-TREAT was compared to EEN it was more palatable and elicited similar changes in the gut microbiome and metabolome to that of EEN. Its use also reduced ileitis in an animal model and reduced clinical and biochemical disease activity in a pilot study of 4 out of 5 children with active CD. The CD-TREAT diet approach shows promise but needs to be reproduced in a larger study before being used in routine clinical practice.

### Other elimination diets

Other diets proposed to treat active disease include exclusion diets with varied degrees of restriction such as the Autoimmune Protocol (APD), Anti-Inflammatory Diet (IBD-AID), Specific Carbohydrate Diet (SCD) and Mediterranean Diet (MD), see Table 5 for a summary of commonly used dietary approaches (Konijeti et al., 2017; Olendzki et al., 2014; Kakodkar and Mutlu, 2017; Cohen et al., 2014; Chiba et al., 2010; Bodini et al., 2019; Sasson et al., 2021; Lewis et al., 2021).

On the whole, they exclude refined sugars and grains which are postulated to provide substrates to pathogenic bacteria in the gut lumen and enable overgrowth (Sasson et al., 2021). In largely uncontrolled trials these diets have shown improved rates of clinical remission, however, these studies were small and many lacked a comparator group and there is a paucity of data demonstrating an improvement in objective markers of disease activity. It should also be noted that up to a third of patients decline to start these interventions due to the restrictive nature of the diet and they can lead to significant obsessive food focus, whereby adhering to the prescribed dietary inclusions and exclusions can impact on social life and psychological wellbeing (Olendzki et al., 2014; Kakodkar and Mutlu, 2017).

A randomized controlled trial comparing SCD with the Mediterranean Diet (MD) in a cohort of patients with mild to moderately active CD demonstrated equivalent improvements in disease activity indices as well as quality of life and fatigue measures (Lewis et al., 2021). The MD has the appeal of being less restrictive as well as offering broader health benefits in the prevention of cardiovascular disease, as such, if dietary therapy is being pursued, a MD may be a good wholistic approach (Hoevenaars-Blom et al., 2012).

In summary, there currently is not enough evidence to recommend elimination diets above standard therapies for active IBD. Elimination diets may be reasonable to consider as an adjunct to standard therapies in patients who are looking to add dietary strategies or in patients who decline medical therapy. As deficiencies in key vitamins have been detected in patients on these diets, patients should start them under professional nutritional supervision (Kakodkar and Mutlu, 2017).

### Elimination diets key points

- Elimination diets have shown improvement in clinical parameters but largely in small, uncontrolled, non-randomized trials
- Evidence of improvement in objective markers of disease activity is lacking
- These approaches may be considered as adjunct or in patients declining SOC or those seeking a dietary adjunct to SOC under professional supervision to ensure nutritional adequacy.

### Future directions and conclusions

While diet has a role in modulating the risk of developing IBD and is a factor that can be modified to manage disease, it is apparent that a one size fits all approach is not effective, nor appropriate. With improved knowledge and utilization of technology we may be

able to tailor an individual's treatment based on specific individual factors (termed "precision medicine"). In IBD, factors such as age, diet, genetics, microbiome, clinical parameters, circulating biomarkers in addition to patient preferences will need to be considered in order to design the most effective treatment strategy. The principles of this approach were demonstrated in a landmark work which explored the relationship between diet and postprandial glycemic response (PPGR) in a generally healthy population (Zeevi et al., 2015). The PPGRs of the study participants were accurately predicted using an algorithm that considered individual participant features including blood tests, diet, physical activity and the gut microbiota, among others. The researchers were then able to generate personalized dietary interventions that lead to improved PPGRs and observed shifts in the microbiome in a way that had previously been associated with lowered metabolic risk. Their findings have now been replicated in a different cohort (Mendes-Soares et al., 2019). This suggests that the application of machine learning principles in tailoring individual dietary treatment strategies in order to improve disease outcomes may be within reach (Laing et al., 2019).

In summary, components of the diet may exert proinflammatory and anti-inflammatory effects in the context of IBD which are mediated via influences on mucosal barrier function, direct immune system interactions and the gastrointestinal microbiome. It is clear that the use of diet in the prevention and treatment of IBD is a desirable treatment strategy.

Epidemiological evidence in humans from large population-based cohort studies suggest that breast feeding, fruit and vegetable derived fiber and n-3 PUFAs have a protective effect, while a diet rich in sugar, red and processed meat and ultra-processed food may increase a person's risk of developing IBD. Current evidence-based SOC in IBD is directed at suppressing the immune response, a strategy which carries risks of significant side effects. Dietary factors that may be protective against flares are high dietary n-3/n-6 FA ratio as well as adopting a semi vegetarian diet. Treatment strategies that have been successful in small cohorts of patients with active disease are EEN, PEN plus CDED and CD-TREAT. Macro- and micro-nutrient deficiencies should be screened for and adequately treated, particularly zinc and vitamin D which if maintained at adequate levels are associated with decreased risk of a disease flare.

In conclusion, dietary factors should gain more prominence as a preventative strategy as well as a therapeutic intervention as part of a personalized treatment approach that takes into account individual treatment factors and minimizes unwanted risks and side effects in order to achieve optimal disease control.

### Key points

- Undernutrition is associated with increased severity of TB disease and poorer treatment outcomes
- Nutritional support, once the mainstay of TB treatment, is being increasingly recognized as an important adjunct to pharmacological therapy
- Nutritional support may improve adherence to TB therapy and promote treatment completion
- Micronutrient supplementation may accelerate clinical improvement and, in HIV-coinfected individuals, has improved treatment outcomes

### Glossary

**Tuberculosis (TB)** An infectious disease caused by *Mycobacterium tuberculosis* which usually affects the lungs, but can be found elsewhere (extrapulmonary disease)

**Antimicrobial drug resistance** The inability of a drug to kill or slow the growth of a microbe due to genetic mutations in the microbe

**Protein-energy malnutrition (PEM)** A potentially fatal body-depletion disorder of which there is inadequate protein intake

**Multi-drug resistant (MDR) TB** Drug resistant TB that is resistant to at least rifampin and isoniazid

**Bacillary load** The amount of disease-causing bacteria found within a medium (i.e., sputum) usually associated with severity of disease

### Introduction

Globally, an estimated 1.5 million tuberculosis (TB) deaths and 10 million new TB cases occur each year (WHO, 2021). One-quarter of the world's population may be latently infected with *Mycobacterium tuberculosis* and at risk for reactivation TB (Cohen et al., 2019). Before the advent of specific anti-TB drugs, nutritional support was a mainstay of the treatment of TB. Highly effective anti-TB drugs were first developed in the 1940s and 1950s (McMillen, 2015). In the 1970s, the combination of isoniazid, rifampin, and pyrazinamide enabled the duration of treatment to be shortened to 6–9 months. However, TB staged a dramatic comeback in the late 20th century in both affluent and developing countries, especially in countries of the former Soviet Bloc and in countries with a high prevalence of HIV infection in sub-Saharan Africa and parts of Southeast Asia. Today, TB is the leading cause of death among persons with HIV infection, one of the top five leading infectious cause of death, and one of the leading causes of maternal mortality worldwide.

TB patients may be difficult to cure for many reasons, including antimicrobial drug resistance, drug toxicity and intolerance, advanced TB disease, and comorbidities such as HIV infection. Therefore, there is renewed interest in nutritional support in the management of TB.

### Nutritional status of tuberculosis patients

Undernutrition is an important risk factor for developing TB, and TB causes anorexia, weight loss and cachexia. Weight loss and wasting in TB may result from the production of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and other pro-inflammatory cytokines that play a critical in protection against TB but also precipitate anorexia. Using the lactose-mannitol excretion test, a study in Brazil found evidence of altered intestinal mucosal integrity in persons with TB as compared to healthy controls which suggests that malabsorption may also drive weight loss among persons with TB (Pinheiro et al., 2006). Protein utilization may be altered by the cytokine milieu as evidenced by negative nitrogen balance. Studies in the United Kingdom (UK) documented that TB patients had significantly lower serum albumin levels than controls (mean, 37 g/L vs. 46 g/L), suggesting protein undernutrition and/or a systemic inflammatory response. Anabolic pathways may be functionally blocked due to preferential oxidation of ingested amino acids for energy rather than for protein synthesis, contributing to wasting despite nutritional support (MacAllan et al., 1998).

Weight loss among persons with TB can be severe. Compared to healthy individuals, TB patients have significantly lower body mass index (BMI), skin fold thickness, limb circumference, and overall proportion of body fat. In the United States, weight loss was present at diagnosis in 45% of patients. In Tanzania, among 200 consecutive adults with sputum smear-positive pulmonary TB, 77% of males and 58% of females had a BMI < 18.5 kg/m<sup>2</sup>, while 20% had a BMI < 16 kg/m<sup>2</sup> (Kennedy et al., 1996). In India, the median BMI among men with TB was 15.6 kg/m<sup>2</sup>; the median BMI among women with TB was 16.4 kg/m<sup>2</sup> (Padmapriyadarsini et al., 2016). In Malawi, TB patients were substantially weaker than controls as measured by hand-grip dynamometry, suggesting loss of skeletal muscle protein (Harries et al., 1988). In addition, these patients had 35% lower fat mass and 19% lower lean body mass than the control group. More extensive TB disease and longer duration of symptoms were associated with lower BMI. BMI among Asian TB patients living in the UK (19.3 kg/m<sup>2</sup>) was lower than controls (22.2 kg/m<sup>2</sup>), skin fold thickness was 13% lower, and arm muscle circumference was 20% lower. Patients with concurrent HIV infection tend to be even more undernourished.

Protein-energy malnutrition (PEM) rarely occurs without micronutrient deficiencies as well. TB patients have been found to be deficient in vitamins A, B6, and D as well as zinc, copper, iron, and selenium, although serum levels of fat-soluble vitamins A, carotene, and D, and certain micronutrients like zinc, iron, and selenium also fall while serum copper levels rise with systemic inflammation. In Ecuador, Koyanagi et al. observed that TB patients had significantly lower serum concentrations of zinc, retinol and selenium (Koyanagi et al., 2004). More than 800 TB patients in Malawi demonstrated deficiencies in circulating selenium, carotenoids and vitamin A (van Lettow et al., 2004). These deficiencies were exacerbated in the most severely wasted group (BMI < 16). There were no significant differences between the HIV-infected and HIV-uninfected TB patients. Low plasma selenium levels were associated with anemia.

In a study of 155 Ethiopian TB patients, HIV co-infection was associated with lower serum zinc and selenium concentrations and an elevated copper/zinc ratio compared with HIV-negative TB patients (Kassu et al., 2006). After the intensive phase of antibiotic therapy, serum levels of both selenium and zinc improved in both patient groups. Another study in Ethiopia reported serum concentrations of vitamins C, E and A were significantly lower in TB patients than in healthy controls (Madebo et al., 2003). High malondialdehyde concentrations, an indicator of overall oxidant stress, were associated with increased clinical severity of TB, and these parameters were exacerbated in HIV co-infected individuals (Madebo et al., 2003).

Wiid and coworkers observed significantly lower total antioxidant status (TAS) in TB patients compared with community controls, and TAS values increased during anti-mycobacterial chemotherapy (Wiid et al., 2004). Similar results were seen with vitamin A and zinc levels, but not with vitamin E. The vitamin A status of 100 TB patients was studied in Tanzania before and after the intensive phase of anti-TB therapy (Jeremiah et al., 2014). Vitamin A levels were low in TB patients and improved with therapy in HIV-negative, but not in HIV infected patients. HIV infection was also associated with low vitamin A status in otherwise asymptomatic controls.

Ramachandran et al. observed low serum vitamin A levels in 47 newly-diagnosed TB patients compared with household contacts and healthy controls (Ramachandran et al., 2004). Their vitamin A status improved significantly following anti-TB therapy without the need for vitamin A supplementation. Pediatric TB patients in India had markedly reduced levels of plasma zinc, irrespective of their general nutritional status, and there was significant improvement after 6 months of anti-TB therapy (Ray et al., 1998). Turkish investigators also observed a significant improvement in serum zinc (which increased) and copper/zinc ratios (which decreased) after 2 months of anti-TB therapy in adult patients (Ciftci et al., 2003).

Vitamin D is critical for induction of innate macrophage functions via Toll-like receptor ligation of mycobacterial cell surface molecules, mycobacteria-specific activation of T lymphocytes by infected macrophages, and fusion of phagosomes containing mycobacteria with lysosomes within infected macrophages. Thus, having adequate vitamin D at the time of initial infection may be important in developing the immune response that prevents the progression to active TB disease. Vitamin D receptor genetic polymorphisms are associated with vitamin D deficiency and increased incidence of TB. TB patients of Asian and African origin in the UK were significantly vitamin D deficient. Studies in India and Africa also found vitamin D deficiency associated with receptor polymorphisms in TB patients (Wilkinson et al., 2000).

### Effect of nutritional factors on the course of TB

Several observational studies have found an association between undernutrition and increased disease severity. A study of 173 persons with drug-susceptible TB in India found that after controlling for diabetes and cavitary disease, patients who were severely undernourished had 11% more of their lungs affected on chest x-ray (95% confidence interval [CI]: 4.0–13.3) as compared to those with normal BMI (Hoyt et al., 2019). Severely undernourished individuals also had a four-fold higher risk of cavitary lung disease (odds ratio [OR]: 4.6; 95% CI: 1.5–14.1). This association has also been noted in persons with MDR-TB. A Latvian study comprising 995 persons with TB found that individuals with BMI < 18.5 kg/m<sup>2</sup> were more likely to have smear positive TB (adjusted odds ratio [aOR]: 1.7; 95% CI: 1–2.9) and more likely to have bilateral cavitation (aOR: 2.1; 95% CI: 1.3–3.5) (Podewils et al., 2011).

Studies have also found an association between undernutrition at the time of diagnosis and poor treatment outcomes. A large study of 1695 persons with drug-susceptible TB from central India found a dose-dependent decrease in mortality as the BMI increased (aOR: 0.78; 95% CI: 0.68–0.90) (Bhargava et al., 2013). Chemotherapy is less effective in MDR-TB, and the impact of nutritional deficits may be more pronounced. In the aforementioned MDR-TB study from Latvia, patients with BMI < 18.5 kg/m<sup>2</sup> had a higher risk of mortality (adjusted hazard ratio (aHR): 1.9; 95% CI: 1.1–3.5) (Podewils et al., 2011). Although low BMI may be a sign of worse disease, these studies controlled for disease severity by multivariable regression. Low serum albumin, anemia, weight loss, and lack of weight gain were associated with the severity and clinical course of TB. Among 373 patients hospitalized for TB in Ecuador, hypoalbuminemia increased the odds of in-hospital death >3-fold after controlling for HIV infection and other co-morbidities (Matos and Moreira Lemos, 2006). A prospective cohort study in the Philippines of 439 adults with pulmonary MDR TB found that failure to gain weight during the first 6 months of treatment strongly predicted poor treatment outcomes (Gler et al., 2013).

The timing of mortality may also be predicted based on baseline BMI. In one study of nearly 1200 TB patients followed prospectively, 10.9% of patients with moderate to severe undernutrition died in the first 4 weeks compared with 6.5% of the patients with normal nutritional status or mild undernutrition. Another study found that TB patients with a body mass index < 17.0 kg/m<sup>2</sup> were at increased risk of early death. In children, weight for age is an important indicator of prognosis (Pranay et al., 2021).

The severity of undernutrition is an important indicator of the progress of the disease, and normalization of body weight in response to treatment is a positive sign. In Brazil, a study of 547 persons with TB found that the risk of unsuccessful outcomes decreased by 12% (95% CI: 5%–19%) per kilogram increase in weight at the end of the first two months (Peetluk et al., 2020). Conversely, a study of 650 persons with TB in Peru found that those who did not gain 5% or more of baseline weight at the end of treatment had a higher likelihood of treatment failure (risk ratio [RR] 2.05; 95% CI 1.10–3.80) (Krapp et al., 2008). In the US, Khan and coworkers demonstrated that TB patients who were underweight at diagnosis had a 4-fold increased risk of relapse within 2 years after completing treatment, and patients who did not gain weight had a 2-fold increase in risk of relapse (Khan et al., 2006).

### Controlled intervention studies of nutritional supplements in the management of TB

Historically, the use of cod-liver oil for the treatment of TB was the taproot from which grew the broader field of nutritional management of TB. In 18th and 19th century Europe, TB was responsible for 25% of adult deaths. Survival after diagnosis was approximately 2 years (Tiemersma et al., 2011). Treatment for TB was revolutionized by the use of cod-liver oil which had been used for its medicinal properties (Grad, 2004). Treating TB patients with cod-liver oil in the 18th century resulted in weight gain and increased survival rates from 2 to 8 years. In the early 20th Century, one US study reported that TB patients treated with cod-liver oil gained weight and only 10% died in contrast with weight loss and 70% mortality in the comparison group during approximately 1 year of observation. Cod-liver oil contains vitamins A and D which are important in host defense against TB.

With the advent of highly effective *anti*-TB drugs in the 1940s and 1950s, interest in cod-liver oil and other nutritional interventions waned. An influential clinical trial was carried out in Madras, India, in the 1950s to compare sanatorium treatment with outpatient treatment with regard to nutritional influences on treatment outcome (Tuberculosis Chemotherapy, 1959). Patients treated in the sanatorium had substantially better diets and gained more weight than home-treated patients. Improvement was slightly faster in the sanatorium treated group, but the outcomes were nearly the same in the two groups after 12 months after controlling for baseline differences in disease severity. Chemotherapy was so effective that the effects of nutritional support apparently were overshadowed.

Chemotherapy is less effective in MDR TB and HIV-associated TB, renewing interest in nutritional interventions. In the past decade, trials of nutritional intervention during chemotherapy of TB patients have shown modest to no benefits. Eighty Indonesian TB patients with low BMI, low plasma retinol, and low plasma zinc were treated with a retinol and zinc supplement versus placebo in addition to standard *anti*-TB drugs (Karyadi et al., 2002). Sputum conversion, radiographic improvement, and increased plasma retinol levels were observed in the treated group after 6 months of therapy. Two weeks post-therapy, the percentage of patients with negative sputum smears was significantly higher ( $p < 0.01$ ) in the micronutrient-treated group (23%) compared with the placebo group (13%). Lesion area was significantly reduced in the treated group after two months of therapy ( $p < 0.01$ ). Plasma retinol concentrations were correlated inversely with reduction in mean lesion size at 6 months ( $r = -0.367$ ;  $p = 0.02$ ).

A much larger randomized control trial (RCT) in Tanzania examined the effect on treatment of supplemental zinc alone, multiple micronutrients (MMN: vitamins A, B, C, D, E and minerals Se, Cu), MMN + zinc, or a placebo (PrayGod et al., 2011). Approximately 43% of each group was HIV-infected, and all received standard *anti*-TB chemotherapy. After 8 weeks of therapy,

neither supplement had a significant effect on sputum culture positivity; however, patients receiving the MMN experienced a significant improvement in body weight. HIV status had no influence on the outcome. On the other hand, after 8 months of therapy, the MMN + zinc group had significantly reduced mortality (RR = 0.29; 95% confidence interval 0.10–0.80), but only in the TB-HIV co-infected patients.

Several RCTs have examined the impact of supplemental zinc, iron or vitamin D on the outcome of chemotherapy in TB patients. Sixty-six HIV-infected TB patients in Singapore who were receiving antiretroviral and *anti*-TB therapies were assigned to 28 days of oral zinc sulfate supplements or placebo. Zinc supplements had no effects on mycobacterial antigen-stimulated IFN $\gamma$  production; however, nearly all (94%) of the subjects had normal plasma zinc levels at baseline (Green et al., 2005). In the second study, 117 anemic, adult male TB patients in India were enrolled in an RCT of iron supplementation during the first 2 months of conventional *anti*-TB therapy. During 6 months of follow up, hematological status improved as the TB disease improved, but supplemental iron had no additional benefit as determined by the extent of radiographic abnormalities (Devi et al., 2003). In Egypt, 24 newly diagnosed pediatric TB patients were enrolled in an RCT to examine the effect of vitamin D supplementation (1000 IU/day for 8 weeks) on the outcome of *anti*-TB therapy (Wejse et al., 2009). Most of the children were vitamin D-deficient at baseline and serum levels of 1,25 (OH) $_2$ D $_3$  improved in both groups during chemotherapy, but, supplementation did not affect this parameter. The supplemented group showed significant radiological and clinical improvement at follow-up with significantly increased body weights (3.3 kg) compared with the placebo group (2.2 kg) ( $p < 0.05$ ). Two placebo-controlled trials of vitamin D supplementation in India and the Republic of Georgia found that although serum 25(OH)D levels increased to normal among those with baseline vitamin D deficiency, there were no significant difference in the mean to sputum culture conversion between the placebo and vitamin D groups in both studies (Tukvadze et al., 2015).

Hanekom et al. conducted a RCT of vitamin A supplementation in 85 South African children with TB who were not co-infected with HIV (Hanekom et al., 1997). Children were given either 200,000 IU of retinyl palmitate or placebo on day 0 and day 1 and then followed up during 3 months of conventional *anti*-TB therapy. Nearly two-thirds of the patients were vitamin A-deficient at the beginning of the study, and the deficiency was more pronounced in children with extra-pulmonary disease. Vitamin A status improved in both groups, but supplementation had no significant effect on treatment outcome. Vitamin A supplementation was associated with significant decreases in a plasma protein biomarker of a Th2-type cytokine response which may indicate that vitamin A supplementation promoted a protective Th1-type 1 cytokine profile.

Inducible nitric oxide (NO) is a critical proximal mediator of anti-mycobacterial resistance in rodent models of TB, while its role in human TB remains controversial. Arginine is the substrate for inducible nitric oxide synthase, the enzyme that produces NO in macrophages. An RCT of oral arginine supplementation (1 g/day) was conducted in 120 HIV-infected and HIV-uninfected Ethiopian TB patients for 4 weeks along with standard *anti*-TB therapy (Schön et al., 2003). At 8 weeks, arginine supplementation resulted in significant improvement in serum arginine levels, weight gain, sputum conversion, and reduction of symptoms compared with the placebo group, but these benefits were observed only in HIV-negative patients. No treatment effect was observed in HIV co-infected patients.

The cholesterol content of macrophage vesicle membranes (i.e., phagosomes, lysosomes) has been shown to affect the ability of the phagocytes to suppress intracellular growth of mycobacteria. In a small RCT in Mexico City, investigators compared the clinical responses of 10 TB patients who received a cholesterol-rich diet (800 mg/day) with 11 TB patients who consumed a control diet (250 mg/day) during the first 8 weeks of standard *anti*-TB chemotherapy (Pérez-Guzmán et al., 2005). Respiratory symptoms improved in both groups; however, culture-negative sputum at 2 weeks was more frequent in patients consuming a high-cholesterol diet (91%) compared to the placebo group (20%) ( $p < 0.002$ ). The bacillary load in sputum was much lower in the cholesterol-supplemented patients (0.05 colony forming units [cfu]) than in the placebo patients (3.4 cfu) ( $p < 0.0002$ ).

One mechanism by which nutritional supplementation may improve treatment outcomes is by improving adherence to TB therapy. For instance, a retrospective cohort study of 573 persons with smear-positive TB who were living below the poverty line in India found that those receiving nutritional support had a 50% reduced risk of unsuccessful treatment outcome than those who did not receive nutritional support (95% CI: 30–86%) (Samuel et al., 2016). In the nutritional support group, only 1 individual (1%) was lost to follow up whereas 41 individuals (10%) were lost to follow up. Similarly, in Senegal, a small study of 26 HIV-TB individuals found that nutritional supplementation was associated with 95% adherence to both TB and HIV treatments. All subjects in this study completed therapy successfully.

### Nutritional management of TB

The goal of nutritional interventions is to (1) compensate for the elevated resting energy expenditure and catabolic state associated with TB, (2) support the extensive cellular proliferation and protein production associated with anti-mycobacterial immune responses, (3) allow repair of diseased tissues, and (4) replenish somatic reserves. Supplementation with specific nutrients (e.g., vitamin A, vitamin D, zinc) may be required to correct specific deficiencies. The research reviewed above provides limited support for the use of dietary supplementation with specific macro- and micronutrients for their beneficial impact on both nutritional status and treatment outcomes in TB.

While this article is not intended to offer recommendations for medical practice, some general guidelines are discussed. The expertise of clinical nutritionists and dieticians should be sought in managing persons with TB with complex nutritional

requirements. In the absence of such expertise, reference works focusing on the nutritional management of patients with infectious diseases should be consulted. In 2013, the World Health Organization published a guidance document to guide nutritional assessment and care for persons with TB which can also serve as a roadmap.

Careful assessment of nutritional status is the starting point, including the medical history and physical examination, anthropometric data, dietary information, as well as laboratory tests. Nutritional interventions to correct specific nutrient deficiencies can be based on this assessment. In endemic regions, it may be reasonable to ask about a history of intestinal parasitic infections and diarrheal diseases or severe anemia as important contributing factors to nutritional status.

The medical history and physical examination should include questions to identify unintentional weight loss which is associated with poorer treatment outcomes, higher risk of relapse, and increased mortality. Anorexia, abdominal discomfort, nausea, vomiting, and diarrhea will affect nutritional status and nutritional support. Co-morbidities that have nutritional implications such as diabetes mellitus, hepatitis, alcohol abuse, and HIV infection should be identified. In endemic regions, it may be reasonable to screen for intestinal parasitic infections among persons with TB who are manifesting symptoms such as diarrhea or anemia.

Fever affects resting energy expenditure and caloric requirements. The expert clinician's subjective global assessment is one of the critical aspects of evaluating nutritional status. The clinical manifestations of specific nutrient deficiencies have been described in many other reference works to which the interested reader is referred. Peripheral neuropathy deserves special mention because it is a common side effect of isoniazid, one of the primary *anti*-TB drugs (see below), and vitamin B6 supplements are routinely prescribed with *anti*-TB treatment to prevent peripheral neuropathy.

Anthropometric data should include weight and height in relation to age, sex, and reference standards. BMI can be calculated to determine the overall macronutrient deficit. Skin fold thicknesses, linear and circumferential measurements of specific body parts, and bioelectric impedance may help categorize the nutritional deficit as involving energy, protein, or essential fats.

A dietary survey should include questions regarding recent patterns and quantities of food consumption pre- and post-illness (e.g., food availability and intake, dietary restrictions, preferences). Standardized tools include 24 h diet recall, 72 h food diaries, and food frequency questionnaires used in clinical and epidemiological research, but they also may be useful in patient care. The information is translated into nutrient intakes based on the known composition of foods and estimates of the quantities consumed. Dietary information should include specific requirements and restrictions based on age, co-existing medical conditions, cultural and religious practices, personal preferences, food allergies, and intolerance of certain foods. Dietary assessment will set specific boundaries around possible dietary recommendations and, the availability and cost of foods and nutritional supplements will affect these boundaries.

Basic hematology and biochemistry laboratory tests can be supplemented as indicated by the history, clinical examination, and abnormalities identified in these basic tests. Anemia is common in inflammatory conditions such as TB. However, anemia may also result from deficiencies of iron, folate, or vitamin B12. Apart from anemia, serum albumin level may be the most important predictor of nutritional risk for poor outcomes associated with TB. Since albumin is synthesized in the liver with a half-life of 21 days, hypoalbuminemia may reflect inadequate protein intake over a period of weeks or longer, although hypoalbuminemia is also a marker of systemic inflammation which is minimally affected by nutritional support until the inflammatory response remits.

Nutritional support of the TB patients should include a varied diet containing ~50% of calories from carbohydrates, 20%–30% from proteins (with an emphasis on high quality proteins), and 20%–30% from fats. Energy requirements start at a basal level of approximately 30 kcal/kg body mass, increasing to 40 kcal/kg or more for persons with significant deficits or with increased resting energy expenditure (e.g., fever). Respiratory function may be modestly or severely compromised, including both oxygenation and ventilation, in TB. As an energy source, dietary carbohydrates generate 20% more carbon dioxide than proteins and 30% more than fats. Thus, for patients who are short of breath, hypercapnic, or lack adequate ventilation, fats and proteins may be preferred dietary sources of energy. This is generally only a problem when the carbohydrate content of the diet exceeds the energy expenditure where the respiratory quotient can exceed 1.0 and substantially increase CO<sub>2</sub> production.

Inflammation drives the utilization of both endogenous and exogenous proteins for energy due to hepatic gluconeogenesis and an anabolic block in protein synthesis created by the immune cell cytokines. Protein requirements may be as high as 1.5 gm/kg body mass/day. TB patients who are acutely ill, have advanced disease, or substantially compromised nutritional status, and whose dietary intake has been inadequate for an extended period of time may benefit from a gradual increase in dietary macronutrients up to the recommended amounts. Overfeeding is not recommended.

Omega-3 polyunsaturated fatty acids in the diet have anti-inflammatory and immunomodulatory effects, including increased susceptibility to TB in guinea pigs and mice, while dietary omega-6 polyunsaturated fatty acids have pro-inflammatory qualities, either of which may prove to be undesirable in the management of TB. The effects of different fatty acids on the nutritional management of TB remain to be established.

A multivitamin and mineral supplement is recommended to ensure the availability of micronutrients. Higher doses of individual components to treat specific micronutrient deficiencies should follow guidelines established for the treatment of those conditions. Otherwise, doses of vitamins and minerals above those demonstrated to be safe and beneficial are not recommended.

Iron deficiency and iron replacement also merits special mention. Increased severity of TB has been observed in individuals with hemochromatosis, an iron overload syndrome, and in indigenous societies with high levels of iron intake from drinking a type of traditional beer fermented in iron vessels. Moreover, epidemics of malaria have been reported during refeeding programs in refugee and famine situations, related to the increased availability of iron for the parasite from supplements provided for the treatment of

iron deficiency. *M. tuberculosis* acquires iron by means of highly developed scavenging mechanisms that must out-compete the host's iron-binding proteins (e.g., lactoferrin, transferrin). Iron deficiency is not necessarily more deleterious to the host than to the pathogen, and iron replacement therapy may benefit the microbe as well as the patient.

### Nutrient-drug interactions

The standard treatment for all newly diagnosed patients with active, drug-susceptible TB includes four drugs, isoniazid, rifampin, pyrazinamide, and ethambutol, taken for two to three months followed by two of these drugs, isoniazid and rifampicin, taken for an additional four to six months. Isoniazid (INH) interferes with the metabolism of vitamin B6 which includes pyridoxine, pyridoxal, and pyridoxamine. Isoniazid combines with pyridoxal or pyridoxal phosphate to form potent inhibitors of pyridoxal kinase, thus, blocking formation of the coenzyme form of the vitamin. In the absence of vitamin B6 supplements, TB patients treated with INH may experience peripheral neuritis, manifested as tingling, numbness, or a painful "prickly" sensation in a stocking and glove distribution. Approximately 20% of patients treated with high doses of INH or patients who are otherwise predisposed to peripheral neuropathy (e.g., alcoholics, diabetes mellitus) will develop peripheral neuritis. Administration of 25–50 mg daily of vitamin B6 prevents peripheral neuritis in nearly all TB patients treated with INH. Importantly, excess vitamin B6 may also precipitate symptoms of peripheral neuropathy.

Patients treated with cycloserine, an important second-line drug used in the treatment of MDR TB, should also receive vitamin B6 supplements in doses of 200 mg–300 mg/day because of central nervous system side-effects (psychosis, depression) also related to pyridoxine metabolism.

Other *anti*-TB drugs that have adverse consequences on nutrition include para-aminosalicylic acid (PAS) and ethionamide, because these drugs commonly cause nausea, abdominal pain, anorexia, or vomiting. Such side effects will have a significant negative impact on the patient's nutritional status and well-being.

Treatment of TB may induce other problems that affect nutritional status and nutrient intake. Three of the first line drugs, isoniazid, rifampicin, and pyrazinamide all carry a small risk of chemical hepatitis characterized by anorexia, nausea, vomiting and decreased nutrient intake. In its more severe forms, drug-induced hepatitis results in disturbances in carbohydrate, protein and lipid homeostasis that clearly impact the patient's metabolic and nutritional status. Although nutritional factors do not contribute to the cause, TB drug-induced hepatitis has many important consequences affecting nutritional status and nutrient intake.

Conversely, poor nutritional status has important implications for the pharmacokinetics of antimycobacterial drugs. After conducting the lactulose-mannitol excretion assay among 41 persons with TB and 28 healthy controls, a study in Brazil found that, compared to healthy controls, persons with TB had evidence of altered intestinal mucosal integrity (Pinheiro et al., 2006). In a study of 84 Indian children with HIV/TB, stunted and underweight children had significantly lower serum peak concentrations of rifampin and isoniazid (Ramachandran et al., 2013). Similarly, in a Tanzanian study of 51 HIV-negative children, undernutrition was significantly associated with lower estimated peak concentrations of rifampin and isoniazid in multivariate analyses (Justine et al., 2020). However, as undernutrition decreases fat-free mass, it can also result in supratherapeutic doses of drugs, such as ethambutol and aminoglycosides, and increase the risk of drug toxicity (Ter Beek et al., 2019). There may be a role for ensuring safe and effective drug concentrations among undernourished persons through therapeutic drug monitoring.

### Conclusions

Nutritional support is an important component of comprehensive care for persons with TB which must be adapted to each geographic region and socioeconomic context. Specific nutritional recommendations should be adapted to each patient depending on their clinical condition, nutritional status, and the practical possibilities of supplementation. Simplified, more generic approaches may be most suitable in some circumstances. These considerations notwithstanding, all TB patients should be offered nutritional/dietary advice based upon their nutritional status and accompanying diseases. While a specific, often costly diet that targets the individual nutritional needs of a TB patient may improve treatment outcome, it may be difficult to achieve this level of care in the absence of sufficient economic resources. This may be an entry point for policy interventions in countries with large burdens of both food insecurity and TB. Some national TB programs such as India's do provide monthly cash transfers to improve the nutritional status of persons with TB. More remains to be done. However, we believe a deeper understanding of the essential role of nutrition in TB pathogenesis and treatment will help improve current TB treatment practices and improve outcomes of TB patients.

## Key points

- Water insecurity, like food insecurity, is a multidimensional concept that captures availability, accessibility, use, and stability across time
- The nutrition community has primarily focused on water in the context of waterborne diseases and hydration, but water security is critical for many other aspects of diet and physical well-being
- Water security shapes food production and preparation; infant and young child feeding; development and maintenance of the gut microbiome; and sanitation and hygiene practices that limit exposure to harmful substances that undermine nutrient uptake and function
- Validated measures of household and individual water insecurity should be implemented concurrently with other nutritional assessments to advance our understanding of the linkages between water insecurity and nutrition

## Glossary

### Water insecurity

The inability to reliably access water in appropriate quantities and acceptable quality for all household uses (Jepson et al., 2017).

## Introduction

Water is life. It is an essential nutrient that serves a critical role in absorbing, storing, and metabolizing other nutrients (Jéquier and Constant, 2010). Reliable access to water in sufficient quantities and quality for all household uses, or “water security” (Jepson et al., 2017), is also integral for food production and preparation, personal hygiene, and psychological health (Young et al., 2021a). In other words, water security creates an enabling environment for good nutrition (Miller et al., 2021).

Multifarious and growing threats to water security, including prolonged droughts, excess flooding, and water contamination (Kummu et al., 2016; Mekonnen and Hoekstra, 2016), present substantial challenges to achieving global nutrition targets. Yet few studies to date have explored the interconnections between water security and nutrition, including how water needs and challenges change throughout the life course (Rosinger and Young, 2020b). We therefore describe how water security is conceptualized, operationalized, and quantified for empirical analysis. We then synthesize available evidence about the linkages between water (security) and nutrition and conclude by identifying future research opportunities.

## Defining and measuring water insecurity

Water has traditionally been quantified in terms of physical availability at the national, state, watershed, or service-provider level by physical scientists and engineers. In recent decades, social scientists have increasingly examined the ways by which diverse water problems manifest at the individual and household level. This shift in unit of analysis was catalyzed, in part, by a seminal 1998 report that introduced “water insecurity” as a multidimensional concept that considers the dual role of water as both a nutrient for maintaining good health and a critical resource with sociocultural, political, and spiritual significance (Webb and Iskandarani, 1998). Although researchers continue to debate the degree to which definitions of water insecurity should emphasize environmental welfare, infrastructure development and management, or human capabilities (Bigas, 2013; Cook and Bakker, 2012; Slaymaker et al., 2020), there is broad consensus that a more holistic understanding of water beyond availability is required to address the global water crisis.

Experience-based constructs and metrics of food insecurity have gained prominence in global public health as a useful way to explore how resource insecurities shape behavior and well-being (Pérez-Escamilla, 2012; Pérez-Escamilla and Segall-Corrêa, 2008), and there is growing recognition of their utility for understanding water insecurity (Jepson et al., 2017; Miller et al., 2021; Young et al., 2021a). Such household- and individual-level measures are often more proximal to outcomes of importance to nutrition researchers, dietitians, practitioners, and policymakers than those measured at the community or national level (Young, 2021). By analogy, the development and widespread implementation of experience-based food insecurity scales has exposed nutrition issues and inequities that are masked by less granular data on food availability or use, such as food balance sheets or calories per capita (Barrett, 2010; Jones et al., 2013; Leroy et al., 2015). Our focus herein is therefore on experiential water insecurity.

## Domains of water insecurity

Definitions of water insecurity consider one or more of the following: water availability, access, use, and stability (Fig. 1) (Rosinger and Young, 2020b; Slaymaker et al., 2020). These domains align with those used in the conceptualization of food security (Jones et al., 2013).

Availability refers to the physical existence of water in the environment. Water security can also be conceived of in terms of access, or whether water can be acquired (e.g., affordable) through socially appropriate means. Availability is necessary, but not sufficient, for access. Access, in turn, is necessary but not sufficient for use, which considers if there is enough acceptable and safe water for all personal or household needs. Finally, stability (sometimes referred to as reliability) considers continuity in availability, access, and use across time.

Water availability is a physical phenomenon that can be measured directly, but access is a more complex construct that is shaped by structural, social, and individual factors. For example, physical access may be hampered by infrastructural problems (e.g., groundwater is available but inaccessible due to power cuts) and age, pregnancy status, or disease that limit one’s ability to travel to water sources or haul heavy containers. Economic access, or water affordability, can be hampered by poverty or vagaries in water pricing. Additionally, cultural proscriptions and sociopolitical exclusion, biases, or discrimination may be barriers to equitable water access. For example, in North America, inequity in water access is predominantly experienced by indigenous people and people of color due to environmental racism and water policies that disproportionately benefit majority white communities (Meehan et al., 2020a,b).

**Fig. 1** Conceptual framework detailing the primary domains of experiential water security, including water availability, accessibility, use, and stability across time. Adapted with permission from Rosinger and Young (2020b), Slaymaker et al. (2020).

Use is also a multi-faceted domain, in part because water serves many purposes and the quality, quantity, or provenance of water considered acceptable for each use varies. We therefore distinguish between acceptability for consumptive and non-ingestive uses (Fig. 1). Consumption-related water use includes that which is drunk or eaten, including water that is embedded in foods (“virtual water”) (Virtual Water Trade: Proceedings of the International Expert Meeting on Virtual Water Trade, 2003). Non-ingestive uses of water are numerous and include sanitation and hygiene practices (e.g., washing hands, food, utensils, or clothing), recreational activities, and income-generating activities that are integral to the economic productivity of many households. For instance, water is necessary for raising crops and livestock as well as producing goods that can be sold for profit.

Water acceptability is based on myriad factors including objective or subjective safety, organoleptic properties (e.g., taste, smell), spiritual and cultural beliefs, trust in water providers and public institutions, and the intended use for the water (Collins et al., 2019; Doria, 2010; Pierce and Gonzalez, 2017). Many households globally use multiple water sources since water for one activity may be deemed to be of inappropriate quality for another (e.g., different water sources for drinking and washing clothes) (Elliott et al., 2019).

The fourth domain of water security is stability (or reliability). Social, economic, environmental, and political issues can affect the constancy of water security across time, such as change in water availability due to seasonal variations or climatic shocks. Further, water access can be shaped by fluctuations in health, income, infrastructural damage, and relationships with those who control water delivery (i.e., perturbations in social and economic capital). Diurnal stability can be shaped by queues for water (Collins et al., 2019) or power shortages (Biggs et al., 2015).

It is important to note that myriad resource-based conceptualizations of water are used interchangeably with experiential water insecurity, although they are distinct phenomena (Octavianti and Staddon, 2021). Sometimes the concepts are defined, such as in the case of water stress, water scarcity, and water risk (Schulte and Morrison, 2019). Other times such terms are used without explicit operationalization. This can create ambiguity about whether issues with water quantity, access, or quality are being assessed (Young, 2021).

### Tools for quantifying water insecurity

Household or individual water insecurity is commonly measured using tools that ask respondents to report how frequently they experienced limitations to or deficiencies in water availability, accessibility, and use over a defined period (Jepson et al., 2017). Most items in experience-based scales probe about access and use (e.g., being unable to bathe or prepare foods because of problems with water) because these domains are contingent upon water availability (Fig. 1). Specific emotions related to one’s water situation, such as worry or anger about insufficiency, are also sometimes asked about. Since issues with acceptability or safety manifest in suboptimal use or negative emotions, experiential scales implicitly capture these subdomains. Stability across time can be captured by asking respondents to recall the frequency of experiences across multiple timepoints (e.g., water insecurity in the prior month and year) in cross-sectional studies, or by using repeated measures in longitudinal assessments.

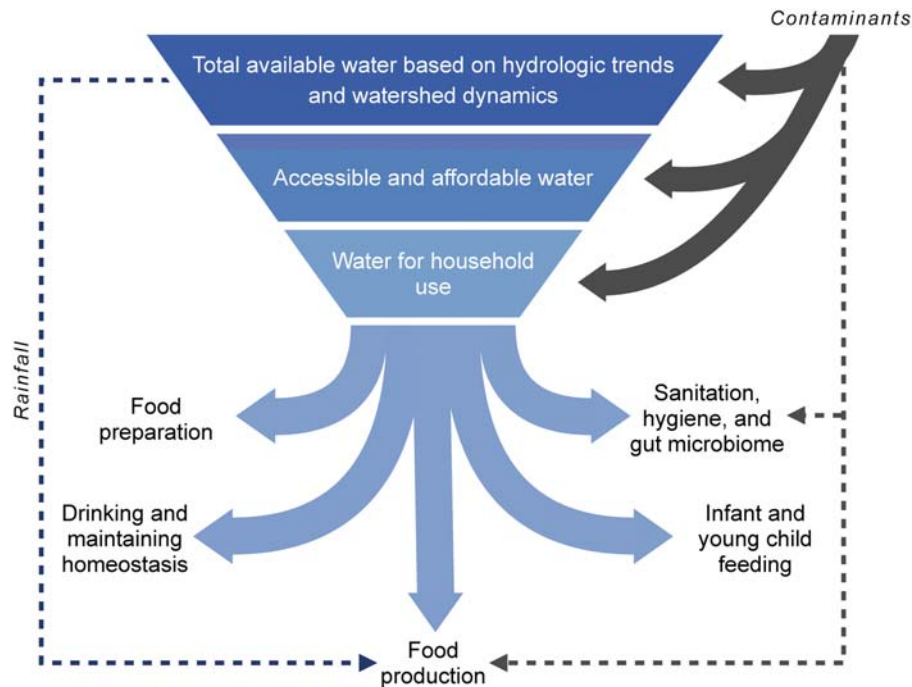

Experiential measures of food insecurity have been assessed by governments and international agencies in large-scale surveys for decades (Jones et al., 2013; Young et al., 2019a). In contrast, tools for measuring experiential water insecurity have only recently been developed, and their implementation has not been nearly as broad (Young et al., 2021a). The first effort at quantifying experiential water insecurity was done in a 2004–2005 study among 72 household heads in an urban setting in Bolivia (Wutich and Ragsdale, 2008). Since then, numerous scales have been developed to measure either household or individual experiences with water insecurity in specific settings (Octavianti and Staddon, 2021), such as western Kenya (Boateng et al., 2018), Ethiopia (Stevenson et al., 2012), and Nepal (Aihara et al., 2015). Typically, these scales ask about the frequency of a small subset of water-related activities in a specified timeframe, usually the prior month. The first scale validated from cross-cultural comparison is the 12-item Household Water Insecurity Experiences (HWISE) Scale (Young et al., 2019a,b), which was finalized in 2019. It is now being used in a range of venues, including nationally representative surveys to estimate water insecurity globally (Young et al., 2021b); in clinical studies to understand links to health and well-being (Miller et al., 2021); by NGOs like Oxfam to understand the impacts of interventions (Miller et al., 2020; Vonk, 2019); and by multi-lateral agencies such as IFPRI and UNICEF to assess the determinants and impacts of COVID-19 (Barooah et al., 2020).

### Linkages between water insecurity and nutrition

Given that tools for measuring experiential water insecurity have only recently been developed, few studies have concurrently examined water availability, accessibility, use, and stability at the household or individual level in relation to nutrition. To illustrate the potential linkages between water insecurity and nutrition (Fig. 2), we therefore present findings from studies that either measure water insecurity directly or consider at least one of its four sub domains.

#### Water: an essential nutrient

The most obvious use of water is for drinking. Water is needed to maintain hydration and support normal physiological function. Chemically, water has a unique structure and properties that make it an essential nutrient (Jéquier and Constant, 2010). In the gut, water aids in digestion and serves as a universal solvent for maintaining concentration gradients to facilitate the uptake, transport,

**Fig. 2** Conceptual framework demonstrating the relationship between water security and nutrition. Water security is shaped at multiple ecological levels, from environmental factors (dark blue) to intra-household dynamics (light blue). Problems at any level can have negative impacts on downstream health and well-being, including key nutrition-related activities highlighted here. Adapted with permission from Miller et al. (2021).

and storage of other nutrients. Water is also used in many metabolic processes and hydrolytic reactions throughout the body. Further, it serves structural functions, including providing protection as a physical shock absorber at the cellular and tissue levels. Thermoregulation and waste excretion additionally depend on sufficient water stores (Jéquier and Constant, 2010; Popkin et al., 2010). Simply put, life cannot occur without water.

There are numerous and sometimes redundant pathways to ensure optimal total body water. Fluid balance is primarily maintained by matching outputs (e.g., urine excretion, insensible water loss through respiration) with inputs (e.g., direct fluid intake, consumption of foods that contain water) (Jéquier and Constant, 2010). Water needs vary based on individual characteristics, level of physical activity (Kenefick and Cheuvront, 2012), and across critical developmental periods (Rosinger, 2020). Net water loss results in dehydration and increases the risk of numerous morbidities, from headaches to kidney stones (Manz and Wentz, 2005; Popkin et al., 2010). Prolonged water restriction results in altered osmoregulation, hypotension, organ damage, and eventually death (Rosinger, 2020).

### The nutritional importance of safe drinking water

Plain drinking water sometimes contains dissolved minerals in concentrations that are important for micronutrient metabolism (World Health Organization, 2005). For instance, millions of people drink “hard” groundwater that has biologically relevant concentrations of calcium and magnesium. Greater magnesium in drinking water is associated with lower risk of coronary heart disease and stroke mortality (Jiang et al., 2016; Rosanoff, 2013); higher calcium concentrations are associated with greater bone mineral density and lower risk of hip fracture (Dahl et al., 2015; Sengupta, 2013). Recommended sodium intakes can typically be achieved through food alone, such that drinking water with a high salt concentration is often associated with excess sodium consumption and concomitant hypertension (Choi et al., 2015; Talukder et al., 2017). Sodium is typically found in low concentrations in drinking water, but the salinity of many drinking water sources is increasing globally due to greater saltwater intrusion from excessive groundwater withdrawal and sea level rise (Vineis et al., 2011).

Although daily consumption of water is paramount for good health, few studies or national reporting agencies systematically measure hydration status or collect water intake data because of measurement challenges, including biases associated with dietary recall and limitations with biomarkers of hydration status (Cheuvront and Kenefick, 2014; Committee, 2020). Current recommended daily intakes can therefore only be considered crude estimates because they do not account for variations by climate, physical activity, body composition, medication use, or disease states (Howard et al., 2020). Indeed, the current MyPlate initiative to help inform healthy eating patterns in the United States does not include explicit recommendations about how much water to drink per day (although it encourages individuals to replace sugar-sweetened beverages [SSBs] with water) (Zizza et al., 2015). Taken together,

this has resulted in substantial confusion within the public about how much plain drinking water is required for good health (Stookey and Kavouras, 2020).

Non-water beverages have varied impacts on hydration status. Drinks with alcohol and caffeine can induce diuresis, with varied impacts on total body water (Maughan and Griffin, 2003). Juices and sugar-sweetened beverages (SSBs) can help restore hydration but can also contribute to excess caloric intake, thereby increasing the risk of overweight and obesity (Hu, 2013). Greater water intake may therefore complement weight maintenance strategies by decreasing overall energy intake and increasing fat oxidation (Stookey, 2016).

Non-water beverages may be preferentially consumed for their taste or sociocultural importance, but also because of distrust of drinking water (Onufrak et al., 2014). Non-water beverages may also be consumed in the face of water insecurity because of their convenience. For instance, one study found that individuals in rural Alaska who lacked in-home piped water consumed SSBs more frequently than their counterparts with greater water accessibility (Mosites et al., 2020). Infrastructural and economic disparities (Meehan et al., 2020a) may thereby contribute to disparate trends in SSB and plain water intake between racial groups and socioeconomic strata (Rosinger and Young, 2020a; Vieux et al., 2020).

Water acquisition can also have nutritional consequences. Traveling to and fetching water from off-premises water sources is a physically demanding activity that necessitates considerable energy expenditure (Geere et al., 2018). One study among individuals living in a rural village in Laos estimated that, on average, 8.7% of daily calories consumed were spent on water fetching during the wet season and 12.8% during the dry season (Frenierre, 2017), meaning that having an off-premises water source may increase one's risk of undernutrition. Hauling heavy water is also associated with greater risk of injury (e.g., cervical spinal cord compression due to head-loading water, falling) (Geere et al., 2018; Venkataramanan et al., 2020b) that can indirectly impact nutrition by taking away time from income-generating activities or limiting an individual's ability to access or prepare preferred foods. This is substantial given that millions of households must travel more than 30 min roundtrip to collect water (WHO/UNICEF, 2017). More research is needed to understand how experiential water insecurity informs decisions about drinking water intake and associated health impacts.

### **Water security for food production**

Just as water is necessary for human well-being, water is also fundamental for the growth and well-being of all plants and animals. As such, water is a critical resource for agricultural and aquacultural food production. More than two-thirds of freshwater withdrawals are currently used for agricultural activities like irrigating crops and watering livestock (Jury and Vaux, 2007). To support a growing global population in the context of climate change and intensifying water scarcity, innovative strategies will be required to grow more food with less water (Ringler and Paulo, 2020).

Smallholder farmers produce most domestic food supplies in sub-Saharan Africa and South Asia (IFAD and UNEP, 2013). The majority of these farmers rely on rainfed agriculture, which is less productive than irrigated operations (which more efficiently distribute water to crops and livestock) and more susceptible to climatic shocks (e.g., droughts) and changing weather patterns (Rockström et al., 2010). Expanding access to the financial and infrastructural resources required for irrigation could reduce market volatility and increase agricultural yields (Rosa et al., 2020). Greater food availability could in turn reduce rates of hunger and undernutrition in these regions, which are the highest globally (FAO et al., 2020).

Irrigation technologies can also indirectly improve nutritional well-being. Greater agricultural yields can increase a household's income, allowing individuals to purchase more (diverse) food (Ricciardi et al., 2020). Further, irrigation systems that produce potable water can also be used for drinking and other household activities, such as the cleaning and preparation of foods (Ringler et al., 2018).

### **Water security for a healthy diet**

#### **Cooking and meal preparation**

Water is needed for the safe preparation and serving of foods. Washing fruits and vegetables with water can remove potentially harmful pesticides and residual soil matter, which can contain parasitic helminths that cause intestinal bleeding or other pathogens, and reduce one's ability to absorb nutrients (Stephenson et al., 2000). Water is also needed to wash hands and clean utensils before eating. Limited access to safe water can therefore increase the risk of foodborne illness and diarrhea (Gil et al., 2014).

Water is also needed to improve the palatability and digestibility of starchy staples. For instance, households in Kenya reporting having porridge but were unable to boil it because they lacked water (Collins et al., 2019; Zolnikov and Blodgett-Salafia, 2016). Other foods require water to remove toxins. Consumption of cassava that has not been boiled or soaked in water exposes individuals to glucosides that the body breaks down to neurotoxic cyanide, resulting in a disease known as konzo (Boivin et al., 2013). Individuals may therefore cope with water insecurity by consuming less food or substituting preferred foods with alternatives that require little or no water to prepare, including meals prepared outside the home (Venkataramanan et al., 2020a). For these reasons, water and food insecurity are strongly associated (Brewis et al., 2020; Miller et al., 2021; Young et al., 2021a), and water insecurity may precipitate future food insecurity (Boateng et al., 2020).

### Human milk production and feeding

Water security is important for infant and young child feeding. Approximately 88% of human milk is comprised of water (Martin et al., 2016). Lactating individuals have greater water needs (Montgomery, 2002), particularly if they live in hot-humid climates where insensible water loss is greater (Rosinger, 2015). It is plausible that fluid intake and milk production are directly linked, such that even mild dehydration could result in lower output, but no human studies to date have found an association. This could be because most studies on this topic were conducted among small samples without substantial variation in fluid intake (Bentley, 1998). Alternatively, it is possible that humans have evolved to prioritize limited water for milk production, even during periods of dehydration, to ensure offspring survival (Kuzawa, 2020). More research is clearly needed to understand the dynamics between fluid restriction and human milk synthesis (Rosinger, 2020).

Water quality can also impact initiation and duration of human milk feeding. When drinking water is contaminated with heavy metals (e.g., mercury, lead), toxic compounds can bioaccumulate in human milk (Samiee et al., 2019). This is significant because repeated heavy metal exposure during sensitive periods of brain development, particularly early infancy, can result in lifelong neurocognitive deficits (Sanders et al., 2015). Exclusive human milk feeding, however, remains the preferred feeding method, even when drinking water quality is suboptimal, because infant formula and other foods prepared with contaminated water can expose infants to greater heavy metal concentrations (i.e., lactating individuals partially metabolize these substances before incorporation into human milk) (Rebello and Caldas, 2016). Additionally, contaminated drinking water can contain waterborne pathogens or chemicals that cannot pass from caregiver to child through human milk (Baisley et al., 2011). As such, healthcare providers should address persistent caregiver misconceptions that water supplementation is needed to prevent human milk fed infants from becoming dehydrated (Nsiah-Asamoah et al., 2020; Yotebieng et al., 2013).

Other experiences with water insecurity may also negatively impact human milk feeding (Schuster et al., 2020). Greater water insecurity is associated with worse mental health and greater stress (Wutich et al., 2020; Young et al., 2019a), which can increase maternal sympathetic nervous system activity and thereby impair lactogenesis (Stuebe et al., 2013). Water insecurity may also exacerbate feelings of milk insufficiency or inadequacy, leading caregivers to introduce non-human milk foods before six months (Khatun et al., 2018). The physical burdens and opportunity costs associated with water insecurity also present barriers to caretakers' abilities and time to feed their infants (Schuster et al., 2020).

### Complementary feeding

Water insecurity shapes complementary feeding as well. To date, most studies looking at water and complementary feeding have focused on pathogen transmission (Makasi et al., 2020). But as described above, problems with water can also limit the diversity and quantities of foods a household is able to purchase, produce, or prepare (Schuster et al., 2020). An analysis of DHS data from India, for instance, found that optimal water access, compared to intermediate or basic access, was associated with approximately a 2% higher probability of an infant meeting minimum dietary diversity (Choudhary et al., 2020). The small magnitude of effect may be due to the operationalization of water access, which did not capture other salient components of water insecurity, such as whether the water was of sufficient quantity or quality for preparing foods. Indeed, qualitative evidence from 19 sites globally suggests that caregivers experiencing issues with water may substitute preferred dishes with less nutrient-dense foods (Schuster et al., 2020). Caregivers who are experiencing water insecurity may also have more limited time and resources to notice or respond to feeding cues, which can influence an infant's lifelong dietary patterns and eating practices (Black and Aboud, 2011). More data are clearly needed to better characterize the relationships between water insecurity and infant and young child feeding.

## Pathogens and pollutants: threats to water security and health

### Pathogens, heavy metals, and emerging pollutants

Despite increasing global access to centralized piped water systems, unsafe water continues to substantially contribute to the global burden of disease, even in high-income countries (Murray et al., 2020). Drinking contaminated water can cause gut dysbiosis, limit nutrient absorption and increase gut leakage, and contribute to a pro-inflammatory state that is detrimental to overall well-being (Millward, 2017). Waterborne pathogens can cause illness after brief exposures, whereas chemical contaminants are typically harmful over longer periods of exposure (Damania et al., 2020).

There are hundreds of known waterborne pathogens, which include viruses, bacteria, parasitic protozoa and helminths, and fungi (Damania et al., 2020). Among these, viruses and bacteria are the most common cause of gastrointestinal distress globally (Gibson, 2014). Inhalation of mist containing bacteria can also cause respiratory disease. Outbreaks of Legionnaires' disease, for instance, are often attributed to poor water treatment and infrastructure maintenance (e.g., infrequent cleaning of HVAC systems), including in communities with centralized piped water networks (Phin et al., 2014). Antibiotic-resistant bacteria are also increasingly found in water sources, due in part to inappropriate disposal of antibiotics, and can transfer resistance to human pathogens (Sanganyado and Gwenzi, 2019).

Water can also be problematic because of heavy metal (e.g., cadmium, lead, mercury, and arsenic) contamination. Broadly, heavy metals can be detrimental by acting as competitive inhibitors and interfere with, for example, erythropoiesis and bone formation (Fernández-Luqueño et al., 2013; Zhang et al., 2020). Heavy metals can also alter the composition of the gut microbiota and induce dysbiosis (Duan et al., 2020).

"Contaminants of emerging concern" are those that are not commonly monitored or regulated but have known or suspected human health risks (Daughton, 2004). There are hundreds of such contaminants of emerging concern; they are found in household

goods, personal care products, and industrial additives and solvents (Geissen et al., 2015). Our understanding about the impacts of these emerging contaminants on nutritional health is extremely limited due to their novelty and the limited methods for their assessment. It is plausible that the relationship is bidirectional: contaminants may affect nutrient absorption, and nutritional status may modulate the effect of these pollutants (Hennig et al., 2012).

It is difficult to track water contamination due to numerous testing constraints (Thavarajah et al., 2020). Many national reporting agencies only assess the primary water source used by households, although use of multiple water sources—each of which may have its own suite of contaminants—is common globally (Daly et al., 2021). Additionally, few studies have investigated the use of inter-household water sharing networks, despite their ubiquity (Rosinger et al., 2020).

### **Diarrhea and environmental enteropathy**

Disability-adjusted life-years attributable to diarrhea remain high despite decades-long efforts to limit exposure to pathogen-contaminated drinking water. The issue is particularly severe for children under five: unsafe water and sanitation caused nearly three-quarters of the almost 450,000 diarrheal deaths in 2016 (Troeger et al., 2018) and 16% of stunting among children under five in low- and middle-income countries (Prüss-Ustün et al., 2019).

Whereas diarrhea is most often an acute health hazard, environmental enteric dysfunction (EED) is a chronic, subclinical condition characterized by increased intestinal inflammation, gut permeability, and flattened villi that may severely undermine child well-being (Humphrey, 2009). EED has gained prominence within the water, sanitation, and hygiene (WASH) sector as a potentially under-appreciated mediator between environmental pathogens and poor child development. Most likely, EED is the result of repeated exposure to one or more (waterborne) pathogens that ultimately alter the structure and function of the gut (Owino et al., 2016). Numerous observational studies have found an association between indicators of EED and suboptimal nutrient absorption, stunted linear growth, restricted early childhood development, and lower oral vaccine effectiveness (Kosek et al., 2017).

Given its prevalence and adverse health effects, ameliorating the burden of EED is considered a public health priority. To that end, three large-scale randomized trials (WASH Benefits Bangladesh; WASH Benefits Kenya; Sanitation, Hygiene, Infant Nutrition Efficacy in Zimbabwe) in the 2010s received considerable attention for their efforts to reduce stunting by limiting environmental exposures to pathogens through improvements in both drinking water quality and sanitation and hygiene practices (Cumming et al., 2019). Many within the WASH sector were disappointed, however, when the interventions were found to only have mixed impacts on diarrhea and no effect on child linear growth, although improvements in water quality likely had beneficial impacts on other unmeasured aspects of child well-being (Leroy and Frongillo, 2019). The implementers of these studies concluded that strategies that address additional routes of exposure and other dimensions of water insecurity beyond quality (i.e., “transformative WASH”) may be needed to meaningfully reduce the risk and impacts of EED (Cumming et al., 2019). It will be important to assess whether improvements in experiential water insecurity, as broadly conceptualized herein, decrease the risk of EED and related outcomes.

### **Altered microbiome and inflammation**

The gut microbiome serves numerous critical functions, including providing energy to enterocytes, producing essential micronutrients, and preventing the colonization of pathogenic organisms (D’Argenio and Salvatore, 2015). It is broadly understood that the composition and stability of the gut microbiome is responsive to dietary and environmental factors, but the role of water (security) is only starting to be investigated.

Each drinking water source contains a signature microbiome that can directly alter the composition of an individual’s gut microbiota or indirectly by changing the gut ecology (Jha et al., 2018; Pinto et al., 2012). Similarly, the chemical properties of drinking water may also influence the gut microbiota. For instance, work in the United Kingdom has found regional differences in the number and richness of species within fecal samples (i.e., alpha diversity) by the sodium, sulfate, and chloride content of local tap water sources (Bowyer et al., 2020). Enteric pathogen contamination may also shape gut colonization. In Nicaragua, investigators found that infants and young children living in households with higher levels of total coliforms in their drinking water had lower alpha diversity and a greater relative abundance of potentially predatory or pathogenic gut bacteria compared to those in households using water sources with low coliform concentrations (Piperata et al., 2020). This suggests that exposure to unsafe water may render the gut more susceptible to harmful bacteria.

Diet is a strong predictor of gut microbiota development and colonization (Scott et al., 2013). Given that water insecurity may cause food insecurity (Boateng et al., 2020) and lead to altered diets (Schuster et al., 2020), water problems can indirectly impact the gut microbiota. For instance, greater consumption of foods away from home and SSBs in response to limited water availability may favor the development of obesogenic gut microbiota (Ley, 2010). Gut microbiota can also be adversely affected by chronic stress (Carabotti et al., 2015; Zheng et al., 2013); the psychological distress that accompanies water insecurity (Workman et al., 2021; Wutich et al., 2020; Young et al., 2019a) may therefore shape the gut microbiome. Without better data on exposure to water insecurity and the microbiome, these relationships cannot be accurately ascertained.

## **Conclusion**

Water security is essential for good nutrition. Recently developed tools for measuring experiential water insecurity are helping to advance our understanding of the many ways by which water availability, access, use, and stability influence diet and health.

Primary linkages between water security and nutrition include food production and preparation, sanitation and hygiene, psychosocial well-being, and the gut microbiome. Going forward, strategies to improve nutrition must consider the diverse ways by which water insecurity can be compromised. Sustained investment in interdisciplinary research, including systematic collection of high-resolution data on water insecurity in nutrition studies (Miller et al., 2021; Young, 2021), will advance our understanding of the global water and food crises and identify where resources should be targeted for greatest impact.

Is it better to have lost and re-gained than never to have lost at all? (Weight cycling refrain, loosely adapted from Alfred, Lord Tennyson)

### Weight Cycling – A Health Risk?

The term weight cycling is used in the fields of nutrition and obesity research to refer to losses and subsequent regains of body weight typically, but not exclusively, occurring in association with dieting. Interest in this phenomenon was initially based on the observation that conventional weight loss programs are often unsuccessful in the long term. Dieting recidivism thus sets the stage for weight cycling, popularly referred to as yo-yo dieting, whereby dieters undergo multiple cycles of weight loss and regain in pursuit of their ideal body weights.

There seems to be little disagreement that weight cycling is one of the most difficult therapeutic aspects in the management of obesity. Most of the obese subjects seeking treatment have previously experienced cycles of weight loss and regain. Examples of weight cycling in two case studies are shown in [Figure 1](#). These figures illustrate several phenomena that are important when considering weight cycling in humans: Weight losses and subsequent regains occur in conjunction with intentional weight loss dieting; however, weight changes vary in magnitude, and important fluctuations may be missed if weight measurements are taken at infrequent time intervals. Moreover, these two cases illustrate the common observation that intentional weight losses are frequently followed by regains in excess of the original body weight, and that true weight stability may be difficult to achieve.

Dieting to control body weight is not confined to overweight individuals, but has been widely reported even among men and women who have never been overweight. As described by Jeffery in 1984, 72.5% and 43.7% of surveyed women and men, respectively, had dieted to lose weight; even among women who had never been overweight, the majority reported having been on weight-loss diets. Although it is traditionally assumed that adherence to weight-reduction diets is beneficial to health, the high rates of dieting and weight regain, among the nonobese as well as the obese, have naturally created concern regarding potentially negative health consequences. However, weight loss can be intentional or unintentional, and the most recent generation of research on weight cycling has specifically focused on intentional weight loss as the risk factor of relevance to the weight-cycling debate, as reviewed by Simonsen.

In this article, some of the main points of this debate will be highlighted. The first epidemiological studies suggesting health implications of weight cycling were reviewed by Lissner and Brownell, when the majority of available observational evidence indicated adverse consequences. Subsequently, this topic became a source of considerable controversy, and a number of investigators continued to examine this issue, focusing on possible effects of weight cycling on metabolism, chronic disease, and mental health. This article will offer an overview of knowledge in this area, together with some methodological controversies surrounding existing research on weight cycling.

### The Metabolic Hypothesis

Given the fact that most people who lose weight are unable to sustain their losses, a ‘metabolic’ hypothesis was formulated. It was proposed that if weight loss dieting caused permanent decreases in metabolic rate, the weight would be easily regained and every subsequent weight loss attempt would be more difficult. In 1994, the National Task Force on the Prevention and Treatment of Obesity in the US reviewed the evidence and reported an overall lack of support for the hypothesis that weight cycling promoted obesity, increased body fat, or had permanent effects on metabolism. This report also concluded that the majority of available data in animals did not independently link weight cycling to any parameter of energy balance (food intake, body composition, or energy

**Figure 1** Monthly body weights (average of daily weights) of two female subjects, self-monitored over time. Reproduced from Black DR, Pack DJ, and Hovell MF (1991) A time-series analysis of longitudinal weight changes in two adult women. *International Journal of Obesity* 15: 623–633, with permission from Nature.

expenditure). This conclusion was supported by studies in humans, using a variety of designs, which failed to document irreversible effects of weight loss on metabolic rate, body composition, or adipose tissue distribution after regain. Also of interest in this context is the observation by Field in 2001 that weight-cycling women, in spite of their regains of lost weight, tended to gain less weight over time than their nonweight-cycling peers. In contrast, Van Wye reported that a history of weight cycling in healthy subjects did not seem to modify the risk of long-term weight gain in men and was associated with marginally more weight gain in women.

## Weight Cycling and Mortality

Although most studies did not bear out the original idea that weight cycling alters metabolic rate, the possibility that weight fluctuation predicts chronic disease and death has been more difficult to discount. A number of prospective epidemiological studies have shown that an individual's own variations in body weight over time, a proxy for weight cycling, can statistically predict subsequent risk of mortality and disease. Positive associations have been reported between body weight fluctuation and all-cause mortality in several but not all such studies, as reviewed by the National Task Force on the Prevention and Treatment of Obesity in 1994. These findings are often expressed in terms of relative risk estimates, which represent the mortality rates in a weight-fluctuating group compared with the rates in a weight-stable group. The relative risk estimates for all-cause mortality have been reported to be as high as 2, indicating a double excess mortality risk in the weight-fluctuating individuals. Some investigators have reported that significant associations are restricted to certain types of individual, that is, nonobese or nonsmoking subgroups. For instance, data from the Multiple Risk Factors Intervention Trial (1993) concluded that any adverse effects of weight fluctuation were occurring in relatively normal-weight subjects.

By way of example, results are shown from a reanalysis from a longitudinal population study of Swedish women, started in 1968 when subjects were 38–60 years old. Women were weighed on three occasions over a 12-year observation period, based on which four subcategories of weight change could be created: stable, weight gain, weight loss, and weight cycle. Specifically, these categories were defined as: (1) women whose weights remained stable within plus or minus 3 kg; those who; (2) gained or; (3) lost at least 3 kg between the first and last observation; and (iv) those who had lost and then regained at least 3 kg, or gained then lost 3 kg, without an overall change of more than 3 kg from the first to final observation. When these groups were followed up for an additional 20 years, it was found that the weight-loss group and weight-cycling group both had approximately double risk of mortality, compared with the weight-stable women (**Figure 2**). It may be argued that the weight losses and subsequent gains may not be voluntary but rather reflect preexisting diseases. However, after exclusion of women with prevalent or incident cancer, diabetes, or cardiovascular disease during the entire period of weight observations, the excess mortality in the fluctuating group was not attenuated, suggesting that morbidity from these conditions was not the underlying cause of the fluctuations or reason for the association. These findings and similar observations in a number of other populations have not been adequately explained by biologically plausible mechanisms.

A systematic literature review focusing on intentional weight loss in healthy men and women, rather than weight cycling per se, identified nine studies that could address this issue. The review yielded no consistent evidence that intentional weight loss either increased or decreased mortality. Simonsen concluded that it is still not possible to make secure recommendations that intentional weight loss will increase longevity. This is in contrast to research on severely obese bariatric surgery patients showing improved

**Figure 2** Relative risks of 20-year all-cause mortality, in relation to previous 12-year weight changes in the Prospective Population Study of Women in Göteborg. Triangular symbols refer to risks of total mortality, adjusted for age and final body mass index in 800 women. Circular symbols display results after excluding 99 prevalent cases of coronary heart disease, diabetes, or cancer during 12 years of weight observation.

longevity following elective weight-loss surgery, as reviewed in a recent meta-analysis by Pontiroli. Other factors may influence the associations between intentional weight loss and survival. The age at which weight fluctuations/cycles occurs may be of some relevance as weight loss among the younger adults may be less hazardous than in old age, when even apparently successful weight loss may in fact result from underlying disease. Similarly, weight gain early in adulthood may be more deleterious to overall health and mortality than weight gain later on. However, more research is needed to examine the influence of timing on the relation between weight variations and later disease and death.

### Weight Cycling and Cardiovascular Disease

Most investigators have considered it more informative to focus the association between weight fluctuation and specific diseases, and causes of death, and have frequently observed positive associations between weight fluctuation and cardiovascular disease endpoints. However, as reviewed by Lissner and Brownell, the results were not always in agreement; data from the Framingham study showed excess cardiovascular disease among male and female weight-fluctuating individuals, whereas in men from the Baltimore Longitudinal Study on Aging there was no association between weight fluctuation and coronary heart disease. Two additional studies in male populations are illustrated in **Figure 3**. Both show a pattern of elevated risk of mortality from cardiovascular or coronary heart disease among weight-cycling men, and consistently lowest risk associated with stable body weight, based on which Jeffery in 1996 concluded that "stable weight over time is associated with best health. All patterns of weight change other than stable weight – gains, losses, and both combined – appear to be associated with increased mortality risk."

It has been hypothesized that some of the observed associations between weight fluctuation and cardiovascular disease might be explained by changes in cardiovascular risk factors occurring during weight gain that are not fully reversible with weight loss. This possibility has been explored using longitudinal data on body weight and risk factors that are concurrently measured on multiple occasions. A systematic review of these studies by the National Task force on the Prevention and Treatment of Obesity (1994) revealed no consistent associations between weight fluctuation and concomitant increases in traditional cardiovascular disease risk factors such as blood pressure and serum cholesterol.

In particular, hypertension has been examined as an endpoint in a number of studies with somewhat mixed results. Using data from the Nurses' Health Study II, Field and coworkers in 1999 reported that intentional weight cycling was not associated with significant excess risk of development of hypertension. In contrast, a retrospective study by Guagnano indicated that a positive history of weight cycling among obese women as well as the sum of weight regained increased the likelihood of being hypertensive. Interestingly, Stevens reported a possible beneficial effect of one weight cycle: In this blood pressure reduction trial, weight returned to baseline levels after 3 years, although blood pressure remained well below control levels. Control subjects in this study experienced a net weight gain, and one interpretation of this study is that a weight cycle did not predispose further hypertension, but rather, seemed to deter further weight gains at control levels, as also observed in the Nurses' Health Study II (2001). However, intentional weight loss may not have persisting beneficial effects on blood pressure, as shown by the Swedish Obesity Study (2000) where a large weight loss induced by gastric surgery and maintained over 8 years had no effect on the 8-year incidence of hypertension. In contrast, the beneficial effect on blood pressure was of a transitory nature, with dramatic initial reductions in both systolic and diastolic blood pressure during the initial 12 months of weight loss, and although an 18- to 30-kg weight loss was maintained over the subsequent 7 years, both the systolic and diastolic blood pressure of the surgically treated group increased. After 8 years

**Figure 3** Total and cardiovascular disease mortality in male subjects with different weight change patterns. On the left, data from the Chicago Western Electric Study (Hamm, 1989) and on the right data from MRFIT (Blair, 1991).

there was no difference in systolic blood pressure between the surgically treated and the control groups, and diastolic blood pressure ended up higher in the surgical group than in the controls.

### Other Health Outcomes: Cancer and Diabetes

Although several of the original weight-cycling studies also tested associations between weight cycling and cancer, cancer endpoints have typically not followed the same patterns as cardiovascular disease. It has been observed by Trentham-Dietz in 2000 that temporary weight cycling (weight loss followed by weight gain) was not associated with increased risk of postmenopausal breast cancer.

A number of studies have examined associations between weight cycling and diabetes, and yielded little evidence of a relation. In 1997, a study by Podar monitored glucose tolerance and weight fluctuations in obese patients, and reported no deterioration directly associated with weight cycling. In the Nurses' Health Study in 2004, no association was found between weight fluctuation and diabetes incidence. Interestingly, the Diabetes Prevention Program Research Group in 2002 found that the diabetes reduction achieved for more than 4 years with a lifestyle intervention was not diminished with the gradual regaining of more than half of the weight lost. This observation is an indication that a period of weight reduction may exert a net benefit for diabetes, even if weight is subsequently regained.

### Psychological Consequences

It has often been assumed that the experience of dieting followed by involuntary regain of the lost weight must take a psychological toll, independent of any medical consequences of weight fluctuation. The possible psychological effects of weight cycling among obese persons were the topic of a literature review by Foster, who reported that weight cycling was not associated with depression, other psychopathology, or depressogenic cognitive styles. However, it was observed that weight cycling was associated with decreased perceptions of health and well-being, decreased eating self-efficacy, and weak increases in binge eating severity. Subsequently, Friedman concluded that an individual's perception of being a weight cycler may be more related to psychological problems than the actual number of pounds lost and regained over time. In 2000, the National Task Force on the Prevention and Treatment of Obesity concluded that concerns that dieting induces eating disorders or other psychological dysfunction in overweight and obese adults are generally not supported by empirical studies. A more recent prospective study of weight changes in relation to women's self-rated health found that that weight gain was associated with significant worsening of self-rated health but that weight loss did not result in an improvement in the same index. The observation that initially poor self-rated health actually predicted more weight gain suggests that causality is not simple, but that the association is more likely to be bidirectional.

### Methodological Issues

Although a number of studies have shown that increased weight fluctuations are associated with subsequent occurrence of adverse health outcomes, a number of methodological problems make interpretation of these findings difficult. For example, weight gain, weight loss, and weight cycling are often considered separately, but it is almost impossible to determine their degree of overlap in observational studies. An individual who is observed to be systematically gaining weight at two points in time may experience a number of unmeasured fluctuations in the interim. However, as both loss and gain have been shown to increase risk of dying prematurely, it is possible that the increased mortality risk associated with weight cycling depends on the cumulated risk contributions from repeated weight loss and gain. The statistical complexities in defining weight cycling were reviewed in 1994 by the National Task Force on the Prevention and Treatment of Obesity.

A common observation surrounding this type of research is that different studies may be measuring quite different kinds of weight change – voluntary and involuntary. Involuntary changes may reflect serious underlying illness, depression, and other non-dieting phenomena. However, intentional dieting may also occur by a variety of dietary methods, some of which are more detrimental to health than others, as discussed by French in 1993. The issue of volition may shed light on the problem, but the specific impact of previous and current illness on epidemiological associations between weight cycling and longevity is still not fully understood. Other covarying factors besides intentionality of weight change and underlying illness may be producing artifactual associations in observational studies. These include aging, smoking and other lifestyle choices, degree and regional pattern of adiposity, and psychological factors. In epidemiological analyses, various types of statistical corrections can be made for potential confounding factors of this type, although adjustment may be incomplete. Finally, biological plausibility is always an issue to consider when reviewing any epidemiological evidence and has been a particular concern when considering the observations of excess risk in association with weight fluctuations.

**Table 1** Summary of hypothesized weight cycling effects and selected sources of evidence

<i>Hypothesized adverse health consequences of weight cycling</i>	<i>Comments (with suggested reading)</i>
Psychological consequences	Not supported by evidence (reviewed by the US National Task Force, 2000)
Metabolic rate and body composition	Not supported by evidence (reviewed by the US National Task Force, 1994)
All-cause mortality	Supported by most prospective studies, for example, Hamm, 1989; Lissner, 1991; Blair, 1993 (reviewed in Obesity 1992, and by the US National Task Force, 1994)
Cardiovascular disease	Supported by most prospective studies, for example, Hamm, 1989; Lissner, 1991; Blair, 1993 (reviewed in Obesity 1992 and the US National Task Force, 1994)
Diabetes	Not supported by epidemiological studies (Field, 2004). Mixed evidence from clinical setting (Guagnano, 2000)
Cancer	Not supported by epidemiological studies (Lissner, 1991; Trentham-Dietz, 2000)

## Conclusions

As summarized in **Table 1**, many – but not all – epidemiological studies indicate that men and women undergoing body weight fluctuations are at higher risk of mortality and/or cardiovascular disease than individuals experiencing less fluctuation, but the lack of biologically plausible mechanisms to explain these associations has limited the conclusions that can be drawn. Moreover, the evidence for effects on psychological and other health endpoints is inconclusive. Uncontrolled confounding from disease states resulting in a loss–gain or gain–loss pattern must be considered a plausible explanation for some of these findings, underscoring the difficulty of using observational data to study weight cycling. Some studies are suggesting that even limited periods of weight reduction may be beneficial in the long run, whereas others are not. Experimental data and intervention studies are required for confirmation of the weight-cycling hypothesis. The published observational studies of subjects whose weight changes are known to be caused by dieting have been important contributions to the critical discussion of the weight-cycling phenomenon, but additional studies are needed in which weight fluctuations are assessed in a more controlled manner.

Regarding the hypothesis that dieting exacerbates the problem of obesity and weight gain, most studies have failed to demonstrate that weight fluctuation per se depresses metabolic rate. Available research on the effects of weight cycling on both metabolism and disease thus provides little basis to discourage overweight patients from losing weight. Nevertheless, one of the conclusions of the 1994 report from the National Task Force on the Prevention and Treatment of Obesity was that individuals who are not obese and who have no risk factors for obesity-related illness should not undertake weight loss efforts. The only uncontroversial message of the weight-cycling research is that overweight individuals need to be counseled in skills to maintain weight loss, and that relapse prevention should be a more central focus of weight loss programs.

In conclusion, although this research has drawn attention to the necessity of developing improved behavioral and nutritional strategies for sustaining weight reductions and thus preventing weight cycling, the evidence relating weight cycling to adverse health outcomes must be considered equivocal. Regarding the hypothesis that weight cycling exacerbates weight problems, a 1995 opinion survey of obesity researchers conducted by Bray concluded that weight cycling was not considered a very important cause of obesity, and little convincing evidence has emerged in subsequent years to change that conclusion. With regard to the question in the ‘weight cycling refrain’ regarding possible consequences of weight cycling, the current knowledge would suggest that it is probably not worse to have lost and regained than never to have lost at all. However, there remain some curious and persistent results in the experimental as well as epidemiological literature suggesting that we do not completely understand the phenomenon.

## Key points

- Successful weight loss maintenance is generally defined as an intentional loss of 5–10% of initial body weight maintained for at least 1 year.
- The complex interaction of physiological, environmental, and psychological factors associated with weight status make long-term maintenance of weight loss challenging.
- In general, successful weight loss maintainers consume a low-calorie diet, eat breakfast regularly, self-monitor weight frequently, and maintain consistent eating patterns across time. Successful maintainers also engage in substantial levels of physical activity (approximately 1 h per day).
- No optimal diet has been identified for weight loss maintenance. The best dietary strategy is one that provides fewer calories than the individual consumed prior to weight loss and that the individual can adhere to long-term.
- Obesity and weight management should be treated using a chronic care approach that emphasizes ongoing behavioral support over time, such as extended professional contact and social support.

## Introduction

Nearly 3 out of 4 adults in the United States have overweight or obesity (Fryar et al., 2020). Obesity is a risk factor for numerous serious diseases, including type 2 diabetes, hypertension, and some cancers, and the condition constitutes a significant economic burden in developed countries (Bianchini et al., 2002; Tremmel et al., 2017; Paeratakul et al., 2002). Thus, understanding how

individuals can achieve and maintain weight loss is an important public health issue. The goal of this article is to review current research related to successful weight loss maintenance. A definition of weight loss maintenance is provided and is discussed within the context of the field's evolving perspective of obesity as a chronic disease. Next, current explanations for why weight loss maintenance is difficult are described. Finally, factors important for successful weight loss maintenance are identified from observational and experimental research examining the behavioral, psychological, and environmental determinants of maintenance. The article closes with recommendations for achieving weight loss maintenance, as well as directions for future research.

## Definition of successful weight loss maintenance

There is currently no standard definition for weight loss maintenance. In general, an intentional weight loss of 5–10% of initial body weight that is sustained for at least 1 year is considered successful weight loss maintenance (Rössner, 1997; Wing and Hill, 2001). This magnitude of weight loss is supported by the 2013 AHA/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults, which recommends 5–10% weight loss for clinically meaningful improvements in cardiometabolic health (Jensen et al., 2014). However, losses as low as 3% may also result in modest improvements in cardiovascular risk factors, with greater weight loss resulting in greater benefits (Jensen et al., 2014).

## Data on prevalence of long-term weight loss maintenance

Obesity treatment studies with long-term follow up provide important insight into the maintenance of weight loss over time. A systematic review of different weight loss interventions (e.g., lifestyle, meal replacements, pharmaceutical) with at least 1-year follow up found that initial weight losses ranged from 4.8% to 8.0%, with sustained weight losses of 3.0%–4.3% maintained up to 4 years later (Franz et al., 2007). In general, weight loss tended to plateau around 6 months, at which time partial weight regain occurred. In behavioral lifestyle interventions (which include diet, physical activity, and behavior modification components), 35%–60% of participants maintain a loss of at least 5% of initial body weight for 2 or more years (Jensen et al., 2014).

Weight control registries in the United States and Europe, which enroll adults who are successful weight loss maintainers, also provide information on the prevalence of weight loss maintenance. While each registry has unique enrollment criteria (an initial loss of 5 kg, 13.6 kg, or 10% of body weight maintained for at least 1 year or 2 years), successful maintenance (defined as maintaining at least 3%–10% weight loss, depending on the registry) was observed in 60.5%–88.0% of participants at follow-up 1–10 years later. It is unclear whether or in which type of intervention registry members participated for either initial weight loss or the weight loss maintenance period (Paixão et al., 2020).

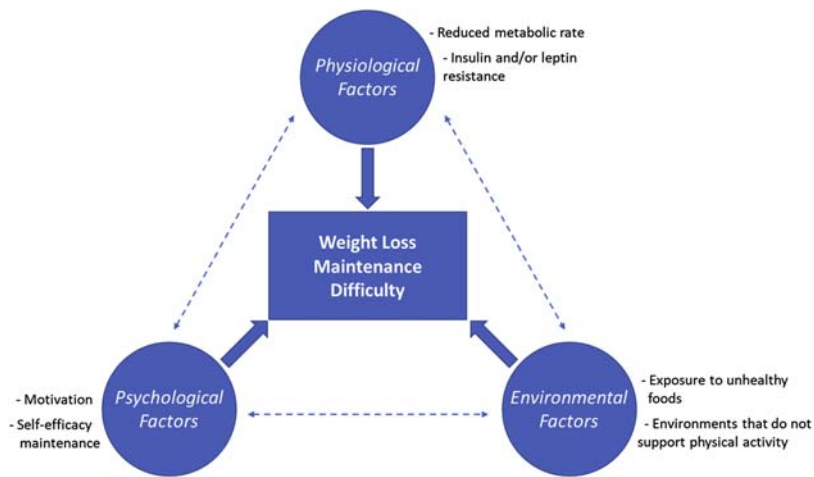

## Why is weight loss maintenance difficult?

A complex interaction of physiological, environmental, and psychological determinants contributes to the challenges associated with weight loss maintenance (Fig. 1) (Huang et al., 2009; Varkevisser et al., 2019). Researchers speculate that weight loss, in response to dieting, produces physiological (e.g., decrease in energy expenditure) and psychological changes that may result in consequent weight regain (MacLean et al., 2015). The interplay of environmental cues, such as exposure to unhealthy foods or lack of sidewalks, may affect energy balance through encouraging increased energy intake and decreased energy expenditure (Li et al., 2009; McCormack and Shiell, 2011). The psychological processes (e.g., motivation) that are needed to supersede unhealthy behavior cues in an obesogenic environment may also be difficult to maintain over a long period of time (Metzgar et al., 2015). Additionally, greater weight loss earlier in treatment predicts better outcomes at the end of treatment, and the weight loss attributed to diet and physical activity changes may provide positive reinforcement that supports treatment adherence (Handjieva-Darlenska et al., 2012). During the maintenance period, however, there is no continued weight loss (and often at least some weight regain), which may reduce reinforcement and decrease the behaviors associated with healthy eating and regular physical activity. Finally, accountability and social support may also wane over time, making weight loss maintenance more difficult (Metzgar et al., 2015).

## Observational studies of weight loss maintenance

Observational research uses non-experimental study designs to identify factors associated with weight loss maintenance. In observational research, the variable of interest is observed as it naturally occurs and is not manipulated by the researchers. These study designs provide important information about the relationships between behavioral, psychological, and environmental factors and maintenance of weight loss over time. However, since researchers do not have control over the variable of interest, the ability to determine causality is limited.

**Fig. 1** Conceptual model of the complex interaction of physiological, psychological, and environmental factors that influence weight loss maintenance.

## The National Weight Control Registry

The National Weight Control Registry (NWCR) is the largest prospective observational study investigating weight loss maintenance to date ([The National Weight Control Registry](#)). NWCR was established in 1994 and now tracks more than 10,000 individuals identified as successful weight loss maintainers. To be eligible for enrollment in NWCR, adults aged 18 years or older must have a previous weight loss of at least 13.6 kg (30 pounds) that has been maintained for at least 1 year. The participants in NWCR are predominantly women (77.5%) and white (95.7%).

A 10-year follow up study was conducted among NWCR members ([Thomas et al., 2014](#)). With an average weight loss of 31.3 kg at enrollment, participants maintained an average weight loss of 23.8 kg at 5 years and 23.1 kg at 10 years. Additionally, participants with greater initial weight loss at enrollment maintained substantially greater weight loss at 10 years, suggesting that the magnitude of initial weight loss is important in for successful weight loss maintenance over the long term.

Despite heterogenous approaches to weight loss maintenance reported by NWCR members, certain behaviors have been consistently identified among successful maintainers. These include consuming a low-calorie diet, eating breakfast regularly, self-monitoring weight frequently, and engaging in consistent eating patterns across time ([Wing and Phelan, 2005](#)). In a 2014 study, registry members reported consuming around 1410 kilocalories per day, with 29% of daily calories coming from fat, 19% from protein, and 50% from carbohydrates ([Catenacci et al., 2014](#)). This marks a shift in macronutrient composition from two decades earlier, when registry members reported percent of daily calories from fat and carbohydrates to be around 24% and 56%, respectively (protein intake stayed relatively constant) ([Klem et al., 1997](#)). This shift toward fat and away from carbohydrates is consistent with national trends in the United States and may reflect dieting trends that emphasize lower-carbohydrate recommendations (e.g., keto diet) ([Klem et al., 1997](#); [Shan et al., 2019](#)). Additionally, more than three-quarters of registry participants report eating breakfast daily, and self-reported dining at restaurants and fast-food establishments is limited ([Wing and Phelan, 2005](#)). More than half (59%) of NWCR members report maintaining a consistent eating pattern across weekdays and weekends, as well as during holidays and vacations ([Wing and Phelan, 2005](#)). Additionally, self-monitoring of weight is an important determinant of successful weight loss maintenance. Nearly half (44%) of NWCR members report weighing themselves every day, and nearly a third (31%) more weigh themselves at least once per week ([Wing and Phelan, 2005](#)). This frequent self-monitoring of weight may contribute to increased awareness of weight fluctuations, allowing individuals to self-evaluate how diet and activity behaviors are affecting their weight and to adjust as needed.

Physical activity is also an important part of long-term weight loss maintenance ([Catenacci et al., 2008](#)). The vast majority of NWCR members (85%) report using physical activity as a strategy for maintaining their weight loss. NWCR members report an average energy expenditure of about 2600 kilocalories per week from physical activity, which equates to approximately 1 h of moderate-intensity physical activity per day. Walking is the most reported leisure time physical activity, with cycling and cardiovascular exercise machines also being popular activities among both women and men ([Catenacci et al., 2008](#)).

## Psychological factors associated with weight loss maintenance

Observational studies have also examined psychological factors related to successful weight loss maintenance. NWCR members with higher levels of depression, binge eating, and disinhibition (i.e., loss of control while eating) experienced greater weight

regain at 1-year follow up (McGuire et al., 1999). Research in other populations suggests that individuals who feel confident and in control of their weight-related behaviors are more likely to be successful maintainers. Having higher self-efficacy (i.e., a person's confidence in his or her ability to perform behaviors related to weight management) and an internal locus of control (i.e., believing that success or failure is related to personal attributes rather than external factors outside of one's own control) have been associated with better weight loss maintenance, as have higher levels of autonomous motivation (Teixeira et al., 2015; Anastasiou et al., 2015). While behavioral lifestyle interventions focus on building skills related to self-regulation and self-efficacy, more research is needed investigating how weight interventions can address other psychological determinants of weight loss maintenance.

## Experimental studies examining weight loss maintenance

In experimental research, variables thought to be related to weight loss maintenance are manipulated by the researchers, and weight is measured to examine change over time. Randomized controlled trials (RCTs), a type of experimental design, use rigorous methodology to investigate treatment factors associated with weight loss maintenance (Miller et al., 2020; Fisher, 1937). The process of randomizing study participants to treatment groups reduces the influence of both measured and unmeasured confounding variables, resulting in improved ability to determine causality (Miller et al., 2020; Fisher, 1937). Experimental studies in the weight loss maintenance literature typically investigate long-term weight loss (e.g., weight change from baseline to study completion) rather than the maintenance of weight loss from the end of the initial treatment (usually 6 months) to study completion (Look AHEAD Research Group, 2014). While recent long-term weight loss trials have increased in sample size, these interventions are still often limited in study duration (usually not more than 1–2 years in length). Table 1 outlines three major experimental trials examining behavioral lifestyle interventions for successful maintenance of weight loss.

## Energy balance

Interventions for the treatment of obesity encompass a broad spectrum of dietary and physical activity strategies. For any diet to cause weight loss, it must produce an energy deficit in which energy consumed is less than energy expended through lifestyle and activity. To successfully maintain weight loss, an individual must sustain energy balance (energy intake equals energy expenditure) at a lower energy intake than prior to initial weight loss. Early dietary research in this area focused primarily on caloric restriction and dietary structure (Cordain et al., 2005). However, the scope of recent research has expanded to include regulation of metabolic pathways through adaptations of macronutrient composition (Freire, 2020; Cordain et al., 2005). Research has also shown that behavioral lifestyle interventions, which combine diet, physical activity, and behavioral strategies, are the most effective non-surgical treatment for long-term maintenance of weight loss.

## Diet

Behavioral lifestyle interventions have traditionally recommended a balanced low-fat, low-calorie diet for weight loss (Baker, 2006; Expert Panel on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults, 1998). This diet includes goals to consume 1000–1500 kilocalories per day, depending on initial body weight and to reduce dietary fat intake to 20–30% of total calories. The MyPlate method, developed by the United States Department of Agriculture, offers dietary recommendations that prioritize portion control (Chang and Koegel, 2017). MyPlate encourages consumption of all macronutrients and has no strict guidelines related to food group restriction or inclusion. In general, the method emphasizes consumption of whole grains, fruits and vegetables, low-fat dairy, and lean proteins and recommends limiting added sugars, saturated fat, and sodium (Chang and Koegel, 2017).

## Structured low-calorie diets

Dietary structure refers to the amount of control imposed on the types and/or amount of food consumed. A structured dietary regimen can be achieved through a variety of strategies, including limited food choice variety, structured meal plans, meal replacements, and the use of comprehensive grocery lists (Ditschuneit and Flechtner-Mors, 2001). In general, weight loss outcomes tend to improve with increasing dietary structure (Raynor and Champagne, 2016). One RCT investigated the effect of providing portion-controlled lunch and dinner entrées compared to self-selection of foods during participation in a behavioral lifestyle intervention. The provision of portion-controlled entrées promoted greater weight loss and fat mass loss at 12 weeks compared to control [8.6 kg (3.9%), 7.8 kg (5.1%), and 6.0 kg (4.4%), respectively] (Rock et al., 2016).

Meal replacements (MRs) can be characterized as portion-controlled food products or beverages that replace complementary foods. The strategy can be a cost-effective approach for weight loss and weight loss maintenance, including in populations with economic limitations (Huerta et al., 2004). MRs are commonly used to reduce total caloric intake to simultaneously promote

**Table 1** Major experimental studies examining weight loss maintenance.

Trial name (author, year)	Sample characteristics (sample size, sex, race/ ethnicity, mean BMI, mean age)	Study design, duration, assessment timepoints	Intervention components					Key findings

ILI was more likely than DSE to weigh themselves daily or weekly, and participants who weighed themselves more frequently were more likely to maintain ≥10% wt loss at yr 8.

Weight loss maintenance trial (Svetkey et al., 2008)	N = 1032 63% female 38% African American 62% non-African American Ethnicity not reported 34.1 kg m <sup>-2</sup> 55.6 yrs	RCT 30 mos Assessments: 0, 6, 12, 18, 24, 30 mos	Phase 1 (Mos 1–6): Wt loss Phase 2 (Mos 7–36): Wt maintenance; participants losing ≥4 kg randomized to one of the following groups: <b>Experimental:</b> Personal Contact (PC) Interactive Technology (IT) <b>Active comparator:</b> Self-Directed (SD)	Phase 1: Reduce kcal intake; adopt DASH dietary pattern <sup>b</sup> Phase 2: Individualized calorie goals; DASH dietary pattern	Phase 1: ≥180 min wk <sup>-1</sup> of moderate-intensity PA Phase 2: ≥225 min wk <sup>-1</sup> of moderate-intensity PA	Phase 1: Social support, goal setting, decision making, problem solving, self-monitoring, contingency planning Phase 2: <b>PC &amp; IT:</b> self-monitoring, feedback, problem-solving, relapse prevention, social support, motivational interviewing <b>SD:</b> none	Phase 1: Weekly 1.5 h grp mtgs Phase 2: <b>PC:</b> 1 mtg per mo (45 min face-to-face mtg every 4 mos, telephone contacts in between) <b>IT:</b> 45 min orientation mtg at randomization plus 1 “re-orientation” mtg at 12 mos; unlimited access to intervention website; automated telephone calls and emails <b>SD:</b> minimal contact (only at f/u visits)	All groups maintained significant wt loss from study entry to 30 mos: <i>SD:</i> 2.9 kg <i>IT:</i> 3.3 kg <i>PC:</i> 4.2 kg PC regained less wt than SD and IT at 24 mos (group diff of –2.0 and –1.1 kg) and 30 mos (group diff of –1.5 and –1.2 kg). Wt loss was greater in IT than SD for all f/u assessments (6, 12, 18, 24 mos) except 30 mos.
Study to prevent regain (STOP regain) trial (Wing et al., 2006)	N = 314 81.2% female Race/ethnicity not reported 28.6 kg m <sup>-2</sup> 51.3 yrs	RCT 18 mos Assessments: 0, 6, 12, 18 mos	No phases. To be eligible, individuals were required to have lost ≥10% of body wt in prior 2 yrs. <b>Experimental:</b> Face-to-Face (F2F) Internet-Based (IB) <b>Comparator:</b> no-intervention control	<b>F2F &amp; IB:</b> for participants with wt regain of ≤2.2 kg, no specific strategies recommended; for participants with wt regain ≥2.3 kg, either initial wt loss approach or standard low-kcal/low-fat diet with MRs recommended	<b>F2F &amp; IB:</b> ≥60 min d <sup>-1</sup> of PA <b>Control:</b> none	<b>F2F &amp; IB:</b> self-monitoring, positive reinforcement <b>Control:</b> none	<b>F2F &amp; IB:</b> weekly group mtgs for 1 mo, then monthly mtgs for remaining 18 mos (in-person for F2F and online via chat room for IB); additional individual counseling for participants with ≥2.3 kg wt regain (telephone for F2F and email for IB) <b>Control:</b> none	F2F, but not IB, had less wt regain at 18 mos compared to control (2.5 kg in F2F, 4.7 kg in IB, and 4.9 kg in control). Fewer participants in F2F and IB regained ≥2.3 kg compared to control at 18 mos (45.7% in F2F, 54.8% in IB, and 72.4% in control).

Abbreviations: BMI = body mass index; d = day; DASH = dietary approaches to stop hypertension; diff = differences; f/u = follow up; hr = hour; kcal = kilocalorie; kg = kilogram; m = meter; min = minute; mo = month; MR = meal replacement; mtg = meeting; PA = physical activity; RCT = randomized controlled trial; wk = week; wt = weight; yr = year.

<sup>a</sup>Participants were taught an approach to eating a low energy-dense diet following the book *Volumetrics* (Rolls and Barnett, 2000).

<sup>b</sup>The DASH dietary pattern encourages increased consumption of fruits, vegetables, low-fat dairy and reduced consumption of saturated and total fats.

weight loss over time. MRs used in weight loss interventions have been considered a helpful strategy as delivery can occur within a community or via an over-the-counter purchase without external support from healthcare systems. A recent systematic review and meta-analysis of MRs found that MR use resulted in greater weight loss over one year compared to alternative interventions using conventional foods only (Astbury et al., 2019).

### Very low-calorie diets

Very low-calorie diets (VLCDs) were designed to produce rapid weight loss while minimizing loss of lean muscle mass (Expert Panel on the Identification, 1998; Saris, 2001). In VLCDs, calorie intake is restricted to 450–800 kcal per day, and a protein-enriched diet (often in the form of liquid formulation or specially formulated bars) is provided to maintain lean body mass. The diet is usually prescribed for no more than 12 weeks, and patients receive intensive medical supervision during this period to monitor for health complications or adherence issues (Expert Panel on the Identification, 1998; Saris, 2001). VLCDs can induce large initial weight losses of 14.2–21.0 kg over 11–14 weeks (Jensen et al., 2014). Despite this large initial weight loss, a period of rapid weight regain is typically observed after stopping the VLCD, and VLCDs do not necessarily result in better long-term weight loss outcomes compared to LCDs with less severe calorie restriction (Franz et al., 2007; Jensen et al., 2014).

### Diet composition

A large body of research has investigated how dietary composition affects weight loss and weight loss maintenance. Different macronutrients may influence perceptions of satiety, hunger, and fullness differently and may, therefore, also affect energy intake (Hill and Blundell, 1986). Despite these differing qualities, a large behavioral lifestyle intervention trial examining four diets with distinct macronutrient compositions (i.e., differing percent of energy from fats, carbohydrates, and proteins) found no differences among the diets in either initial magnitude of weight loss or weight loss maintenance two years later (Sacks et al., 2009). However, a body of research suggests that consuming a diet high in protein may have a significant beneficial effect on the prevention of weight regain (van Baak and Mariman, 2019).

Another potentially useful dietary strategy for weight loss maintenance is consumption of a diet high in low-energy dense foods. Energy density is a measure of kilocalories per gram of food. Fewer calories are consumed when eating the same volume of a lower energy density food as compared a higher energy density food (Rolls, 2009). Reducing the energy density of the diet has been shown to produce weight loss, even in the absence of explicit goals for calorie restriction (Ello-Martin et al., 2007). One year-long intervention trial conducted in women with obesity found that the group with goals to reduce fat and consume water-rich foods ate a diet with lower energy density, were less hungry, and had greater weight loss (7.9 vs. 6.4 kg lost, respectively) than the group with goals to reduce fat intake only (Ello-Martin et al., 2007). Furthermore, a secondary analysis of two separate intervention trials found that successful weight loss maintainers reported consuming a diet with lower energy density than participants who were both overweight and healthy weight (Raynor et al., 2011).

At this time, little experimental research has looked at the effectiveness of food group-related dietary patterns (e.g., Mediterranean diet) for long-term weight loss maintenance. One weight loss maintenance trial implemented the Dietary Approaches to Stop Hypertension (DASH) diet during the initial weight loss phase (Svetkey et al., 2008). Results showed that all treatment conditions maintained significant weight loss at 30 months; however, groups receiving extended contact experienced less weight regain. The Mediterranean diet, which emphasizes consumption of plant-based foods and healthy fats and seafood, has been shown to be effective at producing weight loss at  $\geq 12$  months and, in one systematic review, performed better than low-fat diets (Mancini et al., 2016).

### Intermittent fasting

In recent years, there has been increased interest in nutrient timing as a mechanism for weight loss and improved metabolic health (Templeman et al., 2020; Patterson and Sears, 2017). Intermittent fasting (IF) encompasses a broad spectrum of dietary timing approaches that partially or completely restrict energy intake within a consistent, recurring temporal period (e.g., alternate day fasting, fasting up to 4 days per week) (Patterson and Sears, 2017; Harris et al., 2018; Templeman et al., 2020). One such strategy is time-restricted feeding (TRF). TRF eating patterns restrict caloric consumption to a specific period of 8–10 h or less for every day of the week, and common variations include early- and mid-day TRF (Rynders et al., 2019). An evaluation of recent evidence related to intermittent energy restriction strategies as a treatment for overweight and obesity found equivalent results when intermittent energy restriction (IF or TRF) was compared to continuous energy restriction (Rynders et al., 2019). Nine out of eleven studies included in the review reported no significant between-group differences in weight change or total fat loss.

Few long-term studies of IF diets have been conducted. A 12-month RCT compared continuous energy restriction (CER) to two different IF strategies: week-on-week-off energy restriction (alternating each week between the same energy restriction as CER or habitual diet) and a 5:2 diet (habitual diet on 5 days per week and a modified fast of approximately 500 and 600 kcal on 2 days per week for women and men, respectively) (Headland et al., 2019). Mean weight loss was not significantly different between groups at 12 months (−5.0 kg for 5:2, −5.1 kg for week-on-week-off, and −6.6 kg for CER), and discontinuation rates were also similar, indicating that adherence to IF does not appear to be more difficult than traditional

weight loss diets. A separate 12-month RCT in adults with type 2 diabetes also compared CER (1200–1600 kcal/day) to a 5:2 IF diet (two non-consecutive fasting days with energy intake limited to 500 and 600 kcal for women and men, respectively) (Carter et al., 2018). At the end of the 12-month treatment period, the 5:2 condition lost significantly more weight than the CER condition (−6.8 kg vs. −5.0 kg, respectively); however, there were no differences in change in weight from baseline at 12 months post-treatment (Carter et al., 2019).

### Conclusions on dietary strategies and weight loss maintenance

A larger initial weight loss is associated with better weight loss maintenance over time. However, any diet that produces a calorie deficit can induce weight loss, and current research does not clearly support the recommendation of one dietary strategy over another for the weight loss phase. Similarly, no optimal dietary strategy has been identified for long-term successful weight loss maintenance. Instead, identifying a dietary strategy that an individual is able to follow closely over time may be most important, as adherence, regardless of dietary strategy, is associated with improved weight outcomes (Alhassan et al., 2008).

### Physical activity

Observational research suggests that physical activity (PA) is one of the strongest predictors of long-term weight maintenance. In addition to increasing energy expenditure, PA has other benefits, such as elevated mood and reduced hunger (Kanning and Schlicht, 2010; Vatansever-Ozen et al., 2011). Multiple robust RCTs have associated volume of PA with successful maintenance of weight loss (Jeffery et al., 2003).

The 2018 Physical Activity Guidelines for Americans recommend that adults participate in at least 150 min–300 min of moderate-intensity exercise per week or 75 min–150 min of vigorous-intensity aerobic activity per week for good health (Piercy et al., 2018). They also recommend that adults engage in 2 or more days of muscle-strength training per week. These guidelines emphasize that adults who even modestly increase their moderate-to-vigorous activity will experience beneficial effects for weight loss. However, even greater levels of PA may be needed to maintain weight loss long-term. The American College of Sports Medicine (ACSM) recommends even higher levels of PA—200–300 min per week—to prevent weight regain after weight loss, and successful maintainers in NWCR report engaging in approximately 1 h of moderate-intensity activity per day, which exceeds the recommendation in the Physical Activity Guidelines for Americans (Donnelly et al., 2009).

### Strategies for improving maintenance of physical activity

While the best diet for long-term obesity treatment is still to be identified, research consistently indicates that moderate-to-vigorous PA is integral to long-term weight loss maintenance success. Research in this area primarily focuses on maintaining increases in moderate-to-vigorous intensity PA.

For individuals with obesity, maintenance of increased PA levels is complicated by physiological, psychological, and environmental factors. The main perceived barriers to PA adherence include low fitness, pain, lack of stimuli, body image dissatisfaction, time, and weather constraints (Patel et al., 2013). Behavioral and cognitive strategies may mitigate these challenges to PA adherence (Patel et al., 2013; Dalle Grave et al., 2011). One beneficial technique may be intermittent bouts of exercise, such as 4 short (~10 min) bouts of exercise for at least 5 days a week, vs. one long bout of continuous exercise (Jakicic et al., 1995). Though one RCT showed promise using this strategy, larger studies were unable to produce comparable outcomes in long-term adherence to intermittent exercise (Jakicic et al., 1995). A more recent study investigated how and when weight loss maintainers engage in PA throughout a single day and across 7 consecutive days (Creasy et al., 2021). Weight loss maintainers were found to engage in high amounts of moderate-to-vigorous PA ( $\geq 60$  min/day) on more days of the week and accumulated more moderate-to-vigorous PA in uninterrupted bouts, and during morning hours compared to the control group. Further research on temporal patterns of PA across days and weeks among weight loss maintainers may help inform behavioral interventions targeted at long-term PA adherence.

A wide array of other types of support to achieve PA adherence has also been tested, such as personal trainers, home exercise equipment, and financial incentives (Mitchell et al., 2013; Burns et al., 2012). Research suggests that as financial incentives increase, attendance at group exercise sessions increases, at least in the short term or during periods when the provision of incentives is active (Mitchell et al., 2013; Wall et al., 2006; Paul-Ebhohimhen and Avenell, 2008). However, programs that provide financial incentive may not be sustainable over time do prohibitive implementation costs.

### Behavioral component

#### Obesity as a chronic disease

Healthcare's perspective on obesity has changed substantially in recent decades. In 1998, the National Institutes of Health published treatment guidelines that described obesity as a "complex multifactorial chronic disease" (Expert Panel on the Identification, 1998). However, viewing obesity as a disease was not widely accepted at that time (Kyle et al., 2016). Over the next 15 years, research began

to identify genetic and environmental factors that contribute to obesity, and consequently professional organizations and governmental agencies began to recognize the condition as a chronic disease rather than simply a cosmetic issue due to poor personal choices (Kyle et al., 2016; American Society for Metabolic and Bariatric Surgery). Concurrent with this perspective shift, the field has also moved toward a chronic care approach to obesity treatment. The Chronic Care Model (CCM) emphasizes several areas related to care of patients with chronic illnesses: (1) quality improvement is ongoing and incentivized within the care delivery system, (2) behavioral self-management support is provided to patients that increases their self-efficacy to manage their illness, (3) care teams and systems function in a way to meet the needs of patients with chronic illnesses, (4) evidence-based guidelines are implemented for care, and (5) information systems are improved and disease registries are developed to provide feedback on treatment performance (Wagner, 1998). Thus, the CCM highlights the need for ongoing, high-quality care that focuses on improving health care delivery systems to support successful disease management in patients with chronic illness. Similarly, the 2013 AHA/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults provides a treatment algorithm for physicians treating patients with obesity that uses a “Chronic Disease Management Model” (Jensen et al., 2014). The algorithm emphasizes frequent monitoring of patient weight and related risk factors, as well as referral to intensive lifestyle intervention when warranted.

### Extending professional contact

Research suggests that obesity treatment should extend beyond the initial weight loss phase and should include ongoing professional contact, behavioral skill development, social support, and physical activity adherence (Perri and Corsica, 2002). The healthy behaviors acquired through behavioral lifestyle interventions require continuous effort and practice to achieve long-term maintenance goals and sustained health benefits (Perri and Corsica, 2002; Latner et al., 2000).

An advisable recommendation is the extension of program delivery (Latner et al., 2000). Duration of treatment is correlated with weight loss following intervention, suggesting that the poor long-term maintenance of weight loss may be attributed to loss of support after termination of intervention. An RCT was implemented to compare two weight loss maintenance interventions with an individual-driven control (Svetkey et al., 2008). After the weight loss phase, participants were randomly assigned to either a monthly personal contact, a technology-based intervention, or a control group for 30 months (Svetkey et al., 2008). Following the intervention, participants in the personal-contact group regained less weight (4.0 kg) compared to the control group (5.5 kg). At 18 months, the interactive-technology group had lower weight regain compared to the self-directed group (mean difference, −1.1 kg); however, no difference was observed at 30 months.

The use of an extended care model that includes clinic-based follow-up is warranted. A recent meta-analysis assessed the evidence related to extended care and long-term weight maintenance (Ross Middleton et al., 2012). The effect of the extended care was additional weight loss maintenance of 3.2 kg over 17.6 months compared to both no-contact and education control groups. The domains deemed most effective at supporting weight loss maintenance included regular contact with an interventionist, group sessions coupled with reinforcement of behavioral strategies, and use of problem-solving skills to overcome perceived barriers.

### Social support

Both dimensions of social support, structural (e.g., support-benefactor) and functional (e.g., perceived support), are thought to produce beneficial health outcomes such as weight maintenance (Karfopoulou et al., 2016). The obesity intervention literature consistently emphasizes the role of social support; however, the degree of effectiveness in weight loss maintenance remains unclear (Karfopoulou et al., 2016). A cross-sectional analysis examined if participants who experienced weight loss and weight maintenance differ by the amount and type of support they received. One cross-sectional study found that functional support may be a contributor to weight loss maintenance, such that maintainers perceived a greater degree of social support regarding healthy eating and physical activity. The authors concluded that social support should be focused on positive and not instructive feedback from peers and family members (Karfopoulou et al., 2016).

### Self-monitoring

Self-monitoring is an important strategy for successful weight loss maintenance. Regularly weighing oneself has consistently been linked to more successful weight loss maintenance over time (Butryn et al., 2007; O’Neil and Brown, 2005). Almost half (44%) of NWCR members weigh themselves daily, and nearly a third (31%) more weigh themselves at least once per week (Wing and Phelan, 2005). Self-monitoring of diet and physical activity is also associated with greater success in maintaining weight loss (Laitner et al., 2016; Akers et al., 2012; Burke et al., 2011). Frequent self-monitoring can increase awareness of energy balance-related behaviors (i.e., diet and physical activity) and provide information on how these behaviors affect weight, allowing individuals to make timely adjustments to their diet and activity routines when they experience a weight increase.

## Technology

Recent advances in technology offer unique opportunities for the field of weight management, such as streamlined intervention components (e.g., digital food and beverage tracking) and decreased barriers to treatment (e.g., bypassing issues due to lack of vehicle access). The efficacy of web-based interventions for weight loss has been studied for decades, and web-based interventions have consistently been shown to be effective in producing greater weight loss than control or minimal intervention conditions (Sorgente et al., 2017). However, research is mixed regarding whether web-based interventions are equally as effective as face-to-face delivery (Sorgente et al., 2017). The Weight Loss Maintenance Trial, which enrolled more than 1000 adults who had successfully lost 4 kg of body weight during an initial 6-month phase, found that both the personal-contact and interactive technology-based conditions regained less weight than the self-directed condition at 18 and 24 months (Svetkey et al., 2008). However, only the personal-contact condition regained less weight than the self-directed group at 30 months, with no difference between the interactive technology-based and self-directed conditions at this timepoint.

Furthermore, intervention technologies have begun to move beyond simply providing traditional treatment in an online format. One RCT tested the effects of using virtual reality (VR) in combination with a cognitive behavioral therapy approach on weight outcomes (Manzoni et al., 2016). Multiple VR modules were implemented, such as simulated environments important for maintenance and relapse prevention (e.g., supermarkets, pubs) that allowed participants to practice problem solving and decision-making skills. Participants in the VR-enhanced cognitive behavioral therapy condition had increased odds of weight maintenance and improved weight at 1-year post-intervention than both the standard behavioral inpatient program and the standard behavioral inpatient program plus standard cognitive behavioral therapy. Another increasingly common technology-based strategy is the use of avatars, or graphical representations of the user within the virtual environment, to elicit healthy behaviors. While evidence for the utility of this strategy is promising, additional research is needed to better understand the effect of avatars on health behaviors and outcomes, particularly compared to interventions that do not use them (Rheu et al., 2020).

Advances in smartphone technology have also provided novel approaches to support weight loss maintenance. Dozens of apps are now available in the commercial app market that allow users to track their food and beverage consumption and macro- and micronutrient intake more quickly and easily than conventional pen-and-paper methods (Wharton et al., 2014). Algorithms that provide real-time feedback on dietary choices within dietary self-monitoring apps are in early stages of testing (Burke et al., 2017). Additionally, text messages provide a convenient, low-cost method for engaging individuals in extended contact that can improve long-term weight maintenance (Spark et al., 2015). More sophisticated applications of phone-based technology to weight research include ecological momentary assessment (EMA). EMA allows researchers to gather information about individuals' behaviors and psychological state while in real-world settings, at or very near the moment that a behavior of interest takes place. EMA has been used for a variety of research-related purposes, from improving the accuracy of self-reported dietary data (users submit pictures of the foods and drinks they are about to eat) to understanding the contextual factors that lead to dietary lapses (users respond to prompts about lapses sent to their phones) (Forman et al., 2017; Loth et al., 2021).

## Incentives

A systematic review found that randomized control trials investigating the efficacy of material incentives on weight loss and obesity-related behavior change showed incentives can increase targeted outcomes (e.g., physical activity, weight change, and program attendance) (Burns et al., 2012). However, researchers were less likely to see effects on outcomes that were not directly targeted by the interventionist (Burns et al., 2012). Employers have also increasingly used health insurance premium adjustments to incentivize healthy behavior change, reducing the financial contribution required from employees who meet the targets (Mattke et al., 2013). However, empirical evidence to support this strategy is limited. An RCT examining the effectiveness of offering a \$550 premium reduction found no differences in weight loss from control group (Patel et al., 2016). Premium adjustments, which are by nature delayed, may not be valued in the same way as cash or other tangible incentives that can be offered more immediately.

## Systems-level programs

As the prevalence of overweight and obesity increases, medical practice and public health interventions have shifted to consider societal and environmental factors. The literature suggests that multi-level interventions, which address factors at one or more levels of influence (e.g., individual, relationship, community, and society/policy levels), be implemented to address the physiological, environmental, and psychosocial determinants that influence weight loss maintenance (MacLean et al., 2015). Optimal environments can strengthen an individuals' capacity to make sustainable healthy choices, ultimately influencing their health and behavioral outcomes. Integrative primary care models deliver comprehensive healthcare that comprises conventional and complementary domains (e.g., population health, equity, governance, culture, advocacy) to reflect a holistic standard of care approach. Moreover, intervening across multiple levels of the socioecological model to encompass communities, organizations (e.g., school systems and worksites), and legislation would support individuals in the maintenance of healthy eating and physical activity behaviors.

**Table 2** Strategies for supporting successful weight loss maintenance identified from the literature.

<i>Area</i>	<i>Strategy</i>
Diet	<ul style="list-style-type: none"> <li>• Consume a low-calorie (~1400 kcal per day) diet</li> <li>• Choose a dietary strategy that can be adhered to over the long-term</li> </ul>
Physical activity	<ul style="list-style-type: none"> <li>• Be active at a moderate-intensity level for at least 200–300 min/week</li> </ul>
Self-monitoring	<ul style="list-style-type: none"> <li>• Weigh frequently (at least daily or weekly)</li> <li>• Track dietary intake</li> <li>• Track physical activity</li> </ul>
Professional contact	<ul style="list-style-type: none"> <li>• Extend professional contact beyond initial treatment—contact should be ongoing in keeping with the chronic care model of disease management</li> </ul>
Technology	<ul style="list-style-type: none"> <li>• Internet- and smartphone-based technologies may be helpful for extending professional contact, as well as increasing the ease of self-monitoring</li> </ul>

## Conclusion

Obesity is now recognized as a chronic disease that results from a milieu of physiological, psychological, environmental factors. It is well-known that moderate weight loss confers meaningful improvements in metabolic health; however, long-term weight loss maintenance can be challenging. Information from weight loss registries and results from experimental studies have helped to identify several strategies that support successful weight loss maintenance in the long term. Critically, individuals wishing to maintain their weight loss must engage in behaviors that support a favorable energy balance for weight maintenance, such as eating fewer calories and being more active than before their weight loss. If these behaviors are not sustained, weight regain will occur.

Experimental studies show that a variety of dietary approaches can be effective during the weight loss phase, if an energy deficit is achieved. For weight loss maintenance, energy intake needs to be lower than what occurred prior to weight loss, as well as, balanced with energy expenditure, such that energy balanced is achieved. No one specific dietary strategy has been found to be more effective for weight loss maintenance, and as with dietary intake during weight loss, an individual's ability to adhere to the dietary approach appears to be key. Engaging in 200 or more minutes of physical activity per week is also recommended to support successful weight loss maintenance. Additionally, extending contact beyond the initial intensive phase of intervention is vitally important for the maintenance of weight loss over time, which aligns with a chronic care model of obesity treatment. Technological advancements also continue to offer new approaches for improving weight loss maintenance, including web-based interventions that decrease access barriers, text messaging that can extend contact at low cost, and apps that streamline self-monitoring of diet and physical activity behaviors (Table 2).

Current research suggests that long-term treatment of obesity requires multiple intervention strategies and extended contact. Future research should view obesity through a chronic care lens and examine the frequency of contact and intensity of support needed after the initial weight loss phase to support optimal long term weight loss maintenance. Identifying intervention components that assist in maintaining energy-balance behaviors long-term should be emphasized. Additionally, novel approaches to using technology to improve both intervention outcomes and how research data are collected should continue to be investigated.

## CONTENTS OF VOLUME 4

---

<i>Contributors to Volume 4</i>	<i>ix</i>
<i>Editor Biographies</i>	<i>xiii</i>
<i>Preface</i>	<i>xvii</i>

### **NUTRITION IN THE LIFE CYCLE**

Adolescents: Nutrient requirements <i>CHS Ruxton and E Derbyshire</i>	1
Aging <i>P Hyland, Y Barnett, and LH Allen</i>	12
Breastfeeding <i>Chessa K Lutter</i>	20
Children: Nutritional requirements <i>I Thorsdottir and B Thorisdottir</i>	30
Complementary feeding <i>Nirupama Shivakumar</i>	43
Early origins of disease <i>DB Hardy and DJ Hoffman</i>	50
Early origins of disease: Non-fetal <i>Daniel J Hoffman and Alessandra D Sommer</i>	58
Growth and development: Physiological aspects <i>William W Hay, Jr.</i>	66
Growth monitoring and promotion <i>Leila M Larson, Edward A Frongillo, and Jef L Leroy</i>	83
Lactation: Dietary requirements <i>H Lochen and H Tymann</i>	91
Lactation: Physiology <i>JL McManaman and MC Neville</i>	98
Low birth weight and preterm infants: Nutritional management <i>H Tymann and H Lochen</i>	107

Low birth weight and preterm infants: Causes, prevalence, and prevention <i>M Merialdi and JH Requejo</i>	116
Nutrition during the preschool years <i>Samantha L Huey, Julia L Finkelstein, and Saurabh Mehta</i>	121
Nutrition for sport and exercise <i>RJ Maughan</i>	127
Nutrition guidance for infants: Nutrient-based reference intakes and feeding recommendations <i>Stephanie A Atkinson</i>	133
Nutritional problems of adolescents <i>S Gordon and CHS Ruxton</i>	143
Older people: Nutritional requirements <i>N Solomons</i>	150
Older people: Physiological changes <i>N Solomons</i>	157
Pregnancy: Energy requirements and metabolic adaptations <i>GR Goldberg</i>	163
Pregnancy: Nutrient requirements <i>Melissa F Young and Usha Ramakrishnan</i>	168
Pregnancy: Placental regulation of nutrient delivery to the fetus <i>P Haggarty</i>	177
Pregnancy: Pre-eclampsia and diet <i>Doris González-Fernández, Kristine G Koski, and Zulfiqar Bhutta</i>	185
Pregnancy: Prevention of neural tube defects <i>Helene McNulty, Aoife Caffrey, and Kristina Pentieva</i>	198
Pregnancy: Safe diets <i>S Stanner and H Gibson-Moore</i>	212
Pregnancy: Weight gain <i>Melissa F Young and Usha Ramakrishnan</i>	222
Stunting: Prevalence and prevention <i>Nandita Perumal, Diego G Bassani, and Daniel E Roth</i>	230
<b>NUTRITION EPIDEMIOLOGY</b>	
Coronary heart disease: Dietary patterns <i>Danielle E Haslam, Shatabdi Goon, Saloni Gautam, and Shilpa N Bhupathiraju</i>	241
Dietary issues in coronary heart disease prevention <i>Rajeev Gupta and Shalini Singhal</i>	261
Food culture <i>Johanna T Dwyer</i>	270
Food environment <i>Manuel Franco and Julia Díez</i>	282
Food fortification programs <i>Helena Pachón</i>	288

Food labeling <i>Barbara Schneeman</i>	301
Food security <i>Saskia de Pee and Rafael Pérez-Escamilla</i>	306
Harmonizing the approach to deriving nutrient requirements <i>Ann L Yaktine</i>	316
Health inequities <i>R Perez-Escamilla</i>	327
Religious customs, influence on diet <i>K Albala</i>	336
School food systems <i>Manuel Franco and Marta Fajó-Pascual</i>	341
Seasonality of nutrition <i>Ilana R Cliffer, Anastasia Marshak, Kate R Schneider, Aishwarya Venkat, and Elena N Naumova</i>	350
<b>GLOBAL ASPECTS OF HUMAN NUTRITION</b>	
Climate change: Effects on health and nutrition <i>Shweta Khandelwal, Sarah Parwez, and Mahima Mehra</i>	369
Dietary guidelines, international perspectives <i>B Schneeman</i>	379
Dietary surveys: Surveys of food intake in groups and individuals <i>Katherine L Tucker</i>	385
Displaced populations <i>Daniel J Hoffman and Hannah Posluszny</i>	392
Double burden of malnutrition <i>Daniel J Hoffman, Angelica A Pozzoli, and Hannah R Posluszny</i>	401
Famine: Causes, consequences and responses <i>Shannon Doocy, Shelley Walton, and Keith P West, Jr.</i>	411
Food security and nutrition surveillance in low- and middle-income countries <i>Kathrin M Demmler, Valerie M Friesen, and Lynnette M Neufeld</i>	420
Nutrition transition, diet change, and its implications <i>Daniel J Hoffman and Hannah Posluszny</i>	435
Nutritional surveillance: Developed countries <i>EW Harris</i>	444
Supplementation: Developing countries <i>R Shrimpton</i>	454
<i>Index</i>	459

## EDITOR BIOGRAPHIES

---

### Editor in Chief

#### Professor Benjamin Caballero

*Emeritus Professor, Bloomberg School of Public Health and School of Medicine, Johns Hopkins University, Baltimore, MD, United States.*

Dr. Caballero is Professor Emeritus at the Department of International Health, Bloomberg School of Public Health, with joint appointment at the Department of Pediatrics, School of Medicine, Johns Hopkins University. He obtained his MD from the University of Buenos Aires, Argentina, and his PhD (in neuroendocrine regulation) from MIT, in Cambridge, Massachusetts. He started his academic career at Boston Children's Hospital, Harvard Medical School, and subsequently became the Founding Director of the Center for Human Nutrition at Johns Hopkins University.

Dr. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries.

He is currently a member of the Council of the International Union of Nutritional Sciences. He has served on the Food and Nutrition Board of the US National Academy of Medicine and on a number of expert panels, including the Dietary Reference Intakes Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the U.S. Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration, and of advisory committees of the National Institutes of

Health and the Department of Agriculture. He is a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK), and a member of the Spanish Academy of Nutritional Sciences.

He is the Editor-in-Chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption, and biological effects. He is also Editor-in-Chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. He also co-edited a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

## Section Editors

### Section 1: *The Foundations of Human Nutrition*

#### Professor Angel Gil

Honorary President of the Iberoamerican Nutrition Foundation (FINUT), Emeritus Professor, Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology, Centre of Biomedical Research, University of Granada, Campus de la Salud, Avda. del Conocimiento, 18100 Armilla, Granada, Spain.

**Angel Gil** is an Emeritus Professor at the University of Granada and a Full Professor in the Department of Biochemistry and Molecular Biology. He is Doctor Honoris Causa at the Autonomous University of Nuevo León, Monterrey, México, and a visitant Professor of the University of Chile, Santiago de Chile, and University of San Miguel de Tucumán, Argentina. He got a major degree in Biology (1973) and PhD in Biochemistry and Molecular Biology (1978).

Prof. Gil is an internationally recognized authority in Food and Nutrition: His expertise extends from the study of human milk composition to the molecular effects of food bioactive compounds and probiotics and the design and development of novel products for infant and clinical nutrition. He conducted pioneering and innovative research, leading 7 international, 27 national, and more than 50 projects and 120 contracts; he has taught since 1981, supervising more than 50 PhD students.

Prof. Gil has several areas of interest that include evaluating the role of dietary nucleotides in early life and the development of infant nutrition products. Besides, the isolation, identification, and description of the mechanism of action of probiotics and the metabolic, molecular, and genetic factors involved in obesity and the early onset of metabolic syndrome (MS) in childhood; and the design, development, and evaluation of enteral clinical nutrition products. What describes Prof. Gil best is the variety of fields

and problems he has faced during his professional carrier and his significant ability to combine his knowledge and expertise in Food Science and Human Biochemistry. This has allowed him to design, develop, innovate, and evaluate exclusive products for Human Nutrition, which are demonstrated in his published articles and his patents' impact.

The multi- and interdisciplinary nature of his work is reflected in the variety of international journals in which he has published 546 articles. Also, he has published 28 books and about 180 book chapters. His five volumes *Treatise of Nutrition*, 3rd Edition, Ed. Medica Panamericana, 2017, with more than 3500 pages, is the "bedside" book for the study of Nutritional Sciences in Spain and all Latin American countries.

He has also been the Chairman of the International Union of Nutritional Sciences (IUNS) 21st International Congress of Nutrition (2013) and the Executive Director of the 23rd International Congress of Nutrition (2017) and has been engaged in the organization of other renowned international congresses. He is a member of prestigious international and national nutrition societies and Honorary President of the Iberoamerican Nutrition Foundation (FINUT), a nonprofit organization promoted by the IUNS, in which the main goal is to contribute to the formation of young scientists in Food and Nutrition in the setting of Iberoamerica. He has received 42 National and International Awards for his contribution to Nutrition and Food Science, among them, the Class Fellow 2022 of the American Society of Nutrition; the Sir David Cuthbertson Lecture Award of the European Society of Clinical Nutrition and Metabolism for scientific achievement in clinical nutrition on 2021; the Award "Granada, City of Science and Innovation" 2021 to the Scientific Career; the Gregorio Marañón Award 2018 to the best Spanish Scientist in the field of Food Science and Nutrition; the Institute Danone Spain Award 2017; the Award of the Spanish Federation of Dairy Industries, 2015; the Nutra Excellence Award 2014, Nutra India Summit; the UIB Honorary Award of 2013; and the NAOS Strategy Prize 2012, Special recognition for his extensive professional experience in the field of nutrition and obesity, Spanish Ministry of Health, Social Services and Equality (AESAN).

### Section 2: *Molecular Mechanisms for the Interaction of Nutrients and Health*

#### Dr. Noel W. Solomons

Center for the Studies of Sensory Impairment, Aging, and Metabolism (CeSSIAM), Guatemala City, Guatemala, Guatemala

**Noel W. Solomons** was Assistant and Associate Professor from 1977 to 1984 in the former Department of Nutrition and Food Science of MIT. A resident of Guatemala since 1975, he cofounded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) in 1985, where he has been Scientific Director ever since. He is an Adjunct Professor at Tufts University in both the Friedman School of Nutrition Science and Policy and the Department of Public Health and Community Medicine.

Dr. Solomons received his MD degree from Harvard Medical School and subsequently undertook clinical and research training in infectious diseases and in gastroenterology and clinical nutrition at the Universities of Pennsylvania and University of Chicago, respectively. He was Editor-in-Chief of the *Food and Nutrition Bulletin* from 2016–2020. He has 364 publications indexed on PUBMED. In addition, he has edited 2 books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection. Also, he has supervised doctoral dissertations for 12 PhD candidates from the USA, Canada, Germany, Spain, the UK and the Netherlands through CeSSIAM.

## Section 3: Diet Composition

**Professor Anura Kurpad**

Department of Physiology, St John's Medical College, Bengaluru, India

**Anura Kurpad** works at St. John's Medical College, Bengaluru. He received his MBBS and MD from St. John's, and his PhD from Bangalore University in 1992. He was a Postdoctoral Fellow at the Rowett Research Institute and at Cambridge University, UK, and a visiting Scientist at MIT, Cambridge, United States. He is an elected Fellow of the Royal College of Physicians (London), Fellow of the Indian National Academy of Medical Sciences, Indian Academy of Sciences, and International Union of Nutritional Sciences. His interests are in human, clinical, and public health aspects of nutrition, applied throughout the life cycle. His research focuses on the physiology and clinical aspects of human energy and protein requirements and metabolism, with more recent interests in micronutrient status and metabolism. He is an Associate Editor of *The American Journal of Clinical Nutrition*. He was the President of the Nutrition Society of India from 2012 to 2016 and is the current President of the Asia Pacific Clinical Nutrition Society. He has been, and is, on many national and international advisory bodies, including being the Chair of the Indian Nutrient Requirements Committee.

## Section 4: Disorders Directly Related to Inadequate Nutrient Intake

**Dr. Katherine L. Tucker**

Department of Biomedical and Nutritional Sciences, Center for Population Health, University of Massachusetts Lowell, Lowell, MA, United States

**Katherine L. Tucker**, PhD, is University Distinguished Professor of Nutritional Epidemiology in the Department of Biomedical and Nutritional Sciences, and Director of the Center for Population Health, at the University of Massachusetts Lowell. She holds an adjunct appointment at the University of Massachusetts Medical School. She received her PhD from Cornell University and her undergraduate degree from the University of Connecticut, both in nutritional sciences. Between these degrees, she spent 2 years as a Peace Corps volunteer in the Philippines. Before joining UMass Lowell, she was at the USDA Human Nutrition Research Center on Aging at Tufts University, and McGill University. Dr. Tucker has contributed to more than 450 articles in scientific journals. Her research focuses on dietary intake and risk of chronic disease, including osteoporosis, cognitive decline, obesity, metabolic syndrome, and heart disease, with an emphasis on health disparities. She is the PI of the Boston Puerto Rican Health Study, an ongoing cohort study, to examine the roles of diet, health behaviors, stress, and genetic predisposition in relation to chronic conditions, including heart disease, cognitive decline, and bone health; and is actively involved as a scientific advisor for the NHLBI Jackson Heart Study. She served two terms on the Food and Nutrition Board of the National Academies of Science and Engineering. She is a Fellow of the American Society for Nutrition (ASN), the Gerontological Society of America, and the American Society for Bone Mineral Research and is

currently the Editor-in-Chief of *Advances in Nutrition*, the international review journal of the ASN, and Senior Editor of the forthcoming 12th edition of the textbook, *Modern Nutrition in Health and Disease*.

## Section 5: Nutrition in Disease States

**Dr. Paolo M. Suter**

Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital, Zurich, Switzerland.

**Paolo M. Suter**, MD, MS, is a Professor of Medicine presently affiliated with the Department of Endocrinology, Diabetology and Clinical Nutrition at the University Hospital Zurich (Switzerland). He received his MD at the University of Zurich and an MS in Nutrition at Tufts University (Boston, USA). He specialized in Internal Medicine and was a Faculty Member at the Medical Polyclinic of the University Hospital Zurich, where he was directing the well-known Hypertension and Obesity Outpatient Consultation. His research activities focused on vitamin nutriture in the elderly, alcohol metabolism and obesity, blood pressure and hypertension, as well as nutrition and lifestyle in non-communicable disease prevention. During his clinical work he focused on the ideal combination of pharmacological therapy with nonpharmacological strategies and on the therapy and prevention of diseases especially hypertension and obesity. Besides many research publications and review articles he authored a widely used textbook entitled *Checkliste Ernährung (Checklist Nutrition)*. He served on different national and international boards in the area of his expertise.

**Section 6: Nutrition in the Life Cycle****Professor Lawrence J. Cheskin**

*Department of Nutrition and Food Studies, George Mason University, Fairfax, VA, United States*

*And*

*Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD, United States*

**Lawrence J. Cheskin, MD, FACP, FTOS**, is Professor and Chair of the Department of Nutrition and Food Studies at George Mason University in Fairfax, VA, and an Adjunct Faculty Member of the Department of Medicine at the Johns Hopkins School of Medicine in Baltimore, MD, United States. He received his medical degree from Dartmouth and was a Postdoctoral Fellow in gastroenterology and liver diseases at Yale University-New Haven Hospital. Dr. Cheskin's work is at the intersection of public health nutrition and clinical medicine and has dedicated his career to research, education, and program building in the service of combating obesity, through both treatment and prevention. He founded the Johns Hopkins Weight Management Center, a multidisciplinary clinical research and treatment program. He was also Director of Clinical Research of the Global Obesity Prevention Center at Johns Hopkins and directed its Pilot Studies Core, which evaluated systems-focused proposals worldwide to study such areas as school policies and the built environment in preventing childhood obesity. He is co-PI of the Mason Cohort Study of entering college freshmen and has authored over 240 peer-reviewed journal articles and 8 books. He is committed to mentoring the next generation of public health and clinical scholars dedicated to nutrition and obesity.

**Section 7: Nutrition Epidemiology****Dr. Manuel Franco**

*Associate Professor at the Department of Surgery, Medical and Social Sciences, University of Alcalá, Madrid, Spain, and adjunct faculty at the Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

**Manuel Franco, MD, PhD**, Epidemiologist, is an Associate Faculty at the University of Alcalá and an Adjunct Faculty at the Johns Hopkins Bloomberg School of Public Health.

He is the Principal Investigator of the European Research Council Starting Grant Heart Healthy Hoods (<http://www.hhhproject.es>) studying urban characteristics in relation to eating patterns, physical activity levels, smoking, and alcohol consumption. He is also the PI of the Participatory Project on food in the cities: Photovoice Villaverde (<https://youtu.be/VliFggKzVas>).

Manuel Franco trained in Medicine both in Madrid and Berlin. As a Fulbright Scholar he joined the Johns Hopkins Bloomberg School of Public Health Department of Epidemiology to obtain his PhD and Postdoctoral Fellowship in the fields of social epidemiology and urban health.

His work focuses on the prevention of chronic diseases and their major risk factors as nutrition. He has published 94 international peer-reviewed articles and has led 15 studies as PI raising over 2.9 million € in competitive international research bids. His methodological interests include the measurement of urban characteristics related to chronic diseases and nutrition, the use of mixed methods, and the conduction of participatory action research methods.

**Section 8: Global aspects of Human Nutrition****Professor Daniel J. Hoffman**

*Department of Nutritional Sciences and director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States*

**Daniel J. Hoffman, PhD**, is a Professor in the Department of Nutritional Sciences and Director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States. He graduated from St. John's University, Collegeville, MN, United States, and received his PhD in Human Nutrition from the Tufts University Friedman School of Nutrition Science and Policy, Boston, MA, United States. For his doctoral training, Dr. Hoffman studied the metabolism of children living in the shantytowns of São Paulo, Brazil. He then completed a Postdoctoral Fellowship at Columbia University, New York, NY, United States, before joining the faculty at Rutgers University.

Dr. Hoffman's research focuses on the long-term impact of undernutrition early in life on body composition and metabolism later in life. This work is complemented by research on sustainable methods to improve diet and growth in lower- and middle-income countries, including Brazil, Mexico, Kenya, South Sudan, and Vietnam. He also directs the Center for Childhood Nutrition Research at the New Jersey Institute for Food, Nutrition, and Health where members conduct interdisciplinary research on childhood growth and development. Dr. Hoffman is an Associate Editor of the *Food and Nutrition Bulletin* and a Section Editor for the *Annals of Human Biology*. His other responsibilities include serving on the editorial board of the *Journal of Nutrition*, serving in leadership positions for the American Society for Nutrition, and advising international and national agencies on matters related to childhood nutrition. Aside from his

academic life, Dr. Hoffman is a published documentary photographer whose portfolio includes work on the life of Roma in Europe, urban landscape of São Paulo, Brazil, gentrification of Times Square in New York City, and punk music as the "American Mosaic."

## PREFACE

---

By the middle of last century, the science of nutrition had identified most of the essential nutrients and had provided evidence to propose specific dietary intake recommendations for many diet constituents, with the practical aim of preventing nutrient deficiencies. As chronic, noncommunicable diseases such as cardiovascular disease, cancer, etc., began to emerge as an important causal factor for disability and early death, scientists turned their attention to the potential effects of nutrients and diet patterns on chronic disease risk. Pioneering studies by Burkitt, Keys, Breslow, and others were followed by a large number of studies on the role of dietary patterns and constituents on certain chronic diseases. Many important studies were completed over the second part of the century, providing the evidence to support specific dietary recommendations to reduce disease risk.

The 21st century ushered the next transition in nutrition science, this time centered on the interrelationships between nutrients, dietary patterns, and the human genome. Over the past few decades, advances in our understanding of the human genome and on the molecular tools to explore it have permitted to probe those interactions in increasing detail. In turn, findings from nutrient–gene interaction studies have informed population-wide and clinical and metabolic studies, further advancing our understanding of the effects of diets on human health at the molecular level. This understanding of the links between genotype, phenotype, and nutrient/dietary intake became a key contributor to the emerging area of personalized nutrition/precision medicine.

All those phases of research emphasis, to different degree, continue to exist today and result in a vast, multidisciplinary, ever-expanding amount of information reaching the peer-reviewed literature. This massive amount of information needs to be organized and summarized in a way that makes it accessible to experts, teachers, and, as much as possible, the general public. This has been and continues to be the goal of the *Encyclopedia of Human Nutrition* since its first edition, over 20 years ago.

Such an ambitious task can only be achieved by the collective work of many people. We all have experienced the challenge of writing an article that combines focus and relevance with conciseness, so we are very appreciative of the work of our contributors. Their effort was backed up by an excellent editorial board, which reviewed and provided feedback on every manuscript. Finally, we must acknowledge the outstanding support of the Major Reference Works division at Elsevier. A publication like this *Encyclopedia* has a lot of moving parts, and it is a great privilege to be able to concentrate on the content, knowing that the other parts of the process are in the hands of excellent professionals.

We hope that this book will help satisfy the need for accurate and concise information to the many students and professionals who are committed to use nutrition science as a tool to improve people's quality of life.

## Glossary

**Cross-sectional study** A study that provides a one-off observation of a population.

**Growth percentile** A way of comparing individual children to a reference group using percentages.

**Longitudinal study** A study that provides a series of observations of a population, or follows a specific cohort of individuals for a defined period of time.

**Osteoporosis** A progressive disease which causes bone loss, leading to fractures.

**Reference nutrient intake** A nutrient recommendation which would be expected to meet the needs of 97.3% of the population.

**Underreporting** Self-reporting of food intake that deliberately or unconsciously underestimates food, energy or nutrient intakes.

## Abbreviations

**BMI** Body mass index

**EAR** Estimated average requirement

**NMES** Nonmilk extrinsic sugars

**NSP** Nonstarch polysaccharide

**RNI** Reference nutrient intake

## Introduction

Adolescence is the period of transition between childhood and adulthood. This reflects not only the physical and emotional changes experienced by the adolescent, but also the development of dietary behaviors. Although younger children tend to resist new foods (i.e., neophobia), adolescents may use food to assert their independence, but not always in a beneficial way. This section covers development during adolescence and highlight nutrients that are important during this time. Information on adolescent energy and nutrient intakes from a broad range of countries is presented. The findings are put in context with dietary recommendations.

## Physical Changes During Adolescence

Adolescence is generally assumed to be the period of human development from 10 to 18 years, a time during which rapid growth and physical maturity take place.

### Growth

During prepubescent childhood, the growth of boys and girls follows a similar trajectory, although boys may be slightly taller and heavier than girls. The pubertal growth spurt begins around the ninth year in girls, lasting up to 3½ years, with boys starting their growth spurt approximately 2 years later. This means that girls can reach their full height 2 years before boys do. UK standards for height and weight during adolescence are presented in [Table 1](#). International reference growth standards are developed by the World Health Organization (WHO). Maximum height velocity is generally seen in the year preceding menarche for girls and at around 14 years of age for boys. On average, weight velocity peaks at 12.9 years of age for girls and 14.3 years of age for boys. Annual growth rates during adolescence can be as much as 9 cm/8.8 kg in girls and 10.3 cm/9.8 kg in boys. It is not fully known when growth ceases. Certainly, height gains of up to 2 cm can still occur between 17 and 28 years of age.

Energy and protein intakes per kilogram body weight have been observed to peak during maximal growth, suggesting increased requirements during adolescence. Undernutrition in this crucial window of development can result in a slow height increment, lower peak bone mass, and delayed puberty. Overnutrition is not without its risks. It is believed that obesity in young girls can bring about an early menarche, which then increases the risk of breast cancer in adulthood. Menarche is deemed precocious if it occurs before the age of 8 years. Rising childhood obesity levels in Western countries have resulted in more girls experiencing precocious menarche.

Important nutrients for growth include protein, iron, calcium, vitamin C, vitamin D, and zinc. Calcium, in particular, has a key role in bone development, and huge increments in bone density are seen during adolescence under the influence of sex hormones. Bone density peaks in the early twenties and a low bone density at this time is related to an increased risk of osteoporosis in later life, especially for women. Studies have suggested that body mass index (BMI) in adolescence is the best predictor of adult bone density, explaining why children who experience anorexia nervosa are likely to have a higher risk of osteoporosis.

## Adipose Stores

There are few differences in body fat between boys and girls in the prepubertal stage. However, during puberty, girls develop adipose tissue at a greater rate than boys, laying down stores in the breast and hip regions. The pattern for boys is rather different and tends toward a more central deposition. Methods for estimating fatness in adolescents include weight for height, BMI (weight in kilograms/height in square metres), skinfold thickness measures, bioelectrical impedance analysis, densitometry, magnetic resonance imaging, dual-energy X-ray absorptiometry, and computed tomography. Waist circumference is gaining popularity as a useful proxy of fatness in the field. Many researchers argue that it is a better predictor than BMI of the central adipose stores that place the individual most at risk from later obesity, diabetes, and coronary heart disease.

UK standards for BMI and waist circumference are shown in [Table 1](#). As adolescents are still growing, it is important to use age- and sex-appropriate appropriate standards to assess over- and underweight. The 85th percentile of BMI is often used as the lower cutoff point for classification of overweight, whereas the 5th is taken as an upper cutoff for underweight. Some surveys have suggested that adult obesity risk can be tracked from childhood, citing BMI at adolescence as a strong predictor of adult obesity. However, this information should be used with caution in practice because adolescents have not yet reached their full height and may still revert to a normal BMI without dietary intervention.

## Sexual Development

In girls, the onset of menarche at around 13 years is triggered by the attainment of a specific level of body fat, with taller, heavier girls more likely to experience an early menarche. Vigorous exercise, for example, gymnastics and endurance running, can delay the menarche, both due to the physiological effects of regular training and the depletion of body fat. Iron becomes more important for girls as menstrual periods become regular and heavier, and there is good evidence that the iron status of many teenage girls is inadequate. Low iron status is due to a combination of higher requirements (i.e., menstrual periods and growth) and poor nutritional practices, such as dieting, missing breakfast; and avoiding red meat.

## Dietary Recommendations

In general, each country has its own nutritional recommendations for adolescents, which are developed by expert bodies using a combination of deficiency studies and extrapolations from adult studies. In the UK, US, and Canada, guidelines have evolved from a simple Recommended Dietary Intake to the more complex bell-shaped distribution with a mean representing the intake likely to satisfy the needs of 50% of the population. The upper extreme, at the 97.5th centile, represents the intake likely to meet the needs of the majority of the population, whereas the lower extreme, at the 2.5th centile, represents the lowest acceptable

intake. Current UK Reference Nutrient Intakes (RNI), presented in [Table 2](#), cover a range of nutrients from fat and sugars to the main micronutrients. Dietary guidelines are an important reference point for nutrition scientists and dietitians, but it must also be borne in mind that they relate to the average needs of populations, rather than to the needs of individuals.

As well as numerical recommendations, many nations have adopted more descriptive or visual methods of promoting the ideal diet. This makes sense as recommended nutrient intakes are poorly understood by the public and need to be put into context by health professionals. Communication tools such as the plate model, pyramid system, food groups, and traffic light systems can help to get healthy eating messages across to adolescents.

## **Dietary Intakes**

It is often assumed that most adolescents in Western countries have a nutritionally inadequate diet yet, despite reported low intakes of some micronutrients in surveys, there is little evidence of widespread clinical deficiencies, or indications that adolescents are failing to achieve appropriate heights and weights. Iron is the exception, where mean intakes are low and clinical markers suggest deficiency across several age groups, particularly in girls. There is also justifiable concern about the general healthiness of diets eaten by 'at risk' subgroups of adolescents such as dieters, smokers, vegans, and those who regularly consume alcohol.

Mean daily intakes of energy and selected micronutrients from a selection of major international surveys of adolescents are presented in [Table 3](#). Caution should be taken when interpreting data from dietary surveys because underreporting can be a feature of these. Selective underreporting, often focused on energy-dense or high-fat foods, can partially explain low reported intakes of energy and certain micronutrients. It is also difficult to make comparisons between the data from different countries given the range of dietary assessment methods used. There is normally a trade-off between the sample size and methodology that sees the larger surveys favoring less precise methods such as 24 h recalls or food frequency questionnaires in order to make data collection more economical.

## **Energy, Protein, and Salt**

Despite height and weight data that are consistent with expected results, mean energy intakes appear to be low when compared with dietary recommendations in many studies of adolescents, particularly in lower income groups. Although low energy intakes can be of concern in individuals, on a population level, this phenomenon may be due to a number of reasons. These include dieting, low physical activity levels, and underreporting, where subjects subconsciously or deliberately misreport dietary intakes. Popular sources of energy in the adolescent diet included cereal products (providing around one-third of energy), savory snacks, potatoes, meat/meat products, white bread, milk/dairy products, biscuits/cakes, spreading fats, and confectionery. Beverages (i.e., soft drinks, juices, and alcohol) provide a significant amount of energy due to their popularity with adolescents and this has led to concern about their impact on obesity risk. In UK dietary surveys, beverages not including milk provided 9% of total daily calories in 11–18 years old.

In Western countries, average protein intakes are considerably in excess of requirements for all ages and both sexes. The main sources in adolescent diets are meat and meat products (contributing around one-third of protein), cereals, bread, and dairy products. It is believed that protein requirements in adolescents are between 0.8 and 1.0 g kg<sup>-1</sup> body mass, although this does not take into account any additional needs that may relate to regular participation in sport and exercise. As a proportion of energy, protein intakes tend to be higher in Southern European countries, Australia, and New Zealand compared with intakes in the United States and Northern European countries.

High intakes of salt are a risk factor for abnormal blood pressure which, in turn, increases the risk of heart disease. Health experts believe that reductions in salt from childhood can help to maintain normal vascular health. UK dietary surveys of 11–18 years old report daily sodium intakes of approximately 2280 mg in girls and 2970 mg in boys. This equates to daily salt intakes of 5 and 6.5 g, respectively, with the target being less than 6 g day<sup>-1</sup>. Meat products, such as burgers and sausages, provide around one-third of salt intakes with bread and processed foods also contributing significantly.

## **Fats**

Average fat intakes as a proportion of energy vary considerably across Western countries. In the UK, intakes are close to the recommendation of 35% energy, suggesting increased public awareness as previous surveys reported intakes of 38–40% energy from fat. However, intakes of saturated fat, at 14% energy, still exceed the target of 11% food energy. It is worth noting that population averages hide subgroups with more extreme intakes. In the case of saturated fat, a considerable number of adolescents have intakes approximately 17% energy that may increase their risk of heart disease. Main sources of saturated fat in the adolescent diet include meat and meat products (approximately 20%), savory snacks and fried foods. Fat intakes in other European countries are 36–38% energy, with the highest fat intakes reported in Finland, Greece, Belgium, Germany, Switzerland, and Spain. In the United States, where the dietary target for fat is 30% of energy, intakes are approximately 32% energy from fat.

Not all dietary fats need to be reduced. There is increasing evidence that long-chain  $\omega$ -3 fats from marine sources, specifically docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), are beneficial for health. Rich sources of these are oily fish, such as salmon, trout, mackerel, and sardines, whereas shellfish also make an important contribution. Studies show that high intakes of oily fish, DHA, and EPA can help maintain heart health and cognitive function in adults. Emerging data suggest a role for

Vitamin A=micrograms retinol equivalent.

Dates refer to when the surveys were carried out. For some countries, data refer to a combination of more than one survey.

<sup>a</sup>Folic acid data only.<sup>b</sup>Folate from food sources only.

DHA and EPA in brain development in infants, and maintenance of the normal cognitive function in school-age children. Adolescents often have poor intakes of oily fish and, unless offered alternative sources such as marine oil supplements, may miss out on the benefits offered by DHA and EPA.

### **Carbohydrates and Fiber**

Average carbohydrate intakes in Western populations are close to the recommendation of 50% energy. The main sources in the adolescent diet are breakfast cereals, bread, savory snacks, vegetables and potatoes. Fiber intakes, expressed as nonstarch polysaccharide (NSP), are 10–13 g per day in the UK, which is approximately 70% of the adult guideline. Vegetables, potatoes, and savory snacks together contribute 40% of NSP. Interestingly studies have not always found consistent relationships between fiber intakes and bowel movements in young people. Sugar intakes peak in adolescence before declining to adult levels and are higher in boys compared with girls. In UK surveys, mean intakes of added sugars are 16% of energy and the largest contributor is nondiet soft drinks, providing 40% of sugars, followed by confectionery and preserves. Children from lower income households tended to have lower intakes of protein and NSP but higher intakes of sugars and fats compared with their more affluent peers.

Recommendations to reduce fat are often accompanied by those urging a decrease in added sugars due to concerns about obesity, dental health, and micronutrient adequacy. However, inverse relationships between fat and sugars are often seen in observational surveys suggesting that reductions in dietary fat may occur, in part, due to increases in foods containing added sugars. Most cross-sectional surveys also report inverse relationships between sugar intakes and BMI, suggesting that leaner people have higher sugar intakes, but lower fat intakes. This may seem counterintuitive given concerns about the impact of sugar on obesity risk; however, an explanation could be that heavier people either restrict their sugar intake or underreport sugar-containing foods. Nevertheless, apart from one intervention study relating to soft drinks, the available evidence does not support a relationship between higher sugar intakes and an increased risk of obesity. This was confirmed by the European Food Safety Authority in 2010 following a review of the evidence.

Several reviews have also considered the evidence linking sugar consumption with diet adequacy, responding to concerns that higher sugar intakes result in diets, which are low or inadequate in vitamins and minerals. The findings, based on surveys of children and adolescents in the United States and Europe, suggest that a broad range of sugar consumption is consistent with adequate micronutrient intakes. This may be due to fortification of popular sugar-containing foods, for example breakfast cereals and dairy foods. Lower levels of vitamins and minerals tend to be seen only at the upper and lower extremes of sugar consumption, suggesting that these diets lack variety.

### **Micronutrients**

The main contributors to sources of vitamins and minerals are breakfast cereals, milk, bread, chips/potatoes, and eggs. Surveys that report comparisons between intakes and recommendations have found satisfactory intakes for most micronutrients when population averages are considered. Intakes of vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, B<sub>12</sub>, vitamin C, and niacin greatly exceeded recommendations in the UK, perhaps reflecting high-protein intakes and the fortification of breakfast cereals, bread, and beverages. Average intakes that fall below recommendations have been seen for iron, calcium, magnesium, and zinc. In girls, mean selenium and iodine intakes can also be lower than recommendations.

As mentioned earlier, averages hide subgroups of adolescents whose nutrient intakes fall below acceptable levels for health. UK data suggest that 3–47% of adolescents have intakes of vitamin A, iron, calcium, magnesium, potassium, zinc, selenium, and iodine that fall below the population minimum, suggesting that they may be at risk from deficiency. The nutrients of most concern in adolescence are iron and calcium, which are important for the normal growth and development. Intakes of folate are particularly important for girls, some of whom may fall pregnant in their teens. Certain practices, such as smoking and drinking alcohol, can increase requirements for micronutrients, suggesting that specific groups of adolescents may be more at risk from a poor nutritional status.

Mean iron intakes are particularly low in 11–18 year old girls, at 58–63% of the recommendation (see [Table 4](#)), reflecting avoidance of iron-rich foods, such as red meat and offal. It is important to address low iron intakes because these can lead to poor iron status and, in some case, anemia. The best source of iron is red meat which provides the easily absorbed form, called heme iron. However, most iron in the adolescent diet comes from foods, such as breakfast cereals, which supply the less-well-absorbed non-haem iron. Iron absorption can be improved by consuming vitamin C rich foods or beverages at meal times.

An adequate calcium intake during childhood and adolescence is important for establishing an optimal peak bone mass that can be maintained throughout adulthood. Low intakes of calcium are a risk factor for osteoporosis in later life. Although average calcium intakes tend to be close to recommended levels, there are groups of adolescents with intakes below adequate levels. In UK 11–14 year olds, 12% of boys and 24% of girls had intakes below the lower reference nutrient intake, while in 15–18 year olds, the figures were 9% and 19%, respectively. This suggests a risk of deficiency. Good sources of calcium are milk, cheese, yogurt, soya products, tinned fish and, in many countries, fortified grain products.

Concern has been expressed that the rise in soft drink consumption has displaced milk from the diets of adolescents and this could be contributing to the low calcium intakes found in many surveys. Fluid milk consumption has fallen dramatically over the last decade in Western countries and this is due to a range of factors including preference for other beverages, concerns about

weight management, and the perception that milk is for younger children. Although improving diet is important, it should not be forgotten that physical activity is also important for optimal bone health.

## Impact of Lifestyle on Nutrition

Young people consume particular foods and diets for a variety of reasons, mostly unrelated to their nutritional content. These include weight control (whether justified or not), peer group pressure, celebrity endorsement, convenience, personal ideologies (e.g., veganism), or enhancement of sporting prowess. As energy and nutrient intakes are influenced by eating patterns, it is important to consider lifestyle when interpreting dietary information or development health promotion messages.

### Breakfast

Breakfast can be a nutrient-dense, low fat meal, yet is often omitted by adolescents. Around 10% of younger children miss breakfast, rising to 20% as adulthood is approached. Boys are more likely than girls to eat breakfast, and favor cereals rather than bread or cooked foods. Data on breakfast habits reveal higher intakes of sugars, fiber and micronutrients, such as folate, niacin, iron, calcium, and zinc, amongst regular consumers of breakfast cereals. Fat intakes, as a proportion of energy, are lower when breakfast cereals are consumed. Surveys of adolescents have found an inverse relationship between breakfast cereal consumption and body mass index, suggesting that eating breakfast is a useful strategy for weight control.

### Food Choices at School

Although the popularity of school lunches has diminished over the last 10 years, they are still eaten regularly by many children, particularly those from lower socioeconomic groups. School lunches have been criticized in the past for containing a high proportion of fat and delivering low levels of vitamins, minerals, and  $\omega$ -3 fatty acids. The introduction of school meal standards in a number of countries has significantly improved the nutritional content of school lunches. However, this has not always benefited adolescents who often prefer to assert their independence by buying food out with the school environment. Foods purchased from cafes and take-aways tend to be less healthy than the meals offered at school, and opportunities to choose fruits and vegetables are few.

### Fruit and Vegetable Consumption

Data on intakes of fruit and vegetables show that adolescents, particularly girls, have lower intakes than adults and younger children. In the UK, where the recommendation is 400 g (expressed as five portions of fruit/vegetables per day), average intakes in 15–18 year old are only 200 g. Indeed, only 22% of boys and 7% of girls meet the five portions-a-day target.

### Snacking and Soft Drink Consumption

There has been a general shift over the last few decades toward more meals eaten outside the home and a greater proportion of daily energy consumed as snacks and soft drinks. Concerns about the possible impact of snacks on diet quality and the risk of obesity are not always borne out by the evidence, although dietary assessment is hindered by a lack of consensus on what constitutes a 'snack'. Observational studies have found that frequent snackers have similar nutrient intakes to those who snack infrequently. With respect to body size, snacking is often associated with a lower, rather than a higher, BMI. The few intervention studies that have examined snacking behavior report full or partial compensation for the additional calories provided by snacks by a reduction in the energy from meals. This suggests that snacking itself is not harmful but that adolescents should choose their snacks wisely, focusing on those that make some contribution to micronutrient intakes. Intervention studies looking at the impact of sugar-sweetened soft drinks give a different picture and tend to find less compensation for the additional calories and a reduction in nutrient density of the diet. This suggests that high intakes of sweetened soft drinks, as are often found in adolescence, pose a risk for obesity and could be detrimental for diet adequacy.

### Smoking

The proportion of adolescent smokers rises with age and is between 8 and 20% with an average exposure, in older children, of around 40 cigarettes per week. Since the 1980s, smoking has decreased in adolescent boys but not in girls. Smokers tend to have different dietary habits from nonsmokers and this is reflected in their nutrient intakes. Studies have found that smokers consume fewer dairy foods, wholemeal bread, fruit, breakfast cereals, and more coffee, alcohol, and chips. Smokers' diets tend to be lower in fiber, vitamin B<sub>1</sub> and vitamin C compared with nonsmokers. In a study of 18 year olds, male smokers had a higher percentage energy from fat and lower intakes of sugars and iron. Contrary to beliefs, there is no evidence that smoking helps to control body weight in young people.

## Alcohol Consumption

In the UK, alcohol is consumed by 10% of 11–14 years old, and 37–46% of 15–18 year olds with older boys most likely to drink alcohol. Other European surveys have found higher proportions, 60–90% in 14–18 year old males, Although US surveys have found similar proportions to the UK. The average contribution of alcohol to energy intakes in the NDNS is just over 1%, with higher contributions reported by Danish and Irish studies (around 2–5% energy). Excess alcohol intake can increase micronutrient requirements but few younger adolescents fall into this category. However, regular consumption of alcohol contributes to obesity because the energy provided by alcoholic drinks rarely displaces energy from other food sources.

## Socioeconomic Status

Differences in diet are sometimes seen between children from different social classes or income groups. In the UK, children from a lower socioeconomic background consume fewer low fat dairy foods, fruit juice, salad vegetables, high fiber cereals, fruit juices, and fruit than children from a higher socioeconomic background. This impacts on mean daily nutrient intakes with poorer children consuming lower amounts of protein, sugars, carbohydrate, vitamin C and fiber. Some surveys have also found higher fat intakes and a greater risk of obesity in children from lower socioeconomic backgrounds.

## Physical Activity

Regular physical activity impacts on nutrition and health in a number of ways, for example, by maintaining normal energy balance that lowers the risk of obesity, by supporting the normal heart function, and by promoting bone density. However, adolescents, particularly girls, have become far less physically active in recent years. The European Youth Heart Study found that 82% of 15–

<sup>a</sup>Data presented as ranges.

year old boys, but only 62% of girls of that age, met physical activity targets. At present, WHO recommends that children and young people are physically active for at least 60 min per day<sup>-1</sup>. This includes sports and exercise, but also walking. Reducing sedentary behaviors, for example, TV viewing, video games, is also important for obesity prevention.

### Sleep

Although sufficient sleep is vital for normal growth and cognitive development in childhood and adolescence, short sleep duration can also impact on nutritional intake and obesity risk. Studies in adolescents and young adults have found associations between a lack of nighttime sleep and increases in BMI. Short sleep duration could influence body weight by disrupting appetite control, reducing physical activity levels (e.g., due to tiredness), or affecting thermoregulation.

### Conclusions

Most adolescents in Western countries are consuming adequate energy and protein to support normal growth. However, intakes of micronutrients in subgroups of the population are lower than recommendations and may not be sufficient for optimal health. These include iron, calcium, zinc, folate, and vitamin A. For iron, there is good evidence of clinical deficiency in low iron consumers, particularly girls. As energy intake is the best predictor of micronutrient adequacy, care must be taken when advising adolescents about weight management because calorie restriction can reduce intakes of vitamins and minerals.

Longitudinal studies that attempt to link early diet with the incidence of later disease suggest that high intakes of fruit, vegetables, wholegrains, and oily fish are markers of good health in later life. However, this beneficial dietary pattern has not been adopted by most adolescents. Indeed, despite the public health efforts of government and health professionals, adolescents remain a hard to reach group. (Table 5).

### Acknowledgments

The authors are very grateful to the dietitians and nutritionists around the world who provided data, both published and unpublished, for Table 3.

## Glossary

**Aging** A progressive sequence of detrimental age-related changes that occur in every individual of a given species, at varying rates. These changes lead to a breakdown in normal homeostatic mechanisms so that the functional capacity of the body and its ability to respond to a wide variety of extrinsic and intrinsic agents is often reduced. This causes degradation of structural elements within the cells, tissues, and organs of the body, leading eventually to the onset of age-related disorders and ultimately death.

**Apoptosis** Programed cell death which is important for changes that occur during development, and for cell turnover. Approximately 50–70 billion cells per day die through apoptosis in the human adult. Apoptosis is a normal event and differs from necrosis, which is cell death due to injury. Insufficient atrophy results in excessive cell proliferation such as in cancer.

**Hayflick phenomenon (or Hayflick limit)** The number of times a cell population can divide before it dies.

**Senescence** The process of becoming old.

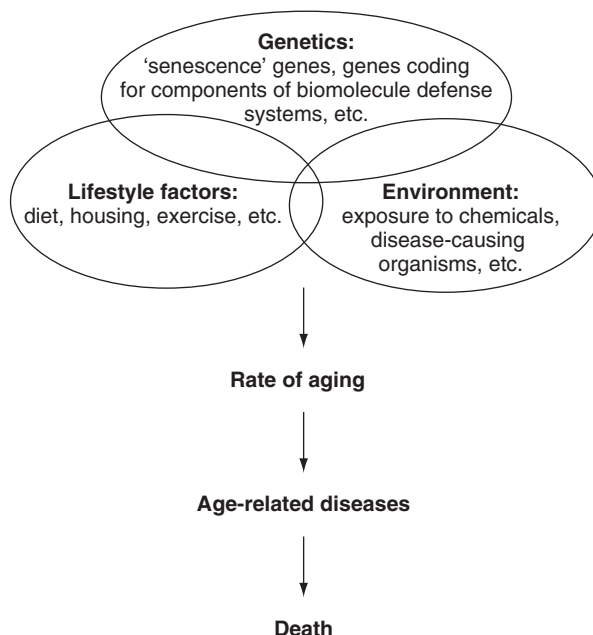

**Somatic mutation** Changes in DNA that can occur in any cell except sperm or eggs. They cannot be passed on to the next generation, but can cause cancer or other diseases.

## Introduction

The aging processes, and interventions to ameliorate them, have fascinated humans since the dawn of civilization. Research into aging is now a vital area of human endeavor, as our species reaches the limits of its longevity and faces the prospect of an aging population.

An individual's life expectancy is contributed to by the interaction of intrinsic (genetic and epigenetic) factors with extrinsic (environmental and life style) factors (**Figure 1**). In the world's more developed countries (MDCs) life expectancy at birth in the 1900s was around 47 years. By the end of the twentieth century this rose to a mean of 78 and 76 years in Western Europe and North America, respectively, with many individuals living much longer. This dramatic increase in average life expectancy has been largely

**Figure 1** Interactive factors that contribute to the aging process. Reproduced from Barnett YA (1994) Nutrition and the ageing process. *British Journal of Biomedical Sciences* 51: 278–287.

due to improvements in environmental conditions such as nutrition, housing, sanitation, and medical and social services, leading to a large increase in the number of older people around the world. This change in the age structure of society is compounded by the decreasing fertility levels in the world's populations leading to large gains in worldwide median population ages. Our aging populations have a growing number and proportion of older people and, importantly, a growing number and proportion of very elderly people.

Based on current rates and trends in population growth by the year 2025 the elderly population (aged 65 and above) in the world's MDCs will increase by more than 50%, and will more than double worldwide. The very elderly (aged 80 and above) is the fastest growing section of the elderly population. This changing demographic picture will result in a large increased prevalence worldwide of long-term illness, disability, and the degenerative diseases associated with aging. These alterations in the proportions of the population of working age and those beyond working age will significantly impact the funding and costs of healthcare for all nations, making research into aging of critical international importance.

## Theories of Aging

The biological manifestations that occur with aging affect the entire hierarchical structure of living systems. Age-related effects are seen in the accumulation of damaged cellular biomolecules (e.g., advanced glycosylation end products, lipid peroxidation products, genetic damage, and mutation), damaged organelles (mitochondria), and loss of cellular function, which contributes to dysfunction of the body's tissues, organs, and systems. These hierarchical changes have paved the way for more than 300 theories in an attempt to explain how and why aging occurs. They have previously been broadly categorized into: (1) programed or genetic theories; and (2) damage accumulation (stochastic) theories. However, these categories are not proven to be entirely comprehensive or mutually exclusive and it is likely that there is a shifting range throughout the life span that reflects a decreasing influence of genetic factors and an increasing influence of stochastic events.

### Programed and Genetic Theories

Programed and genetic theories propose that the process of aging follows a biological timetable, perhaps a continuation of the one that regulates childhood growth and development. There are a number of lines of evidence supporting these theories.

#### Longevity Genes

It is clear that aging is controlled to some extent by genetic mechanisms. The distinct differences in life span among species are a direct indication of genetic control, at least at the species level. A number of genes have been identified in yeast, nematode worms (*Caenorhabditis elegans*), and fruit flies (*Drosophila melanogaster*) that significantly increase the organism's potential maximum life span. The products of these genes are involved in stress response and resistance, development, signal transduction, transcriptional

regulation, and metabolic activity. However, the genetics of longevity have not been as revealing in mammalian studies. In mouse systems genes involved with immune response have been implicated in longevity, as has the 'longevity gene' *p66<sup>shc</sup>*, which is involved in signal transduction pathways that regulate the cellular response to oxidative stress. In humans, a number of mitochondrial DNA polymorphisms are associated with longevity. Linkage analysis in human systems has associated certain genes on chromosome 4 with exceptional longevity. Further support for human longevity genes may be provided by the observation that siblings and parents of centenarians live longer. The major histocompatibility complex (MHC), the master genetic control of the immune system, may also be a gene system controlling aging, because a number of genetic defects that cause immunodeficiency shorten the life span of humans. Certain MHC phenotypes have also been associated with malignancy, autoimmune disease, Alzheimer disease, and xeroderma pigmentosum in humans.

### **Accelerated Aging Syndromes**

No distinct phenocopy exists for normal aging, but several genetic diseases/syndromes display some features of accelerated aging, including Hutchinson-Gilford syndrome (classic early onset Progeria), Werner syndrome, and Down syndrome. Patients with these syndromes suffer from many signs of premature aging including hair loss, early graying, and skin atrophy, and premature age-related diseases such as atherosclerosis, osteoporosis, and glucose intolerance. The defined genetics involved in these syndromes provides strong evidence for the genetic basis of aging.

### **Neuroendocrine Theories**

These theories propose that functional decrements in neurons and their associated hormones are pivotal to the aging process. An important version of this theory suggests that the hypothalamic-pituitary-adrenal (HPA) axis is the key regulator of mammalian aging. The neuroendocrine system regulates early development, growth, puberty, the reproductive system, metabolism, and many normal physiological functions. Functional changes to this system could exert effects of aging throughout an organism. However, the cells of the neuroendocrine system are subject to the normal cellular aging processes found in all cells, and changes in the neuroendocrine system may be secondary expressions of the aging phenotype.

### **Immunologic Theory and Immunosenescence**

Deterioration of the immune system with aging ('immunosenescence') may contribute to morbidity and mortality due to decreased resistance to infection and, possibly, certain cancers in the aged. T-cell function decreases and autoimmune phenomena increase in elderly. Although the immune system obviously plays a central role in health status and survival, its cells are subject to the normal cellular aging processes found in all cells. Changes to the immune system may be secondary expressions of the aging phenotype.

### **Cellular Senescence**

At the cellular level, most, if not all, somatic cell types have a limited replicative capacity *in vitro* before they senesce and die. The number of cell population doublings *in vitro* is inversely correlated with donor age. This is called the 'Hayflick phenomenon' after the scientist credited with its discovery. This limit in the capacity of a cell type or tissue to divide and replenish itself would have major repercussions *in vivo*. There is evidence that replicative senescence is related to *in vivo* aging, but definitive evidence that senescent cells accumulate *in vivo* is lacking to date. Many alterations to normal cellular physiology are exhibited with the senescent phenotype, indicating that senescent cells exist in a growth state that is quite distinct from that of young cells and are subject to a complex alteration to their cellular physiology. Several explanations for limiting the number of cell population doublings have been proposed, including a tumor suppressive mechanism. One is that the shortening of telomeres, the sequences of noncoding DNA located at the end of chromosomes, is a measure of the number of cell divisions that a cell has experienced. These telomeres may act as specialized regions of the genome, a sacrificial 'sentinel' zone, for the detection of DNA damage being noncoding, more prone to damage, and less prone to repair than the genome as a whole. Damage to telomeres transposes to telomere shortening, and loss of telomere higher order structure may trigger senescence and/or apoptosis.

Studies involving fusion of normal cells (subject to senescence) with immortal cell lines *in vitro* have clearly demonstrated that the senescent phenotype is dominant, and that unlimited division potential results from changes in normal growth control mechanisms. These fusion studies have also revealed the existence of several dominant genes associated with the process of cellular senescence. These genes reside on a number of chromosomes, including 1, 4, and X.

### **Disposable Soma Theory**

The disposable soma theory suggests that aging is due to stochastic background damage to the organism, i.e., damage that is not repaired efficiently because the energy resources of the somatic cells are limited. So, instead of wasting large amounts of energy in maintaining the whole body in good condition, it is far more economical to simply repair the heritable stem cell genetic material, in order to ensure the survival of the species. In this way the future of the species is secured at the expense of individual lives. When the somatic energy supply is exhausted, the body ages and dies, but the genetic material survives (in the next generation).

### **Damage Accumulation (Stochastic) Theories**

The 'damage' or 'error' theories emphasize intrinsic and environmental insults to our cellular components that accumulate throughout life and gradually cause alterations in biological function and the physiological decline associated with aging.

### Somatic Mutation and DNA Repair

Damage to DNA occurs throughout the lifetime of a cell. If this damage is not repaired or removed then mutations may result. Mutations may result in the synthesis of aberrant proteins with altered or absent biological function; alterations to the transcriptional and translational machinery of a cell; and deregulation of gene control. The accumulation of mutations on their own, or in combination with other age-related changes, may lead to alterations in cellular function and ultimately the onset of age-related disease.

### Error Catastrophe

This theory suggests that damage to mechanisms that synthesize proteins results in faulty proteins, which accumulate to a level that causes catastrophic damage to cells, tissues, and organs. Altered protein structure has been clearly demonstrated to occur with age; however, most of these changes are posttranslational in nature, and hence do not support this theory of aging. Such changes to protein structure may result in progressive loss of 'self-recognition' by the cells of the immune system and thus increase the likelihood that the immune system would identify self-cells as foreign and launch an immune attack. Indeed, the incidence of autoimmune episodes is known to increase with age.

### Cross-Linking

The cross-linking theory states that an accumulation of cross-linked biomolecules caused by covalent or hydrogen bonds damages cellular and tissue function through molecular aggregation and decreased mobility. The modified malfunctional biomolecules accumulate and become increasingly resistant to degradation processes and may represent a physical impairment to the functioning of organs. There is evidence *in vitro* for such cross-linking over time in collagen and in other proteins, and in DNA. Many agents exist within the body that have the potential to act as cross-linking agents, e.g., aldehydes, antibodies, free radicals, quinones, citric acid, and polyvalent metals, to name but a few.

### Free Radicals

The most popular, widely tested and influential of the damage accumulation theories of aging is the 'free radical' theory, first proposed by Harman in 1956. Free radicals from intrinsic and extrinsic sources (Table 1) can lead to activation of cytoplasmic and/or nuclear signal transduction pathways, modulation of gene and protein expression, and also alterations to the structure and ultimately the function of biomolecules. Free radicals may thus induce alterations to normal cell, tissue, and organ functions, which may result in a breakdown of homeostatic mechanisms and lead to the onset of age-related disorders and ultimately death. It can be predicted from this theory that the life span of an organism may be increased by slowing down the rate of initiation of random free radical reactions or by decreasing their chain length. Studies have demonstrated that it is possible to increase the life span of cells *in vitro* by culturing them with various antioxidants or free radical scavengers. Antioxidant supplementation with a spin-trapping agent has been demonstrated to increase the life span of the senescence accelerated mouse, although as yet there is little evidence for increasing the life span of a normal mammalian species by such strategies.

### Mitochondrial DNA Damage

This hypothesis combines elements of several theories, covering both the stochastic and genetic classes of aging theories. It is proposed that free radical reactive oxygen species generated in the mitochondria contribute significantly to the somatic accumulation of mitochondrial DNA mutations. This leads to a downward spiral wherein mitochondrial DNA damage results in defective mitochondrial respiration that further enhances oxygen free radical production, mitochondrial DNA damage, and mutation. This leads to the loss of vital bioenergetic capacity eventually resulting in aging and cell death.

**Table 1** Extrinsic and intrinsic sources of free radicals

Extrinsic sources	Intrinsic sources
Radiation: ionizing, ultraviolet	Plasma membrane: lipoxygenase, cyclooxygenase, NADPH oxidase
Drug oxidation: paracetamol, carbon tetrachloride, cocaine	Mitochondria: electron transport, ubiquinone, NADH dehydrogenase
Oxidizing gases: oxygen, ozone, nitrogen dioxide	Microsomes: electron transport, cytochrome p450, cytochrome b <sub>5</sub>
Xenobiotic elements: arsenic (As), lead (Pb), mercury (Hg), cadmium (Cd)	Peroxisomes: oxidases, flavoproteins
Redox cycling substances: paraquat, diquat, alloxan, doxorubicin	Phagocytic cells: neutrophils, macrophages, eosinophils, endothelial cells
Heat shock	Auto-oxidation reactions: Metal catalyzed reactions
Cigarette smoke and combustion products	Other: hemoglobin, flavins, xanthine oxidase, monoamine oxidase, galactose oxidase, indolamine dioxygenase, tryptophan dioxygenase
	Ischemia – reperfusion

The absence of evidence that exclusively supports any one theory leaves no doubt that aging is due to many processes, interactive and interdependent, that determine life span and death.

## Age-Related Diseases

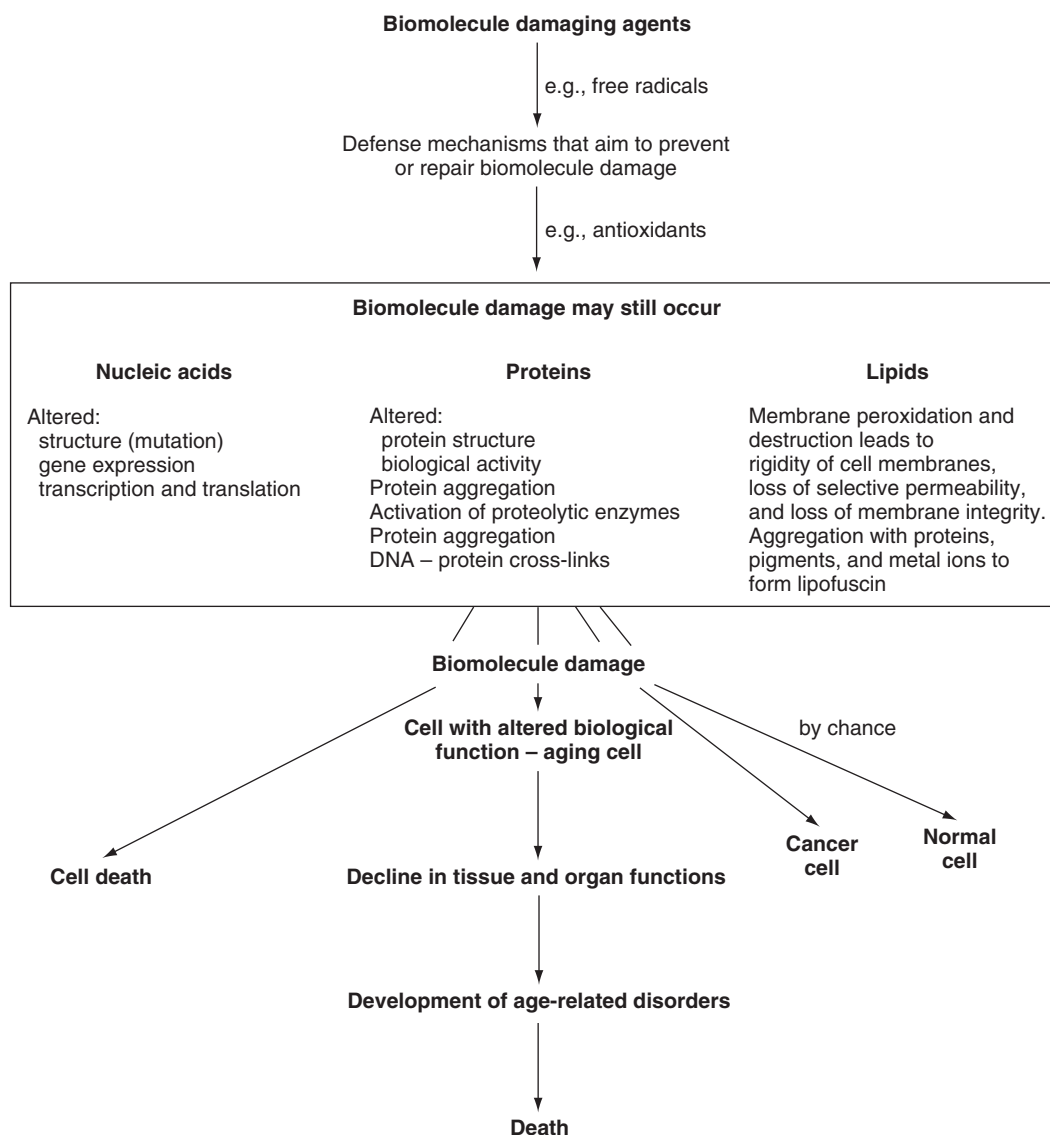

Regardless of the molecular mechanisms that underlie the aging process, a number of well-characterized changes to the structure and therefore the function of the major cellular biomolecules (lipids, proteins, carbohydrates, and nucleic acids) are known to occur with age (Table 2). The age-related alterations to the structure and therefore the function of cellular biomolecules have physiological consequences and may directly cause or lead to an increased susceptibility to the development of a number of diseases (Figure 2).

Cellular biomolecules are constantly exposed to a variety of extrinsic and intrinsic agents that have the potential to cause damage. A number of defense systems exist, e.g., antioxidant enzymes and DNA repair systems, which aim to reduce, remove, or repair damaged biomolecules. These defense systems are not perfect, however, and biomolecular damage may still occur. Such damage can result in the degradation of structural elements within the cells, tissues, and organs of the body, leading to a decline in biological function and eventually to disease and death.

The physiological alterations with age proceed at different rates in different individuals. Some of the common changes seen in humans are: the function of the immune system decreases by the age of 30 years, reducing defenses against infection or tumor establishment and increasing the likelihood of autoimmune disorders; metabolism starts to slow down at around 25 years of age; kidney and liver function decline; blood vessels lose their elasticity; bone mass peaks at the age of 30 years and drops approximately 1% per year thereafter; the senses fade; the epidermis becomes dry and the dermis thins; the quality of and need for sleep diminish; and the brain loses 20% of its weight, slowing recall and mental performance. A number of age-related diseases may develop due to the tissue, organ, and system deterioration (Table 3).

**Table 2** Major age-related alterations in biomolecule structure and the resultant physiological consequences of such structural changes

<i>Biomolecule</i>	<i>Alteration</i>	<i>Physiological consequence</i>
Lipids	Lipid peroxidation	Oxidized membranes become rigid, lose selective permeability and integrity. Cell death may occur Peroxidation products can act as cross-linking agents and may play a role in protein aggregation, the generation of DNA damage and mutations, and the age-related pigment lipofuscin
Proteins	Racemization, deamination, oxidation, and carbamylation	Alterations to long-lived proteins may contribute to aging and/or pathologies. For example, modified crystallins may aggregate in the lens of the eye thus leading to the formation of cataracts Cross-linking and formation of advance glycosylation end-products (AGEs), which can severely affect protein structure and function
Carbohydrates	Fragmentation, depolymerization glucose auto-oxidation	Effects on the maintenance of cellular homeostasis Alters physical properties of connective tissue. Such alteration may be involved in the etiology and pathogenesis of osteoarthritis and other age-related joint disorders Glycosylation of proteins <i>in vivo</i> with subsequent alteration of biological function; for example, glycosylation of insulin in patients with diabetes may result in altered biological function of insulin and contribute to the pathogenesis of the disease
Nucleic acids	Strand breaks base adducts loss of 5-methyl cytosine from DNA	Damage might interfere with transcription, translation, and DNA replication, reducing a cell's capacity to synthesize vital polypeptides/proteins. In such circumstances cell death may occur. The accumulation of hits in critical cellular genes associated with the control of cell growth and division results in the process of carcinogenesis Dedifferentiation of cells (5-methylcytosine plays an important role in switching off genes as part of gene regulation) If viable, such dedifferentiated cells may have altered physiology and may contribute to altered tissue/organ function

**Figure 2** Biomolecule damage and the aging process. Reproduced from Barnett YA (1994) Nutrition and the aging process. *British Journal of Biomedical Sciences* 51: 278–287.

## Modification of the Aging Process

Can the adverse consequences of aging be prevented? Through the ages many have pursued the elixir of life. Attempts to increase the average life expectancy and quality of life in the elderly can only succeed by slowing the aging process itself. In humans, the rate of functional decline associated with aging may be reduced through good nutrition, exercise, timely health care, and avoidance of risk factors for age-related disease.

### Nutritional Modification

It is clear that diet contributes in substantial ways to the development of age-related diseases and that modification of the diet can contribute to their prevention and thus help to improve the quality of life in old age. Macronutrient intake levels can play a significant role in the progression of age-related diseases and affect the quality of life. For example, the total and proportional intakes of polyunsaturated fatty acids and saturated fatty acids in the Western diet may have an effect on the incidence of atherosclerosis and cardiovascular diseases.

Our dietary requirements also change as we age and if such changes are not properly addressed this could lead to suboptimal nutritional status. This challenge is compounded by a decrease in the body's ability to monitor food and nutrient intakes. Dietary

**Table 3** Major age-related alterations *in vivo* and the resultant pathological conditions

<i>Body system</i>	<i>Pathological changes</i>
Cardiovascular	Atherosclerosis, coronary heart disease, hypertension
Central nervous system	Reduction of cognitive function, development of various dementias (e.g., Alzheimer's disease and Parkinson's disease)
Endocrine	Noninsulin-dependent diabetes, hypercortisolemia
Hematopoietic	Anemia, myelofibrosis
Immune	General decline in immune system function, particularly in T cells
Musculoskeletal	Osteoporosis, osteoarthritis, skeletal muscle atrophy
Renal	Glomerulosclerosis, interstitial fibrosis
Reproductive	Decreased spermatogenesis, hyalinization of semeniferous tubules
Respiratory	Interstitial fibrosis, decreased vital capacity, chronic obstructive pulmonary disease
Sense organs	Cataracts, senile macular degeneration, diabetic retinopathy
All systems	Cancer

intake and requirements are complex issues, intertwined with many health and life style issues. However, most research points toward the need for a varied diet as we age, with an increased emphasis on micronutrient intake levels.

An exemplary diet for healthy aging can be found in the traditional diet of Okinawa, Japan. Okinawans are the longest-living population in the world according to the World Health Organization, with low disability rates and the lowest frequencies of coronary heart disease, stroke, and cancer in the world. This has been attributed to healthy life style factors such as regular physical activity, minimal tobacco use, and developed social support networks as antistress mechanisms, all of which are underpinned by a varied diet low in salt and fat (with monosaturates as the principal fat) and high levels of micronutrient and antioxidant consumption.

### Vitamins and Micronutrients

The mechanisms by which certain vitamins and micronutrients mediate their protective effect on age-related disorders is based on their abilities to prevent the formation of free radicals or scavenging them as they are formed, either directly (e.g., vitamins C, E, and  $\beta$ -carotene) or indirectly (e.g., copper/zinc superoxide dismutase, manganese-dependent superoxide dismutase, selenium-dependent glutathione peroxidase) (Table 4). Only by exploring more fully the underlying molecular mechanisms of aging and the major classes of antioxidants will it be possible to establish their role, and develop strategies for using various classes of antioxidants to reduce the effects of aging. Other dietary components may also have a beneficial effect in preventing or delaying the

**Table 4** Effects of vitamins and micronutrients on age-related disorders

<i>Vitamin or micronutrient</i>	<i>Possible effect on age-related disorder</i>
Vitamins B <sub>6</sub> , E copper, zinc, and selenium	Impairment of immune function in older humans if inadequate amounts
Vitamins C, E, and carotenoids	Increased amount in the diet is associated with delayed development of various forms of cataract
Carotenoids and zinc	Dietary supplementation associated with a decreased risk of age-related macular degeneration
Selenium	Absolute or relative deficiency associated with development of a number of cancers (not breast cancer)
Vitamin C, $\beta$ -carotene, $\alpha$ -tocopherol, and zinc	Dietary supplementation may decrease the rate of development of atherosclerosis
Selenium, copper, zinc, lithium, vanadium, chromium, and magnesium	Dietary deficits are associated with an increased risk of cardiovascular disease
Vitamins B <sub>12</sub> , B <sub>6</sub> , and folate	Adequate levels throughout a lifetime may prevent some of the age-related decrease in cognitive function
Chromium	Deficiency is associated with an increased risk of Type 2 diabetes mellitus

onset of age-related disease. For example, as a deterrent against the onset of osteoporosis, adults should ensure adequate calcium and vitamin D intakes.

### Dietary Energy Restriction

The effect of caloric restriction on life span has only been demonstrated convincingly in rodents. Feeding mice and rats diets deficient in energy (approximately 35% of that of animals fed ad libitum, after the initial period of growth) retards the aging of body tissues, inhibits the development of disease and tumors, and prolongs life span significantly. The exact mechanism of action of dietary energy restriction remains to be elucidated, but may involve modulation of free radical metabolism, or the reduced hormone excretion that occurs in dietary restricted animals may lower whole body metabolism resulting in less 'wear and tear' to body organs and tissues.

Current investigations into the effects of dietary energy restriction (by approximately 30%) on the life spans of primates, squirrels, and rhesus monkeys continue. Caloric restriction in rhesus monkeys leads to reductions in body temperature and energy expenditure consistent with the rodent studies. These investigations should have direct implications for a dietary energy restriction intervention aimed at slowing down the aging process in humans, should any humans wish to extend their life span at such a cost. Once the mechanisms of effects of caloric restriction on longevity are understood it may be possible to develop drugs that act through these mechanisms directly, mitigating the need for diets that interfere with the quality of life.

### Molecular Biological Interventions and the Aging Process

Accelerated aging syndromes show degenerative characteristics similar to those appearing during normal aging. The mutations leading to these disorders are being identified and their roles in the aging process are being elucidated. Examining differences in the genetic material from normal elderly people and those with progeria should provide a better understanding of the genetic mechanisms of aging. Identification of a control gene or genes that inhibit the action of the genes producing the progeroid phenotype might make it possible to slow down aberrant protein production in normal people as well.

As an example, the genetic defect that predisposes individuals to the development of Werner syndrome has been elucidated. Individuals with this disease carry two copies of a mutant gene that codes for a helicase enzyme (helicases split apart or unwind the two strands of the DNA double helix). DNA helicases play a role in DNA replication and repair. In light of the biological function of these enzymes it has been proposed that premature aging in Werner syndrome is caused by defective helicase preventing DNA repair enzymes from removing background DNA damage, which thus becomes fixed as mutations, with consequent deleterious effects on cellular function. It remains to be determined whether increasing the fidelity or activity of helicases in cells will extend their life span.

Because loss of telomeric DNA sequences may lead to replicative senescence in dividing cells, in theory by preventing such telomere loss the life span of the cell could be extended. A naturally occurring enzyme, telomerase, exists to restore telomeric DNA sequences lost by replication. Telomerase is normally only functional in germ cells. Manipulating certain cell types (e.g., cells of the immune system) to regulate the expression of telomerase may extend their functional life span. Drugs that enhance telomerase activity in somatic cells are being developed. However, cellular senescence has been implicated as a tumor suppressor mechanism and it has been found that cancer cells express telomerase. An uncontrolled expression of this enzyme in somatic cells may lead to the onset of malignancy through uncontrolled cell proliferation. Thus, any intervention aiming to increase life span based on the cellular expression of telomerase must strike a balance between maintaining controlled cell division and uncontrolled proliferation.

A number of single gene mutations have been identified that affect metabolic function, hormonal signaling, and gene silencing pathways. In future it may be possible to develop drugs to mimic the antiaging effects that these genes exert.

## Key points

- Breast milk is a unique bioactive substance that changes composition to suit the nutritional, developmental, and immunological needs of the growing infant and young child
- While breast milk and lactation can be viewed as a biological system, the act of breastfeeding is a behavior that involves complex social and cultural norms and maternal and infant attributes
- Successful breastfeeding is not the sole responsibility of a mother, but requires collective social responsibility and supportive public policies
- Breastfeeding not only benefits child health and development, it also holds benefits for maternal health
- Rates of exclusive breastfeeding are increasing; however, rates of continued breastfeeding are declining

## Introduction

Incomparable to any other mammalian milk, breast milk is a unique bioactive substance that changes composition, within and between feedings and over time, to suit the nutritional, developmental, and immunological needs of the growing infant and young child. Its composition and biological functions, which have evolved over millions of years to meet the specific needs of a child, are more than the sum of their parts (Christian et al., 2021). As a perfectly adapted source of nutrition and immune protection, breast milk has been referred to as the ultimate personalized medicine (Victora et al., 2016). While breast milk and lactation can be viewed as a biological system, the act of breastfeeding is a behavior that involves complex social and cultural norms and maternal and infant attributes. As such, successful breastfeeding is not the sole responsibility of a mother, but requires collective social responsibility and supportive public policies (Rollins et al., 2016). Breastfeeding not only benefits child health and development, it also holds benefits for maternal health (Victora et al., 2016). This article provides a broad overview of the science of breast milk and the benefits and determinants of breastfeeding, including sections on breast milk composition, breastfeeding and maternal and infant health, global and community factors affecting breastfeeding, breastfeeding protection, promotion, and support, and breastfeeding rates and trends. Recommendations for breastfeeding by the World Health Organization (WHO) and the United Nations Children's Fund (UNICEF) are summarized in **Box 1**.

## Breast milk composition

As a dynamic and bioactive fluid, the composition of breast milk changes during the course of lactation and is also affected by interactions between the mother-infant dyad (Ballard and Morrow, 2013; Christian et al., 2021). It is also influenced by maternal diet,

**Box 1 WHO and UNICEF breastfeeding recommendations**

- Early initiation of breastfeeding within 1 h of birth
- Exclusively breastfed, defined as breast milk as the sole source of infant nutrition with no other liquids (including water) or food, except for oral rehydration solution, drops, syrups (e.g., vitamins, minerals, or medicines)
- Continue to breastfeed for 2 years of age or more
- Breastfed on demand day and night

health, and nutritional status. Breast milk is composed of fat, protein, carbohydrates, vitamins, minerals, and water. It also includes a large array of non-nutritive substances, which include immunoglobulins, hormones proteins, human milk oligosaccharides, white blood cells, anti-microbial peptides, cytokines, chemokines, micro RNAs, and commensal bacteria, all of which are highly effective in protecting infant health ([Christian et al., 2021](#)). Knowledge about the number and function of these non-nutritive substance continually increases with new analytic techniques.

Milk composition varies by the three stages of lactation: colostrum, transitional milk, and mature milk. Colostrum, produced in low quantities and secreted during the first 4–5 days after birth, is rich in immunoglobulins and other proteins, carotenoids and electrolytes (e.g., calcium and sodium), and developmental factors such as epidermal growth factor ([Ballard and Morrow, 2013](#); [Christian et al., 2021](#)). Transitional milk, secreted between around the fifth to tenth day after birth, shares some characteristics of colostrum but increases in volume to support the rapidly increasing nutritional and developmental needs of the newborn. Mature milk, secreted when lactation is fully established at about day 10, is higher in fat and carbohydrates but still rich in immunological factors.

Breast milk contributes all the energy an infant needs for about 6 months and a substantial proportion of energy beyond 6 months of age ([Taren and Lutter, 2017](#)). In low- and middle-income countries, average breast milk intake between 12 and 23 months of age contributes between 35% and 45% of a young child's energy needs. Between 15 and 18 months, breast milk provides approximately 70% of a child's vitamin A requirements, 40% of his or her calcium requirements, and 37% of his or her riboflavin requirements. Breast milk is also an important source of choline, a nutrient critical for brain development and function.

Fats in breast milk contribute about 44% of total energy intake in young infants and provide essential vitamins, polyunsaturated fatty acids, and bioactive components. Fats are the most variable component of the three macronutrients in breast milk, with wide interindividual and intraindividual variation. They also change during a single breastfeeding episode, with markedly higher concentrations at the end of feeding compared to the beginning. Maternal fatty acid status affects breast milk concentrations of these lipids and there is some evidence to suggest that infants fed breast milk with a higher content of docosahexaenoic acid (DHA) have better vision and neurodevelopmental outcomes.

Proteins in breast milk contribute 45% of total energy intake in young infants, providing a source of amino acids and improving the bioavailability of vitamins, minerals, and trace elements. Proteins also provide immunologic benefits, stimulate intestinal growth and maturity, shape the microbiome, and contribute to learning and memory.

Carbohydrates in breast milk contribute about 8% of total energy intake in young infants, with the majority being lactose. Other carbohydrates include oligosaccharides, which positively affect neurodevelopmental outcomes, and fructose, the health and nutrition role of which is less well understood, though it may have an effect on infant growth. Maternal diet influences fructose concentrations in breast milk. Because fructose can negatively alter areas of the brain that support learning and memory, more research is needed to understand the role of fructose on infant health and nutrition.

Vitamins and minerals in breast milk are generally divided into two categories: those that are affected by maternal nutritional status and diet and those that are not affected by maternal nutrition ([Table 1](#)). However, there are some nutrients that are not affected by maternal nutritional status but are affected by maternal diet. In general, water-soluble vitamins are most affected by maternal nutrition, though there are some important exceptions such as thiamin and folate. Minerals are not generally affected by maternal nutrition, though iodine and selenium are important exceptions. Iron content of breast milk is low, though highly bioavailable. Exclusively breastfed infants, particularly those born preterm, are at risk of iron deficiency if they do not receive placental blood at delivery through delay of clamping of the umbilical cord and if their mothers had poor iron status during pregnancy. For full term infants, delayed cord clamping results in increased hematocrit and hemoglobin at 2–4 months of age and reduces the risk of iron deficiency. For the preterm infant, delayed cord clamping decreases the risk of intra-vernacular hemorrhage, necrotizing enterocolitis, and late-on-set sepsis among other benefits.

## Breastfeeding and maternal and infant health

Breastfeeding has multiple health benefits for mothers and children in both low- and high-income settings ([Victora et al., 2016](#)). Systematic reviews of multiple health outcomes, briefly summarized below, are available in an open-access supplement in *Acta Paediatrica* ([Grummer-Strawn and Rollins, 2015](#)).

**Table 1** Summary of effects of maternal nutritional status and diet on vitamins and minerals in breast milk.

<i>Nutrient</i>	<i>Affected by maternal nutritional status</i>	<i>Affected by maternal diet</i>
Thiamin	–	+

In women, breastfeeding reduces a woman's risk of breast cancer, ovarian cancer, and type-2 diabetes (Victora et al., 2016) (Table 2). There is also some data suggesting that breastfeeding reduces a woman's risk of cardiovascular disease. A set of systematic reviews on maternal health outcomes associated with breastfeeding, summarized by Victora et al. showed that each 12-month period of breastfeeding in a woman's lifetime was associated with a reduction of 4.3% in breast cancer and did not vary substantially according to menopausal status (Victora et al., 2016). Current rates of breastfeeding are estimated to prevent nearly 20,000 excess deaths from breast cancer each year and research indicates that another 20,000 deaths could be prevented by improving breastfeeding rates. Highest versus lowest durations of breastfeeding were associated with a 30% reduction in ovarian duration cancer. Never versus ever breastfed, longer versus shorter duration of exclusive breastfeeding; or longer versus shorter duration of any breastfeeding was associated with 35% reduction of type-2 diabetes. As is well-known, breastfeeding is associated with lactational amenorrhea and, in the absence of use of modern contraceptives, contributes substantially to birth spacing (Victora et al., 2016). Breastfeeding had no discernible effect on a woman's risk of osteoporosis and evidence on post-partum weight is inconclusive.

Breastfeeding has short- and long-term effects on children's health and cognitive development (Victora et al., 2016). In low- and middle-income countries, exclusively breastfed infants had only a 12% risk of death compared to non-breastfed infants and, among children 6–23 months of age, any breastfeeding was associated with a 50% reduction in death (Victora et al., 2016). An estimated 820,000 lives a year could be saved though improved breastfeeding practices, 87% of them in infants less than 6 months of age. There is also some evidence that breastfeeding might also protect against death in high-

**Table 2** The association of breastfeeding and maternal health outcomes.

<i>Outcome</i>	<i>Types of comparisons (# studies)</i>	<i>Pooled effect (95% CI)</i>
Breast cancer	Highest versus lowest duration of breastfeeding (76)	Odds ratio 0.81 (0.77–0.86)
Ovarian cancer	Highest versus lowest duration of breastfeeding (41)	Odds ratio 0.70 (0.64–0.75)
Osteoporosis (distal radius)	Highest versus lowest duration of breastfeeding (4)	Standard deviation score 0.132 (–0.260 to –0.003)
Osteoporosis (femoral neck)	Highest versus lowest duration of breastfeeding (5)	Standard deviation score –0.142 (–0.426 to 0.142)
Type 2 diabetes	Highest versus lowest duration of breastfeeding (6)	Risk ratio 0.68 (0.57–0.82)
Post-partum weight change	Qualitative review (45)	Not estimated because of different outcome measures at variable post-partum ages
Lactational amenorrhea	Highest versus lowest duration of breastfeeding (13)	Risk ratio 1.17 (1.04–1.32)

Based on Table in Victora, C., et al., 2016. Breastfeeding in the 21st century: epidemiology, mechanisms, and lifelong effect. *Lancet* 387, 1–16.

income countries, including from sudden infant death syndrome and necrotizing enterocolitis (Victora et al., 2016). A large number of research studies have examined the effect of different lengths of breastfeeding (more versus less breastfeeding and any breastfeeding versus no breastfeeding) on risk of diarrhea and respiratory infections. From these studies, researchers estimate that increased breastfeeding could prevent nearly half of all diarrhea episodes and one-third of all respiratory infections (Victora et al., 2016). Breastfeeding is also protective against malocclusion. Systematic reviews found no effect of breastfeeding on eczema or food allergies and evidence was inconclusive regarding asthma and wheezing. Breastfeeding appears to have a negative effect on dental caries. With respect to long-term effects, children who were breastfed were 35% less likely to contract type-2 diabetes and 26% less likely to suffer from overweight or obesity (Table 3). Breastfeeding has also been associated with a 19% reduction in childhood leukemia. It has no effect on systolic blood pressure, diastolic blood pressure, and total cholesterol. The effect of breastfeeding on intelligence has received particular attention from researchers, with the most recent systematic review showing consistently higher performance on intelligence tests in breastfed children and adolescents, with a pooled increase of 3.4 IQ points.

Globally, the estimated economic cost of lower cognitive ability associated with lower rates of breastfeeding amount to about US \$300 billion, annually (Victora et al., 2016). Annual reductions in health care costs for mothers and children associated with breastfeeding have been estimated to be US \$312 million in the United States, \$48 million in the United Kingdom, US \$6 million in Brazil, and US \$30.3 million in urban China.

There are several maternal health conditions that affect breastfeeding and this article reviews only a few of them. Early in the human deficiency virus (HIV) epidemic researchers determined that the virus could be transmitted through breast milk. Risk of transmission is related to the health and viral load of the mother and breastfeeding conditions, such as whether the mother suffered from mastitis, breast abscesses, or nipple fissures. Current WHO guidance for infant feeding in the context of HIV recommends that mothers known to be HIV infected should be provided with lifelong antiretroviral therapy (ART) or antiretroviral prophylaxis interventions to reduce HIV transmission through breastfeeding and national or sub-national health authorities should decide whether health services will principally counsel mothers known to be HIV infected to either breastfeed and take antiretrovirals or to avoid all breastfeeding. In settings where national health authorities are recommending breastfeeding for HIV-infected mothers, guidance recommends that: (1) Mothers known to be HIV infected (and whose infants are HIV uninfected or of unknown HIV status) should exclusively breastfeed their infants for the first 6 months of life, introducing appropriate complementary foods thereafter, and continue breastfeeding; (2) Mothers living with HIV should breastfeed for at least 12 months and may continue breastfeeding for up to 24 months or longer while being fully supported to optimize ART adherence as outlined in the *WHO Consolidated guidelines on the use of antiretroviral drugs for treating and preventing HIV infection*; (3) In settings where health services provide and support lifelong ART, including adherence counseling, and promotion and support of breastfeeding among women living with HIV, the duration of breastfeeding should not be restricted; and (4) Breastfeeding should only stop once a nutritionally adequate and safe diet without breast milk can be provided. The guidelines also stated that national and local health authorities should actively coordinate and implement services in health facilities and activities in workplaces, communities, and homes to protect, promote, and support breastfeeding among women living with HIV.

WHO and UNICEF guidance on acceptable medical reasons for use of breast-milk substitutes identifies other situations and circumstances when it is best to avoid breastfeeding. The American Academy of Pediatrics provides information on the transfer of drugs and therapeutics into breast milk that have implications for the safety of breastfeeding when a mother is taking certain medications.

**Table 3** The association of breastfeeding and long-term child health outcomes.

<i>Outcome</i>	<i>Types of comparisons (# studies)</i>	<i>Pooled effect (95% CI)</i>
Systolic blood pressure	Never versus ever breastfed; or longer versus shorter breastfeeding duration (43)	−80 mm Hg (−1.17 to −0.43)
Diastolic blood pressure	Never versus ever breastfed; or longer versus shorter breastfeeding duration (38)	−0.24 mm Hg (−0.50 to 0.02)
Overweight or obesity	Never versus ever breastfed; or longer versus shorter breastfeeding duration; or longer versus shorter duration of breastfeeding (113)	Odds ratio 0.74 (0.70–0.78)
Total cholesterol	Never versus ever breastfed; or longer versus shorter breastfeeding duration (46)	−0.1 mmol/L (−0.05 to 0.02)
Type 2 diabetes	Never versus ever breastfed; or longer versus shorter breastfeeding duration of exclusive breastfeeding; or longer versus shorter duration of breastfeeding (11)	Odds ratio 0.65 (0.49–0.86)
Intelligence	Highest versus lowest duration of breastfeeding (16)	IQ points 3.44 (2.30–4.58)

Based on Table in Victora, V., et al., 2016. Breastfeeding in the 21st century: epidemiology, mechanisms, and lifelong effect. *Lancet* 387, 1–16.

The COVID-19 pandemic has had an effect on breastfeeding caused by reduced face-to-face professional support and the virtual elimination of face-to-face peer support. Some women also received inaccurate advice regarding the safety of breastfeeding with COVID even though WHO recommends that mothers with both suspected and confirmed cases should be encouraged to initiate and continue breastfeeding (WHO, 2019). In the United Kingdom, an online survey conducted among 1219 breastfeeding mothers with a child under 12 months of age indicated two different experiences: 42% of respondents felt that breastfeeding was supported during the lockdown whereas 27% reported a struggle to get support, while some stopped breastfeeding before they had planned to do so. Mothers with lower levels of education, those living in more difficult circumstances, those who are Black, and those with minority ethnic backgrounds were most negatively impacted.

Maternal obesity increasing in low-, middle-, and high-income countries, leads to adverse breastfeeding outcomes resulting from both biological and social factors. A recent study reported that mothers with a body mass index (BMI) greater than 25 were less likely to exclusively breastfeed at 6 weeks and at 6 months compared with mothers with a “healthy” BMI between 18.5 and 25 (Marshall et al., 2019). A dose response effect was also found; cessation of breastfeeding was higher with increasing maternal BMI.

## Global and community factors affecting breastfeeding

The sociocultural model is useful to frame the multiple levels of factors that affect a woman’s choice of how to feed her infant and, if she chooses to breastfeed, how long she is likely to continue (Fig. 1). It also illustrates that a comprehensive approach to support breastfeeding is needed. Fig. 1 highlights four levels of support: public policies and declarations; the health system; the community and maternal. Relevant public policies and declarations are discussed in detail in the last section.

### Health system

At the level of the health system, important interventions that have been proven to improve breastfeeding behaviors include the Baby Friendly Hospital Initiative (discussed in detail in the last section), immediate skin-to-skin contact at birth, rooming in throughout time in the health facility, kangaroo care when indicated for a preterm infant, health worker education and training, counseling support, and lactation management support when a mother needs more skilled care.

Following birth, immediate skin-to-skin contact between mothers and their healthy newborn infants, continuing until the first breastfeed, evokes neuro-behaviors that fulfill a basic biological need of the mother-infant dyad (Moore et al., 2016). Researchers hypothesize that this period may represent a sensitive period for programming future physiology and behavior. After mode of delivery, how a newborn is fed is the next most basic determinant of the infant microbiome, which fosters important immune response in the infant and possibly brain development and cognitive functioning (Victora et al., 2016). Breast milk, provided early in life when gene expression is being fine-tuned for life, has been called the most specific personalized medicine an infant is likely to receive (Victora et al., 2016). Immediate skin-to-skin contact also affects breastfeeding outcomes. A recent systematic review showed that women who experienced skin-to-skin contact breastfed their infants longer and were more likely to exclusively breastfeed between discharge and 1 month post birth and between discharge and 6 weeks post birth (Moore et al., 2016). Furthermore, such women had higher scores for breastfeeding effectiveness and their newborns were more likely to breastfeed successfully during their first feed. The authors concluded that the evidence reviewed supported the recommendation that early skin-to-skin contact be a normal practice for healthy newborns, including those born by cesarean section and as early as 35 weeks gestation. A systematic review of rooming-in throughout a woman’s and baby’s stay in a health facility found little evidence to support or refute the practice of rooming-in compared to mother-infant separation for different breastfeeding outcomes. Nonetheless, both WHO and UNICEF continue to recommend rooming-in as the standard of care for healthy newborns.

The kangaroo mother care method was developed in the mid-1980s to support the growth and development of preterm infants, particularly in settings where advanced neonatal care was not available. A systematic review found that among low birthweight newborns, kangaroo mother care was associated with a 36% lower mortality rate, a 47% decrease in neonatal sepsis, a 78% decrease in hypothermia, a 88% decrease in hypoglycemia, and a 58% decrease in hospital readmission after discharge when compared to conventional care. Furthermore, kangaroo mother care increased exclusive breastfeeding by 50%.

A systematic review found that counseling and support increased the duration and exclusivity of breastfeeding (McFadden et al., 2017). Characteristics of effective support included that it was offered as standard of care during antenatal and postnatal care by trained personnel, that it included ongoing scheduled visits so that women knew when support would be available, and that it was tailored to the setting and needs of the population group. Face-to-face support was more likely to succeed with women exclusively breastfeeding. Lastly, support could be provided by either professional or lay/peer counselors or both. Lactation management provided by highly skilled personnel is important for the management of breastfeeding complications, such as mastitis, when they arise. A systematic review to assess if lactation education and support programs using lactation consultation specialists would improve rates of initiation and duration of any breastfeeding and exclusive breastfeeding compared with the standard of practice found that breastfeeding interventions using lactation consultants and counselors increased the number of women initiating breastfeeding by 35%. The interventions improved any breastfeeding rates by 51%. The odds of exclusive breastfeeding rates up to 1 month compared to non-exclusive breastfeeding (i.e., breastfeeding with some sort of supplementation) increased by 71%.

**Fig. 1** Social-ecological model of breastfeeding.

### Community

At the level of the community, important factors influencing breastfeeding include family support, workplace support, social norms and practices, and breastfeeding-friendly places that mothers frequent (e.g., stores, religious institutions, schools, etc.). Family support, especially from the child's father, has been shown to be important for positive breastfeeding outcomes. The results of a systematic review showed that father support was associated with a two-fold increase of exclusive breastfeeding at 6 months whereas lack of father support was associated with a risk of both full formula feeding and lactation-related problems. Returning to work outside the home is associated with early breastfeeding termination. A recent systematic review examined the effect of workplace-based breastfeeding/lactation support programs, policies, or interventions to promote breastfeeding among female employees. It found that mothers were more likely to maintain breastfeeding when employers provided the support that women need to do so, such as adequate space, tools, and time needed. It also found that it was possible for employers to implement a breastfeeding support program that fit their company's budget and resources.

Breastfeeding practices are influenced by descriptive social norms, or beliefs about the prevalence of breastfeeding by other women, and injunctive social norms, or beliefs about the degree of approval of the behavior. As part of a multiyear program to

improve infant and young child feeding practices in Bangladesh, an intensive social and behavior change communication intervention was implemented between 2009 and 2014. To evaluate the effectiveness, the program was implemented in both areas of intensive intervention and areas with less intensive intervention. Results of the evaluation showed that compared to mothers in the non-intensive areas, mothers in the intensive areas had larger social networks that increased over time. Compared to the non-intensive group, sharing of information by mothers in the intensive group increased by 17–23% points. Breastfeeding practices were also found to be associated with social networks, diffusion of information about infant and young child feeding, and social norms around breastfeeding. Although data are lacking, it seems intuitive that the more places that welcome breastfeeding mothers, the more likely she is to feel comfortable breastfeeding. Such places include stores, markets, schools, parks, religious institutions, etc. Pope Francis's support of breastfeeding in the Sistine Chapel in 2014 highlighted the importance of making mothers comfortable to breastfeed wherever they are.

## Maternal

At the most basic level, maternal factors influence breastfeeding, as does the mother-infant relationship and attributes. A systematic review examined the associations between breastfeeding and mother-infant relationships, concluding that the association is highly complex but that how breastfeeding was carried out appeared to be a decisive factor. This was in turn influenced by a number of additional variables. Positive maternal knowledge, beliefs, and values about breastfeeding have long been known to be associated with good breastfeeding outcomes in multiple countries and settings. For example, in Ghana mothers with greater knowledge of exclusive breastfeeding were nearly 6 times more likely to practice exclusive breastfeeding. Higher scores of breastfeeding knowledge and attitude were also associated with exclusive breastfeeding. Maternal beliefs about what are normative infant and young child feeding practices, including breastfeeding, have been shown to be influenced by individuals within a mother's social network. Such networks include other mothers, husbands, mothers-in-law, grandparents, other family members or neighbors within the community, and healthcare providers. Social networks, diffusion of information, and social norms are also highly interrelated and can affect maternal infant feeding behaviors. Social networks developed through social media, which are becoming increasingly important, have been shown to lead to a longer duration of breastfeeding. Self-efficacy, a critically important attribute for breastfeeding, has been defined as an individual's belief in his or her capacity to execute behaviors necessary to produce specific performance attainments. A systematic review of observational studies found that maternal intention and breastfeeding-efficacy were important predictors of the duration of breastfeeding. Interventions to improve maternal breastfeeding self-efficacy have also been found to improve breastfeeding rates in mothers of full-term infants.

Researchers hypothesize that the role of breastfeeding in maternal depression has several effects. Breastfeeding can lead to hormonal changes that protect against postpartum depression, including by helping to regulate sleep and wake patterns of the mother and child and improve maternal self-efficacy and her emotional interaction with the child. At the same time, maternal depression can also lead to poorer breastfeeding outcomes, including decreased early initiation and duration of exclusive and any breastfeeding, increased difficulties, and decreased levels of self-efficacy. Interventions to prevent post-partum depression have been shown to be effective.

Insufficient breast milk is frequently cited as a reason for stopping exclusive and any breastfeeding. Although there is a biological basis for some instances of insufficient breast milk, the most common cause is perceived insufficiency by the mother. A recent systematic quantitative and qualitative review identified 11 studies in which mothers stopped practicing exclusive breastfeeding because of perceptions of insufficient breast milk to satisfy their infant's needs.

## Breastfeeding protection, promotion, and support

Global policies for breastfeeding have been centered around three key themes: protection, promotion, and support, which are summarized in [Box 2](#). The International Code of Marketing of Breast-milk Substitutes, commonly referred to as the Code, was approved by the World Health Assembly (WHA) in 1981 and is the key policy measure protecting breastfeeding. The Code resulted from compelling accounts of inappropriate and unethical marketing of breast-milk substitutes in low-income countries, which resulted in large numbers of young children becoming malnourished or dying as a result of contaminated or diluted infant formulas. It recognized that health workers, pregnant women, mothers of young children, and their families are susceptible to direct and indirect marketing strategies. The Code includes 11 articles and, since 1981, the WHA has passed a number of resolutions to clarify and strengthen aspects of the Code. Together these outline the responsibilities of governments, the health care system, and companies that manufacture or market breast-milk substitutes. Although commonly thought to refer only to infant formula, the Code defines a breast-milk substitute as any food being marketed or otherwise represented as a partial or total replacement, whether or not suitable for that purpose. The Code represents the collective will of the member states of the WHO; however, countries must pass a regulation or law and an enforcement mechanism for it to be effective. Enforcement of country laws and regulations has generally been weak and violations frequently occur in many countries ([WHO et al., 2020](#)). Marketing by the large and growing breast-milk substitute industry continues to undermine breastfeeding as well as other aspects of young child feeding.

Breastfeeding is also protected through the Maternity Protection Convention, 2000 (No. 183) of the International Labor Organization (ILO), which recommends 14 weeks of maternity benefit for whom it applies. In addition, it stipulates women on

- World Health Assembly Target for Exclusive Breastfeeding, 2014

maternity leave shall be entitled to a cash benefit, no less than two-thirds of her previous earnings, to ensure that she and her child can be maintained in proper living conditions. The convention also prohibits employers from terminating the employment of a woman during pregnancy and on maternity leave or during a period following her return to work, except on grounds not related to pregnancy, childbirth and its consequences, or breastfeeding. It further stipulates women must return to the same or equivalent position at the same pay. Lastly, it provides a woman with the right to one or more daily breaks or a daily reduction of hours of work to breastfeed. A subsequent ILO recommendation (No. 191) promotes the optimal maternity leave to be at least 18 weeks. Similar to the Code, countries must adopt the convention through legal or regulatory measures for it to take effect. Short maternity leaves, 6 weeks or less, increase the odds of not breastfeeding or stopping early by 400% and only 23% of countries meet or exceed the ILO's recommended 18 weeks of maternity leave ([Victora et al., 2016](#)).

The Innocenti Declaration on the Protection, Promotion, and Support of Breastfeeding, signed by multiple countries in 1990, set an international agenda with ambitious targets for action. The Declaration identified four operational targets: (1) appoint a national breastfeeding coordinator of appropriate authority and establish a multisectoral breastfeeding committee; (2) ensure that every facility providing maternity services practice all 10 steps to successful breastfeeding; (3) take action to give effect to the principles and aim of the Code and subsequent relevant WHA resolutions in their entirety, and (4) enact imaginative legislation protecting the breastfeeding rights of working women and established means for its enforcement. It also stated that breastfeeding of all infants should be a global goal for optimal maternal and child health and nutrition and promoted the practice of exclusive breastfeeding.

The Baby Friendly Hospital Initiative (BFHI), launched by WHO and UNICEF in 1991, promotes and supports breastfeeding in the health system, particularly around the time of birth. It outlines 10 steps facilities that provide maternity care should follow to become certified as “baby friendly.” The recommendations to support the initiative were recently updated in which the 10 steps were separated into critical management procedures and key clinical practices. Detailed implementation guidance of the recommendations is also available. Health worker training has been a key component of the initiative and a course has been developed for this purpose. A recent systematic review on the impact of the BFHI on breastfeeding and child health outcomes concluded that the initiative led to a positive impact on short-term, medium-term, and long-term breastfeeding outcomes ([Pérez-Escamilla et al., 2016](#)). It also found a dose-response relationship between the number of steps a woman was exposed to and the likelihood of early initiation of breastfeeding, exclusive breastfeeding at hospital discharge, any breastfeeding, and the duration of exclusive breastfeeding. Community support, the 10th step, was found to be essential for sustaining the breastfeeding impacts in the long term.

Article 24 of the Convention on the Rights of the Child spells out the obligations to reduce infant and young child mortality and combat disease and malnutrition by taking measures to ensure that all sectors of society, including parents, know about the advantages of breastfeeding.

The aim of the Global Strategy for Infant and Young Child Feeding, endorsed by the WHA in 2002, is to improve young child nutrition through optimal feeding and included for the first time the recommendation to exclusively breastfeed for the first 6 months. The strategy is intended as a guide for action and identifies a set of evidence-based interventions and emphasizes the importance of providing mothers and families with the support they need to provide optimal nutrition for their young children. Similar to the Code, it also defines the obligations and responsibilities of governments, international organizations, and other important stakeholders.

In 2014, the WHA endorsed 6 global nutrition targets to be achieved by 2025. The importance of breastfeeding is reflected by the fact that exclusive breastfeeding is included as 1 of the 6 targets; specifically, to increase the rate of exclusive breastfeeding in the first 6 months up to at least 70%. A process indicator to measure interventions needed to achieve this goal is the number of births that occur in baby-friendly facilities.

**Breastfeeding rates and trends**

Endorsement by the WHA of the Code initiated a concerted global and national-level efforts to improve breastfeeding rates and provide conditions possible for women to breastfeed over the past 40 years. Efforts have especially focused on early

initiation of breastfeeding and exclusive breastfeeding. To measure progress, WHO and UNICEF have defined a set of indicators to measure breastfeeding rates, which include ever breastfed, early initiation of breastfeeding, exclusively breastfed for the first 2 days after birth, exclusive breastfeeding under 6 months, mixed-milk feeding under 6 months, and continued breastfeeding 12–15 months.

Improvements have been seen in some indicators, including early initiation of breastfeeding and exclusive breastfeeding, while declines have been seen in others such as breastfeeding 12–15 months (Rollins et al., 2016). Globally, exclusive breastfeeding among infants less than 6 months has increased from 35% in 2005 to 42% in 2018 though progress is uneven when measured by world regions (Fig. 2). As of about 2018, less than half of all newborns benefited from early initiation of breastfeeding (44%) and about the same percentage (43%) of newborns received only breast milk during the first 3 days (Fig. 3). Progress has also not been even among socioeconomic groups. Although the WHO global target for exclusive breastfeeding is that 70% of infants less than 6 months of age are exclusively breastfed, currently the rate is only 42%. Although all children should continue to be breastfed for 2 years or more, breastfeeding at 1 year (between 12 and 15 months) was 70% and breastfeeding at 2 years (between 20 and 23 months) only 45% (Fig. 3). Detailed information on early initiation of breastfeeding, exclusive breastfeeding, and continued breastfeeding, by country, are available from UNICEF, which tracks infant and young child feeding through its global databases.

**Fig. 2** Regional trends in exclusive breastfeeding, 2005–2018. Based on data presented in Figure 2.2 in UNICEF. 2019. *The State of the World's Children 2019. Children, Food and Nutrition. Growing Well in a Changing World.* UNICEF, New York.

**Fig. 3** Global rates of selected breastfeeding indicators, 2018. Based on data presented in UNICEF. 2019. *The State of the World's Children 2019. Children, Food and Nutrition. Growing Well in a Changing World.* UNICEF, New York, pp. 78–79.

The Global Breastfeeding Collective, coordinated by WHO and UNICEF and composed of numerous non-governmental organizations, has published a global breastfeeding scorecard every year since 2017. It also has defined 8 indicators to measure levels of investment, supportive policies and programs, and monitoring systems to gauge progress toward established goals to be measured annually at the country level. Progress by country, however, is uneven. For example, only 6% of donors contribute at least US \$5 per newborn to support breastfeeding, only 18% fully implement the Code, only 14% of births are in Baby-friendly facilities, 56% of primary healthcare facilities provide counseling on infant and young child feeding, 47% of districts have community infant and young child feeding programs, 41% have had breastfeeding programs assessed in the last 5 years, and 36% have had breastfeeding data collected in the past 5 years.

## Conclusion

Evidence continues to grow around the positive effects of breastfeeding on maternal health and child health and development in all countries, regardless of their level of wealth. However, for women to be made aware of breastfeeding's benefits and to meet their breastfeeding goals, an enabling environment is essential. Creating this environment is the responsibility of governments, employers, the community, and family members. Creating an enabling environment is also the responsibility of manufacturers and distributors of infant formula and other breast-milk substitutes; they must comply with the spirit and aim of The International Code of Marketing of Breastmilk Substitutes. The past 20 years have seen increases in early initiation of breastfeeding and exclusive breastfeeding; however, breastfeeding duration has decreased throughout much of the world. At present, countries are not on track to reach the global target for exclusive breastfeeding set by the WHA. Further investments in breastfeeding protection, promotion, and support are needed so that all mothers and children can benefit from the multiple health and developmental advantages provided by breast milk and through the act of breastfeeding.

### Key points

- Nutrient requirements and recommended intakes for children older than 1 year of age are discussed.
- Methodology used to construct the values is explained.
- Physiological role of nutrients and possible symptoms of deficiency and excessive intake of nutrients in children are mentioned.
- Nutritional terminology used in different countries and organizations is presented.
- A few reasons for similarities and dissimilarities in recommended nutrient intakes between these organizations are discussed.

### List of abbreviations

µg microgram(s)

E% percent of total energy coming from the energy-giving nutrient

g gram(s)  
kcal kilocalorie, 1 kcal = 4.184 kJ  
kg kilogram  
MJ megajoule, 1 MJ = 1000 kJ = 239 kcal  
PUFA(s) polyunsaturated fatty acid(s)

## Introduction

Proper nutrition in early life is very important. Nutritional status is known to affect the rate of growth, maturation, learning ability, and neurological development. It also can affect health in adulthood, such as risk of cardiovascular disease, obesity, and type 2 diabetes. Poor nutrient intake may affect the immune system, making one more susceptible to infections and unhealth.

This article will describe nutrient requirements for children between 1 and 18 years of age. It includes the methodology for determining nutrient requirements and recommended intakes and reviews the physiological importance of select nutrients, including the risks of inadequate and excessive intakes. **Table 1** shows the nomenclature used by authorities in select countries and institutes in setting nutrient reference values, a set of recommendations for daily nutritional intake for groups of individuals. Note that several different names exist for similar definitions. Additionally, most authorities set reference values for energy and recommended intake ranges for macronutrients.

Nutrient needs vary throughout the lifespan and correspond with growth velocity, stages of maturation, and other factors. The requirement for a particular nutrient is defined by the physiological role that it plays in the body and its bioavailability from the diet. If the requirement is not met, symptoms of nutrient deficiency may appear, and severe deficiency can lead to disease. The recommended dietary intake set for a nutrient meets the needs of 97.5% of individuals. **Tables 2–5** shows the daily recommended dietary intakes for minerals, trace elements, water-soluble vitamins, and fat-soluble vitamins set by authorities in select countries and institutes: Australia and New Zealand ([National Health and Medical Research Council, 2006](#)), the DACH countries Germany, Austria and Switzerland ([Die Referenzwerte für die Nährstoffzufuhr, 2021](#)), the European Food Safety Authority (EFSA) of the

**Table 1** Terminology for nutrition recommendations.

Authority	Intake threshold below which is risk of adverse effects	Intake meeting needs of 50% of individuals (average)	Intake meeting needs of 97–98% of individuals (average + 2SD)	Less evidence-based data available	Intake threshold above which is risk of adverse effects
Australia/ New Zealand		Estimated average requirement (EAR)	Recommended dietary intake (RDI)	Adequate intake (AI)	Upper level of intake (UL)
DACH <sup>a</sup>			Recommended nutrient intake (RNI)	Adequate intake (AI)	Tolerable upper intake levels (UL)
EFSA <sup>b</sup>	Lower threshold intake (LTI)	Average requirement (AR)	Population reference intake (PRI)	Adequate intake (AI)	Tolerable upper intake levels (UL)
NNR <sup>c</sup>	Lower intake level (LI)	Average requirement (AR)	Recommended intake (RI)		Upper intake level (UL)
UK	Lower reference nutrient intake (LRNI)	Estimated average requirement (EAR)	Reference nutrient intake (RNI)	Safe intake	Upper intake
USA/ Canada		Estimated average requirement (EAR)	Recommended dietary allowance (RDA)	Adequate intake (AI)	Tolerable upper intake level (UL)
WHO/FAO <sup>d</sup>		Estimated average requirement (EAR)	Recommended nutrient intake (RNI)		Upper tolerable nutrient intake level (UL)

European Union ([Dietary reference values for nutrients: Summary report, 2017](#)), the Nordic countries Denmark, Finland, Iceland, Norway, and Sweden ([Nordic Nutrition Recommendations, 2012](#)), United Kingdom ([Government recommendations, 2016](#); [Salt and Health](#)), United States and Canada ([Oria et al., 2019](#); [Ross et al., 2011](#); [Nutrition and Physical Activity](#)), and the World Health Organization (WHO) and Food and Agriculture Organization (FAO) of the United Nations ([Vitamin and mineral requirements, 2005](#)). The age-groups in the tables may differ between nutrients since they are chosen to represent the exact ages set by different authorities. The origin of the figures in the tables can be found in the article List of references.

## Methodology for definition of nutrient requirements and recommended intakes

Studies on specific energy levels and nutrient requirements for children are scarce. Variations between countries may be due to distinct dietary habits and nutrient bioavailability, differences in rate of childhood growth and average body size, different climates, or how the nutrient requirement is categorized. For example, countries categorize the needs for children by using different age ranges.

The estimated amounts of required nutrients for children are determined by several methods. Extrapolation from infant and adult data is the usual approach to estimate the required amount of nutrients in childhood. The factorial approach defines the requirement in a two-step equation that includes maintenance and growth. The amount required for maintenance is calculated from clinical trials, which estimate unavoidable losses during a period of negligible intake. The amount required for growth is a calculated accretion of the nutrient in the body. Another method of determining requirements is through balance studies, where nutrient intake is manipulated to equal losses. The required amount of a nutrient also can be established through avoiding deficiency symptoms that represent a biological nutrient inadequacy, such as iron deficiency anemia.

The World Health Organization has suggested using the grading of recommendations, assessment, development, and evaluation (GRADE) system for judging the quality of evidence for nutritional recommendations. The highest grades are on high-quality randomized clinical trials. The World Cancer Research Fund has developed recommendations based on relationships between nutrition and health or disease (e.g., cancer), which are evaluated as convincing or probable. Such an approach is especially valuable for recommendations regarding the energy-providing nutrients and development of food-based dietary guidelines.

## Energy

Reference values for children are based on energy required per kilogram of body weight. The stage of childhood growth dictates specific energy requirements. Other components in calculating energy needs are the same as for adults, i.e., basal metabolic rate, diet-induced thermogenesis, and physical activity. Basal metabolic rate comprises the majority of energy requirements and is largely determined by fat-free mass, more so by the vital organs than skeletal muscles. Young children have twice or more the energy requirement of adults per kg body weight, depending on body composition and growth stage. Higher fat mass lowers the energy requirement, an important factor to consider when determining reference values. After the first year of life, the fraction of energy intake used for growth decreases rapidly. By 1–3 years of age, approximately 3% of energy intake is used for growth, and thereafter less than 2%. Although still important, the energy needed for growth is a relatively small proportion of the total energy intake for children after 1 year of age. However, the energy cost of growth still must be taken into consideration.

Basal metabolic rate may be estimated using equations based on age, weight, height, and gender. Total energy expenditure is estimated by adding the energy required for physical activity, diet-induced thermogenesis (approximately 10%), and growth (approximately 3% at the age of 1–3 years, and less than 2% in older children).

As energy requirements depend on several different factors, variation in reference values exists among countries. Growth standards have been used to estimate the long-term adequacy of energy intake. Feeding practices in infancy and childhood, genetic variations, and other possible determinants of growth also will contribute to differences in growth standards.

## Carbohydrate

Daily requirements of carbohydrate intake (g per day or g per kilogram body weight per day) have not been defined as they have for total energy and essential nutrients. Very low carbohydrate intake causes ketosis and can be avoided by ingesting only a small

<sup>c</sup>Adequate intake (AI) for Australia/New Zealand.

<sup>d</sup>In settings of moderate bioavailability, mixed diets containing animal or fish protein.

<sup>e</sup>Estimated ARs and Population Reference Intakes (PRIs) for zinc are provided for phytate intake levels of 300, 600, 900 and 1200 mg/day, which cover the range of mean/median phytate intakes observed in European populations. PRIs for adults were estimated as the zinc requirement of individuals with a body weight at the 97.5th percentile for reference body weights for men and women.

Data sources: see list of references.

	18	40	90/105	95/110	75	40	65/75	40

Data sources: see list of references.

amount of carbohydrates. It is generally advised that carbohydrates should comprise 45–60% of total energy intake (45–60E%). This is partly to avoid very high fat and protein intake, but high-quality carbohydrates are of key importance to obtain the beneficial health effects of high-carbohydrate diet. Early introduction of high-quality carbohydrates is believed to have an impact on dietary habits throughout life. The quality is based on where the carbohydrates originate and the nutrient density of the food.

Intake of added sugars may be unfavorable for young children, as they are especially vulnerable to developing dental caries. In addition, a high-sugar diet generally includes foods with low nutrient value, and sugar-sweetened beverages have been associated with increased risk of overweight and obesity. It is widely recommended for children to avoid added sugar, and it should be less than 10% of total energy intake (10E%).

Some health authorities recommend fiber intake to equal the age of the child plus five (i.e., 7-year-old child = 12 g fiber  $\text{day}^{-1}$ ). This concept has been criticized when determining fiber intake for older children. From the age of 2 years 2–3 g/MJ can be advised and school children can easily adopt the same recommendation as adults, 3 g fiber  $\text{MJ}^{-1}$  or 25–35 g  $\text{day}^{-1}$ . Fiber intake should be increased gradually in early childhood to reach the level of 3 g/MJ slowly.

## Fat

Dietary requirements have been defined for the essential polyunsaturated fatty acids (PUFAs): linoleic acid (C18:2, *n*-6) and  $\alpha$ -linolenic acid (C18:3, *n*-3). Fat gives energy in a concentrated form, and essential fatty acids are involved in important physiological functions in the body. They are required for regulation of renal function, blood coagulation, inflammatory and immunological reactions, and blood pressure control. Human physiology does not have the enzymes necessary to introduce double bonds in the *n*-3 and *n*-6 positions; therefore, these fatty acids must be obtained from the diet. Studies strongly suggest that the *n*-3 fatty acids are important for normal brain and vision development in children. Although the *n*-3 and *n*-6 fatty acids are essential, excess intake is possible.

Adequate intake of fat is necessary to meet the needs for essential fat-soluble vitamins and fatty acids. Dietary fat intake, providing less than 20% of total energy intake, can be inadequate. High intake of saturated fat is associated with cardiovascular disease. Decreases in intake of saturated and *trans*-fatty acids in the Nordic countries after 1970 and 1980 was followed by a reduction in prevalence and mortality rate of ischemic heart disease.

The recommended combination of dietary fat in most countries is similar for children as for adults, but for young children the recommended total fat intake is sometimes higher. The Nordic Nutrition Recommendations advise a total fat intake of 30–40E% for

**Table 5** Recommendations for fat-soluble vitamins for children, for all or for female/male (F/M).

1–2-year-olds, but 25–40E% after the age of 2 years. In addition, energy from saturated fat should be lower than 10E% and *trans*-fatty acids as low as possible, energy from PUFAs 10–20E% with at least 1E% *n*-3 fatty acids, and energy from monounsaturated fatty acids 10–15E%.

## Proteins

Dietary protein requirements include the essential amino acids and protein needs to maintain a positive nitrogen balance necessary for growth. Nitrogen is a part of amino acids, which are the building blocks of proteins. Proteins are important for the transport of various substances in the body, antibody action, enzyme functions, repairing processes, and building cellular structures. The quality of proteins depends on the combination of essential amino acids it contains. A deficiency of protein can result in protein energy malnutrition, a serious condition causing muscle weakness, changes in hair and skin, and edema. Malnourished or wasted children have higher protein requirements than a child of normal body composition and normal growth. Early protein malnutrition may lead to permanent impairment of cognitive functions. Conversely, a high protein intake early in life has been associated with the onset of overweight and obesity.

Infants, children, and even adolescents who have requirements for catch-up growth due to an earlier malnutrition or stunting need a larger portion of total energy intake from protein than the ordinary healthy child. Adequate protein intake from 1 year of age is generally equivalent to  $1 \text{ g kg}^{-1}$  body weight, and from 2 years of age approximately  $0.9 \text{ g kg}^{-1}$  body weight. In the Nordic Nutrition Recommendations, the recommended protein intake is 10–15E% for one to two years old children, and 10–20E% after 2 years of age which is the same as for adults.

### Physical activity

Physical activity comprises part of the energy balance and contributes to the prevention of many noncommunicable diseases, such as cardiovascular disease, osteoporosis, and certain types of cancer and mental illness. For children and adolescents, a minimum of  $1 \text{ h day}^{-1}$  of physical activity has been advised.

### Water

Water is an essential nutrient, but very few health authorities have defined the daily requirements and recommended intake of water. A general estimated requirement for children is  $1 \text{ mL water kcal}^{-1}$  energy intake, or approximately  $1.5\text{--}2 \text{ L of fluid day}^{-1}$ . The requirement for water is quite variable, and needs change based on climate, physical activity, and diet.

### Sodium

Sodium is part of salt (sodium chloride), which is a common food ingredient. Sodium ions are essential for many metabolic processes. There is no recommendation for sodium, and the required amount of sodium intake for children is not well known. Excess water loss increases the risk for hyponatremia and dehydration. Most Western countries have health problems related to high intake of sodium. Clinical trials show that even in childhood, salt intake is associated with high blood pressure. Based on these findings, it is beneficial to limit sodium intake in children to avoid the preference for a high-salt diet and to prevent later hypertension due to high sodium intake.

### Potassium

Potassium is the major intracellular cation. Deficiency is very unlikely, as the average diet provides adequate amounts of potassium. Prolonged diarrhea, vomiting, or abnormal use of laxatives can cause excessive loss of potassium. There is evidence that potassium supplementation can decrease blood pressure, and a balance between potassium and sodium is important for blood pressure regulation.

## Bone minerals: phosphorous, calcium, and magnesium

### Phosphorous

Phosphorous is essential for bone health and an important nutrient during growth. It is widespread in the diet, and deficiency is very seldom observed. Phosphorous requirement is closely related to calcium, as it is a major part of the skeleton in the form of hydroxyapatite, which contains phosphorous and calcium in the ratio 1:2.

### Calcium

Calcium is stored in the bone as hydroxyapatite. The bone continuously undergoes remodeling. Bone formation exceeds bone resorption in children, and their rate of remodeling is higher than in adults. A small but important role of calcium is in the bloodstream, extracellular fluids, and all cells in the body. The absorption of calcium is dependent on 1,25-dihydroxyvitamin  $\text{D}_3$ , the hormonal form of vitamin D. Calcium is absorbed more efficiently in the body during periods of increased physiological need, i.e., infancy, early childhood, puberty, and when dietary intake is low. The absorption can be diminished by certain factors, such as phytic acid, oxalic acid, or phosphates. Physical inactivity also increases bone resorption and loss of calcium. Risk of osteoporosis has been related to high sodium, high protein, and a lack of physical activity. Very high calcium intake can result in hypercalcemia, kidney stones, and kidney damage.

### Magnesium

Magnesium is involved in many metabolic reactions and depends on vitamin D for its absorption. Deficiency is rare, but the symptoms are hypokalemia, hypercalcemia, neuromuscular hyperexcitability, and cardiac arrhythmias. Epidemiological studies have suggested the importance of magnesium to protect against noncommunicable diseases, but the evidence is weak. Excess magnesium intake can cause diarrhea. However, if kidney function is normal, it is highly unlikely.

## Essential trace elements

Recommended daily intake values exist for the essential trace minerals iron, zinc, iodine, selenium, and copper. Other essential minerals include molybdenum, manganese, chromium, and fluorine, but there is still limited information available about the requirements for these.

### Iron

Iron has many essential functions in the body. An important function of iron is to alternate between two oxidation states, ferrous iron ( $\text{Fe}^{2+}$ ) and ferric iron ( $\text{Fe}^{3+}$ ). Iron forms the oxygen-binding part of hemoglobin, which transports oxygen from the lungs to the tissues, and myoglobin, which transports oxygen within the muscle. Absorption of nonheme iron is increased in diets with meat or fish, as well as in diets including vitamin C. Factors that inhibit iron absorption are phytic acids, tannins, and calcium. Iron-deficiency anemia reduces work capacity and impairs cell-mediated immunological defenses. Prolonged iron deficiency in children slows mental development and permanently affects cognitive function. Iron overload is also possible, particularly in a hereditary condition of nonselective high absorption.

Infants can utilize the iron stores that they are born with for several months. After 6 months of age, they require more iron than can be obtained solely from breast milk, and this is the reason for iron fortification of infant formula and food. It is estimated that more than 40% of infants and children below 5 years of age worldwide suffer from anemia, most often due to iron deficiency. The recommendation for iron in childhood is relatively high and is based on the need for iron and proportional absorption.

### Zinc

The largest portion of zinc is located in the body cells. It is an essential part of many enzymes involved in metabolism, comprises part of the cell nucleus, and participates in gene expression. Mild deficiency symptoms are skin lesions and hair loss. Severe zinc deficiency leads to growth retardation and delayed sexual maturation. Excess zinc intake can occur with dietary supplements, and high intakes can reduce the absorption of copper, another essential mineral.

### Iodine

Iodine is an essential component of the thyroid hormones, tetraiodothyronine and triiodothyronine, necessary for normal growth, development, and metabolism. Iodine deficiency is one of the most common nutrition disorders in the world and the leading cause of preventable brain damage. When physiological requirements for iodine are not met, a series of functional and developmental abnormalities occur as a result of thyroid dysfunction. The main deficiency symptom is goiter, which is characterized by enlargement of the thyroid gland.

When iodine deficiency is severe, cretinism can occur, resulting in impaired growth, mental disorders, and disturbances in speech. The recommended intake for children is based on the amount needed to prevent goiter, urinary iodine excretion, and data from adults. Iodine fortification of salt has decreased the incidence of deficiency worldwide. Iodine toxicity may occur when the intake of iodine-fortified foods is increased drastically in a short time period.

### Selenium

Selenium is a trace mineral that has antioxidant properties. The main biological function of selenium is thought to be mediated through glutathione peroxidase and other selenoproteins. Low intake of selenium has been associated with cardiomyopathy, affecting children in particular. The recommended intake is based on the levels needed to maximize glutathione peroxidase activity or derived from studies on selenium-deficient children and adolescents. Toxicity is rare; however, excess intake has been associated with nausea, nail and hair deformities, and in very severe cases, peripheral nerve and liver damage.

### Copper

Copper plays a role in the formation of connective tissue, defense against free radicals, and is a part of several enzymes involved in energy metabolism. Copper deficiency is uncommon but has been seen in premature and malnourished infants and children with chronic diarrhea. The symptoms of copper deficiency are leukopenia, anemia, and abnormal hair and skin pigmentation. Some organ dysfunctions have also been observed. Risk of copper deficiency may increase after breastfeeding is discontinued, especially when coupled with low dietary intake. Acute copper toxicity causes gastric pain, nausea, vomiting, and diarrhea. Copper requirements have been calculated from adult reference values.

## Water-soluble vitamins

Most data on physiological requirements and recommendations for water-soluble vitamins in childhood are extrapolated from adult data. Deficiency of water-soluble vitamins is rare. The vitamins are widely found in food and easily absorbed, as well as excreted. Therefore, the risk of inadequate or excess intake is minimal. However, diseases associated with water-soluble vitamin deficiencies have been well described and will be discussed in this section.

### Thiamine (vitamin B<sub>1</sub>)

Thiamine is converted to its biologically active form, thiamine pyrophosphate, in the liver. It is involved in nerve and muscle function, and is essential for the utilization of carbohydrates and branched-chain amino acids. Beriberi is caused by thiamine deficiency. Symptoms include nervous system dysfunction, heart failure, muscle weakness, anorexia, and weight loss. These are generally more severe in children than in adults. Risk of thiamine toxicity is very low.

### Riboflavin (vitamin B<sub>2</sub>)

Riboflavin is important for the coenzymes flavine mononucleotide and flavine adenine dinucleotide, which are oxidizing agents. Recommended values are set by calculating the amount of riboflavin per energy or protein unit. Deficiency has been associated with poor iron status, and symptoms include skin changes, glossitis, anemia, and mental disturbances. Toxicity from excess riboflavin intake is rare.

### Niacin (vitamin B<sub>3</sub>)

Niacin can be formed in the body from tryptophan. It functions as the coenzymes nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, which are involved in a number of redox reactions in the metabolism of all the energy-given nutrients. A deficiency of niacin causes pellagra, which has mainly been observed in populations with a corn (maize)-based diet. There is no known toxic effect of niacin from food. However, high doses of niacin in the form of nicotinic acid may induce liver damage.

### Vitamin B<sub>6</sub>

The main role of vitamin B<sub>6</sub> is in protein metabolism, where it acts as a coenzyme in the metabolism of amino acids. Dietary deficiency of vitamin B<sub>6</sub> alone is not common, and it is usually seen with other B-vitamin deficiencies. Symptoms of deficiency in infants and children include epileptic convulsions, weight loss, gastrointestinal problems, and anemia. The recommended amount is based on protein intake ( $0.015 \text{ mg g}^{-1} \text{ protein}$ ) and is the same for adults. Toxicity is not common but has been seen with prolonged intake at  $15 \text{ mg/day}$ .

### Folate

Folate is indirectly involved in the metabolism of amino acids and the synthesis of nucleic acids required for normal cell division. Signs of deficiency are observed first in rapidly replicating tissues, such as blood cells and bone marrow. Folate deficiency is the most common cause of megaloblastic anemia in childhood. The Nordic recommendation is based on body weight at  $5 \text{ } \mu\text{g}$  per kg per day. Folate toxicity cannot occur from dietary intake alone. Excess use of folate supplements may mask vitamin B<sub>12</sub> deficiency.

### Vitamin B<sub>12</sub>

Cobalamin or Vitamin B<sub>12</sub> is necessary for normal red blood cell formation and neurological functions. Vitamin B<sub>12</sub> must be bound to a protein called intrinsic factor to be absorbed properly. Deficiency results in macrocytic megaloblastic anemia and in severe cases may cause neurological changes. There is no known risk of vitamin B<sub>12</sub> toxicity. Children who are breastfed by vegan mothers may be at risk for vitamin B<sub>12</sub> deficiency if the mother is not taking supplements. In general, B<sub>12</sub> deficiency in childhood is rare. The recommended intake for children is approximately  $0.05 \text{ } \mu\text{g kg}^{-1} \text{ body weight}$ .

### Vitamin C

Vitamin C (ascorbic acid) is a potent antioxidant with multiple roles in the body. Deficiency of vitamin C causes scurvy. Signs of mild deficiency include reduced antioxidant capacity, fatigue, and irritability. The requirement for children is extrapolated from adult values and a growth factor. Toxicity is rare, but high intakes can cause diarrhea and gastrointestinal disturbances. Excess intake over a long period increases oxalate formation and risk of kidney stones. Vitamin C is important in childhood due to its ability to enhance the absorption of nonheme iron from porridge and cereal foods commonly given to young children. The iron level in cow's

milk is very low and infantile scurvy is regularly reported; therefore, formulas must be fortified with vitamin C. Some studies indicate that low vitamin C intake may be associated with asthma in childhood.

## Fat-soluble vitamins

Most countries have set recommendations for vitamin A, D, and E, and some have developed recommendations for vitamin K, an important factor in blood clotting. This section discusses the requirements for vitamin A, D, and E.

### Vitamin A

Vitamin A is important for vision, maintenance of epithelial surface, immune competence, growth, development, and reproduction. Vitamin A deficiency is one of the most common nutrient deficiencies in the world. Epidemiological and intervention studies on children found low intake of vitamin A and poor vitamin A status to be associated with an increased rate and severity of infections, and increased mortality from infectious diseases, e.g., measles. Retinol is the active form of vitamin A and is found in foods of animal origin. Inactive forms, e.g.,  $\beta$ -carotene, are found in plant sources and can be activated in the body. Conditions that can affect the bioavailability and bioconversion of retinol and carotenoids are protein energy malnutrition, zinc deficiency, infections, and degree of food processing. There are no direct studies on vitamin A requirements in childhood; thus, the recommended intakes are extrapolated from studies on adults. High intake of vitamin A can cause hepatotoxicity, and during pregnancy, it increases the risk of infant malformations.

### Vitamin D

Vitamin D is a prohormone converted to 1,25-dihydroxyvitamin D<sub>3</sub> in the body. Active vitamin D is a steroid-like substance that can be synthesized in the skin from ultraviolet B light exposure. In areas where exposure to sunlight is limited, vitamin D must be obtained from diet. A sufficient level of vitamin D in the body ensures that the concentrations of calcium and phosphate in plasma are regulated. Vitamin D enhances the absorption of calcium from the intestine and, together with parathyroid hormone, stimulates the release of calcium from bone, resulting in increased concentration of calcium in plasma. Vitamin D is essential through this mechanism for normal bone mineralization.

Vitamin D deficiency in childhood causes rickets. Insufficient intake also has been associated with cancer, autoimmune diseases, infections, and decreased muscle strength. Supplemental vitamin D early in life has been recommended. The recommended daily intake has been increasing slowly for some decades, and recently, the US recommended dietary allowance was highly elevated. Vitamin D can be toxic in large amounts; possible adverse effects are hypocalcaemia, nephrocalcinosis, and possible kidney failure.

### Vitamin E

Vitamin E comprises two groups of components: tocopherols and tocotrienols. It is a fat-soluble antioxidant essential for neurological function. Vitamin E deficiency in children can occur with high intake of iron and PUFAs, or if they suffer from protein energy malnutrition. The recommendations for children are generally based on dietary intake of PUFAs. Vitamin E is less toxic than the other fat-soluble vitamins. However, high intakes may interfere with blood coagulation.

## Conclusion

Proper nutrition in early life is very important. This article discusses the physiological role of nutrients and possible symptoms of deficiency and excessive intake of nutrients in children and shows the dietary recommended dietary intakes set by select authorities for minerals, trace elements, water-soluble vitamins, and fat-soluble vitamins for children aged 1–18 years.

## Key points

- Appropriate and timely introduction of complementary feeding is crucial for child development and growth
- Developmental readiness includes motor coordination, gastrointestinal and renal maturation
- Taste preferences up to childhood can be modulated by developmental programming through exposure to specific tastes in utero and during infant feeding
- Parents play an important role in establishing good dietary habits with responsive feeding
- Meal frequency, nutrient density and consistency of complementary foods need to be tailored to suit an infant's requirements
- Foods to avoid include artificial, packaged, commercial, ultra-processed, refined products and those with an excess of sugar, salt and trans-fatty acids
- Baby led weaning as an alternative approach is gaining popularity over conventional parent spoon-feeding
- Allergenic foods should be introduced early as opposed to late, as previously suggested

## Introduction

Complementary feeding has been defined as “the process starting when breast milk alone is no longer sufficient to meet the nutritional requirements of infants, and therefore other foods and liquids are needed, along with breast milk.” The World Health Organization (WHO) recommends exclusive breastfeeding for 6 months and continued breastfeeding thereafter (along with the provision of safe and appropriate complementary foods) until 2 years of age or beyond. Therefore, the period of complementary feeding usually refers to the age range of 6–24 months. This is a crucial time as there is rapid growth and development with a high demand for nutrients, and equally higher vulnerability to growth faltering, micronutrient deficiencies and childhood illnesses. This article will present information mainly from three documents on guidelines related to complementary feeding; first, a joint publication by WHO and UNICEF in 1998, entitled Complementary Feeding of Young Children in Developing Countries: A Review of Current Scientific Knowledge, second, an update to the first document in 2003, and third, a separate document published by Pan American Health Organization and WHO, titled Guiding Principles for Complementary Feeding of the Breastfed Child (summarized in Table 1). Most of the material presented here are for breastfed children, for information on non-breastfed children, refer to the WHO document published in 2005, entitled Guiding Principles for Feeding Non-Breastfed children 6–24 months of age. Along with these, recent updates and additional information are from other resources provided in references and further reading.

## Age of introduction of complementary foods

In 2001, the WHO Expert Consultation on the Optimal Duration of Exclusive Breastfeeding reviewed the evidence regarding the age of introduction of complementary foods and concluded that exclusive breast-feeding for 6 months is beneficial for both the infant and the mother. Initiating complementary foods too early or too late have adverse consequences on child growth and development. Risks arising from the early introduction of complementary foods include displacement of breastmilk by foods that are usually less

**Table 1** Guiding principles for complementary feeding of the breastfed child.

1. Duration of exclusive breastfeeding and age of introduction of complementary foods	Practice exclusive breastfeeding from birth to 6 months of age, and introduce complementary foods at 6 months of age (180 days) while continuing to breastfeed.
2. Maintenance of breastfeeding	Continue frequent on-demand breastfeeding until 2 years of age or beyond.
3. Responsive feeding	Practice responsive feeding, applying the principles of psychosocial care. Specifically: (a) feed infants directly and assist older children when they feed themselves, being sensitive to their hunger and satiety cues; (b) feed slowly and patiently, and encourage children to eat, but do not force them; (c) if children refuse many foods, experiment with different food combinations, tastes, textures, and methods of encouragement; (d) minimize distractions during meals if the child loses interest easily; (e) remember that feeding times are periods of learning and love—talk to children during feeding, with eye-to-eye contact.
4. Safe preparation and storage of complementary foods	Practice good hygiene and proper food handling by (a) washing caregivers' and children's hands before food preparation and eating, (b) storing foods safely and serving foods immediately after preparation, (c) using clean utensils to prepare and serve food, (d) using clean cups and bowls when feeding children, and (e) avoiding the use of feeding bottles, which are difficult to keep clean.
5. Amount of complementary food needed	Start at 6 months of age with small amounts of food and increase the quantity as the child gets older, while maintaining frequent breastfeeding. The energy needs from complementary foods for infants with "average" breast-milk intake in developing countries are approximately 200 kcal day <sup>-1</sup> at 6–8 months of age, 300 kcal day <sup>-1</sup> at 9–11 months of age, and 550 kcal day <sup>-1</sup> at 12–23 months of age. In industrialized countries these estimates differ somewhat (130, 310, and 580 kcal day <sup>-1</sup> at 6–8, 9–11, and 12–23 months, respectively) because of differences in average breast-milk intake.
6. Food consistency	Gradually increase food consistency and variety as the infant gets older, adapting to the infant's requirements and abilities. Infants can eat pureed, mashed, and semi-solid foods from the age of 6 months. By 8 months most infants can also eat "finger foods" (snacks that can be eaten by children alone). By 12 months, most children can eat the types of foods consumed by the rest of the family (keeping in mind the need for nutrient-dense foods, as explained in #8 below). Avoid foods that may cause choking (i.e., items that have a shape and/or consistency that may cause them to become lodged in the trachea, such as nuts, grapes, and raw carrots).
7. Meal frequency and energy density	Increase the number of times that the child is fed complementary foods as he/she gets older. The appropriate number of feedings depends on the energy density of the local foods and the usual amounts consumed at each feeding. For the average healthy breastfed infant, meals of complementary foods should be provided two or three times per day at 6–8 months of age and three or four times per day at 9–11 and 12–24 months of age. Additional nutritious snacks (such as a piece of fruit or bread or chapatti with nut paste) may be offered once or twice per day, as desired. Snacks are defined as foods eaten between meals—usually self-fed, convenient, and easy to prepare. If energy density or amount of food per meal is low, or the child is no longer breastfed, more frequent meals may be required.
8. Nutrient content of complementary foods	Feed a variety of foods to ensure that nutrient needs are met. Meat, poultry, fish, or eggs should be eaten daily, or as often as possible. Vegetarian diets cannot meet nutrient needs at this age unless nutrient supplements or fortified products are used (see #9 below). Fruits and vegetables rich in vitamin A should be eaten daily. Provide diets with adequate fat content. Avoid giving drinks with low nutrient value, such as tea, coffee, and sugary drinks such as soda. Limit the amount of juice offered to avoid displacing more nutrient-rich foods.
9. Use of vitamin–mineral supplements or fortified products for infant and mother	Use fortified complementary foods or vitamin–mineral supplements for the infant, as needed. In some populations, breastfeeding mothers may also need vitamin–mineral supplements or fortified products, both for their own health and to ensure normal concentrations of certain nutrients (particularly vitamins) in their breast milk. (Such products may also be beneficial for pre-pregnant and pregnant women.)
10. Feeding during and after illness	Increase fluid intake during illness, including more frequent breastfeeding, and encourage the child to eat soft, varied, appetizing, favorite foods. After illness, give food more often than usual and encourage the child to eat more.

Reproduced from Pan American Health Organization/World Health Organization, 2003. Guiding Principles for Complementary Feeding of the Breastfed Child. Washington, DC: Pan American Health Organization.

nutrient dense than breastmilk and a higher incidence of gastrointestinal infections. Late introduction of complementary foods results in risk of inadequate nutrient intakes, due to the gap in requirements with reducing nutrient contribution from breastmilk. By 6 months of age, infants are also developmentally ready to transition to semi-solids and progress to solid foods with advancing age. Developmentally motor coordination improves with voluntary control over sucking and swallowing, initiation of biting movements, decrease in tongue thrust tendency, and the eruption of teeth. At around 9 months infants can clear a spoon using lips and maneuver the tongue to move food between teeth. Additionally, the pancreatic amylase and lipase activity, and bile production increase from birth to first year of life (McClean and Weaver, 1993). The renal and gastrointestinal function are also sufficiently mature to metabolize nutrients from CF by the age of 4 months, and the gastrointestinal maturation is largely driven by the foods ingested (Fewtrell et al., 2017). There is also an innate and evolutionary preference for sweet and/or salt and dislike of bitter tastes, which is a potential disadvantage in the current obesogenic environment. However, these predispositions can be modulated by early experience, through fetal (exposure to specific tastes in utero) and infant (via breast milk) programming of taste acceptance. Parents thus play an important role in establishing good dietary habits, where it is necessary to introduce and reinforce, that is to be persistent in introducing a new flavor at least 8–10 times, with effects that last up to 6 years (Fewtrell et al., 2017). Nevertheless,

breastfeeding should be continued till 2 years and beyond, as it provides an additional source of energy, fat, protein, several micro-nutrients and other bioactive components. For the mother, breastfeeding delays maternal fertility (ensuring adequate spacing between births) and impacts faster post-partum weight loss.

At a population level, introducing complementary foods after 6 months has no adverse effect on growth and the risk of micro-nutrient deficiencies is low among infants born at term with normal birth weight and well-nourished mothers. In conditions of low nutrient stores in infants, either due to poor maternal stores or low transfer of nutrients from breastmilk, micronutrient deficiencies can manifest before 6 months of life. For example, iron and zinc status may be marginal in low-birth-weight infants or infants born to iron deficient mothers, where the recommendation is to provide iron or zinc supplements at a dose adjusted for body weight from 2 to 3 months of age, rather than early introduction of complementary foods. The concentrations of certain vitamins (e.g., vitamin A and many of the B vitamins) and trace elements (e.g., iodine and selenium) in breast milk may be lower than desirable due to poor diversity in maternal diets. In such situations, dietary counseling or supplements to the mother are the preferred approaches.

### Nutrient needs from complementary foods

The amounts of nutrients provided daily to the baby by breast milk can be estimated by multiplying the average breast-milk intake by the concentration of each nutrient in human milk (Dewey, 2001). By subtracting these values from the total recommended nutrient intakes (RNIs) one can derive estimates of the amounts of nutrients needed from complementary foods after 6 months of age. Using this approach, Table 2 lists these estimates for three age ranges: 6–8, 9–11, and 12–23 months. In this table, the RNIs for energy and protein are taken from the update report on complementary feeding published in 2003, and the RNIs for micro-nutrients were taken from the FAO/WHO estimates or the US dietary reference intakes. The estimated amount of each nutrient provided by breast milk is based on the average milk intake during each of the age intervals, calculated separately for infants in developing countries and in industrialized countries, using data from the studies compiled in the 1998 WHO/UNICEF document. Because of differences between developing and industrialized countries in average milk intake and in the assumed breast-milk concentration of vitamin A, the estimated amount of each nutrient provided by breast milk may vary. Within each column of Table 2, the first value listed refers to developing countries, and the second to industrialized countries.

The first row of Table 2 shows the total energy requirements and the estimated amounts of energy obtained from breast milk and required from complementary foods at each age. In developing countries, the average expected energy intake from complementary foods is approximately 200 kcal (837 kJ) at 6–8 months, 300 kcal (1256 kJ) at 9–11 months, and 550 kcal (2302 kJ) at 12–23 months. These values represent 33%, 45%, and 61% of total energy needs, respectively. In industrialized countries, the corresponding values are approximately 130 kcal (544 kJ) at 6–8 months, 310 kcal (1298 kJ) at 9–11 months, and 580 kcal (2428 kJ) at 12–23 months (21%, 45%, and 65% of total energy needs, respectively). These values will differ if the child is consuming more or less breast milk than the average.

The second row of Table 2 shows the same estimates for protein. Assuming average breast-milk intake, the amount of protein needed from complementary foods increases from about 2 g day<sup>-1</sup> at 6–8 months to 5–6 g day<sup>-1</sup> at 12–23 months, with the percentage from complementary foods increasing from 21% to about 50%. The remaining rows show the estimates for the key vitamins and minerals. For vitamin B12 and selenium, the amounts needed from complementary foods prior to 12 months are zero because human milk contains generous amounts of these nutrients if the mother is adequately nourished. For the other micronutrients, the percentage of the RNI needed from complementary foods varies widely. At 6–8 months, for example, complementary foods need to provide less than 30% of the RNI for vitamin A, folate, vitamin C, copper, and iodine but more than 70% of the RNI for niacin, vitamin B6, vitamin D, iron, and zinc. The values for niacin needed from complementary foods are high in all age intervals (75–88% of the RNI), but, because niacin needs can also be met by the contribution of tryptophan in the diet, niacin is not likely to be a limiting nutrient among infants who receive adequate protein. Similarly, the percentage of vitamin D needed from other sources is very high (more than 92%) because there is relatively little vitamin D in human milk; however, it should be noted that adequate exposure to sunlight can meet the child's needs for vitamin D even if complementary foods are not rich in this nutrient.

Complementary foods need to provide relatively large amounts (at least 80% of the RNI in all age intervals) of iron, zinc, and vitamin B6. Because the amount of iron in human milk is very low (even though what is present is well absorbed), it is likely to be one of the first limiting nutrients in the diets of infants who rely predominantly on breast milk. Dietary lipids are important not only as a source of essential fatty acids but also because they influence dietary energy density and sensory qualities. Breast milk is generally rich in fat (approximately 30–50% of energy) relative to most complementary foods, so as breast-milk intake declines with age, total fat intake is also likely to decline. If one assumes that the percentage of energy from fat in the total diet should be at least 30% and that the concentration of fat in breast milk averages the amount of fat needed from complementary foods (assuming average breast-milk intake) is zero at 6–8 months, approximately 3 g day<sup>-1</sup> at 9–11 months, and 9–13 g day<sup>-1</sup> at 12–23 months, or 0%, 5–8%, and 15–20% of the energy from complementary foods, respectively. As infants decrease their intake of breastmilk, they also need other good sources of essential fatty acids, such as fish, egg, liver, nut pastes, and most vegetable oils.

**Table 2** Recommended nutrient intakes, average amount provided by breast milk, and amount needed from complementary foods at 6–8 months, 9–11 months, and 12–23 months. (Dewey and Brown, 2003; Food and Agriculture Organization/World Health Organization, 2002; IOM, 1991; Krebs et al., 1995).

<sup>a</sup>Recommended nutrient intakes, from FAO/WHO (2002) except for energy and protein (Dewey, K.G. and Brown, K.H., 2003) and calcium, copper, phosphorus, and zinc (from the US-Canada Dietary Reference Intakes).

<sup>b</sup>Based on average milk volumes of 674, 616, and 549 ml d<sup>-1</sup> in developing countries and 688, 529, and 448 ml d<sup>-1</sup> in industrialized countries for 6–8, 9–11, and 12–23 months, respectively (WHO 1998) and milk nutrient concentrations from the Institute of Medicine (IOM 1991), except for vitamin A in milk of women from developing countries (WHO 1998) and zinc (Krebs, N.F., Reidinger, C.J., Hartley, S., et al, 1995). For each nutrient, the first value refers to developing countries and the second value (after the semi-colon) refers to industrialized countries, whenever there is a difference between the two.

<sup>c</sup>CF, complementary foods. For each nutrient, the first value refers to developing countries and the second value (after the semi-colon) refers to industrialized countries, whenever there is a difference between the two.

<sup>d</sup>Assuming medium bioavailability of iron.

## Meal frequency, energy density, and consistency of complementary foods

The frequency (i.e., the number of meals per day) with which complementary foods need to be fed depends on the total quantity of food required and the amount of food that a child can consume at a single meal. The total quantity of food required is a function of the energy requirement, which varies with age and breast-milk intake, and the energy density of foods (i.e., kcal g<sup>-1</sup>). The amount of food per meal that the child can consume depends on the functional gastric capacity of infants and young children, which is assumed to be 30 g kg<sup>-1</sup> reference body weight. To cover the needs of nearly all children, these calculations use as a starting point the average total energy requirement plus two standard deviations (Pan American Health Organization/World Health Organization, 2003). For children with average breast-milk intake consuming foods with an energy density of at least 0.8 kcal g<sup>-1</sup>, the number of meals required is two at 6–8 months and three thereafter. Meal frequency increases with low or no breastmilk intake complemented with meals with a lower energy density. These calculations assume that children are fed to their gastric capacity at each meal, which may not be the case. For this reason, the guidelines recommend that additional nutritious snacks be offered once or twice per day, as desired (see guiding principle 7, Table 1). It is useful to adhere to the meal-frequency guidelines as a greater than necessary frequency may lead to excessive displacement of breast milk and may also require more time and effort by caregivers (Pan American Health Organization/World Health Organization, 2003).

The consistency of complementary foods is important for two reasons, first it should be appropriate for the child's stage of neuromuscular development, second it determines the nutrient density, and in turn the quantity of feed per meal that can be consumed by the child. To start with semi-solid or puréed foods are provided, as young infants do not have the ability to chew and swallow thick or solid foods. By the age of 8 months most infants can eat “finger foods,” and by 12 months they can generally consume “family foods” of a solid consistency. Thus, a gradual advancement is necessary in the consistency of foods offered between 6 and 12 months (see guiding principle 6, Table 1). There is some evidence to suggest that there may be a critical window for introducing lumpy solid foods, and that failure to introduce such foods by approximately 9–10 months of age is associated with an increased risk of feeding difficulties and reduced consumption of important food groups such as fruits and vegetables later. A new feeding approach is being adopted in few countries now, which challenge the traditional approach, see the section on “baby led weaning” for more details.

## Meeting nutrient needs during the period of complementary feeding

As described above and shown in Table 2, breastfed infants need considerable amounts of certain nutrients from complementary foods after 6 months of age. It is a challenge to meet nutrient needs at this age because the amount of food consumed is relatively small. Thus, it is important to provide nutrient-dense complementary foods. The desired nutrient density (the amount of nutrient per kcal of food) can be calculated by dividing the quantity of each nutrient by the total energy from complementary foods (as shown in Table 2). When the desired nutrient densities are compared with the actual nutrient densities of the typical complementary foods consumed in various populations, is generally seen to be adequate but several micronutrients are limiting in diets and are considered problem nutrients. In addition to low nutrient density of certain nutrients, nutrient bioavailability, which includes digestion, absorption and utilization for body functions, also needs to be considered. Particularly, the quality of protein is important to determine the quantity of protein required to meet requirements (Shivakumar et al., 2019). In developing countries, poor sanitary environments adversely impact gastrointestinal functions, further compromising nutrient availability (Kelly, 2021). Selection of foods for complementary feeding should focus on these factors, where animal source foods with relatively higher nutrient density than plant-based foods are recommended.

In most developing and some industrialized countries, fats, iron, zinc, and vitamin B6 are problem nutrients. The fat composition or addition of extra fat (oil), especially when feeding a vegetarian or vegan diet, may be minimal, resulting in a risk for inadequate fat intake. This can be more prevalent in poorer and marginalized communities. Equally, with plant foods and when there is poor consumption of animal source foods, the inclusion of fat as an energy source will displace grains in the mix, and therefore reduce protein intake. Therefore, attention must be given to the use of legumes to improve protein quality in these circumstances. The consumption of iron is likely to be marginal in all populations unless iron-rich foods (e.g., organ meat, fish, eggs, green leafy vegetables), or fortified products are consumed. Riboflavin, niacin, thiamine, folate, calcium, vitamin A, and vitamin C may also be problem nutrients, depending on the local mix of complementary foods. There is insufficient information to determine the extent to which some of the other micronutrients, such as vitamin E, iodine, and selenium, may be problem nutrients. Guiding principles 8 and 9 (Table 1) provide general recommendations to help ensure that the nutrient density of complementary foods will be adequate. It is difficult to develop more specific dietary “prescriptions” to be used globally because of the great variability in foods consumed across populations. Purely plant-based diets are often high in phytate, which reduces the bioavailability of iron and zinc. Therefore, it is recommended that meat, fish, poultry, or egg be offered daily, if possible.

When the amount of animal-source food available locally is limited, the amounts of iron and zinc absorbed from the diet can be enhanced by, first, reducing the phytate concentrations of the staple complementary food through germination, fermentation, and/or soaking, second, reducing the intake of polyphenols (e.g., from coffee and tea), which are known to inhibit iron absorption, and, third, increasing the intake of enhancers of iron and zinc absorption, such as vitamin C (for iron) and other organic acids (for iron and zinc). Protein digestibility is found to improve through de-hulling and extrusion of the source food grain (Kashyap et al., 2019; Devi et al., 2020). Adequate calcium can be obtained from cheese, yoghurt, and other dairy products, however, feeding fresh unheated cow's milk is not recommended before 12 months because it is associated with cow's milk protein allergy, which could

lead to fecal blood loss and lower iron status. Some vegetables can also provide modest amounts of calcium, but the bioavailability of calcium from foods with high amounts of oxalate (such as spinach) is very low. Fruits and vegetables rich in vitamin A are recommended daily because of the importance of preventing vitamin A deficiency, which has been linked with excess child mortality and other adverse outcomes. The bioavailability of pro-vitamin A carotenoids can be enhanced by finely chopping or puréeing the food and serving it with a source of fat to facilitate absorption.

### **Preparation and feeding of complementary foods**

Complementary feeding guidelines also involve directions on how to feed infants and young children. Firstly, it deals with safe preparation and storage of complementary foods (see guiding principle 4, [Table 1](#)) with attention to food hygiene during preparation (clean utensils) and feeding (clean hands), which is essential for preventing gastrointestinal illness. Feeding bottles are a major source of contamination if kept unclean/unsterile, and thus should be avoided in resource poor settings. Additionally, food should be served warm and immediately after cooking, and leftovers stored safely.

Secondly, there is emphasis on caregiver and infant interaction during feeds, termed responsive feeding (see guiding principle 3, [Table 1](#)). This appropriate feeding behavior is being sensitive to the child's hunger and satiety cues than either a laissez-faire style of feeding (the caregiver rarely encourages the child to eat) or, at the opposite extreme, a controlling style of feeding (the caregiver determines when and how much the child will eat, even to the point of force feeding). Responsive feeding also involves feeding slowly and patiently, minimizing distractions, and actively engaging the child in dialog. There is some evidence that indicates promotion of responsive feeding will enhance dietary intake, reduce undernutrition and obesity, and pave way for positive behavioral development.

Thirdly, it is important to know what to feed during and after illness (see guiding principle 10, [Table 1](#)). The need for fluids is often greater during illness, and for this reason in addition to preference for breastfeeding by children, it is critical to increase breastfeeding frequency and offer other fluids on demand. Although poor appetite is often a concern, continued consumption of complementary foods is recommended to enhance recovery. After illness, with improvement in appetite, the child needs more food than usual to make up for nutrient losses during illness and to allow for catch-up growth.

### **Introduction of allergenic food: early as opposed to late as previously suggested**

An increase in prevalence of food allergy has been observed in higher-income countries despite restriction and/or delay in introduction of potentially allergenic foods, including cows' milk, egg, fish, gluten, peanut, and seeds. On the contrary countries in which peanuts are commonly used in complementary feeding have a low incidence of peanut allergy. Animal models suggest that immune tolerance to foods might be regulated by an early and regular exposure to food proteins during a critical window. In support, studies in human infants, show that the introduction of cereal <5 and a half months, fish <9 months and egg <11 months, peanuts between 4 and 6 months, as compared to later introductions, reduces the risk of asthma, allergic rhinitis and atopic sensitization at 5 years of age. Gluten introduction anytime between 4 and 12 months does not seem to impact celiac disease development, albeit consumption in large quantities is better avoided in infants, particularly those with a known risk for the disease. Overall, the evidence is not in favor of delayed introduction of allergenic foods, rather, early introduction with repeated exposure may prove beneficial. Furthermore, continued breastfeeding while introduction of allergenic complementary foods seems to modulate the development of tolerance ([Fewtrell et al., 2017](#)).

### **What NOT to feed as complementary foods?**

Foods to avoid include, artificial, packaged, commercial, ultra-processed, refined, those with excess of sugar, salt, and trans-fatty acids. Avoid adding sugar or salt (in excess) to home prepared foods and beverages, due to the possibility of an increased risk of obesity or hypertension in later life. These practices prevent obesity or non-communicable diseases and promote a diverse and nutrient-rich diet. Constant vigilance on inappropriate marketing and promotion of commercial foods is required as a mandate at all levels of childcare. Use of commercial foods may undermine exclusive and continued breastfeeding, create dependency on commercial products and can undermine the value of home-prepared foods. Excessive animal protein intake >15% of total calories has also correlates with risk of overweight or obesity in later life ([Fewtrell et al., 2017](#)).

### **Baby led weaning (BLW) or “auto-weaning”**

The baby led approach that is popular in some countries, promotes infant self-feeding from 6 months of age (deciding on what, when and how long to feed), instead of the conventional parent spoon-feeding, along with sharing of family foods and mealtimes. The BLW as a complementary feeding practice has gained popularity and grown substantially over the past 10 years. It aims to divide the responsibility of feeding between the infant and caregivers. With BLW, a complex engagement of oral and hand-coordinated

motor skills is required, where the infant is required to manipulate movement of food in the mouth, and consequently exposed to the textures and flavors of a variety of foods. Although, BLW has potential to positively shape interpersonal food environments, it may also carry inherent risks. Based on the current evidence BLW may reduce infant food fussiness and increase satiety responsiveness. The literature also indicates that there is no difference in energy, iron or zinc intake between BLW and traditional feeding practices, but concerns do exist. Recently, a modified version called Baby Led Introduction to Solids (BLISS) has been developed that highlight introducing iron and energy-rich foods and avoiding foods that are a choking hazard. Further research on the effect of this method on nutrient intake, appetite regulation and health outcome such as growth and obesity are proposed (Fewtrell et al., 2017).

## Conclusion

Appropriate and timely introduction of complementary feeding is crucial for child development and growth. The consensus is to introduce complementary feeds not early or later than 6 months (180 days) of age, with continued breast feeding till 2 year and beyond. Infants are developmentally ready by ~4 months of age with improved motor coordination, gastrointestinal and renal maturation. Infants from developing and industrialized countries differ in their requirements based on variation in breastmilk volume and a relatively higher pathogenic burden through unsanitary environment. Depending on the status of nutritional stores of mother and infant, there is potential for problem nutrients, which could be overcome by consuming diverse foods, particularly of animal source, fruits and vegetables. Thus, attention to nutrient density, meal frequency along with responsive feeding and food hygiene is key to successful complementary feeding. It is prudent to avoid foods that are artificial, packaged, commercial, ultra-processed, refined, and those with excess of sugar, salt, or trans-fatty acids. In recent times baby led weaning has gained popularity instead of the conventional parent spoon-feeding, which has potential to positively shape interpersonal food environments. There is supportive evidence for early introduction of allergenic foods to shape immune tolerance as opposed to late introduction as earlier suggested. Overall, the experience of complementary feeding should forge healthy parent-child interactions along with supporting age- and sex-appropriate growth and development.

### Key points

- To understand the history underlying the Developmental Origins of Health and Disease (DOHaD) hypothesis.
- To identify the clinical evidence supporting DOHaD
- To appreciate the role of preclinical animal models in mimicking the adverse *in utero* events leading to fetal growth restriction and long-term dysmetabolism.
- To understand the underlying molecular mechanisms linking a poor *in utero* environment to metabolic disease in postnatal life.

### Glossary

**DNA methylation** Chemical modification of DNA in which methyl group is added usually to cytosine

**Epigenetics** The study of inherited changes in phenotype (appearance) or gene expression that occur without any changes to the underlying DNA sequence

**Histones** Proteins that package and order DNA

**Impaired glucose tolerance** Prediabetic state of increased levels of glucose in the blood

**Insulin resistance** Condition in which insulin is less effective in lowering blood sugar levels

**Metabolic syndrome** A combination of medical disorders including high blood pressure, high triglyceride levels, high cholesterol, obesity, and insulin resistance, that increase the risk of developing heart disease, type 2 diabetes, and stroke

**Mitochondrial dysfunction** Inability of the mitochondria to convert the energy derived from food into the adenosine triphosphate (ATP), which powers most cellular functions

**Oxidative stress** Imbalance between the production of reactive oxygen species within cells and the ability of the antioxidant machinery to detoxify the reactive intermediates, or to repair the cellular damage

## Introduction

Chronic diseases such as cardiovascular disease, type 2 diabetes, liver fibrosis, and cancer account for 60% of all deaths worldwide. In recent years it emerged that these diseases, thought of predominantly as diseases of adulthood, are increasingly prevalent among children. Although a nutritionally unbalanced diet and sedentary lifestyle play a contributing role, a growing body of evidence suggests that the ability of an individual to respond to metabolic challenges encountered throughout its lifetime may be determined during its fetal life. Although fetal growth and development follows the route encoded within an individual's genome, the *in-utero* environment in which a fetus grows can influence this process. The intrauterine environment provides a forecast of conditions for the fetus after birth. The fetus can respond and adapt to a variety of stimuli or insults short-term. However, the adaptations include irreversible changes in the structure and function of the body, that are detrimental to the long-term health of an individual, especially if postnatal conditions differ to the environment experienced *in utero*.

## Epidemiological data

It has been over 75 years since it was suggested, that the de-cline in overall death rates in Sweden and the UK between 1751 and 1930 was attributed to improvements in childhood nutrition and living conditions. Focus on the very early environment was prompted when David Barker and colleagues reported strong correlations between the prevalence of is-chemic heart disease and rates of mortality among newborns suggesting that increased risk of disease was linked to environmental factors affecting fetal development. The association between birth weight (a proxy for a compromised fetal growth) and development of type 2 diabetes was shown for the first time in a study of men born in Hertfordshire, UK, who were 64 years old at the time of study. The prevalence of impaired glucose tolerance among these men steadily in-creased as the birth weight decreased and men with lower birth weights were six times more likely to have type 2 diabetes than those born heavier. Subsequently, it was shown that for every 1 kg increase in birth weight there is 25% decrease in type 2 diabetes risk. In the original cohorts this was linear across the entire birth weight spectrum. However, in contemporary populations as rates of maternal obesity increase and the prevalence of women with gestational diabetes rises, more infants are born large for gestational age (44,000 g). These newborns have increased adiposity and are at a higher risk of developing obesity and features of the metabolic syndrome including impaired glucose tolerance. Therefore, infants with birth weight at both ends of the body weight spectra are more susceptible to the development of chronic diseases in later life, giving rise to U-shaped relationships. Suboptimal *in utero* conditions have now been linked to a broad spectrum of diseases (Table 1).

**Table 1** Diseases associated with suboptimal intrauterine environment in humans.

### Metabolic disorders

Impaired glucose tolerance insulin resistance  
Obesity dyslipidemia type 2 diabetes  
Nonalcoholic fatty liver disease

### Cardiovascular disorders

Breast cancer

## Developmental origins of health and disease hypothesis

On the basis of the epidemiological data, in 1992 Nick Hales and David Barker proposed the thrifty phenotype hypothesis to explain the relationship between fetal growth and development of diseases in later life. They postulated that in response to under-nutrition, a growing fetus adopts strategies to ensure its immediate postnatal survival in conditions of continued poor nutrition. These strategies include redistribution of blood flow to preserve brain growth at the expense of other tissues such as the liver, kidney, endocrine pancreas, and skeletal muscle. In addition, alterations in hormone production (e.g., decrease in fetal insulin and insulin-like growth factor 1 (IGF-1) concentrations) and tissue sensitivity to hormones, as well as programming of whole body metabolism to promote storage of nutrients when available also occur. If the individual is born into conditions of poor nutrition these adaptations are beneficial for his survival. However, if the individual is born into an environment of plenty or adequate nutrition, the adaptations become detrimental to long-term health. Since the proposal of the thrifty phenotype hypothesis, it has become apparent that critical windows of development extend into postnatal life and that the nutrient overload during fetal life is also detrimental. Therefore, the concept that experiences of early life influence an individual's long-term health is now referred to as the "developmental origins of health and disease hypothesis (DOHaD)" (Fig. 1).

## Evidence from human studies

Studies of twins have provided a very strong evidence in support of the link between the intrauterine environment and the risk of developing chronic disease. A study of Danish twin men discordant for type 2 diabetes revealed that in both monozygotic (identical) and dizygotic (nonidentical) twin pairs, the twin born with lower birth weight developed diabetes. As monozygotic twins are genetically identical, the differences in birth weight must reflect differences in the fetal environment. Similar observations were also made in younger Italian twin men (mean age 32 years). The link between nongenetic intrauterine factors and blood pressure has been proven to exist in a huge study involving over 20,000 Swedish twin pairs. Decreased birth weight was associated in this study with increased risk of hypertension independent of risk factors for hypertension in adulthood, including body mass index (BMI).

Aside from cardiovascular defects, several human studies have also reaffirmed the links between a poor *in utero* environment and dysmetabolism. The 2014 EPOCH study demonstrated that IUGR children with catch-up growth in postnatal life exhibit greater

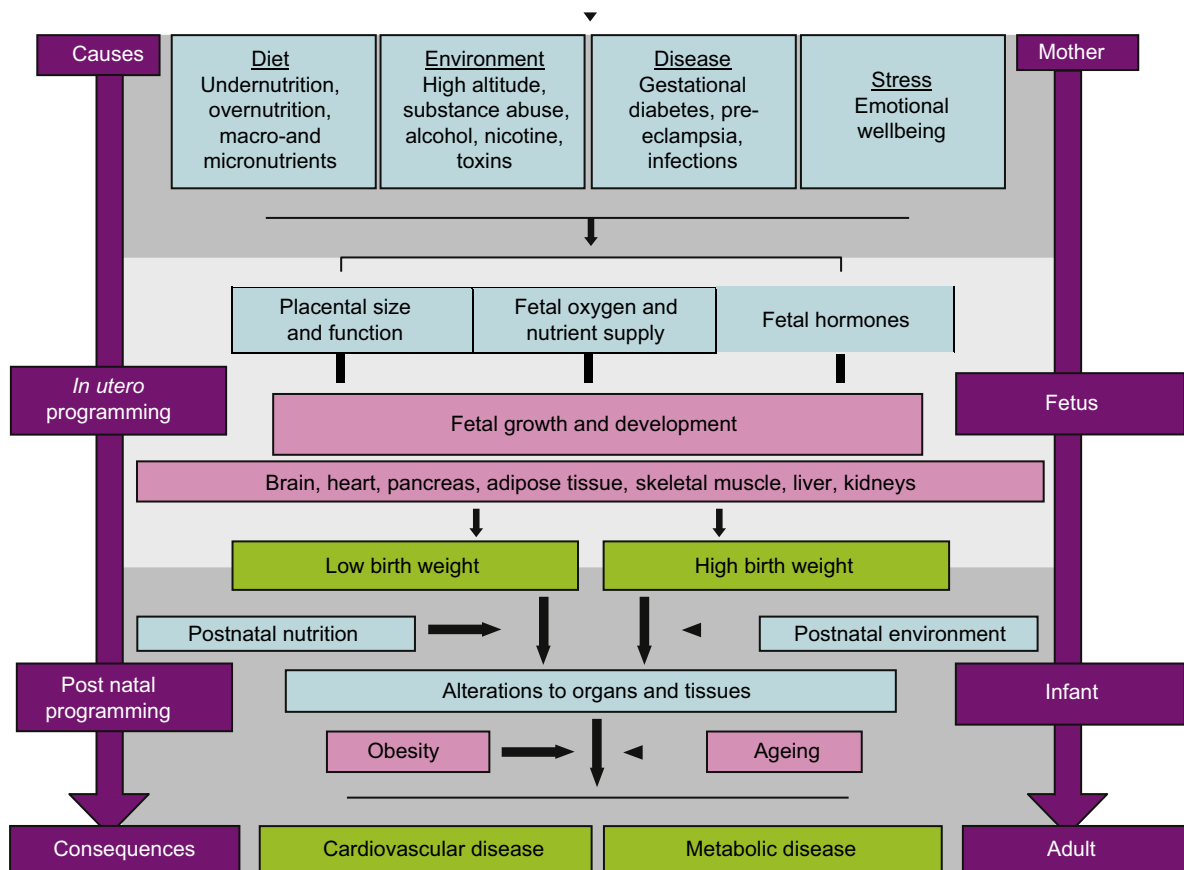

Fig. 1 Intrauterine programming of adult disease.

homeostatic model assessment of insulin resistance (HOMA-IR) and higher circulating insulin. Furthermore, neonatal catch-up growth in IUGR infants, likely attributed to growth-promoting formula diets, is also associated with higher LDL:HDL ratio, and an earlier incidence of dyslipidemia. With respect to triglycerides, fetal growth *in utero* is inversely associated with circulating triglycerides in postnatal life. Given dyslipidemia in the liver can develop into nonalcoholic fatty liver (NAFL)/nonalcoholic fatty liver disease (NAFLD), it is noteworthy that either low- or high-birth weight children exhibit increased risk of NAFLD later in life. This is of great concern considering liver fibrosis is thought to be responsible for up to 45% of deaths in the developed world.

In humans it is difficult to access the direct impact of maternal nutrition on the health of the offspring. Studies of individuals who underwent famine while *in utero* are therefore invaluable in accessing the effect of undernutrition on long-term health. The Dutch famine occurred for 5 months at the end of World War II (from late November 1944 to early May 1945) and before the famine the population of the affected area was reasonably well-nourished. When comparison was carried out between the individuals born during the year before the famine and those *in utero* during the famine, the latter had impaired glucose tolerance as shown by raised plasma glucose concentrations following an oral glucose tolerance test. The timing of the exposure to famine has also proven to be very important. Obesity rates at 19 years of age were increased among individuals exposed to famine in the early gestations, whereas they were decreased among those exposed in late gestation. Exposure to famine in early gestation has also been associated with greater risk of developing coronary heart disease at the age of 50 years.

In addition to fetal undernutrition, fetal overnutrition can also influence an individual's long-term health. Some of the strongest evidence in support of the role of nutritional excess during pregnancy and subsequent development of diseases such as obesity and type 2 diabetes in adulthood have come from the study of the Pima Indians of Arizona, a population with very high incidence of type 2 diabetes, believed to be due to genetic inheritance. A six-fold increase in the prevalence of type 2 diabetes has been shown in this population among children born to diabetic mothers in comparison to children of nondiabetic women. This increase was still present after adjustments for paternal diabetes, age of onset of diabetes in parents and obesity in the offspring. Moreover, compared to siblings born before the mother developed diabetes, children born after her diagnosis were at higher risk of developing diabetes and obesity by early adulthood. The effect was observed in addition to genetic transmission and hence must be related to the diabetic milieu experienced *in utero*. Similar findings have also been obtained from studies in lower-risk populations and in the developing world. In addition to gestational diabetes, paternal and maternal body composition and diet can not only influence the first generation of offspring, but the second generation as well. US studies have demonstrated that a poor maternal diet, as assessed by a low score of the Healthy Eating Index (HEI) and/or a high fat diet led to increased neonatal adiposity. This is of great concern considering that large for gestational age newborns, as early as 2 days old, exhibit decreased insulin sensitivity. Moreover, higher pre-pregnancy body mass index (BMI) increases the risk of being overweight in postnatal life. Specifically, children born to mothers with pre-pregnancy BMI > 25 are 1.7 times more likely to be overweight in early life and twice as likely to be overweight in late childhood. A study of ~250,000 offspring from the Nurses Health Study II have also found children (aged 9–14 years) born to obese mothers exhibit higher percentage body fat, systolic blood pressure, and fasting glucose compared to normal-weight women.

## Animal models

To gain insight into the mechanisms underlying the association between the early environment and adult health, a number of animal models have been established. These include studies in large animals such as nonhuman primates, sheep, horses, or pigs. However, the majority of research has been conducted in smaller animals such as mice and rats to take advantage of their shorter gestation and lifespan.

## Maternal undernutrition models

### Maternal calorie restriction

In this model of prenatal undernutrition caloric intake of mothers is restricted and the outcome is dependent on the timing, length, and magnitude of the caloric restriction. Reduction in maternal nutritional intake to 50% of *ad libitum* during both pregnancy and lactation leads to the birth of low birth weight offspring, who remain smaller throughout adulthood. If such reduction is limited to gestation the off-spring are smaller than controls at birth but become heavier than control offspring by weaning. This is also known as postnatal catch-up growth. By the age of 9 months they have a greater percentage of body fat, increased plasma leptin and triglyceride levels, hyperglycemia, hyperinsulinaemia, and impaired glucose tolerance. This is due, in part, to increased circulating cortisol and higher expression of PEPCK, involved in gluconeogenesis, in the liver. A 50% decrease in maternal food intake during the first two weeks of pregnancy does not have adverse effect on insulin secretion and action in adult male offspring. However, if 50% maternal nutrition is given during the last week of pregnancy the off-spring are born with low birth weights and have decreased pancreatic b-cell mass and insulin content. Even if these animals are fed a standard laboratory diet in postnatal life, pancreatic deficiencies persist into adulthood. Much more severe maternal caloric restriction of 30% of *ad libitum* food intake results in the birth of growth-restricted offspring, who develop hyperphagia and adult-onset obesity with hyperinsulinaemia, hyperleptinaemia, and hypertension. In this model, the impact of decreased maternal and placental weight during pregnancy must also be taken in consideration.

### Maternal protein restriction

This is one of the most extensively studied rodent animal models of developmental programming. The regime involves feeding pregnant dams a low (5–8%) protein (LP) diet during pregnancy and lactation in comparison to a 20% protein diet given to the control group. This maternal diet leads to a deficiency in fetal amino acids which are critical for growth. Moreover, this dietary manipulation does not lead to changes in maternal physiology (i.e., weight gain or food intake), conception rates or litter size. Offspring of LP rat dams have a 15% reduction in birth weight and if offspring are suckled by their mothers, permanent growth restriction occurs despite weaning the animals onto a control diet fed *ad libitum*. After the initial increase in insulin sensitivity in LP offspring in young adult life (6 weeks–3 months of age), these animals undergo an age-dependent loss of glucose tolerance in a sex-dependent manner. Male offspring of LP dams have impaired glucose tolerance by 15 months of age and frank diabetes by 17 months. Female LP offspring develop hyperglycemia and have impaired glucose tolerance at the older age of 21 months. The insulin resistance is associated with decreased protein expression of key insulin signaling proteins including insulin receptor substrate1 (IRS1), protein kinase zeta (PKC  $\zeta$ ), and glucose transporter GLUT4 in skeletal muscle; and the phosphatidylinositol 3-kinase (PI3K) catalytic subunit p110b in adipose tissue. The profile of insulin signaling molecule deficiencies identified in the LP model is strikingly similar to the pattern observed in tissues from low birth weight young men. As the changes observed in humans occurred prior to the development of insulin resistance or type 2 diabetes, they are unlikely to be a secondary consequence of hyperglycemia or hyperinsulinaemia and hence may help predict diabetes risk. Maternal protein restriction has also been linked to development of hypertension in the offspring due to the alterations in the activity of the renin–angiotensin system and to increased early mammary tumor risk among female LP offspring. After weaning, if maternal protein restricted offspring are placed on a normal 20% protein diet, they also exhibit visceral obesity, hypercholesterolemia (e.g., lower hepatic Cyp7a1 expression), alterations in hepatic drug metabolism (i.e., Cyp3a and Cyp2c11), and lower insulin growth factor 1 (Igf-1) despite no changes in postnatal food intake. These LP male offspring also exhibit decreases in circulating testosterone which might account for the sexual dimorphism often observed in this model.

### Maternal overnutrition models

#### Maternal obesity

Maternal obesity has been associated with the development of insulin resistance and type 2 diabetes. Adult offspring of obese mouse dams are hyperphagic, have increased body weight, and raised fat-to-lean mass ratio. With age they develop beta cell failure. As with the maternal low protein model, they have alterations in key hepatic insulin signaling molecules. Diminished protein expression of IRS1 in the liver coupled with increased phosphorylation of IRS serine residues may therefore contribute to the development of type 2 diabetes. Not surprisingly, these offspring develop insulin resistance by 3 months of age and impaired glucose tolerance was observed in males at 6 months of age. Insulin resistance also contributes to the pathogenesis of nonalcoholic fatty liver disease, signs of which have been observed in these animals. Additionally, hypertension and impaired endothelial cell function were reported in the offspring of obese dams implying that maternal obesity can predispose offspring to the development of cardiovascular disease.

#### Maternal high-fat diet

Offspring exposed to maternal high-fat diet while *in utero* became obese in adulthood and demonstrated abnormal cholesterol and lipid metabolism, hyperleptinemia, hyperinsulinemia, and insulin resistance. They have reduced muscle mass and persistent accumulation of lipid in the liver, which predisposes them to the development of nonalcoholic fatty liver disease (NAFLD). In addition, these animals have increased risk of developing hypertension and cardiovascular disease. The phenotypic characteristics of metabolic syndrome are present in most models of maternal overnutrition regardless of type of diet the offspring is exposed to in postnatal life.

### Surgical model of—uteroplacental insufficiency

Uteroplacental insufficiency (UPI) is one of the most common causes (~8% of all pregnancies) of idiopathic intrauterine growth restriction (IUGR) in the western world. It has been attributed to maternal smoking, preeclampsia or abnormalities in the development of placenta. Unilateral and bilateral uterine artery ligation/ablation has been performed to model UPI by reducing oxygen and substrate availability to the fetus and to induce asymmetric IUGR. Following this intervention, fetuses shown to be were hypoxic, hypoglycaemic, and had reduced insulin and IGF1 levels, a profile also found in human growth restricted fetuses. Uterine artery ligation leads to the development of mild insulin resistance, defects in insulin synthesis, and secretion in early life. With time, as beta cells fail to compensate, diabetes ensues. The dysglycemia observed in these offspring is also attributed to increased glucocorticoid activity, impaired glucose transporter expression, augmented gluconeogenesis, and blunted-insulin suppression all within the liver. Moreover, this phenotype is propagated to the next generation when intrauterine artery-ligated females develop gestational diabetes during pregnancy. Of note, uterine ligated guinea pigs also exhibit hepatic perisinusoidal or periportal fibrosis (e.g., higher expression of SMAD4, TGF $\beta$ 1, and MMP-2) underlying the development of NAFLD.

## Pharmacological models

### Maternal glucocorticoid exposure

Glucocorticoids are administered to pregnant women pre-dominantly to advance fetal maturation. In both humans and animals, fetal overexposure to glucocorticoids leads to the birth of IUGR offspring. In early gestation, exposure to glucocorticoids is minimal as the expression of placental 11 $\beta$ -hydroxysteroid dehydrogenase 2 (11 $\beta$ -HSD2)—an enzyme that catalyzes the conversion of active glucocorticoids into their inactive forms—is relatively high. It is noteworthy that children homozygous for mutations of 11 $\beta$ -HSD2 gene are lower in birth weight compared to heterozygous siblings. However, as the adrenal glands are activated in the late gestation, the synthesis of glucocorticoids increases to enable maturation of fetal tissues. Overexposure to glucocorticoids in late gestation leading to IUGR infants. This scenario can be mimicked by administration of synthetic compounds, for example, dexamethasone or inhibitors of 11 $\beta$ -HSD2. Treatment with dexamethasone in rats leads to decreased insulin content in fetal beta cells, due to the downregulation of the transcription factor PDX1—a critical factor involved in the development, differentiation, and function of pancreatic beta cells. In the nonhuman primates, the number of beta cells has also been shown to be decreased in the offspring following maternal dexamethasone treatment. Dexamethasone has proapoptotic effect on beta cells, which further explains its negative impact on endogenous pancreas. Maternal overexposure to glucocorticoids has been associated not only with the development of glucose intolerance and insulin resistance, but also hypertension in the offspring.

### Gestational diabetes

Maternal administration of streptozotocin (STZ) is the most common pharmacological model for studying the effects of gestational diabetes on health of the offspring in rodents and sheep. STZ is a chemical that destroys pancreatic beta cells and acts in a dose-dependent manner. High doses cause severe maternal hyperglycemia and birth of IUGR offspring with hyperglycemia. The maternal hyperglycemia results in hyperstimulation of fetal pancreatic islets leading to their degranulation and consequently beta cell exhaustion. This leads to fetal hypoinsulinemia, which coupled with decreased insulin receptors on target cells, leads to diminished fetal glucose uptake. Low doses of STZ induce mild gestational diabetes and macrosomic offspring that have enhanced development of their endocrine pancreas with hyperplasia and hypertrophy of islets. These offspring also have an increased beta cell mass, increased pancreatic insulin content, and enhanced insulin secretion. However, in adulthood these animals develop a deficit in insulin secretion and impaired glucose tolerance.

## Cellular and molecular mechanisms

The phenotypic outcomes of nutritional, surgical, and pharmacological insults designed to challenge the fetal environment are very similar, indicating the existence of common pathways and mechanisms linking early life experiences to long-term health. These are therefore a major focus of the research in the field to define the mechanisms involved.

### Epigenetic mechanisms

Epigenetics refers to covalent modifications of DNA and histones that alter gene expression without affecting the DNA nucleotide sequence. Epigenetic alterations include DNA methylation and post-translational histone modifications such as methylation, acetylation, phosphorylation, ubiquitination, and sumoylation. In recent years, microRNAs (miRs) have also emerged as a potential epigenetic mechanism. These small, on average 22 nucleotides long noncoding RNAs have been traditionally associated with post-transcriptional gene regulation; however, recently they have been shown to also play a role in DNA methylation, thereby enabling them to further regulate transcription of their targets. The main role of epigenetic modifications is to heritably promote transcriptional silencing of specific gene regions so that varying gene expression levels can be achieved from identical DNA.

A number of studies to date have shown that maternal nutrition during pregnancy can lead to permanent changes in the epigenome of offspring. One of the first studies showing the link between maternal nutrition and methylation status in the offspring was conducted in mice that carried the epigenetically sensitive Agouti viable yellow (*Avy*) allele. Offspring of *Avy* dams fed a diet supplemented with methyl donors (folate, vitamin B12, choline, or betaine) were leaner and had a different coat color (pseudo-Agouti) in comparison to obese and yellow offspring of normally fed dams. The difference in phenotype was caused by hypermethylation of a retro-transposon element downstream of the *Avy* allele, which led to the silencing of the *Avy* gene. Depending on the pattern of methylation, a wide variation in coat color ranging from yellow (unmethylated) to pseudo-Agouti (methylated) could be achieved. Moreover, there is greater hypermethylation of the *HNF4 $\alpha$*  gene in CD34<sup>+</sup> hematopoietic stem and progenitor cells from cord blood from IUGR neonates. The decrease in *HNF4 $\alpha$*  is linked to the development of type II diabetes. Maternal methyl donor supplementation has also been shown to increase in DNA methylation, of another epigenetically sensitive allele *Axin*(*Fu*) resulting in a 50% reduction in the incidence of tail kinking in the offspring. In addition, high levels of methyl vitamins in rodent pregnancy leads to hypermethylation of the *leptin* promoter contributing to obesity and insulin resistance. Hypomethylation has also been reported in sheep that were exposed to a diet deficient in methyl donors during the peri-conceptual period. These sheep developed insulin resistance and hypertension in adult life. Studies in the offspring of protein-restricted dams showed increase hepatic DNA methylation of the insulin-like growth factor 2 (*IGF2*) gene and parallel reduction in gene expression. The methylation status of gene promoters in the offspring can also be affected by maternal protein-restriction. Both glucocorticoid receptor (*GR*) and

peroxisome proliferator-activated receptor- $\alpha$  (*PPAR* $\alpha$ ) gene promoters were found to be hypomethylated in the livers of protein-restricted offspring. Parallel changes in the expression of corresponding genes were also observed. Maternal diet has also been shown to influence epigenetic status in humans. Altered methylation of the *IGF2* gene was observed in the white blood cells of individuals who were exposed *in utero* to the Dutch Hunger Winter. Dietary induced changes in DNA methylation can also lead to transgenerational effects. For example, uterine-ligated IUGR offspring exhibit higher DNA methylation in the promoter of *Igf-1* which persists into the F2 generation even if F1 offspring are completely nourished.

Alterations in histone modifications are also emerging as an important mechanism of developmental programming. In general, euchromatin is associated with histones which are acetylated on specific residues (e.g., K9/K14 on Histone H3) whereas heterochromatin contains mainly hypoacetylated and/or methylated histones. Maternal nutrition has been shown to affect histone acetylation in the offspring. When the diet of *Avy* dams was supplemented with the phytoestrogen genistein (nonmethyl donor) the color of the offspring's coat was shifted toward pseudo-Agouti due to the increased DNA methylation of the *Avy* retrotransposon. It was proposed that genistein altered histone modifications consequently affecting the chromatic structure, DNA methylation, and gene expression. Recently it has been shown that hypomethylation in yellow *Avy* mice corresponds with enrichment of some activating histone acetylation modifications (H3 and H4 diacetylation), whereas hypermethylation corresponded with the repressive histone H4K20 tri-methylation modification. Therefore, it appears that histone modifications act in concert with DNA methylation to affect interindividual variation of epigenetically sensitive genes. Intrauterine artery ligation has been shown to affect both DNA methylation and histone acetylation of the PDX 1 promoter. Additionally, losses in acetylation and an increase in dimethylation of histone, H3 at the GLUT4 locus persisting into adulthood, have been shown in the offspring of calorie-restricted dams. In low protein restricted offspring which exhibit hypercholesterolemia and lower hepatic expression of *Cyp7a1* (involved in cholesterol catabolism), this was associated with higher trimethylated histone H3 [K9] and suppressed acetylation of histone 3 [K9, 14] all surrounding the promoter of *Cyp7a1* from 3 weeks to 4 months. Interestingly, female low protein offspring do not exhibit these epigenetic changes in *Cyp7a1* or altered cholesterol levels. Recently, an association has been reported between periconceptual undernutrition in sheep and marked epigenetic changes in two hypothalamic genes: *GR* and an appetite-regulating neuropeptide, *proopiomelanocortin* (*POMC*). These epigenetic modifications could predispose the offspring to altered regulation of food intake, energy expenditure, and glucose homeostasis in later life.

As previously mentioned, the role of microRNAs (miRs) to epigenetic influence the developmental expression of metabolic genes has emerged in human and animal models of IUGR. In low birth weight humans, higher expression of miR-483-3p in the adipose is associated with higher insulin resistance, decreased lipid storage, and increased lipotoxicity. In low protein rat offspring, the entire miR-29 family (e.g., miR-29a/b/c) is increased in liver silencing the expression of insulin growth factor 1 (*Igf-1*). Moreover, in uterine-ligated IUGR guinea pig offspring, decreased miR-146a was linked to increased expression of its profibrotic target gene *smad4* implicated in NAFLD.

### Mitochondrial dysfunction and oxidative stress

Mitochondria generate most of the cell's supply of adenosine triphosphate (ATP) and are the main source of highly destructive reactive oxygen species (ROS). Evidence of oxidative stress in the fetus has been found following uteroplacental insufficiency. Pups born following this manipulation had increased pancreatic oxidative stress and impaired mitochondria function, which progressively worsens with age. This was associated with a decline in ATP production and accumulation of mitochondrial DNA damage. Pancreatic beta cells are especially vulnerable to ROS due to their high oxidative energy requirement and very low expression of antioxidant enzymes. In addition to the direct effects of the perinatal nutritional environment on oxidative stress/mitochondrial dysfunction, rapid postnatal catch-up growth may further contribute to oxidative stress and long-term dysmetabolism. For example in low protein restricted offspring, postnatal catch-up growth was *exclusively* associated with oxidative stress (i.e., elevated 4-HNE) altered aerobic metabolism (i.e., decreased citrate synthase and TFAM), along with endoplasmic reticulum (ER) stress in the liver. Oxidative stress affects not just mitochondrial DNA but also genomic DNA. ROS induced attrition of telomeres located at the ends of chromosomes has been associated with development of chronic disorders. Impaired antioxidant defense mechanisms and increased ROS production have also been observed when offspring were exposed to intrauterine nutritional excess. ROS production through xanthine oxidase (XO) activation was increased in cord plasma and placenta of neonates born to mothers with gestational diabetes. It has been proposed that exposure to oxidative stress can directly mediate DNA methylation and chromatic remodeling; however, further research is required to understand the underlying mechanisms.

### Excessive intrauterine exposure to lipids

Obese and diabetic mothers often give birth to large for gestational age (44,000 g) babies. However, as only 25% of the differences in birth weight can be attributed to maternal hyperglycemia, the majority of large infants are born to normoglycemic mothers. This would suggest that other factors besides glucose may be involved. Indeed maternal pre-pregnancy BMI, maternal fasting triglyceride, and free fatty acid levels have all been implemented in mediating excessive fetal growth. In rodents, fetal exposure to excessive lipid levels leads to lipid accumulation in the adult offspring's liver, pre-disposing the offspring to nonalcoholic fatty liver disease. Deposition of lipids in liver and muscle can cause mitochondrial dysfunction. Increased fetal lipids may also promote formation of adipocytes over other cell types such as myocytes in early organogenesis. Circulating saturated fatty acids can activate kinases that cause an increase in IRS1 serine phosphorylation, an event that is associated with inhibition of insulin signaling and one of

the hallmarks of insulin resistance. Excessive fetal lipid concentrations may also affect hypothalamic regulators of appetite and satiety. For example, consumption of a high-fat diet during pregnancy in the non-human primate may compromise the development of the melanocortin system in the fetal hypothalamus. Finally, increased pancreatic beta cell mass and excess insulin secretion, which can lead to islet cell failure and contribute to the development of diabetes, can be found in the models of maternal obesity during pregnancy.

## Conclusions

There is no doubt that environmental challenges experienced by a growing fetus can determine the risk of developing chronic diseases such as type 2 diabetes, obesity, hypertension, and other features of the metabolic syndrome in the individual. In light of the increasing prevalence of these disorders across the globe it is of critical importance to understand the mechanisms underlying the developmental origins of health and disease. Further research into the interactions between nutrition and chromatin dynamics and the role that particular nutrients play in fetal metabolic programming will be vital in allowing targeted early interventions to be developed. This may ultimately lead to the establishment of safe prevention strategies.

### Key points

- Nutritional insults early in life may have lifelong effects on health.
- Breastfeeding and proper complementary feeding protect against poor growth and chronic diseases in adulthood.
- Deficits in post-natal growth may promote chronic diseases later in life.
- Mechanisms to explain how early nutrition influences adult health are emerging with a focus on the role of epigenetics

### Introduction

A substantial body of evidence supports the hypothesis that adult chronic diseases have origins in early life, formerly known as the Developmental Origins of Health and Disease or DOHaD (Hoffman et al., 2021; Bianco-Miotto et al., 2017; Bansal and Simmons, 2018). The basic premise of research in this field is that nutritional insufficiency during sensitive developmental periods results in structural changes or programming of metabolic functions. In the short term, such adaptations enhance survival and spare brain growth at the expense of other organs. In the long run, the cost of such adaptive responses may be an increased risk of chronic disease under specific environmental conditions, such as a diet high in ultra-processed foods.

The focus of DOHaD research has been primarily on the fetal origins of adult disease, but there remains substantial potential for nutritional programming of later disease risk during infancy and childhood. The young infant has high energy and nutrient needs to support rapid growth and development. Birth weight typically doubles in the first 4–6 months of life, and length increases by approximately 30% between birth and 6 months. Many organ systems continue to mature after birth, notably the immunologic, gastrointestinal, and renal systems. This combination of rapid growth and continued development make the infant highly susceptible to the effects of environmental exposures and suboptimal nutrition, which might affect the development of disease risk. Differentiating postnatal from fetal origins is challenging, however, owing to the inevitable link between pre- and postnatal growth.

Instances of purely postnatal effects relate primarily to infant feeding or exposure to pathogens or toxins. The potential effects of infant feeding relate to nutritional adequacy, and to exposure, or lack of exposure, to specific substances in human milk or human milk substitutes. Effects of feeding may occur independently of the infant's nutritional status at birth. This topic is discussed further in a separate section below. There is also a continuum of fetal and postnatal effects. Intrauterine growth-restricted infants may experience optimal or even excess postnatal nutrition, or they may continue to be exposed to nutritional insufficiency. The responses to postnatal challenges may be conditioned by the fetal nutritional history, such that there is an interaction or synergism of fetal and postnatal effects.

Prenatal nutritional insufficiency may be thought to result in “downsizing.” It may produce smaller organs, for example, kidneys with a reduced nephron number, a pancreas with fewer islet cells, or a low skeletal muscle mass. Nutritional insufficiency may also alter metabolic or hormonal regulation, for example, hormone secretion or sensitivity of the hypothalamic–pituitary axis. In either case, the effects may be permanent, or subject to compensatory responses once nutritional or other insults are removed. For example, a permanently reduced nephron number is a hypothesized mechanism through which fetal growth restriction affects later blood pressure. Similarly, a reduced skeletal muscle mass may persist and affect insulin sensitivity in later life associated with a reduced number of insulin receptors. In such cases, the physiological capacity to respond to risk factors encountered later in life (e.g., diets high in sodium or excess calories relative to energy needs) may be compromised.

Alternatively, rapid growth following growth restriction (i.e., catch-up growth) or compensatory postnatal growth may occur. Many infants who were underweight for length at birth typically undergo a period of rapid postnatal compensatory growth in weight, whereas those who are relatively short at birth have larger length increments (see Fig. 1 for an example from a Philippines infant cohort). A central finding in many studies is that chronic disease risk is most likely to be elevated in individuals who were growth restricted in utero and thus small at birth, but relatively large at the time health outcomes were measured, leading to the conclusion that excess postnatal growth contributes to disease risk. Indeed, it has been shown that regardless of birth weight, children who grow more rapidly in length, independent of attained body mass, are more likely to have greater adipose tissue mass, a risk factor for many metabolic diseases. The extent to which rapid postnatal growth itself is a risk factor for the development of chronic disease has been the subject of extensive recent research. The relationship of early growth patterns to later disease risk is discussed in detail in a subsequent section.

## Environmental exposures

### Infant feeding and adult health

Much of the literature on the long-term effects of infant feeding is based on comparison of composition and health outcomes associated with human milk versus infant formula feeding however, effects found tend to be modest. Before discussing the results of these studies, it is important to raise several key methodological issues relevant to the interpretation of the literature. First, mothers who breast-feed may differ systematically or have varying health behaviors that contribute to their choice to breast feed. Unfortunately, most studies have insufficient data to adequately control statistically for these other behaviors, particularly because they are often unmeasured or poorly measured. Second, many studies use historical cohorts which may be subjected to recall bias and skewed information about breast-feeding duration and timing of introduction of other foods. Third, the composition of proprietary infant formulas has changed since their introduction in the 1920s. Therefore, results from older versus younger cohorts may differ either because true age-specific effects have emerged or because they were exposed to infant formula of different composition. The ideal study design for determining the long-term effects of infant feeding would require randomization to feeding regimens, and frequent follow-up of subjects up to the time when a disease risk factor or outcome is measured. Such designs are rarely ethical or feasible. Although many of the current studies have focused on neurodevelopment, some are now looking at other health outcomes.

### Selected outcomes related to infant feeding

The following are examples of some chronic disease-related outcomes studied in relation to infant feeding. The selected outcomes are intended to be illustrative of a range of effects rather than a comprehensive treatment of all outcomes related to infant feeding.

#### Infant feeding and blood pressure

Differences in the sodium and fat content in breast milk versus formula are thought to be the relevant determinants of long-term effects of infant feeding on blood pressure. In a recent systematic review, data were compiled to compare exclusive breast-feeding to formula feeding. On average, subjects who were breast-fed had a modestly lower systolic blood pressure than those who had been

**Fig. 1** Early growth of Filipino infants is associated with relative weight at birth. Mean growth increments from birth to 2 months of age in children who were relatively thin (BMI <10th sample percentile) or fat (BMI >90th sample percentile).

formula fed but studies showed no effects on diastolic blood pressure. One study on infants that included a 15-year follow-up, found that a diet of low or normal sodium intake resulted in slightly lowered blood pressure later in life. Another long-term follow-up study found blood pressure to be positively associated with dried formula milk supplement consumed in infancy compared to usual care, suggesting an effect on diet composition independent of growth. Mode of feeding may indirectly affect later disease risk through its effects on energy intake or aspects of metabolic regulation that affect growth and body composition. Numerous studies demonstrate different growth patterns in breast- and formula-fed infants that are hypothesized to reflect differences in nutrient intakes. In fact, evidence of systematic differences in breast- and formula-fed infants led the World Health Organization to undertake the production of growth charts for breast-fed infants.

### **Infant feeding and body composition**

In one careful study of body composition, total energy intakes and weight velocity from 3 to 6 months of age were higher in formula-fed compared to breast-fed infants. Estimates of fat and fat-free mass also indicate higher adiposity in formula-fed infants, however, none of these differences persisted into the 2nd year of life. Similarly, in a study of just over 15,000 children who participated in the Growing Up Today Study, infants who were breastfed for 3 months or less and infants who were breastfed for at least 7 months were less likely to be overweight during later childhood and adolescence (Gilman et al., 2001).

### **Infant feeding and obesity**

The available data on whether breast feeding provides protection against later overweight, or obesity is inconsistent. It has previously been shown that rapid weight gain during infancy is associated with increased risk of obesity later in life. On the other hand, a large prospective birth cohort study suggests that breast-fed and formula-fed infants have the same risk in childhood overweight. Some have proposed that the lipid and protein content in breastmilk is the primary driver of infant body composition. Thus, it is not clear, based on the available data, whether the effects of infant feeding are causal or whether breast-feeding serves as a marker for other health behaviors that may affect child and adolescent growth. Recent studies among siblings, which allow control for maternal characteristics, show no protective effects of breast-feeding on obesity in adolescents and young adults.

### **Autoimmune diseases**

The infant's diet is the main source of exposure to antigens suspected to be related to the development of autoimmune diseases. Exposure to bovine proteins by feeding cow's milk, and to allergenic plant proteins, such as those found in wheat, is suspected to increase risk of developing diseases such as type 1 diabetes and celiac disease in genetically susceptible individuals. First, type 1 diabetes, one of the most prevalent chronic diseases with childhood onset and is characterized by autoimmunity to pancreatic islet cells. Early introduction of cow's milk has received a great deal of attention as a potential risk factor to type 1 diabetes. Some studies found no association while others suggest that eliminating cows' milk proteins in at-risk infants reduces risk of developing islet cell autoantibodies. In terms of mechanisms, it has been suggested that early enteroviral infections play a role in the etiology of type 1 diabetes in genetically susceptible individuals. In fact, some assert that the effect of cows' milk diabetes risk may depend on viral exposures. Moreover, recent studies suggest a role for other food antigens. For example, a study of at-risk German children found that feeding of gluten-containing foods before 3 months of age was associated with risk of having pancreatic islet cell autoantibodies (Ziegler et al., 2003). Another study in the US also found an increased risk of islet cell autoimmunity among at-risk children given cereal before 3 months or after 7 months of age. Furthermore, they found that risks associated with cereal introduction were reduced by breast-feeding. While more studies clearly need to be developed to better understand these relationships, it is clear that the development of autoimmune diseases may be preceded by nutritional insults that may affect the immune response of children.

Few studies have assessed the relationship of infant feeding to later development of T2D. Early feeding may affect patterns of insulin secretion in the newborn period, and thereby program subsequent development of metabolic control. Two studies in native American populations, one in Canada and one among Pima Indians, report a protective effect of breast-feeding on later development of T2D. In the Pima study, exclusive breast-feeding in the first 2 months of life was associated with a lower rate of T2D in children and adults (Pettitt et al., 1997). In the Canadian study, breast-feeding for more than 12 months was associated with decreased risk of T2D (Young et al., 2002). While the mechanisms for these observations are still poorly understood, the developing picture seems to suggest a broad impact of poor growth on a number of developing systems that are associated with normal substrate metabolism.

Based on the discussion above, it is clear that infant feeding, through nutritional adequacy, direct exposure to antigens, and protective substances provided in human milk, has the potential to alter response to subsequent exposures and to directly influence the beginning of disease processes. The real lesson for the future will be to ensure that all children have access to adequate feeding programs from birth through adolescence.

### **Postnatal growth and later risk of disease**

Small body size in childhood may reflect nutritional insufficiency that may program adult disease like that observed in the fetal period. Independent of birth weight, low weight at 1 year of age has been associated with increased risk of cardiovascular disease in adult men. Similarly, poor childhood growth manifested as short stature has been linked with insulin resistance.

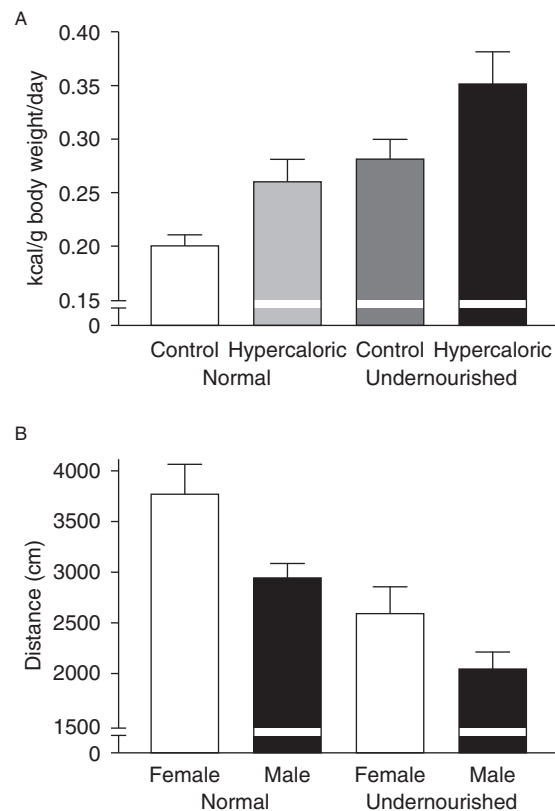

More attention has recently been paid to the effects of rapid childhood growth in height and weight. The observation in much of the fetal programming literature that effects of birth size emerge or are strengthened when current body size (typically represented as BMI) is taken into account suggests an important role for postnatal growth in the origins of adult disease. Individuals who are born small, but who end up relatively large (taller or heavier than their peers) have clearly experienced more rapid growth at some point between birth and when health outcomes and current size are assessed. Whether rapid growth is an independent risk factor or whether it confers increased risk only in individuals with a history of intrauterine growth restriction is a question requiring further research. Moreover, even when strong associations of growth rate and chronic disease risk are found, it is unclear whether the association is causal or whether growth serves as a marker for other underlying causal processes.

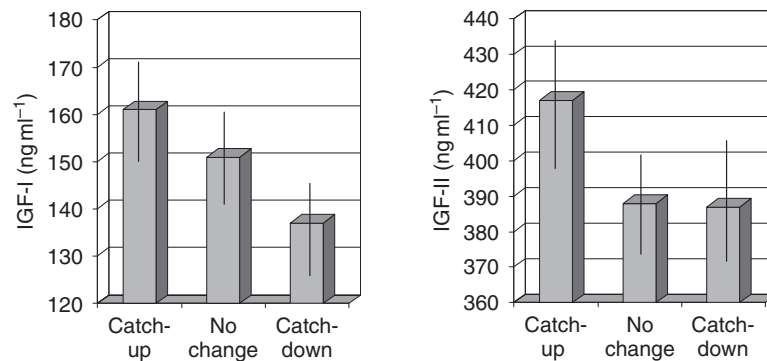

Postnatal growth is clearly related to prenatal growth. Some metabolic changes associated with prenatal nutritional sufficiency may affect postnatal physiology and behavior that, in turn, affect growth. In addition, there is intriguing evidence from animal studies that prenatal nutritional restriction alters appetite and induces hyperphagia, and also reduces physical activity in adult animals (see Fig. 2). If true in humans, this would be an important pathway by which disease risk is affected. Suggestive evidence comes from human infants whose cord blood leptin levels at birth were inversely related to weight gain in the first 4 months of life, independent of birth weight. Leptin may relate to subsequent growth by affecting appetite and energy intake.

Depending on the outcome under study, there are differences in whether linear growth or growth in weight, particularly weight relative to height, matters. Most often, more rapid weight gain is the risk factor, owing to the fact that excess adiposity is an important risk factor for many chronic diseases of adulthood. Another key issue concerns the timing of effects. There is controversy about whether early infancy compensatory growth following intrauterine growth restriction confers risk, or whether it is only later growth that matters. Indeed, one study of children followed from birth through early childhood found that the growth promoting hormones IGF-I and IGF-II were associated with postnatal catch-up growth (Fig. 3). This would suggest that IGF-1 levels in early childhood are positively influenced by rapid post-natal growth.

Where many potential adverse outcomes might be affected by postnatal growth, the following sections focus on adiposity, blood pressure, coronary heart disease, insulin resistance, diabetes, and cancer.

**Fig. 2** Locomotor behavior and food intake in Wistar rats as a consequence of a normal or adverse fetal environment ( $n = 6-8/\text{group}$ ). (A) Food intake (kcal per gram body weight per day over a 5-day period) in females at day 145;  $P < 0.005$  for effect of fetal programming,  $P < 0.05$  for postnatal hypercaloric diet. (B) Locomotor activity at 14 months in males and females;  $P < 0.005$  for effect of fetal programming and gender. Data analyzed by factorial ANOVA, and data are shown as means  $\pm$  SE. Circulating IGF-I levels in childhood are related to both current body composition and early postnatal growth rate. *J. Clin. Endocrinol. Metab.* 87(3), 1041–1044.

### Adiposity and obesity

Early undernutrition followed by later overnutrition as well as early overfeeding independent of prior growth restriction are thought to increase risk of later obesity. Rapid postnatal weight gain occurs in a significant proportion of infants who are born small for gestational age. Prospective studies from a number of cohorts from around the world show that rapid growth in early infancy increases later risk of overweight (Baird et al., 2005; Cameron et al., 2003; Monteiro and Victora, 2005; Okihito et al., 2012). Longitudinal data from the US National Perinatal Collaborative study show that, independent of birth weight, one-third of obesity at age 20 is attributable to rapid weight gain in the first 4 months of life. In a Bristol, UK cohort, nearly one-third of children had an increased weight standard deviation (SD) score of more than 0.67 units from birth to age 2 years, and these children remained fatter, having more central fat distribution at age 5 years compared to children with lower early growth rates. Similarly, data from the South Africa Birth to Ten cohort showed that children with rapid weight gain in infancy were significantly lighter at birth and significantly taller, heavier, and fatter throughout childhood. Finally, a study of growth from birth to age 8 found that children who grew more rapidly than others were more likely to be taller and leaner, independent of current BMI and birth weight.

### Body composition and metabolism

Clinical studies of children who experience growth deficits have revealed much information on the long-term consequences of poor growth. Briefly, it has been found that children born small are more likely to be obese compared to those born with average birth weight. However, most of these studies used BMI or BMI Z-score to assess obesity and did not specifically measure adiposity. In studies that used measures of body composition, children who were growth restricted had more truncal fat mass and more total body fat mass, independent of attained body size. While these differences between studies exist, it is important to recognize that comparing studies that used varying sample sizes and outcomes (body composition versus BMI), the more explicit studies support the conclusion that poor growth early in life is a risk factor for excess adiposity later in life. Several studies have explored the metabolic implications of poor growth. One set of studies from Guatemala and Brazil found no difference in resting metabolic rate (RMR), between growth restricted and normal height children, even after controlling for lean body mass (LBM). On the other hand, some studies have reported that RMR is lower in growth restricted children. Explanations for these apparently divergent results include inconsistent statistical methods as those studies which used RMR per unit body weight, did not properly adjust for body weight or LBM, the most important predictors of RMR.

In terms of specific aspects of energy expenditure, several studies have found that growth restriction is associated with metabolic adaptations that may protect a child during periods of food insecurity or illness but may predispose them to obesity under favorable environmental conditions. As presented in Fig. 4, studies conducted in different cohorts in Brazil, Russia, and South Korea consistently found that children and adults who experienced linear growth restriction had lower rates of fat oxidation compared to peers who had not suffered growth deficits (Hoffman, 2000; Lee et al., 2015; Leonard, 2009.) These studies support the general hypothesis that poor growth early in life is a risk factor for nutrition-related chronic diseases. While specific physiological mechanisms to explain these apparent metabolic differences following episodes of growth restriction, it is most reasonable to assume that a dysregulation of normal metabolism occurs that remains following recovery, perhaps due to poor lean tissue development or biochemical modifications that favor fat storage during periods of nutritional insults.

### Cancer

A large body of literature relates adult height to cancer risk, with the largest volume of evidence on breast, prostate, and colorectal cancers. In each case, risk of disease is increased with taller stature. A role for accelerated childhood growth is inferred as taller

**Fig. 4** Differences in respiratory quotient assessed by indirect calorimetry in growth restricted children compared to normal height peers in three cohorts. Growth Restricted ■ Control □. Data drawn from Hoffman, D.J., Sawaya, A.L., Verreschi, I., Tucker, K.L., Roberts, S.B., 2000. Why are nutritionally stunted children at increased risk of obesity? Studies of metabolic rate and fat oxidation in shantytown children from São Paulo, Brazil. *Am. J. Clin. Nutr.* 72(3), 702–707; Lee, S.K., Nam, S.Y., Hoffman, D.J., 2015. Growth retardation at early life and metabolic adaptation among North Korean children. *J. Dev. Orig. Health Dis.* 6(4), 291–298; Leonard, W.R., Sorensen, M.V., Mosher, M.J., Spitsyn, V., Comuzzie, A.G., 2009. Reduced fat oxidation and obesity risks among the Buryat of Southern Siberia. *Am. J. Hum. Biol.* 21(5), 664–670.

individuals have experienced more linear growth. Possible mechanisms fall into two categories: childhood growth as a marker for other exposures that influence risk (fetal exposures, infections, timing of puberty, and energy intake) or growth as a mediator of risk (effects of growth promoting hormones such as IGF-I and IGF-II).

Few studies have directly addressed the effects of childhood growth, owing to lack of longitudinal data. Based on data from the UK Boyd Orr cohort, a one SD difference in height was associated with a 42% higher risk of overall cancer mortality in later life among males, but no effects were found in females. In another UK birth cohort, risk for breast cancer was elevated among women who were large at birth and tall at age 7 years (Whitley et al., 2009). Based on data from the US Nurse's Health Study, rapid adolescent growth was associated with an increased risk of both pre- and postmenopausal breast cancer.

### Blood pressure and coronary heart disease

Blood pressure is a well-studied outcome in the context of DOHaD, with consistent findings of a modest inverse relationship of birth weight to adult systolic blood pressure. Substantial evidence demonstrates a synergistic relationship of fetal growth restriction with rapid postnatal growth. **Fig. 5** presents the classic picture for systolic blood pressure: the highest pressure is found among adolescent males who were relatively thin at birth, but relatively heavy as adolescents. Current BMI is typically the strongest anthropometric predictor of blood pressure, but at the same BMI, those with a history of fetal growth restriction have higher mean systolic blood pressure and increased risk of having high blood pressure. Using longitudinal growth data in Scandinavia, child growth trajectories can be traced for individuals with and without hypertension or other adverse outcomes such as coronary heart disease. As shown in **Fig. 6**, though initially smaller, adults with hypertension diverged in their BMI trajectory and were relatively heavier after age 7 compared to those without hypertension.

There remains controversy about the age at which faster growth rates pose risk of later disease. Some studies show elevated blood pressure in association with rapid weight gain in infancy, whereas other studies show no effect, or a protective effect (infants with larger weight increments have lower blood pressure as adults). The degree to which rapid infant growth represents risk may depend on whether it occurs in the context of recovery from fetal growth restriction and results in normalization of body weight versus

**Fig. 5** Synergistic effect of BMI at birth and age 16 on systolic blood pressure of Cebu (Philippines) boys: ■ high; ▒ middle; □ low BMI. Data from the Cebu Longitudinal Health and Nutrition Survey.

**Fig. 6** Z-scores for height, weight, and BMI from 7 to 15 years in 975 boys and 983 girls who later developed hypertension. Mean values for all 7086 subjects in cohort are zero. Reproduced from Eriksson, J., Forsen, T., Tuomilehto, J., Osmond, C., Barker, D., 2000. Fetal and childhood growth and hypertension in adult life. *Hypertension* 36(5), 790–794, with permission from LWW.

excess growth leading to infant obesity. In a Philippine cohort, larger weight increments from age 8–15 years increased risk of high blood pressure in boys who were relatively thin at birth (Adair and Cole, 2003). However, higher childhood weight gain in the absence of fetal growth restriction was not a risk factor in this population.

The physiological changes associated with a higher risk of hypertension following fetal undernutrition may include a reduced number of nephrons. Such deficits may not increase disease risk in individuals who remain small, but excess growth may challenge the ability of the kidneys to effectively regulate blood pressure. Catch-up linear growth has not been consistently implicated as a risk factor for later elevated blood pressure. In fact, continued poor linear growth, particularly in association with more rapid weight gain, increases risk of later elevated blood pressure. Thus, it is important to consider both size at birth as well as post-natal growth patterns as possible mediating factors between poor growth and disease development.

### Insulin resistance and diabetes

The relationship between poor growth and T2D suggest that both continued growth faltering in infancy and rapid growth rates are associated with an increased risk of insulin resistance and T2D. As well, postnatal faltering in length is also associated with impaired insulin metabolism. The highest risk of T2D is found when for persons with a small size at birth and rapid postnatal growth gain. In a well-studied cohort in Finland, men and women who developed T2D had lower birth weight, length, and ponderal index, and accelerated growth in weight and height from age 7–15 years. In terms of precursors of T2D, a follow-up study of British children who were born preterm, fasting split proinsulin and glucose concentration 30 min after a glucose load were highest in children with the greatest increase in weight centile between birth and time of measurement, regardless of early size. Thus, it is important to understand how the risk for T2D may vary between those exposed to nutritional insults in utero compared to post-natal periods.

To further illustrate this issue, several studies of the early origins of T2D have been conducted in India where the prevalence of T2D has increased dramatically in the past 20 years. Indian babies who are small at birth have a deficit in skeletal muscle, but not body fat compared to normal size infants. These infants tend to grow into adults that retain a lower skeletal muscle mass but have increased abdominal obesity, a key risk factor for T2D. Prospective studies of Indian children show an interaction between birth weight and subsequent growth. For example, children who were born small but were relatively large at age 4 had higher plasma glucose and insulin concentrations 30 min after an oral glucose load, and greater insulin resistance at age 8.

Higher growth rates in previously growth-restricted individuals may pose excessive demands on systems initially adapted to function in the face of limited resources, leading to increased risk of diseases, particularly those associated with the metabolic syndrome. Rapid growth in weight during infancy and childhood, and in particular, rapid growth following prenatal growth restriction, increases risk of developing obesity, especially abdominal obesity. Factors that contribute to early onset of obesity are therefore important to control, because obesity tracks from early life to adulthood, and is a well-recognized risk factor for diseases such as type 2 diabetes, hypertension, and coronary heart disease.

### Summary

To summarize, the continued vulnerability and responsivity of the developing infant and child suggest the importance of a life course perspective on the development of diseases that are typically thought of as “adult onset.” Based on the review of studies for this article, future research needs to focus on understanding the mechanisms of how infant feeding practices and growth in early childhood may predispose some children to develop chronic diseases later in life compared to those who were fed differently, were born normal size, or grew without delays.

## Key points

- The most rapid rate of growth and development in an organism's life occurs during the embryonic and fetal period of gestation.
- Measurements of fetal growth are difficult to make in utero; they are generally estimated from cross sectional anthropometric measurements of body weight, length, circumferences (head, chest, abdomen), and composition (e.g., fat mass and lean mass) of "normal" infants at birth at different gestational ages, complemented by fetal ultrasound estimates of length and circumferences.
- Fetal growth is regulated by placental size and the rate of placental transfer of oxygen and nutrients (amino acids for protein synthesis, glucose for energy production) to the fetus.
- Insulin and insulin-like growth factors contribute to fetal growth by promoting cell replication earlier in gestation and hypertrophy later in gestation.
- Principal disorders of fetal growth and development include intrauterine growth restriction (IUGR, slower than normal rate of fetal growth) and macrosomia (larger than normal body size, generally due to excess fat).
- Fetal IUGR and macrosomia may predispose the fetus to later life obesity, insulin resistance, and type 2 diabetes.

## Glossary

GUR glucose utilization rate

GSIS glucose stimulated insulin secretion

**IUGR** intrauterine growth restriction (slower than normal rate of fetal growth)  
**AGA** appropriate for gestational age  
**SGA** small for gestational age  
**LGA** large for gestational age  
**IGF** insulin-like growth factor  
**Macrosomia** larger than normal body size due to excess fat  
**Ponderal Index** weight (grams)/[length (cm)]<sup>3</sup>  
**Autocrine** acting at the site of production, such as an autocrine growth factor  
**Paracrine** acting adjacent to the site of production, such as a paracrine growth factor  
**Programming** an insult or stimulus, when applied at a critical or sensitive stage in development, of sufficient magnitude and duration, that produces lasting, even lifelong, effects on the structure or function or both of the organism  
**Monotocous** singleton fetus within the same uterus (e.g., in most human pregnancies)  
**Polytocous** multiple fetuses within the same uterus (e.g., in rats, with 8–10 pups/litter)
