For years, it has been assumed that sodium intake has to equal sodium excretion in order to maintain sodium balance. Consequently, a 24h urine sample would reflect sodium intake. This is only partially true. Of course, in order to maintain sodium-balance the  $\text{Na}^+$  intake has to be equal to the amount of  $\text{Na}^+$  excreted, but Titze et al. (2016) demonstrated that this balance is not reached within 24 h. They investigated how urine sodium correlated with sodium intake in a very controlled environment: in astronauts, who were simulating a mission to mars and were receiving a determined amount of NaCl with their diet: either 3, 6 or 9g/day. Surprisingly, the 24h urine collection could not discriminate between the three groups, but the probability of discriminating increased to 92% if urine was collected for 7 days (Lerchl et al., 2015). They hypothesized that  $\text{Na}^+$  has to be stored in the body and that its excretion is not only dependent on intake, but also on a weekly (circaseptan) pattern. Through  $\text{Na}^+$  magnetic resonance they could demonstrate that  $\text{Na}^+$  gets stored in the skin and that the stores are larger in men, in older and in hypertensive people (Kopp et al., 2013). It has been observed that  $\text{Na}^+$  binds to negatively charged glycosaminoglycan (Titze et al., 2004) and accumulates even more at the site of bacterial infection (Jantsch et al., 2015) and it has been hypothesized that this (antibacterial effect) is probably one of the teleological reasons of why  $\text{Na}^+$  is stored in the skin.

### Osmolarity

The plasma osmolarity expresses the number of osmoles (particles that are osmotically active) in 1 L of plasma. In humans plasma osmolarity in physiologic conditions is 275–299 mmol/L. Sodium accounts for 88% of extracellular fluid *osmolality* (osmoles of solute per kg of solvent). Considering that cell membranes are freely permeable to water, plasma and intracellular osmolarity are the same. It is essential that osmolarity remains in the above-mentioned range because otherwise the shift of water could lead to shrinkage or swelling of the cells compromising their function and eventually leading to cell death. Plasma osmolarity is regulated by the amount of water in the body. Slight increases in osmolarity elicit thirst and lead to the release of the antidiuretic hormone (ADH), which by increasing the expression of aquaporins on the luminal side of the kidney collecting duct epithelial cells increases the renal reabsorption of free water. Regulation of sodium reabsorption or excretion does not have an effect on plasma osmolarity, but rather on body fluid volume.  $\text{Na}^+$  is the main extracellular active osmol and knowing the formula of calculated blood osmolarity makes us understand what an important role  $\text{Na}^+$  has in determining it:  $\text{Posm} = 2 [\text{Na}^+] + \text{glucose (mmol/L)} + \text{urea (mmol/L)}$ .

### ECV

Being the main osmotic cation  $\text{Na}^+$  is also responsible for maintaining the extracellular volume. In virtue of its osmotic activity, water always moves along with sodium. The regulation of  $\text{Na}^+$  and ECV is essential to allow life and is tightly regulated through afferent and efferent inputs that, in physiological state, allow the maintenance of ECV in a quite narrow range.

The afferent inputs give information about volume status, which then activate effector mechanisms, that are responsible to increase or decrease ECV, mainly by regulating  $\text{Na}^+$  excretion via the kidneys.

In order to facilitate the readers' comprehension,  $\text{Na}^+$ -excretion in the kidneys will be discussed first and regulatory mechanisms described subsequently.

### Sodium excretion via the kidney

It has been known since decades, that the kidney has an essential role in the excretion of sodium and in its regulation. Sodium, being a small cation, is freely filtered in the glomerulum. Every day about 1.7 kg of NaCl, which corresponds to about 30 mol of  $\text{Na}^+$ , is filtered, but only 0.1–2% of it is actually excreted in the urine. The renal tubules are responsible for the reabsorption of  $\text{Na}^+$ . The main energetic drive for this process in all tubular segments is the  $\text{Na}^+/\text{K}^+$ -ATPase in the basolateral membrane. The different segments of the tubule contribute to varying degrees and through different transport-mechanisms to this process. A schematic view of sodium reabsorption is presented in Fig. 2.

**Fig. 2** Sodium reabsorption along the nephron. The percentage of sodium remaining in the ultrafiltrate is displayed along the nephron under circumstances of normal sodium intake. Bulk reabsorption takes place in the proximal tubule and TAL, whereas sodium excretion is regulated in the distal nephron. Symbols below show key  $\text{Na}^+$  transporters and channels of each tubular segment. NHE, sodium-hydrogen antiporter; NKCC2,  $\text{Na}^+ \text{K}^+ 2\text{Cl}^-$  cotransporter; NCC,  $\text{Na}^+ \text{Cl}^-$  cotransporter; TAL, thick ascending limb of the loop of Henle; ENaC, epithelial sodium channel; ROMK, renal outer medullary potassium channel. Modified from Palmer and Schnermann (2015).

### Proximal tubule

60–70% of the filtered sodium is reabsorbed in the proximal tubule. The whole process is possible largely due to the  $\text{Na}^+/\text{K}^+$ -ATPase. The main transporter through which  $\text{Na}^+$  is reabsorbed from the luminal side is the  $\text{Na}^+/\text{H}^+$  exchanger (NHE) (Alpern, 1985) in the proximal convoluted tubule (PCT). In addition, the negatively charged interstitium serves as a driving force for the paracellular reabsorption of  $\text{Na}^+$ , which is facilitated by rather leaky tight junctions of the proximal tubule. As matter of fact, the passive reabsorption of  $\text{Na}^+$  in the proximal tubule can even exceed the active one, accounting for up to 2/3 of the total (Alpern et al., 1985; Seldin et al., 1991). Other mechanisms that contribute to  $\text{Na}^+$ -reabsorption in the proximal tubule are cotransporters of  $\text{Na}^+$  and other molecules like glucose (mainly through the SGLT2) amino acids, phosphate, lactate and sulfate (Petrovic et al., 2004) (Fig. 2).

Factors that upregulate  $\text{Na}^+$  reabsorption are cytosolic acidosis, Angiotensin II and sympathetic innervation. Factors that down-regulate it are cytosolic alkalosis, dopamine and PTH (parathyroid hormone). Water moves along with sodium, so that in the permeable proximal tubule,  $\text{H}_2\text{O}$  gets proportionally reabsorbed and the osmolality at the end of the proximal tubule remains isotonic.

### Loop of Henle

The loop of Henle contributes 20–30% of sodium reabsorption. The thin descending limb is water permeable due to the presence of aquaporin-1, but impermeable to solutes. The ascending limb on the contrary is impermeable to water and the main site of  $\text{Na}^+$  reabsorption, especially in the thick ascending limb (TAL). In this segment, sodium reabsorption is driven again by the  $\text{Na}^+/\text{K}^+$ -ATPase. On the luminal membrane,  $\text{Na}^+$  absorption occurs via the  $\text{Na}^+/\text{K}^+/2\text{Cl}^-$  Co-Transporter (NKCC), which is also the target of loop diuretics. The negatively charged interstitium attracts positive cations like  $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$  and  $\text{Na}^+$ , which are also reabsorbed via a paracellular way. Also in the loop of Henle, the paracellular pathway is responsible for a relevant proportion (50%) of the  $\text{Na}^+$  reabsorption. ADH, PTH, calcitonin, glucagon and adrenaline increase the  $\text{Na}^+$  and  $\text{Cl}^-$  reabsorption in the TAL. On the contrary, prostaglandin E2 inhibits this process (Higashihara et al., 1979). Moreover, the amount of reabsorbed sodium and chloride is also dependent on the delivered load: the more delivered, the more reabsorbed.

### Distal tubule

The distal tubule, like the TAL of the loop of Henle is not permeable to water, but mainly a site of ion reabsorption. Also here the major driving force for sodium reabsorption is the  $\text{Na}^+/\text{K}^+$ -ATPase on the basolateral membrane. By extruding sodium from the cell into the interstitium it creates the gradient that leads to  $\text{Na}^+$  absorption from the luminal side. This process happens through the  $\text{NaCl}$  cotransporter (NCC), which is sensitive to thiazide diuretics.

A very important regulatory mechanism that is elicited by the  $\text{NaCl}$  concentration in the distal tubule is called tubuloglomerular feedback (TGF). Specific cells of the distal convoluted tubule (macula densa cells), that are in proximity of the glomerulus, belong to

the so-called juxtaglomerular apparatus. These cells by sensing a higher NaCl load can activate a cascade, which leads to the contraction of the afferent arteriole and by doing so to a reduction of the single nephron GFR leading to a decrease in the amount of filtered sodium. In this way, the nephron is protected from an excessive loss of NaCl.

### Collecting duct

The collecting duct (CD) has the role of fine-tuning the reabsorption of  $\text{Na}^+$  and water. It has three types of cells: principal cells are mainly responsible for water and sodium reabsorption whereas the A and B intercalated cells are involved in acid/base regulation. As described above, water reabsorption is regulated by ADH. The atrial natriuretic peptides (ANP) have the opposite effect, i.e. increase of sodium excretion and diuresis.  $\text{Na}^+$  absorption is once again driven by the  $\text{Na}^+/\text{K}^+$ -ATPase. Reduced intracellular  $\text{Na}^+$ -concentration leads to an increased absorption from the luminal side through the epithelial sodium channel (ENaC), which is the target of the drug amiloride. The mineralocorticoid aldosterone increases the number and activity of ENaC leading to an increase in  $\text{Na}^+$  absorption, expansion of ECV, hypertension, hypokalaemia and metabolic alkalosis.

The mechanisms of sodium retention are impressive in their efficiency. Under salt restriction or loss, urine may become practically sodium-free. Urinary sodium levels may fall well beneath 0.5 mmol/L, which is equivalent to a NaCl concentration of 10 mg/L (less than the mean sodium content of tap water). This means that sodium deficiency does not occur with normal renal function as long as food and water supply is adequate. Therefore, sodium deficiency is a consequence of an acquired or hereditary disease (e.g. chronic diarrhea, renal tubulopathy such as Gitelman syndrome) or an adverse effect of a medical treatment (excessive therapy with diuretics).

## Systemic regulation of ECV and total body sodium

### Afferent inputs

#### Intravascular baroreceptors

There are many afferent signals providing information about volume status both from the venous and arterial side and from the heart itself. Low-pressure baroreceptors are located in capacitance vessels in the thorax and in the atria. In the case of volume expansion these receptors transmit through the vagus nerve to the medulla oblongata, which decreases the sympathetic tone (Oren et al., 1993). The stretching of the atria causes a decrease in antidiuretic hormone (ADH) and renin secretion, as well as the secretion of ANP and brain natriuretic peptide (BNP), which increase the natriuretic response (Jensen et al., 1998).

On the arterial side, baroreceptors are present in the aorta and carotid arteries. High blood pressure stimulates these baroreceptors, which through the glossopharyngeal and vagus nerve stimulate centers in the medulla, which in turn decrease sympathetic tone and by doing so increase natriuresis (Ludbrook and Ventura, 1996; Potts et al., 1996).

#### Intrarenal mechanisms

Another important way to regulate  $\text{Na}^+$  excretion and the ECV, is to maintain intraglomerular pressure and glomerular filtration rate (GFR) constant. Two important intrarenal feedback mechanisms achieve this aim ("renal autoregulation"). One is the myogenic reflex, which consists of the ability of the afferent arteriole of the glomerulus to dilate or constrict in response to systemic pressure changes. The second one is TGF. Also here, the afferent arteriole regulates glomerular filtration pressure, depending on the amount of delivered NaCl to the macula densa: it will dilate if the delivered NaCl is low thereby increasing filtration and constrict if it is high and by this decrease filtration. This kind of feedback allows to maintain the single nephron GFR in a quite narrow range. A more sustained reduction in NaCl delivery to the macula densa will also cause the secretion of renin by the juxtaglomerular cells, which in turn increases the systemic and renal perfusion pressure.

### Hepatic and intestinal regulation

Within the hepatic circulation there are osmoreceptors and NaCl sensitive receptors, which sense the quantity of sodium absorbed by the intestine (Kostreva et al., 1980). In the case of increased stimulation, the release of ADH is increased and sympathetic activity decreases resulting in a natriuric effect. There is also a hepatointestinal reflex by which increased stimulation of these receptors decreases  $\text{Na}^+$  uptake from the intestine (Morita et al., 1997).

### Cerebral sensing mechanisms

In the central nervous system, there are osmoreceptors, which allow modulating the secretion of ADH and by doing so, to maintain plasma osmolarity in a very narrow range.

## Antinatriuretic effector mechanisms

### Sympathetic nervous system

As mentioned above, an increase in sympathetic activity is the typical response to a decreased circulating volume. Postganglionic axons originate in the celiac and paravertebral ganglia and innervate the kidneys. The main sympathetic effector mechanisms which lead to sodium retention are:

- Sympathetic nervous system (SNS) activation increases the systemic blood pressure and by doing so also the renal perfusion pressure and the GFR
- SNS stimulation leads to contraction of the efferent arteriole > contraction of the afferent arteriole, leading to an increased intraglomerular pressure and in this way to an increased GFR. The increased intraglomerular hydrostatic pressure leads to a reduced hydrostatic pressure in the peritubular capillaries, increasing the paracellular reabsorption of  $\text{Na}^+$  in the proximal tubule
- The SNS increases the renin release by juxtaglomerular cells and has a direct effect on the different segments of the tubule leading to an increased  $\text{Na}^+$  reabsorption

### **Renin angiotensin aldosterone system (RAAS)**

The RAAS is the major effector mechanism for ECV maintenance causing  $\text{Na}^+$  retention. Renin release is stimulated by hypovolemia or low perfusion pressure, SNS activity and reduced delivery of  $\text{NaCl}$  to the distal tubule. Renin converts angiotensinogen, a peptide produced by the liver, into angiotensin I, which is then cleaved to angiotensin II. Angiotensin II has direct and indirect antinatriuretic effects. It stimulates the production of the mineralocorticoid aldosterone by the adrenal cortex. Aldosterone increases ENaC expression in the luminal membrane of collecting duct cells thereby leading to  $\text{Na}^+$  reabsorption.

### **Antidiuretic hormone (ADH) or vasopressin (AVP)**

In the case of decreased effective circulating volume, venous and arterial baroreceptors stimulate the release of ADH by the hypothalamus. The main effect of ADH is to increase the expression of aquaporin-2 in the collecting duct increasing the reabsorption of free water. It has also an antinatriuretic effect by increasing  $\text{Na}^+$  reabsorption in the loop of Henle and in the collecting duct.

### **Natriuretic effector mechanisms**

#### **Prostaglandins**

Prostaglandins (PG) derive from the metabolism of arachidonic acid.  $\text{PGI}_2$  is produced by endothelial cells in the renal cortex and its production is stimulated by renin.  $\text{PGE}_2$  in the kidney is produced by interstitial and collecting duct cells and its release is stimulated by angiotensin II. Even if their production is triggered by the RAAS they have an antagonistic role i.e. they have a natriuretic function and lead to local vasodilation. Their role is to oppose the effects of RAAS in order to prevent an excess in vasoconstriction, which eventually could lead to ischemia for example in the medulla. PGs exert their functions through the following mechanisms (Higashihara et al., 1979):

- increase of renal blood flow and increased  $\text{Na}^+$  delivery to the nephron
- vasodilatation of the efferent arteriole, which reduces the intraglomerular hydrostatic pressure and increases it in the peritubular capillaries reducing the paracellular reabsorption of  $\text{Na}^+$  in the proximal tubule
- PGs increase blood flow to the medulla and by doing so, diminish the interstitial solute concentration in the medulla, leaving more water in the loop of Henle and by that reducing the luminal  $\text{Na}^+$  concentration at this level thereby decreasing its paracellular reabsorption
- They reduce directly the  $\text{Na}$  reabsorption, probably by diminishing the activity of the  $\text{Na}^+/\text{K}^+$ -ATPase

### **Kallikrein-kinin system**

Renal kallikrein is a protease which produces two kinins that have vasodilatory effects, which leads to a washout of the medullary interstitium and a decreased  $\text{Na}^+$  reabsorption.

### **Nitric oxide**

Nitric oxide seems support volume induced natriuresis, which is mediated by its vasodilatory properties.

### **Atrial natriuretic peptides**

Increased stretching of the atria leads to production of the atrial natriuretic peptides: ANP and BNP. Their natriuretic effector mechanisms are:

- decrease in renin, angiotensin II and aldosterone production
- increase in medullary blood flow and thereby washout of the medulla (Davis and Briggs, 1987)
- reduction of  $\text{Na}^+$  reabsorption in the medullary collecting duct (Sonnenberg et al., 1986)

### **Conclusions**

The  $\text{Na}^+$  content of the body is responsible for maintaining extracellular volume and its homeostasis has to be tightly regulated. The main regulator of body sodium undoubtedly is the kidney. In recent years however, the skin has gained attention as another important regulator via its ability to store sodium in an osmotically inactive form.

$\text{Na}^+$  has an essential role in life. Evolution in non-marine species thus has prioritized mutations that favored  $\text{Na}^+$ -intake and retention. However, in today's Western societies, humans are exposed to an oversupply of sodium. We are therefore biologically and socially prone to exceed physiologic  $\text{Na}^+$ -intake. A greater  $\text{Na}^+$ -intake can lead to an increase in blood pressure and might also intensify the risk for adverse cardiovascular outcomes even though conclusive interventional data is missing. In addition,  $\text{Na}^+$  has been implicated as an aggravator of autoimmune inflammatory disorders. Thus, strategies ought to be developed to moderate intake in individuals with high sodium consumption.

## Key points

- There is no storage of thiamin in vivo and turnover is rapid, hence a regular dietary supply of thiamin is needed.
- Refined foods e.g., polished rice or white wheat flour are poor sources of thiamin and should either be fortified with thiamin or the diet enriched by eating with other foods.
- Epidemiologically, beriberi can occur where food eaten is poor, dietary diversity is restricted, physical activity is high, food intake has a high calorie to thiamin ratio, there is fever and infection and occurs more often in men than women.
- Experimental thiamin deficiency is followed after 2–3 weeks by progressively worsening signs and symptoms of disease.
- Acute deficiency of thiamin more often affects the younger and stronger members of a community and symptoms are predominantly cardiac; the “wet” form of beriberi. Usually responds rapidly to thiamin treatment.
- The “dry” form of beriberi affects mainly older people. It predominantly causes neurological impairment and ophthalmoplegia. It may be slow to respond to thiamin treatment and may represent a long-term chronic deprivation of thiamin.
- Ethyl alcohol inhibits thiamin absorption hence alcohol abuse can cause acute beriberi which can further deteriorate to Wernicke’s Encephalopathy characterized by cardiac symptoms, peripheral neurological impairment and ophthalmoplegia.
- Severe dietary restriction in the absence of thiamin supplements, e.g., following bariatric surgery, can increase the risk of thiamin deficiency and Wernicke’s encephalopathy
- Infantile beriberi characteristically occurs in infants 2–5 months fed solely on breast milk from mothers at risk of thiamin deficiency due to poverty and/or a thiamin-deficient diet.
- The fundamental importance of thiamin as a source of energy can mean that anorexia and illness can implicate thiamin deficiency in a wide variety of Thiamin Deficient Disorders.

## Glossary

**Ataxic Gait** Inability to coordinate leg muscles

**Confabulation** Description of events that have not happened

**Dysesthesia** Sensation typically described as painful, itchy, burning or restrictive. It results from nerve damage

**Dyspnoea** Labored or difficult breathing in sleep (paroxysmal nocturnal dyspnea is a respiratory distress that awakens patients from sleep)

**Meteorismus** Swelling of the abdominal cavity with gas usually in the large intestine or stomach

**Nystagmus** Involuntary eye movements

**Ophthalmoplegia** A paralysis or weakness of one of the muscles that control eye movement

**Opisthotonus** A type of spasm in which the head and heels arch backward in extreme hyperextension and the body forms a reverse bow

**Paresthesia** A sensation of numbness or tingling on the skin

**Rales** (pronounced Ralz) Wet, crackly lung noises heard on inspiration which indicate fluid in the air sacs of the lungs

**Wernicke Encephalopathy** A syndrome characterized by ataxia, ophthalmoplegia, confusion and impairment of short-term memory

## Introduction

Beriberi is caused by a deficiency of thiamin (also called thiamine, aneurin(e), and vitamin B<sub>1</sub>). Classic overt thiamin deficiency causes a wide range of Thiamin Deficiency Disorders (TDD) including cardiovascular, cerebral, and peripheral neurological impairment, metabolic, respiratory, musculoskeletal and gastrointestinal systems. The rarity of thiamin deficiency and concurrent symptoms and overlapping signs with other disorders can obscure diagnosis and TDD are frequently misdiagnosed with potentially fatal consequences (McConachie and Haskew, 1988; Smith et al., 2021). The disease emerged in epidemic proportions at the end of the 19th century in Asian and Southeast Asian countries. Its appearance coincided with the introduction of the roller mills that enabled white rice to be produced at a price that poor people could afford. Unfortunately, milled rice is particularly poor in thiamin; thus, for people living in Low and Middle-Income Countries (LMIC) for whom food was almost entirely rice, there was a high risk of deficiency and mortality from beriberi (Platt, 1958; Burgess, 1958). Outbreaks of acute cardiac beriberi still occur, but usually among people who live under restricted conditions due either to poverty or imprisonment when freedom of food choice is limited. The major concern today is subclinical deficiencies in patients with trauma or among the elderly. There is also a particular form of clinical beriberi that occurs in patients who abuse alcohol, known as the Wernicke–Korsakoff syndrome (Victor et al., 1971). Subclinical deficiency may be revealed by reduced blood and urinary thiamin levels, elevated blood pyruvate/lactate concentrations and  $\alpha$ -ketoglutarate activity, and decreased erythrocyte transketolase (ETKL) activity. Currently, the *in vitro* stimulation of ETKL activity by thiamin diphosphate (TDP) is the most useful functional test of thiamin status where an acute deficiency state may have occurred and the technology has now been transferred to 96 well plates improving the convenience of the assay (Jones et al., 2020). The stimulation is measured as the TDP effect. Most TDP is in the red cell. Liquid chromatography of thiamin metabolites in plasma extracts will provide an indication of dietary thiamin intakes.

## Epidemiology

Beriberi presents in several different clinical forms (Table 1). Beriberi became endemic following the introduction of steam-powered rice mills, which enabled milled rice to be produced cheap enough so that almost everybody could afford it and consume it. It was particularly serious at the end of 19th and the beginning of the 20th centuries when seasonal epidemics of wet beriberi occurred with many deaths (Burgess, 1958; Platt, 1958). The disease affected mainly the Chinese and Japanese populations, although outbreaks were reported in India and among settlers in the New World during the long cold winters, and the disease

**Table 1** Forms of beriberi in man.

Subclinical beriberi	Identified by transketolase activity or other biochemical tests of thiamin status. May be associated with early subjective symptoms such as anorexia, weakness, dysesthesia, and depression. Responds rapidly to treatment with thiamin.
Wet beriberi	Subacute or cardiac beriberi frequently having muscular pains, edema of feet and legs, enlarged heart, and tachycardia. Responds rapidly to treatment with thiamin. Major form and was typically seasonal in endemic areas. Acute fulminant type of beriberi in which the main feature is dominated by insufficiency of the heart and blood vessels. Responds rapidly to treatment with thiamin.
Dry beriberi	Chronic, atrophic type of polyneuropathy in which the main features are of a weak wasted person, with painful musculature making walking difficult, impaired sensory nerves and tendon reflexes, and flaccid paralysis of the motor nerves. Poor or no response to treatment with thiamin.
Infantile beriberi	Usually acute wet beriberi. Responds rapidly to treatment with thiamin.
Wernicke–Korsakoff syndrome	Predominantly neurological, affecting walking and vision in most and memory and cardiac function in over 50% of patients. Wernicke or ocular component responds rapidly to treatment but the Korsakoff psychosis responds slowly or not at all.

Modified from Thurnham (1978).

was not necessarily confined to rice-eating populations. Where acute cardiac beriberi occurred, dry beriberi was also present but usually in the older members of the community.

Milled rice has a thiamin concentration that is particularly poor (80 µg/100 g), but social conditions at the time of the large epidemics contributed to the problems. Bonded labor was common, with workers living on the work premises most of the time and paid mainly in the form of rice. In addition, reports at the time suggest that the rice was of uncertain freshness and quality, and that it could be so moldy, matted, and lumpy that it had to be remilled and washed, with a further loss of thiamin. The social conditions prevented natural eating practices because workers had little money to purchase additional food and they were dependent on what they were given. Likewise, badly stored cereals can lose up to 90% of the thiamin content, and toxins associated with mold growth have been implicated in causing sickness that may well precipitate clinical beriberi.

Reports suggest that the acuteness of the outbreak of beriberi and the interrelationship of thiamin deficiency with deficiencies of other nutrients probably had a major role in determining the nature of the pathological changes and lesions produced. For example, it is reported that protein energy malnutrition almost always accompanied subacute beriberi, reflecting the link between impoverishment and the disease. In contrast, it is also suggested that severe beriberi more often affected the more active, stronger, or supposedly better nourished members of the community. The younger, stronger rickshaw puller was most likely to suffer severe beriberi. This enigma may be due to thiamin intakes from a diet containing a high proportion of rice being insufficient to meet the thiamin requirement posed by the higher calorie intakes of the more active community members.

In older literature infantile beriberi appeared to affect the male infant who “tended to be overfed” (Fehily, 1940). Human milk is barely adequate in thiamine (0.23 mg/4.2 MJ) and this may be reduced still further in marginally deficient mothers and thiamine status was further compromised if given supplements of thiamin-poor rice. It is a common habit even today for rural mothers in LMICs to give very young infants, even beginning at 1 week of age, a bolus of masticated rice to supplement the milk intake. In 2009, a study in Vientiane reported that 27% of infants were given water or formula milk before receiving breast milk and pre-masticated glutinous rice was the first food supplement in 20–48% of infants in the first week of life. In the same study mothers underwent variable periods of dietary restriction in the first 3 months postpartum including exposure to hot beds of embers (Soukaloun et al., 2003; Barennes et al., 2009). The effects of these traditional practices is not known but pyrexia is known to increase energy and thiamine requirements. It was widely observed that nonspecific pyrexia was a precipitating factor for beriberi. A 1 °C rise in body temperature is associated with a 10% increase in basal metabolic rate. It has been suggested that more than half the mild cases of beriberi were associated with a nonspecific bout of fever, and such cases responded less readily to treatment with thiamin.

Parboiled rice is partially cooked before milling, and this prevents beriberi because some of the thiamin is dispersed through the grain (190 µg/100 g). The advantages of this were clearly seen in Malaya, where at the end of 19th century there were large-scale immigrations of young, able-bodied Chinese to work in the tin mines and Indians to work on the rubber estates. In both cases, immigrants often lived in remote regions where there was little opportunity to purchase local food and they were dependent on imported rice. It was the Chinese who, because of their dietary preference for milled rice, died in enormous numbers (Burgess, 1958). However, parboiling may not be completely protective and is not universal through India. In northern regions like Kashmir, the diet consists of polished, unfortified rice and cases of infantile beriberi have been reported. Cases all occurred in exclusively breastfed infants and most of the mothers followed customary dietary restriction (Whitfield et al., 2018). Clinical data of thiamin deficiency was also presented at a recent workshop in November 2019, from Assam in India, and Bhutan in pregnant and lactating women (Smith et al., 2021).

Although ways of avoiding the disease were known to the Japanese navy at the end of the 19th century, since the director general of the medical department had demonstrated that the disease was almost eradicated if the traditional rice diet was supplemented with fish, vegetables, meat, and barley, this information was not widely available, and supplementation was not feasible by the vast majority of people (Sinclair, 1982). It was widely believed that the cause of beriberi was an infection or toxin resulting from bad food. In particular, Pasteur's work on the microbiological cause of infections led many to search for an infectious agent, but none could be consistently identified. The scale of the problem for the colonial powers in Southeast Asia in the latter part of the 19th and early 20th centuries should not be underestimated. Labor was cheap but the death toll posed enormous problems. Extracts from reports at the time are illuminating: In 1887, there were 690 deaths out of 1931 native government officers in Sumatra, infant mortality was 445 per 1000 live births in the Philippines in 1910, and one report stated that there were so many deaths that “there was insufficient earth to bury the corpses” (Burgess, 1958).

The Dutch government sought to resolve the situation by appointing a medical bacteriologist, Christiaan Eijkman, to travel to Indonesia to investigate the problem (Luyken, 1990). Working in Java, he showed within 6 years that beriberi was a nutritional problem and that a paralytic condition closely resembling the polyneuritic symptoms of beriberi could be produced in chickens by feeding them both stale and freshly cooked polished rice. However, it was Funk (1911) who first reported the isolation of a “vital amine” from rice polishings that had anti-beriberi properties. Funk was the first person to coin the word “vitamine” as a substance essential for life. The structure and synthesis of thiamin were reported in 1936 (Williams and Cline, 1936).

Currently, clinical beriberi no longer occurs with the devastating effects of former years. Considerable improvements have occurred in nutrition worldwide, the diversity of foods available, the quality of food due to improved storage methods, and social and economic development. However, in many LMIC countries, especially in Southeast Asia and Africa, sporadic outbreaks do occur, which are usually of the acute, fulminating type of beriberi causing many deaths often in young men aged 20–40 years. An outbreak of acute beriberi occurred in a Gambian village in 1988 at the start of the wet season and killed 22 young adults before it was recognized and treated (Tang et al., 1989). In Thailand, infantile beriberi was reported in Karen refugees in 2003 and, in Laos, infantile beriberi is currently recognized as a public health problem (Soukaloun et al., 2003). Usually, a combination of factors is

responsible, but once the cause is identified, treatment is cheap and readily available and, if given rapidly, tragic circumstances can be averted.

Two iatrogenic causes of subclinical beriberi are known, namely that associated with diuretic treatment (Yui et al., 1980) and one resulting from alcohol abuse. Both are of concern because the use of diuretics is introduced to manage cardiovascular disease, a condition that will deteriorate if thiamin status is impaired, and alcohol abuse can lead to Wernicke–Korsakoff syndrome (Victor et al., 1971), which can have many of the features of both wet and dry beriberi.

Severe multisystem trauma, endotoxemia, or situations in which there is a raised metabolic demand for thiamin, such as pregnancy, thyrotoxicosis, and intercurrent illness or impaired absorption (e.g., alcohol abuse or gastrointestinal disease or resection), can produce subclinical evidence of TDD or more severe life-threatening aspects of beriberi, such as renal and/or cardiovascular failure (McConachie and Haskew, 1988; Whitfield et al., 2018). There are warnings in the literature concerning the necessity of vitamin, and particularly thiamin, supplements when energy metabolism may be increased e.g., following a dextrose-containing intravenous fluid. The elderly may be particularly at risk of subclinical thiamin deficiency. One Belgian study on patients with a mean age of 83 years reported that 40% had a raised TDP effect (>15%), in whom there was a high proportion of Alzheimer's disease, depression, cardiac failure, and falls. The diuretic furosemide was also more frequently taken by the thiamin-deficient patients.

## Etiology

The factors associated with the various forms of beriberi are listed in Table 2. Beriberi is caused by a lack of thiamin in the diet, but the onset of the disease and the symptoms associated with the disease are influenced by one or more of the other etiological factors. Wet beriberi (i.e., cardiac beriberi) and Wernicke's encephalopathy are conventionally described as acute manifestations of the disease and respond most rapidly to treatment. In contrast, dry beriberi is described as due to a chronic deficiency of thiamin and does not respond well to treatment (Carpenter, 2002). However, experimental acute deficiency studies, which very rapidly produced subjective feelings of malaise and weakness at the slightest exertion, very rarely produced evidence of edema and peripheral pain. These observations suggest that all forms of beriberi are probably preceded by an indeterminate period of chronic thiamin deficiency during which pathophysiological adaptations to the marginal nutritional state occur. Thus, physiological adaptations to the vascular system may well have occurred particularly in those who did heavy physical work and needed to overcome the weakness and malaise imposed by a low thiamin diet. The factor(s) that precipitated the clinical disease may not be thiamin at all. Platt (1958), in his descriptions of beriberi in China, recounts how humid weather and infections such as malaria increased the number of cases of wet beriberi. The extra energy needed to cool the body in hot conditions or fuel the rise in temperature during infection may have imposed a critical burden on energy production that the system could not meet, and beriberi ensued.

However, the increased number of cases associated with heat, humidity, and malaria may also be due to a seasonal decline in the quality of food. A 6–12-fold decline in thiamin content is reported for millet when stored under traditional thatched storage houses in The Gambia (Thurnham et al., 2011), and reports suggest that much of the rice consumed late in the season was not in the best condition. Some of the products introduced by mold growth may possess anti-thiamin properties that impair thiamin bioavailability. Thus, the ratio of thiamin to calories is likely to fall during the agricultural year and to be at its worst when calorie

**Table 2** Etiological factors contributing to thiamin deficiency.

Dietary thiamin deficiency	Commonly milled rice
High dietary carbohydrate to fat ratio	Metabolism of carbohydrate requires thiamin, whereas metabolism of fat spares thiamin requirements
Heavy physical activity	Predisposes to beriberi when accompanied by low intake of thiamin
Protein energy malnutrition	Older literature reports PEM sometimes accompanies subacute beriberi indicating importance of impoverished diet
Poor storage conditions for food	Fall 6- to 10-fold in thiamin content of cereals. Molds may accelerate decay as well as increase risk of toxins
Thiaminases	Two known, but only of importance when uncooked foods are consumed
Anti-thiamin factors	Factors in food that chelate with thiamin and potentially reduce bioavailability
Alcohol abuse	Alcohol impairs the active absorption mechanism for thiamin which can be especially important when accompanied by dietary restriction such as that imposed by bariatric surgery
Infection and trauma	Increase requirements for thiamin to support increased carbohydrate metabolism and energy production
Diuretics, long-term use	Accelerate thiamin excretion and appear to block thiamin control mechanism
Seasonal factors	Combination of heavy work load, impoverished diet, and last season's (badly stored) cereals
Post-partum cultural practices and infantile beriberi	Restricting food intake; exposure to hot coals in early weeks following birth
Male sex	Some evidence that men have higher thiamin requirements than women but more likely to be a combination of the first three factors listed

requirements are at their highest for land preparation and weeding. Land preparation also takes place just prior to or at the beginning of the rainy season, when the prevalence of malaria and diarrheal diseases increases.

The thiaminase enzymes destroy thiamin activity by breaking the thiamin molecule into two parts—the pyrimidine and thiazole moieties. Thiaminases are inactivated by cooking; thus, the enzymes are only a problem where certain foods are eaten raw. It has been suggested that in northern Thailand, where consumption of fermented raw fish products is widely practiced, thiamin status may be impaired by these food habits. Even as recently as 2001, marginal thiamin status was reported in more than 50% of women 3 months postpartum despite thiamin supplements of 100 mg/day during pregnancy. The deficiencies were found in Karen refugee women living on the Thai–Burmese border and whose diet contained fermented fish, tea leaves, and betel nuts—substances suspected of containing thiaminases. Polyphenol compounds in tea and many vegetables may also possess anti-thiamin properties and impair bioavailability, but their etiological importance in causing thiamin deficiency is difficult to assess. In Lao and Cambodia, some postpartum cultural traditions, nutrition practices and socio-economic factors may also impair mothers thiamin status and increase the risk of infantile beriberi (Soukaloun et al., 2003; Barennes et al., 2009).

Alcohol is an important factor in causing thiamin deficiency because it inhibits the active transport of thiamin across the gut and when abused it impairs the quality of the diet consumed. Diuretics accelerate the excretion of thiamin and appear to override the renal conservation mechanism. Their use is of potential concern in elderly people whose diet may be poor for other medical reasons and their physicians may be unaware of their need for supplemental nutrients (Ibner et al., 1982; Pepersack et al., 1999).

Both sexes are vulnerable to the effects of thiamin deficiency, but in many of the sporadic outbreaks that have been reported, there appears to have been a male excess. This may be due to higher thiamin requirements in men than women because of their higher lean body mass or to hormonally driven sex differences. However, it is also possible that the cause is due to a higher risk of a thiamin:calorie imbalance in men compared to women. In many rural communities, men traditionally eat first and may satisfy their calorie requirements, whereas their womenfolk make do with the leftovers. Because of their greater physical strength, men frequently do heavier work than women, requiring more energy (i.e., more food to meet their requirements). Thus, men may consume more of the thiamin-depleted cereals in the diet to satisfy calorie needs and in so doing achieve a poorer thiamin:calorie ratio than women.

### Experimental thiamin deficiency in man and measurement of thiamin status

In young and healthy non-alcoholic subjects, subjective symptoms appear after 2 or 3 weeks of deficient diet but urinary thiamin will already be falling (Table 3) (Brin, 1964). Characteristic early symptoms include anorexia, weakness, dysesthesia, and depression. At this stage, urinary thiamin will be almost zero, ETKL activity depressed, and the TDP effect approximately 15–30%. After 6–8 weeks the only objective signs at rest may be a slight fall in blood pressure and moderate weight loss, although urinary thiamin will now be negligible and the TDP effect  $\geq 35\%$ . After 2 or 3 months, apathy and weakness become extreme, calf muscle tenderness develops, and there is loss of recent memory, confusion, ataxia, and sometimes persistent vomiting. Urinary thiamin will be negligible and the TDP effect may be normal (because apo-ETKL is unstable even in vivo), but ETKL activity should be considerably depressed.

**Table 3** Effects of thiamin deficiency on urinary thiamin, the erythrocyte transketolase TDP effect, and early clinical symptoms of thiamin deficiency in human volunteers.

Days of deficiency	Urinary thiamin ( $\mu\text{g}/\text{day}$ ) <sup>a</sup>	TDP effect (%) <sup>a</sup>	Clinical signs of deficiency following diets containing 150–350 $\mu\text{g}$ thiamin/day <sup>b</sup>
5	50	0–10	Mostly studies report no signs but one study (360 $\mu\text{g}/\text{day}$ ) found within 1 week chest pains, extreme lassitude, anorexia, palpitation, and burning feet
10	25	15	Loss of body weight, anorexia, general malaise, insomnia, increased irritability, fatigue on slightest exertion Increased malaise, loss of body weight, intermittent claudication and polyneuritis, bradycardia, peripheral edema, a cardiac enlargement, ophthalmoplegia Additional signs of nausea and dizziness appeared Additional signs of vomiting, low blood pressure, and tenderness of calves
21–28	<25	30	
30–40	Negligible	$\geq 40$	
>45	10–20	>40	
75	10–20		

<sup>a</sup>Biochemical data and report of edema and cardiac enlargement from Brin (1964), in which healthy male medical students were fed 200  $\mu\text{g}$  thiamin per day for 6 weeks. TDP effect is a measure of thiamin status obtained by measuring the activity of erythrocyte transketolase in the presence and absence of added thiamin diphosphate.

<sup>b</sup>Clinical signs adapted from several studies. Investigators were impressed by the rapid degree of debility induced by the specific withdrawal of thiamin from the diet. In one group (150  $\mu\text{g}/\text{day}$  for 75 days, four female mental patients), the authors reported that the condition more closely resembled 'neurasthenia' than beriberi and noted that edema, cardiac dilation, and peripheral pain characteristic of classic beriberi were all absent (Carpenter, 2002).

The clinical symptoms resulting from experimental thiamin deficiency in man have usually responded rapidly to treatment with thiamin. In one feeding study, however, two mental patients were kept for 110 days on a diet providing 200 µg thiamin daily and 1 mg of thiamin by injection 1 day each week; thus, their overall weekly average was 350 µg/day. They developed a polyneuropathy characterized by defects in the sensory nervous pathways, loss of tendon reflexes, and paralysis of the legs, which took many weeks to respond to large doses of thiamin, and in one case response was still incomplete after 4 months of treatment. The slow cure suggested that degeneration of peripheral nerves had occurred, as is indicated in the dry form of beriberi, in which the neurological lesions are irreversible.

### Clinical features of beriberi

Depletion and repletion studies suggest that intakes >300 µg/4.2 MJ are compatible with normal biochemistry and good health, and clinical signs of thiamin deficiency occur at intakes of thiamin below 200 µg/4.2 MJ (1000 kcal). The disease as studied from the 1880s onward in Asians subsisting on white rice began typically with weakness, "wandering pains" in the legs, and lack of feeling in the feet. Some patients then developed edema (the presence of excessive amounts of fluid in the intercellular tissue spaces of the body) of the legs, trunk, and face. In severe cases, sufferers found it increasingly difficult to catch their breath and would die of heart failure. The clinical features of subacute and acute wet beriberi are summarized in [Table 4](#). The main form was subacute beriberi, which was typically seasonal in endemic areas. There are reports that the peripheral muscles most severely affected were those most frequently used; thus, in male laborers it was the legs. Aching pain, tightness, and cramps in the calf and associated muscles were usually a first cause of complaint, and pain on squeezing the calves was one of the most useful diagnostic tests for beriberi. In women who performed repetitive tasks involving hands and arms, a loss of sensation in the fingers was frequently a first cause of complaint.

Dry beriberi is essentially a chronic condition showing muscular atrophy and polyneuritis and frequently occurring in older adults. Walking is usually difficult because of the weak wasted and painful musculature, and in the later stages feeding and dressing may also become impossible. When bed-ridden and cachectic (extreme state of malnutrition and wasting), patients become very susceptible to infections. Sensory nervous function is impaired (hypesthesia) almost to the point of anesthesia. Hypesthesia is particularly evident in the extremities and progressively extends over the outer aspects of the legs, thighs, and forearms. Motor nerve disturbances also begin in the extremities and ascend progressively. Flaccid paralysis of the extensor muscles precedes that affecting the flexors and results in "wrist drop" and "foot drop" ([Fig. 1](#)). Loss of the Achilles tendon reflex usually precedes an impaired patellar reflex.

### Infantile beriberi

In the early reports, mainly from S.E. Asian countries, mortality from infantile beriberi mainly affected breast-fed infants between the second and fifth months of life, when solid foods were often first introduced ([Fehily, 1940](#)). The introduction of white rice porridges, poor in thiamin, to a rapidly growing child and/or the increased exposure to infections when solids are introduced, may both have exacerbated thiamin deficiency and contributed to infantile beriberi. The onset of the disease was rare in the first month and early signs could be mild and somewhat subjective (e.g., vomiting, restlessness, anorexia, and insomnia). Early signs could progress to subacute infantile beriberi, the acute and usually fatal condition, or a chronic form. Features of acute infantile beriberi are presented in [Table 5](#). The subacute form was characterized by slight edema in the form of puffiness, vomiting, abdominal pain, oliguria, dysphagia, and convulsions. In addition, aphonia (soundless cry) was often a feature of subacute infantile beriberi and may have been due to nerve paralysis or edema of vocal cords. Vomiting was also a feature of chronic infantile beriberi and could be accompanied by inanition, anemia, aphonia, neck retraction, opisthotonus, edema, oliguria constipation, and meteorismus (swelling of the abdominal cavity from gas in the intestine). Opisthotonus is a characteristic of acute thiamin deficiency in birds and is described as due to a tetanic spasm in which the spine and extremities are bent backwards ([Thurnham, 1978](#)).

In contrast to these earlier descriptions, the features of beriberi illustrated by the Israeli infants who consumed thiamine deficient formula appeared somewhat later than those in the S.E. Asian infants. Age of presentation ranged mainly from 5 to 12 months although there was one infant of 2.5 months. However, clinical symptoms were similar with vomiting, refusal to feed, gastrointestinal, neurological and developmental delay being common features and all 9 infants with a raised TDP effect, presented with infection and or fever (see below).

### Accidental thiamin depletion in infants

Western societies are heavily dependent on milk formulas for the nourishment of human infants. Therefore, when a modified form of a well-known formula that only contained one-10th of the reported thiamin content was released onto the market in Israel in the latter half of 2003, it was followed by a wave of hospitalizations of infants in intensive care units, a national state of pandemonium and two infants died of cardiomyopathy ([Fattal-Valevski et al., 2005](#)). Analysis of the data revealed only a single link among them, all infants were fed with a reputable, soy-based infant formula (Remedia Super Soya 1) but the contents printed on the label met the stringent standards of the Israeli Department of Health.

**Table 4** Common features of wet beriberi.

	<i>Subacute beriberi</i>	<i>Acute fulminating beriberi</i> <sup>a</sup>
Digestive system	Anorexia is common; constipation more frequent than diarrhea	Vomiting is common, often with intense thirst
Neurological	Aching pain, stiffness, tightness, or cramps in calf or associated muscles Increasing muscular tenderness and weakness with fatigue pains resembling muscular ischemia, especially at night Pain on squeezing calves Inability to rise from squatting position without use of hands Diminished reflexes of ankle and knees usually bilaterally Hypesthesia or paresthesia presenting as "pins and needles," numbness particularly over the tibia, formication (like ants running on the skin) or itching	Liver enlarged and tender and the epigastric region spontaneously painful Pupils dilated with anxious expression on face Aphonia frequently present and patient moans with cries of a special kind as a result of hoarseness produced by paralysis of laryngeal muscles Reflexes of ankle or knee lost or diminished
Cardiac	Edema of feet and legs often appearing first on dorsa of feet and extending up legs but may also appear on back of hands and as puffiness in face  Heart enlarged with tachycardia and bounding pulse Raised venous pressure (see Fig. 2) with percussion sometimes revealing dilation of right auricle and ventricle Heart murmurs if present are usually systolic Apex beat is downward and outwardly displaced  Neck vein possibly distended showing visible pulsations Dyspnea upon exertion  Palpations, dizziness, and giddiness Extremities possibly cold and pale with peripheral cyanosis but where circulation is maintained, skin warm due to vasodilatation Electrocardiograms often undisturbed but QRS complex may show low voltage and inversion of T waves indicating disturbed conduction	Patients severely dyspneic, have violent palpitations of the heart, are extremely restless, experience intense precordial agony but accessory muscles of respiration on slightly brought into action  Widespread and powerful undulating pulsations visible in the region of the heart, epigastrium, and neck due to a tumultuous heart action Facial cyanosis more marked during inspiration Pulse is moderately full, regular, even with frequency of 120–150/min A wavelike motion may be felt over the heart On percussion, the heart is enlarged both to the left and right but mainly the latter, and the apex beat may reach the axilla  Raised systolic pressure and low diastolic pressure give the "pistol shot" sound on auscultation over the large arteries Rapidly increasing edema may extend from legs to trunk and face with associated pericardial, pleural, and other serous effusions
Urine	Nocturia; no albuminuria	Oliguria or anuria; no albuminuria or glycosuria

<sup>a</sup>The whole picture of acute fulminating beriberi is dominated by insufficiency of heart and blood vessels and this tends to mask all other features of the subacute form, although these are often present and accentuated. Death is accompanied by a systolic pressure falling to 70–80 mm, the pulse becomes thinner, and the veins dilate. The rough whistling respiration deteriorates and rales appear. The patient dies intensely dyspneic but usually fully conscious.

Modified from Thurnham (1978).

The cause of the trouble was revealed when a male infant of 5.5 months was admitted to Sourasky Medical Center with upbeat nystagmus, ophthalmoplegia and vomiting. Wernicke's encephalopathy was suspected and within hours of treatment with thiamin, his condition improved. A brief investigation revealed the infant was fed the same formula. Public health authorities were informed, analyses were done both in Israel and by the manufacturer and the mistake was revealed.

Fortunately, thiamin deficiency was detected in only 20 infants probably because most infants were not fed solely with milk. It is interesting to note the presenting signs and symptoms in these infants, where thiamin deficiency was known to be causal, as it assists detection of sub-clinical beriberi in less-developed countries than Israel. The clinical signs initially reported were constipation, agitation, apathy, vomiting, lack of appetite and later diarrhea, grunting, nystagmus, convulsions and unconsciousness. In 9 patients who met the laboratory criteria for thiamin deficiency (TDP effect 13.8–37.8%) infection was the precipitating factor and 6 of the patients were admitted with fever. Almost all presented with vomiting and gastrointestinal symptoms. Most of the infants were aged between 5 and 12 months and received between 800 and 1100 mL of the formula per day but for a variable amount of time (20–70% of their lives).

Possible long-term neurological consequences in the form persistent cognitive and motor deficits are now being recognized among the Israeli children who survived the deficient formula (Measelle et al., 2021). The most severely affected survivors demonstrated marked intellectual disabilities, seizures, motor disabilities, microcephaly, auditory dysfunction and complete heart block.

**Fig. 1** Patient with dry beriberi showing evidence of motor nerve disturbances resulting in a flaccid paralysis of the extensor muscles and “wrist drop” and “foot drop”. Courtesy of the late Professor B.S. Platt, formally Head of the Department of Human Nutrition, London School of Hygiene and Tropical Medicine, UK.

**Table 5** Features of acute infantile beriberi and frequency of occurrence.

	<i>Features</i>	<i>Frequency (%)</i>
Appearance	Pale and cyanotic appearance, edematous, ill-tempered with abdominal distension	40
Voice	Hoarseness	80
	Sometimes groaning	50
Digestive system	Vomiting	80
	Dyspepsia	46
Cardiac	Tachycardia, <200 beats/min	83
	Heart dilated	31
	Femoral sound on auscultation	5
Lungs	Rapid breathing	83
	Accentuation of the 2nd pulmonary sound	
Neurological	Tendon reflex usually increased	74
	Less frequently decreased	26
	Convulsions	17
Urinary	Oliguria	65
Other	Slight fever	50
	Uneasiness	50

Modified from [Thurnham \(1978\)](#).

Not all infants who received the formula displayed clinical affects initially but a variety of language impairments and learning disabilities have subsequently appeared which suggest that the long term deficiency of thiamin may have caused negative cognitive and developmental outcomes. Thus early life exposure to thiamin deficiency can have both acute and potentially serious long-term consequences but also more insidious neurological effects potentially affecting their health and development through life.

### Alcohol abuse, the Wernicke-Korsakoff syndrome and morbid obesity

In alcoholic and other malnourished subjects, one of the early signs of thiamin deficiency is anorexia. In alcohol abuse, the overwhelming desire for alcohol may outweigh all other interest in food, leading to generalized malnutrition. Alcohol specifically blocks

**Table 6** Clinical features of Wernicke–Korsakoff syndrome and frequency of occurrence.

	<i>Features</i>	<i>Frequency (%)<sup>a</sup></i>
Ocular disorders	Nystagmus (ocular ataxia—rhythmical oscillation of the eyeballs), almost always horizontal and in 50% of cases associated with vertical nystagmus on upward gaze	85
	Paralysis of one or more of the ocular muscles	50
	Sluggish reaction by pupils to light	19
Ataxia (inability to coordinate muscles)	Gait	87
	Legs	20
	Arms	12
Polyneuropathy	Speech	87
	Limbs only affected, mainly the legs only	82
	Of arms and legs	18
	Common symptoms include weakness, paresthesia, pain, loss of tendon reflexes and of sensation and motor power	
Cerebral function	Some cases of foot drop or wrist drop or both	
	Global confusional state, profound disorientation, apathy, deranged perception and of memory, drowsiness, inattentiveness, indifference	56
	Disorder of memory: both retrograde and ante-retrograde amnesia, confabulation	57
Cardiac	Alcohol abstinence syndrome	16
	Tachycardia	51
General medical abnormalities	Disorders of skin and mucous membranes	36
	Redness and/or papillary atrophy of the tongue	29
	Liver disease	60

<sup>a</sup>Percentages based on 188–245 cases.Modified from [Thurnham \(1978\)](#).

the active absorption of thiamin and alcohol abuse can progress to the potentially fatal condition known as Wernicke–Korsakoff syndrome ([Victor et al., 1971](#)). The typical clinical features of Wernicke’s encephalopathy comprise ophthalmoplegia, nystagmus (usually horizontal), ataxic gait, and an abnormal mental state that can range from mild delirium to global confusion. Liver disease and tachycardia occur in more than 50% of cases. Korsakoff’s psychosis is characterized by a profound amnesia, disorientation, and often confabulation. The clinical features of Wernicke–Korsakoff syndrome are listed in [Table 6](#).

A specific group of patients in whom dietary deficiencies can arise are those who undergo bariatric surgery (gastric bypass or also sleeve gastrectomy). The prevalence of morbid obesity has risen to global epidemic proportions and bariatric surgery has been shown to be the most effective treatment to achieve substantial and long-lasting weight loss. A complication of these procedures is the appearance of Wernicke’s encephalopathy (WE) especially in patients who receive no micronutrient supplements and abuse alcohol. Current guidelines for bariatric surgery suggest a preventative multivitamin supplement containing 12 mg thiamin, and for patients showing signs of WE post-surgery, 500 mg parenteral thiamin, 3 times daily until symptoms subside. Rapid correction with thiamin is important to prevent the further progression of WE to the untreatable Korsakoff syndrome ([Oudman et al., 2018](#)).

## Management/treatment

A wide range of clinical disorders exist where thiamin deficiency is involved and there are potentially serious consequences if it is overlooked during treatment. Hence it is not wrong to add thiamin to a therapeutic regimen even though the deficiency may not have been actively assessed especially in a clinical emergency or an obviously at-risk population.

Patients in whom cardiac and renal signs of thiamin deficiency are identified usually respond well to treatment. The dose given and route used will vary with the seriousness of the deficiency. Intravenous doses as high as 250 mg/day for 14 days and intramuscular doses of 25 mg followed by thrice daily oral doses of 10 mg have been reported for wet beriberi and are followed by a marked increase in urinary output and improvement in cardiac function. Peripheral neuropathy (dry beriberi) is more resistant to treatment. Patients with the ocular signs of Wernicke’s disease usually respond to two or three daily injections of 50 mg thiamin. Long-term oral treatment of other manifestations of Wernicke–Korsakoff syndrome with doses up to 50 mg/day is reported, although benefit is variable and considerably influenced by patients’ ability to avoid further alcohol consumption. It is unlikely that patients receiving oral thiamin will absorb more than 5–7 mg/day, but in patients likely to abuse alcohol, absorption by passive diffusion of high thiamin doses is the only way to ensure that the patient will receive any thiamin. In addition, as in all patients who show evidence of nutritional deficiency, the likelihood of other coexisting deficiencies should not be overlooked and multinutrient treatment is probably desirable. Finally, it is important to realize that untreated thiamin deficiency can result in sudden death.

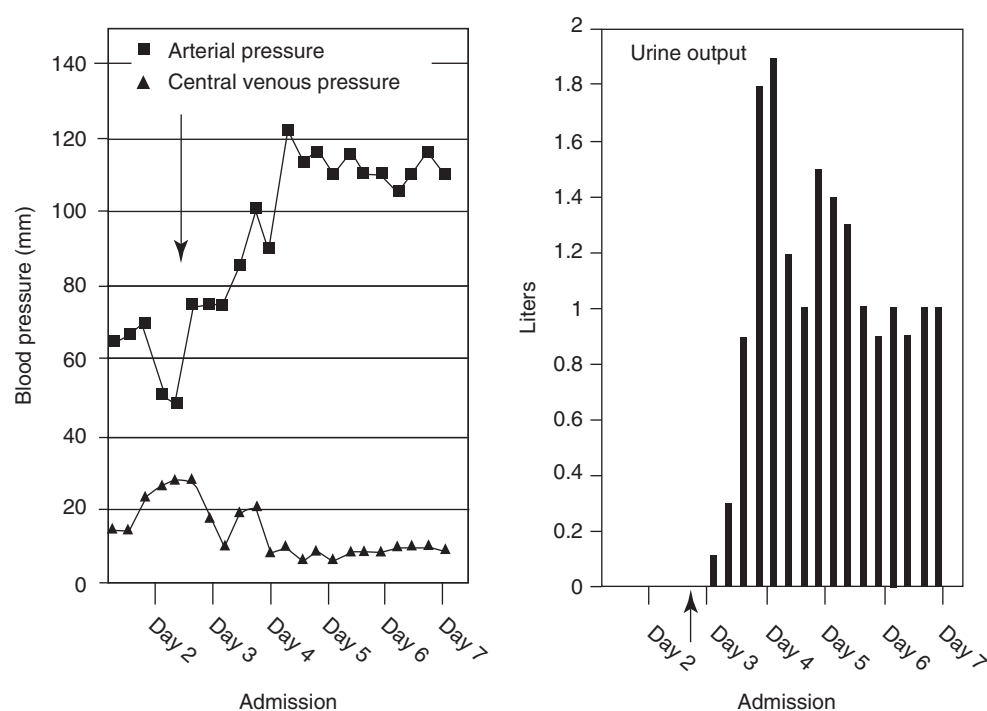

## Lipid-soluble thiamin derivatives

In recent years, several lipid-soluble derivatives of thiamin have been introduced, of which the best known is benfotiamine (Hammes et al., 2003). Advantages of these compounds appear to be increased absorption of thiamin, but by the diffusion mechanism only, and greatly increased transketolase activity. Transketolase is the rate-limiting enzyme of the nonoxidative branch of the pentose phosphate pathway. Benfotiamine has been shown to be useful for the management of rare genetic disorders in thiamin transport and may also prove useful to prevent damage from diabetic hyperglycemia. One study demonstrated that benfotiamine prevented experimental retinopathy. Diabetic hyperglycemia is accompanied by an increase in the potentially pathogenic glycolytic metabolites glyceraldehyde-3-phosphate and fructose-6-phosphate. Benfotiamine, by increasing transketolase activity, stimulates the pentose phosphate pathway to metabolize these glycolytic intermediates into pentose-5-phosphates and prevent the intracellular increase of potentially toxic products.

## Case study

A good example of the specific effect of thiamin in the treatment of beriberi is illustrated by the response of a 29-year-old male who was admitted with an unexplained acute renal failure and had been anuric for 24 h. The physicians' report on his symptoms should be compared with the common clinical features of wet beriberi shown in Table 4. The patient's physical state and voice were extremely weak but speech was copious and confused. He complained intermittently of severe central chest and epigastric pain. A central cyanosis was present and he had a respiratory rate of 36 beats per minute. His temperature was normal and peripheries were lukewarm. He had gross generalized edema. The jugular venous pressure became grossly elevated (Fig. 2). Pulse rate was 100 beats per minute, regular, and weak at the wrist, although the carotid pulses were visibly bounding. Blood pressure was 80/60. There was a marked parasternal heave present, with a loud pulmonary second heart sound. The chest was clear; the abdomen was obese.

The father reported that the patient's usual beer intake was 6–12 pints daily and his one regular meal was usually no more than a sausage roll or a pie. Prior to admission, for 6 weeks he had felt too tired to go out in the evening, and for 2 weeks he had suffered epigastric discomfort and had eaten nothing. Eight days before admission, he developed painful calf stiffness and he became too weak to go to work. He had a painful dry cough and dyspnoea on the slightest exertion. Finally, confusion, cyanosis, and intermittent vomiting led to admission.

**Fig. 2** (Left) Arterial and central venous blood pressure and (right) urine output of a patient who was admitted with unexplained acute renal failure in a very weak physical state and whose speech (although very weak) was copious and confused. The patient was discovered to be a regular beer drinker, consuming 6–12 pints daily, and his usual food intake amounted to no more than a sausage roll or pie. He had become progressively weaker over the past 8 weeks and had eaten nothing at all in the past 2 weeks. After excluding other diagnoses, it was suspected that the patient had fulminant beriberi and he was treated with thiamin after 36 h. The figures display the rapidly increasing arterial pressure, fall in venous pressure, and a rapid resumption in renal function following thiamin treatment. The patient lost ~20 L of urine during the first 7 days in the hospital. Modified from Anderson et al. (1985).

**Fig. 3** Chest radiographs of the patient described in **Fig. 2** obtained on admission (left) and 14 days after high-dose, parenteral thiamin treatment (right). On admission, the heart was grossly enlarged, extending downward and to the right, with a cardiothoracic ratio of 0.63. After treatment for 14 days, the cardiothoracic ratio was 0.44. Modified from [Anderson et al. \(1985\)](#).

The first diagnoses considered were myocardial infarction, pulmonary embolism, and overwhelming septicemia, and he was placed on dialysis and received appropriate treatments. His lack of response at 36 h, continuing low systolic pressure (70 beats per minute), increasingly gross hyperdynamic precordial signs, and moribund appearance led to a diagnosis of beriberi. Treatment with intravenous thiamin (250 mg for 14 days) brought about a dramatic response (**Fig. 2**). Within 6 h peripheral pulses were strong, blood pressure had risen to 105 systolic, and central venous pressure had fallen by half. By 12 h the parasternal heave was less marked and diuresis of up to 6 L per day ensued. After 24 h, plasma urea concentration peaked at 50.4 mmol/L and creatinine at 832  $\mu\text{mol/L}$ , and thereafter there was a steady fall over the next 2 weeks during which thiamin treatment continued and dialysis stopped. He lost a net 20 L of fluid over the first 7 days in the hospital and creatinine clearance 3 weeks after admission was 178 mL/min, indicating a return to normal kidney function. Other biochemical abnormalities resolved over the 2 weeks on high-dose thiamin, including the chest radiograph (**Fig. 3**). It is interesting to note, however, that when he was discharged 3 months after admission, he was walking with a caliper because of a right-sided foot drop (**Fig. 1**). The persistence of the foot drop is a further indication of the greater difficulty in reversing neurological consequences, in contrast to the cardiac effects, of thiamin deficiency.

## Toxicity

Chronic intakes in excess of 50 mg/kg, or more than 3 g/day, are toxic to adults with a wide variety of clinical signs, including headache, irritability, insomnia, rapid pulse, weakness, contact dermatitis, pruritis, and, in one case, death. Early researchers also indicated that regular administration or contact with thiamin occasionally led to allergic response, contact dermatitis, or hypersensitivity ([Sinclair, 1982](#)).

## Beriberi conclusions

Beriberi is a deficiency disease caused by a lack of dietary thiamin. Thiamin has a fundamental role in the metabolic generation of energy from carbohydrate. Situations which increase energy needs increase the need for thiamin. An acute insufficiency of thiamin causes cardiac “wet” beriberi which can be rapidly fatal in both adults and infants. A consistently low or chronic intake of thiamin increases the risk of “dry” beriberi; a peripheral neuropathy with motor nerve damage and ophthalmoplegia. Alcohol abuse can cause Wernicke’s Encephalopathy which can include all symptoms of the disease including cognitive problems. The rapid effects of a thiamin deficiency and the fundamental role of energy provision, imply that the deficiency may influence the clinical presentation of various morbidities which may not be promptly recognized and treated. Thus thiamin deficiency may present as a number of thiamin deficiency disorders.

## Key points

- Thiamin is a water-soluble vitamin with an active turnover in vivo; there is no storage; a regular supply is needed from a variety of food sources.
- Refined foods are generally thiamin-poor, especially rice. There is evidence of the thiamin deficiency disease, beriberi, in some Low and Middle-Income South and SE Asian countries.
- Thiamin supplements can improve breast-milk thiamin in counties where rice is a staple food and potentially lower the risk of infantile beriberi.
- Absorption of thiamin is an active saturable process which is inhibited by ethyl alcohol. There is some diffusion across the gut from high doses.
- Most thiamin in vivo is present as thiamin diphosphate (TDP). TDP acts as a coenzyme in two important dehydrogenase complexes that generate ATP and they are a fundamental source of energy for the whole body.
- The principal symptoms of thiamin deficiency are cardiac and/or neurological but because of the wide variety of presentations, they are now termed Thiamin Deficiency Disorders.
- The measurement of TDP either as the coenzyme for the enzyme transketolase or as the concentration in blood is used to assess thiamin status.

## Glossary

**Achlorhydria** Reduction in gastric acid content

**Acidosis** Raised concentration of pyruvic and lactic acids in the blood when pyruvate cannot be converted to acetyl CoA for onward metabolism by the tricarboxylic acid cycle and a fall in ATP production stimulates more glycolysis and more pyruvate production

**Aleuron layer** Layer in the cereal grain occurring below the husk

**Beriberi** The clinical condition resulting from a lack of dietary thiamin

**Cocarcboxylase** Alternative name for thiamin diphosphate or thiamin pyrophosphate

**Diuretic drug** Increases production of urine to reduce edema in heart failure

**Gut neoplasia** Cancer in the gut

**Parboiled rice** Rice that has been boiled in the husk

**Polished rice** Rice from which the outer husk and aleurone layer have been removed

**Thiamin** Essential vitamin; also called thiamine, aneurin(e) and vitamin B1

**Thiaminase** Enzymes that will inactivate thiamin. Found in a number foods but are inactivated by cooking

**Ulcerative colitis** Inflammation of the gut accelerating food transit and reducing absorption of thiamin

**Wernicke-Korsacoff syndrome** A form of thiamin deficiency that occurs in patients who abuse alcohol

## Introduction

Thiamin is a water-soluble vitamin and the structure comprises a pyrimidine and a thiazole ring linked by a methylene bridge (Fig. 1). In its metabolically active forms, the hydroxyl group on the thiazole moiety is replaced by one, two, or three phosphate groups to form three phosphorylated coenzymes. A well-nourished human adult body contains approximately 30 mg of thiamin—approximately 80–90% as thiamin diphosphate (TDP), 10% as thiamin triphosphate (TTP), and a small amount of thiamin monophosphate (TMP) and thiamin. Like most water-soluble vitamins, there is no definable store in the body; the only reserves are thiamin coenzymes that are present in most cells in combination with appropriate thiamin-requiring enzymes. The predominant need for thiamin is linked to energy production but there is increasing evidence that thiamin is also needed for additional neurological functions. Thiamin is found in the aleuron layer of cereal grains as well as in animal food products such as liver. Man's desire for high-extraction cereal products in situations in which the diets contained little more than the cereal was a main contributory factor to the scourge of beriberi throughout much of Southeast Asia at the end of 19th and beginning of the twentieth century. Thiamin is relatively unstable and destroyed by poor cooking habits, and it is susceptible to degradation in foods that are not stored properly. Thiamin turnover is also quite rapid, and the absence of stores means that a continuous supply of thiamin is required. So thiamin status can be fairly rapidly impaired by factors affecting intake (e.g., vomiting and alcohol abuse) or excessive excretion (e.g., induced by diuretics). Thus, thiamin deficiency is sometimes a problem in pregnancy, in alcohol abuse, and in the elderly. Seasonal outbreaks can also occur in Low and Middle-Income Countries (LMIC) when energy demand is high, cereals may have been badly stored for many months leading to losses of thiamin and food supplies are restricted (Whitfield et al., 2018).

## Dietary sources of thiamin (Paul and Southgate, 1978)

Thiamin is present in most foods but cereal products provide most thiamin for most people in the world, although the source is fundamentally different in developing and more industrialized countries. In the developing world, unrefined cereal grains and/or starchy roots and tubers provide 60–85% of dietary thiamin, whereas most dietary thiamin in industrialized countries is obtained from fortified cereal products. In the United Kingdom, for example, wheat flour is fortified with 2.4 mg thiamin per kilogram and many breakfast cereals contain 30% or more of the daily thiamin requirement per portion. Thiamin is present in greatest amounts in brewers yeast, the germ and aleuron layers of fresh wheat, egg yolk, and mammalian liver. It is also present in meat flesh, particularly pork, and vegetables, nuts, and legumes (Table 1). Milk from both humans (0.49–0.79  $\mu\text{mol/L}$ ; 0.23 mg/4.2 MJ (1000 kcal)) and cows (1.18–1.48  $\mu\text{mol/L}$ ) is a poor source of thiamin. Thiamin is actively secreted into milk by the lactating mother, and it is of interest that in the thiamin-replete woman the amount of thiamin in human milk is not increased by supplements, but the concentration and of course the volume consumed increase during the first 6 weeks of lactation. See also effects of thiamin supplements on milk thiamin concentrations in women living in areas at risk of thiamin deficiency (below).

Refined foods in general, such as fat, sugar, and alcohol, are poor sources of thiamin. Polished rice is particularly low in thiamin (80  $\mu\text{g}/100\text{ g}$ ) and is especially important because of its widespread consumption and importance as a source of calories. Cereal grains lose thiamin during refining, but the process of parboiling rice before milling enables most of the thiamin to be retained (190  $\mu\text{g}/100\text{ g}$ ) since it migrates into the starchy endosperm during the procedure. Proper storage of cereal grains is also important to maintain thiamin activity. Studies in The Gambia, West Africa, found that old season millet, which had been stored under thatch and in high humidity, when consumed 6–8 months later in the middle of the rainy season had thiamin concentrations (11  $\mu\text{g}/100\text{ g}$ ) that were 6–12 times lower than cooked samples obtained immediately postharvest. Imported rice used in the village likewise only contained 10  $\mu\text{g}/100\text{ g}$  at the time of consumption (Thurnham et al., 2011).

Because of the water-soluble properties of thiamin, it can be leached from food during cooking. Thiamin is stable in slightly acid water up to boiling point but is unstable in alkaline solution that oxidizes it quantitatively to thiochrome (Fig. 2). In addition, anti-thiamin factors in food can accelerate thiamin losses. Paralysis in foxes fed raw carp led to the discovery of the thiaminase enzymes. Two thiaminases are found in food. Thiaminase I is found in fish, shellfish, ferns, and some bacteria and catalyzes a base exchange reaction between thiazole and another base. Thiaminase II is a hydrolytic enzyme that cleaves the vitamin at the methylene bridge and is found mainly in bacteria. The thiaminases are heat labile, so only food that is eaten raw or fermented may lose thiamin during its preparation or in the gastrointestinal tract. There are also heat-stable anti-thiamin factors that are found in ferns, tea, betel

**Fig. 1** Thiamin and thiamin diphosphate (asterisk). Thiamin monophosphate and triphosphate are formed by the similar addition of one or three phosphate groups at the asterisk.

**Table 1** Thiamin content of common foods.

Food group	Food item	Thiamin content (mg/100 g)
Bread	Wholemeal	0.26
	White	0.18
	Hovis	0.52
Breakfast cereals	Cornflakes (fortified)	1.8
	Rice krispies	2.3
	Weetabix	1.0

**Fig. 2** Structures of thiamin and thiochrome.

nuts, large numbers of plants and vegetables, and some animal tissues. Anti-thiamin factors bind with varying degrees of attachment to thiamin and may or may not interfere with the bioavailability of thiamin. Diphenols, especially those with the hydroxyl groups in the *ortho* position, tend to react to give products that are both thiochrome negative and microbiologically inactive (i.e., thiamin is deactivated). Thus, in areas of Northern and North-Eastern Thailand where tea drinking, chewing fermented tea leaves, chewing betel nuts, and consuming raw/fermented fish are common practices, thiamin deficiency still occurs despite thiamin intakes of 0.44–0.50 mg/4.2 MJ. Similar food habits are also found in Laos but there, the mean thiamin intake of women during the post-partum period was recently reported to be 0.35 mg/4.2 MJ and infantile beriberi is a public health problem (Soukaloun et al., 2003; Barennes et al., 2009).

## Low-dose thiamin supplements in lactating Cambodian mothers

Infantile beriberi related mortality is still common in South and SE Asia. Recent studies to investigate the effects of thiamin supplements on milk thiamin concentrations of Cambodian women during the first 6 mo postpartum were found to increase mean human milk thiamin concentrations at 24 weeks by 20, 25 and 36%. The doses given were zero, 1.2, 2.4 and 10 mg/d and all mean thiamin concentrations were significantly higher in the supplemented groups than the placebo but the range in concentration of milk thiamin was so wide that there was no significant difference between the 3 supplements. The objective of the study was to determine the dose of supplement that would equate to 90% of the maximum average human milk total thiamin concentration. The resultant figure based on all data was 2.35 mg/d but in fact the milk thiamine concentrations obtained from the 1.2 mg/d group were no different from those obtained with 2.4 mg/d (Gallant et al., 2021).

The large interindividual variation has been previously reported in thiamin-replete American and Cambodian women but the results may indicate one of the problems of supplementing women with a single nutrient where there may be several other dietary deficiencies interacting with the milk thiamin concentration e.g., riboflavin, iron, and other micronutrients. Furthermore the bolus dose of 10 mg was no more effective than 1.2 or 2.4 mg thiamine probably because active absorption of thiamine is restricted to 2 mg per meal (see Absorption below). A portion of higher amounts can be absorbed by passive diffusion but this may well be small. In conclusion, 1.2 mg/d achieved milk concentrations ( $1.83 \pm 91 \mu\text{g/L}$ ) comparable with adequate concentrations in thiamin-replete mothers and there were significant improvements in thiamin status based on the erythrocyte transketolase stimulation assay of both mothers and infants at 24 weeks from all three doses (Gallant et al., 2021).

## Absorption and ethyl alcohol

In food, thiamin occurs mainly as phosphate coenzymes and the predominant form is thiamin diphosphate (TDP; also called thiamin pyrophosphate and cocarboxylase). The phosphate coenzymes are broken down in the gut by phosphatases to give free thiamin for absorption. Thiamin is absorbed mainly from the upper intestine, and less thiamin is absorbed on an empty stomach than when taken with a meal. The latter could be due to the alkaline conditions in the duodenum, which are prevented by the presence of food. Absorption of up to 2 mg per meal occurs by an active saturable process involving a sodium-dependent adenosine triphosphatase and against a concentration gradient. During absorption, thiamin is phosphorylated to the monophosphate ester (TMP). Thiamin is absorbed via the portal venous system. Further phosphorylation to TDP occurs on entry into all tissues. TDP can cross the blood–brain barrier, where a portion is converted to TTP, although even in the brain, TDP is the predominant form of thiamin. A second passive absorption process operates when intakes of thiamin are  $>5$  mg but the maximum that can be absorbed from an oral dose is 2–5 mg (Friedemann et al., 1948; Hoyumpa et al., 1977).

The active process of absorption is impaired by ethyl alcohol. For example, 55% of a 5 mg dose of orally-administered, labeled thiamin was recovered over 72 h in healthy adults, but this was reduced by 25–40% if they were previously given 1.5–2 g alcohol/kg. In people with fatty livers who had previously been abusing alcohol, mean thiamin absorption was reduced by 60%. However, the passive absorption of thiamin is not inhibited by alcohol, nor does it block entry of thiamin into the liver or interfere with thiamin metabolism in the tissues. Absorption of thiamin may also be reduced by gastrointestinal disturbances, such as vomiting and diarrhea, ulcerative colitis, and neoplasia, and in patients with hepatic disease and achlorhydria.

## Transport, storage and excretion

Thiamin with some TMP (19–75 nmol/L) circulates in the blood bound to albumin. When the binding capacity of plasma albumin is exceeded, or thiamin is in excess of tissue needs, it is rapidly excreted in the urine. Most thiamin in erythrocytes is present as TDP principally bound to the enzyme transketolase. Likewise, in most other tissues, there is very little free thiamin and it is mostly present as TDP (90%) in coenzymes bound to respective enzymes and a smaller amount of TTP (10%) in nervous tissues. The concentration of thiamin in specific tissues is of the order of 2–3  $\mu\text{g/g}$  for heart muscle; 1  $\mu\text{g/g}$  for brain, liver, and kidney; and 0.5  $\mu\text{g/g}$  in skeletal muscle. Thiamin supplements can increase these concentrations slightly and prolonged febrile illnesses are likely to reduce them. Thiamin is mainly excreted intact in the urine but there are small amounts of thiochrome (Fig. 2) and other thiazole and pyrimidine metabolites. A linear relationship exists between intake and excretion of thiamin until intake falls to an amount approaching minimum requirements when excretion decreases rapidly indicating a renal conservation mechanism (Sinclair, 1982; Whitfield et al., 2018).

There is concern that the long-term use of diuretics in the management of chronic congestive heart failure (CHF) may impair thiamin status and, as a consequence, impair myocardial function (Seligmann et al., 1991; Suter and Vetter, 2000). The diuretic drug furosemide has been the subject of much attention. In healthy volunteers, a dose-dependent increase in urine flow accompanied by an increase in the urinary thiamin excretion rate have been demonstrated. In furosemide-treated patients, the concomitant presence of thiamin in the urine and biochemical deficiency of thiamin from measurements in blood has been shown. These results suggest that furosemide treatment can override the renal conservation mechanism. In one study, 23 patients with chronic CHF receiving 80–240 mg furosemide daily for 3–14 months were studied along with 16 age-matched controls without heart failure and not taking diuretics. No subjects in either group were identified as consuming inadequate thiamin intake or having increased

thiamin requirements. However, biochemically, 21 of the 23 CHF patients and 2 of the controls were biochemically thiamin deficient. Furthermore, 5 of the CHF patients were treated with intravenous thiamin (100 mg thiamin HCl twice daily for 7 days). Biochemical thiamin status normalized and echocardiographic assessment of left ventricular ejection fraction (the proportion of blood ejected per beat) increased in 4 of the 5 patients. Because no other changes were made in the patients' therapeutic regimen, the results suggest that the improvement in cardiac contractility was due to the correction of the thiamin deficiency.

## Biological functions

Thiamin functions as the coenzyme TDP in the metabolism of carbohydrates and branched-chain amino acids ( $\alpha$ -keto-isocaproic,  $\alpha$ -keto- $\beta$ -methyl valeric, and  $\alpha$ -keto-isovaleric acids). In association with  $Mg^{2+}$  ions, TDP is important (1) in various dehydrogenase complexes for the oxidation of  $\alpha$ -keto acids (pyruvate,  $\alpha$ -ketoglutarate, and the branched-chain  $\alpha$ -keto acids) and (2) in the formation of  $\alpha$ -ketols among the hexose and pentose phosphates catalyzed by transketolase (EC 2.2.1.1). Thus, a deficiency of thiamin has severe consequences for energy generation and amino acid interconnections, and these have important links with lipid metabolism, cell replication, and neural activity (Whitfield et al., 2018).

Two principal dehydrogenase complexes that require the participation of TDP are pyruvate dehydrogenase, which generates acetyl-CoA, and the oxidative decarboxylation of  $\alpha$ -ketoglutarate to succinyl-CoA (Fig. 3). Pyruvate dehydrogenase is situated at the junction of the glycolysis pathway, where it enters the tricarboxylic acid cycle. Acetyl-CoA is a key source of energy for mitochondrial oxidation and the production of adenosine triphosphate (ATP) as well as an important precursor in lipid metabolism. The impaired functioning of pyruvate dehydrogenase leads to a lactic acidosis, with increased concentrations of serum pyruvate and/or lactate especially as a result of exercise. The lactate acidosis can be explained by the fact that ATP depletion stimulates glycolysis, thus generating more pyruvate. As pyruvate concentrations increase, lactate dehydrogenase converts some of the pyruvate to lactate, producing the lactic acidosis. The increases in these compounds formed the basis of the earliest biochemical test for thiamin deficiency, which was later made more reproducible by taking the blood soon after moderate exercise (e.g., climbing a measured number of steps).

Many features of beriberi indicate that thiamin plays an important role in neural tissues (Sinclair, 1982; Bender, 1984). TTP is specifically found in nervous tissues, but although this triphosphorylated metabolite of thiamin has been known for approximately 30 years, its precise role is still in doubt. TDP in the dehydrogenase complexes is undoubtedly also required for normal function. Some of the earliest biochemical studies on the brain documented abnormalities in the oxidative metabolism of glucose and

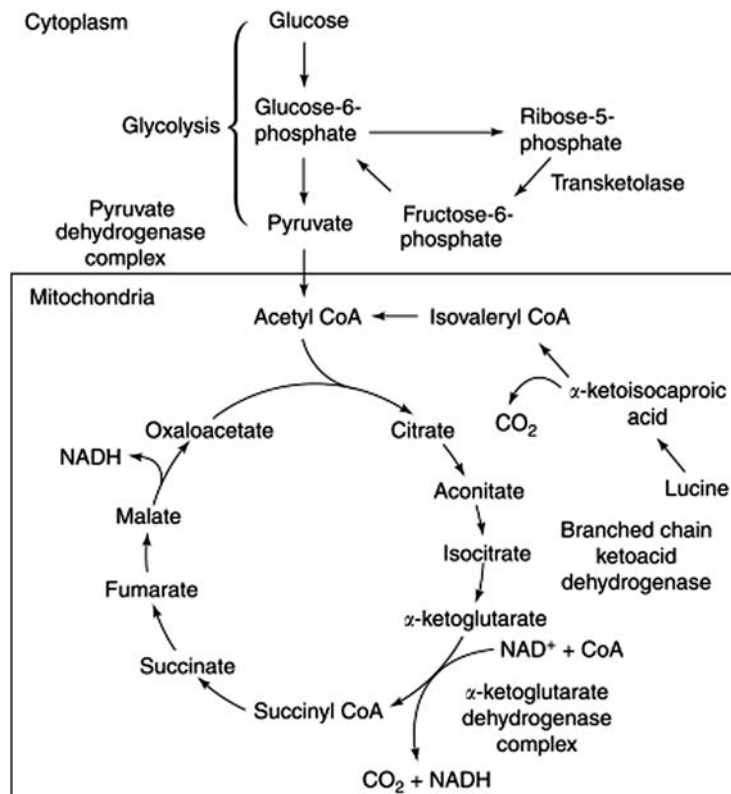

Fig. 3 The four principal sites of action of thiamin diphosphate coenzyme in carbohydrate metabolism.

a disruption in energy supply may underlie many of the neurochemical changes and structural lesions associated with thiamin deficiency. For example, acetyl-CoA produced by pyruvate dehydrogenase is a precursor of the parasympathetic transmitter molecule acetylcholine, but the obligatory requirement of glucose as an energy source for nervous tissue indicates the essentiality of TDP. Likewise, the cytosolic enzyme transketolase is also present in nervous tissue, and as a key enzyme in the hexose monophosphate shunt (HMS) it may be important in minimizing oxidant stress. The HMS generates NADPH, which is required to maintain the antioxidant compound, glutathione, in the reduced state. Thus, thiamin has an important role in maintaining redox homeostasis of tissues.

The cellular and subcellular localization of the enzymes responsible for metabolism of thiamin phosphates in nervous tissues may indicate possible sites of action of the specific metabolites. Thiamin that enters the brain is phosphorylated by thiamin pyrophosphokinase to form TDP. The concentration of thiamin phosphates is 3 or 4 times higher in neurons than in neuroglia, and the activity of thiamin diphosphatase (TDPase), which converts TDP to TMP, is 20 times higher in neurons than neuroglia. Thiamin monophosphatase is only detected in neuroglia. Within the neuron, TDPase is mostly localized in the microsomal fraction. Thiamin triphosphatase (TTPase), which converts TTP to TDP, is particularly enriched in presynaptic terminals. Stimulation of nerves or treatment with certain neuroactive drugs result in decreases in TDP and particularly TTP in the nerve, with an increase in free TMP in the surrounding fluid. It is postulated that TTP plays an essential role in nerve transmission involving a gating mechanism for sodium and potassium ion transport via the specific ATPase. Some evidence for this comes from patients with Leigh's disease (pathologically similar to Wernicke–Korsakoff syndrome), in whom severe neurological disease is accompanied by a deficiency in TTP but normal TDP concentrations.

The well-documented role of mitochondria in programmed cell death and the importance of thiamin for oxidative stability have stimulated investigators to examine brain thiamin homeostasis in neurodegenerative diseases (Gibson and Zhang, 2002). Diminished thiamin-dependent processes, abnormal metabolism, and oxidative stress accompany the neurodegeneration of Alzheimer's disease (AD), Huntington's disease, Wernicke–Korsakoff syndrome, progressive supranuclear palsy, and the adult-onset neurodegenerative diseases that are caused by genes containing variable numbers of DNA-triplets, otherwise known as CAG repeats, within their coding regions. Abnormalities in the thiamin-dependent processes have also been linked with thiamin-responsive maple syrup urine disease, Leigh's disease (a subacute necrotizing encephalomyelopathy), sudden infant death syndrome, cerebellar degeneration, thiamin-responsive anemia, ataxia, and disorders of energy metabolism including pyruvate dehydrogenase deficiency. The extent to which disturbances in thiamin metabolism are a cause or a consequence of the disease process is still under examination. The wide-ranging associations of thiamin deficiency with metabolic diseases justifies the term thiamin deficiency disorders (TDD) which has recently been introduced (Whitfield et al., 2018).

## Assessment of thiamin status

Thiamin status can be assessed using methods that measure thiamin or its metabolites in plasma, erythrocytes and urine (Table 2). Samples are acidified to stabilize the thiamin and precipitate any protein. Usually, thiamin is oxidized to thiochrome (Fig. 2) using cyanogen bromide in alkaline solution and measured by fluorescence with or without chromatography. Concentrations of thiamin in urine and plasma tend to reflect dietary intake, being high when intake is adequate and low when dietary sources are poor. Erythrocyte thiamin is mainly in the form of the coenzyme TDP, which can be extracted from washed erythrocytes, derivatized as described previously, and quantified by high-performance liquid chromatography. The most useful functional test, however, is the erythrocyte transketolase (ETKL) stimulation test, which measures enzyme activity with and without added TDP. The reference range for ETKL activity in well-nourished, thiamin-adequate people is reported to be 570–830 mU/g hemoglobin. The stimulation test measures the proportion of the TKL apoenzyme in red cell homogenate (i.e., the proportion that is not bound to TDP and

<sup>d</sup>Reproduced from Gibson (2005).

represents the degree of thiamin deficiency). Studies have shown that results from the urinary assay for thiamin agree reasonably well with those obtained by the ETKL stimulation test. The ETKL stimulation test can now be done using 96-well plates which will considerably improve the speed of measurement of thiamin status (Jones et al., 2021).

One of the reasons for the usefulness of the ETKL stimulation test is that sensitivity is still good even in the presence of thiamin deficiency. In all other measurements of thiamin status, as deficiency approaches, the quantity of thiamin or its metabolites diminishes in the biological fluid. Low concentrations of a product are usually more difficult to measure and precision deteriorates, or the amount of sample has to be increased to provide sufficient material to detect. In contrast with the ETKL stimulation test, in an acute thiamin deficiency, ETKL activity is maintained and only the amount of TDP decreases, so the test becomes more sensitive. However, in chronic thiamin-deficient states, the apoenzyme of ETKL is reported to be unstable *in vivo*, and in the absence of the coenzyme, concentrations of the apoenzyme decrease, with the result that *in vitro* stimulation may show normal thiamin status and basal ETKL activity may be a better indicator of status than the stimulation test. Thus, in situations in which chronic thiamin deficiency is suspected as a result of a long-term marginal thiamin intake, alcohol abuse, or use of diuretics for many months, one or more of the concentration tests may be useful as an adjunct to the stimulation test.

Certain precautions should be taken in handling samples for thiamin analysis. Urine should be acidified to avoid degradation and stored below  $-20^{\circ}\text{C}$ . Heparinized whole blood should be collected and immediately put on ice. For total erythrocyte TDP measurements, cells are separated from plasma within 2 h when possible, washed in saline, and diluted 1:1 with saline prior to acidification. Centrifugation of the acidified mixture provides a clear extract that can be stored for no more than 5 days at  $4^{\circ}\text{C}$  or longer at  $\leq -20^{\circ}\text{C}$ . Washed red cells are also used for the ETKL assay. Duplicate tubes of the red cells in saline suspension with and without added TDP are mixed and can be stored at  $-70^{\circ}\text{C}$  prior to enzymatic analysis of ETKL activity. Even at  $-70^{\circ}\text{C}$ , however, storage should be for no more than a few weeks. The ETKL apoenzyme is unstable, and even in the tubes to which TDP has been added, if mixing did not thoroughly expose all apoenzyme to the added coenzyme, deterioration will occur and results will be unreliable.

### Recommended dietary allowances (Department of Health, 1991; WHO/FAO, 2002)

Quantifying thiamin requirements is based on a variety of biochemical data (Sauberlich et al., 1979). Early results indicated that a thiamin intake of 0.4 mg/day on a low-energy intake was close to the absolute minimum requirement. Epidemiological evidence suggested that beriberi occurred when the intake of thiamin was  $<0.2$  mg thiamin per 4.2 MJ (1000 kcal); however, when 0.188 mg/4.2 MJ was fed to sedentary elderly men for 2 years, no indisputable alteration in clinical state occurred. Thiamin requirements are strongly influenced by physical activity and at higher energy intakes with liquid formula diets containing 11.76 and 15.12 MJ (2800 and 3600 kcal), there was good agreement between thiamin excretion and ETKL stimulation to interpret thiamin status at different levels of thiamin intake. Increasing intake from 0.2 to 0.23 mg/4.2 MJ moved first the urinary excretion and then ETKL activation out of the deficient range. Both measurements were normalized at intakes of 0.3 mg/4.2 MJ, and to allow for variance the recommended nutrient intake adopted by the Department of Health in the United Kingdom was 0.4 mg/4.2 MJ. This amount is recommended for all groups of the population since additional needs in pregnancy and lactation are met by increased energy intakes. It was recommended that formula feed should contain not less than 0.3 mg/4.2 MJ.

Women are less affected by beriberi than are men even when they are consuming the same diet, but there is no consistent indication that men have greater needs than women. Differences between the sexes that may affect susceptibility to beriberi need further investigation (e.g., the amount of food eaten by the sexes when supplies are short or of poor quality, metabolic responses to infection during illness, and differences in energy requirements). The close association between thiamin metabolism and carbohydrate metabolism means that thiamin requirements are determined by basal metabolic rate (BMR) and physical activity. BMR of men is slightly higher than that of women of the same weight, but total energy expenditure can vary 1.4–2.5 times BMR depending on physical activity.

### Drug–nutrient interactions

Mention has already been made of the influence of alcohol and diuretics on thiamin status. Oral contraceptives are reported to have no effects on thiamin status (Thurnham, 2004). Some recent publications have drawn attention to transporter-mediated drug nutrient interactions in humans which may cause potentially serious adverse events (Vora et al., 2020; Enogie et al., 2021). Genetic mutations of the thiamine transporters SLC19A3 and SLC19A2 which encode thiamine transporters 2 and 1 respectively can be clinically important particularly in vulnerable populations e.g. individuals with alcoholism. Vora et al. (2020) identified 28 oral drugs, including metformin (used in treatment of type-2 diabetes) where intestinal concentrations were predicted to inhibit thiamin absorption. Likewise, others report a case of thiamin-responsive megaloblastic anemia caused by mutations of the SLC19A2 gene. These workers identified 10 drugs that inhibited SLC19A2-mediated thiamin transport but only erythromycin (antibiotic used to treat a number of bacterial infections) was active at clinically relevant concentrations (Enogie et al., 2021).

## Toxicity

High intakes of thiamin administered orally are nontoxic. The rapidly saturable thiamin absorption mechanism limits the amount taken up from a single dose to ~2.5 mg, and thiamin present in excess of protein binding capacity is excreted. However, there are reports of toxicity from chronic intakes in excess of 50 mg/kg or >3 g/day with a wide variety of clinical signs, including headache, irritability, insomnia, rapid pulse, weakness, rapid pulse contact dermatitis, pruritus, and, in one case, death (Sinclair, 1982).

## Conclusions

Thiamin is needed to support all metabolic functions necessary for life. In the absence of a regular supply of thiamin e.g., when deprived by restricted feeding, a lack of food choice, anorexia etc. or, there is increased requirement for thiamin as in fever or infection or increased physical activity or when treated with a glucose load for medical reasons, there is a risk of insufficient thiamin which can impair physical activity, cardiac function and, long term, has neurological consequences. Epidemiologically, those low and middle-income populations that use polished rice as their staple food are at greatest risk of chronic thiamin deficiency and infants may be at the greatest risk of deficiency if they are solely fed with breast milk in the first 6 months of life. Food fortification with thiamin can address this problem as in many developed countries, and governments of LMIC should investigate similar schemes with local foods.

### Key points

- Most ultratrace elements once suggested to be essential based mostly on an apparent beneficial actions in animals and essential functions in lower forms of life have not been established as essential in humans when using the rigorous definition of essentiality, which is: required to prevent death or complete the life cycle.
- Boron, bromine and silicon are ultratrace elements for which there is substantial evidence they will be found to be essential.
- Fluoride and lithium are elements recognized as having beneficial biological activity in supra nutritional amounts, but not enough evidence to be considered nutritionally essential.
- Molybdenum is an essential ultratrace element of limited nutritional concern.
- Nickel and vanadium may have beneficial biological activity in nutritional amounts.

### Introduction

In the early 20th century, scientists could qualitatively detect small amounts of several mineral elements in living organism. In these reports, these elements were described as being present in “traces” or “trace amounts,” and became known as trace elements. Sophisticated analytical techniques have resulted in the accurate determination of many mineral elements, some at very low concentrations in living organisms. Some of these elements are essential, that is, having a defined biochemical function that is needed to prevent death or complete the life cycle. Most mineral elements are nonessential fortuitous reminders of our geochemical origin or indicators of environmental exposure. However, some trace elements not established as essential have been found to have beneficial effects in humans and animals in nutritional or supra nutritional amounts. All the trace elements are toxic when intakes are excessive.

In the 1980s, the term “ultratrace element” appeared in the nutritional literature. The definition given for ultratrace elements for humans was an element with an established, estimated, or hypothesized requirement of less than 1 mg day<sup>-1</sup> or indicated by micrograms per day. Using this definition for ultratrace elements resulted in three recognized essential mineral elements required by humans fitting into the ultratrace category; these elements are iodine, molybdenum, and selenium. Cobalt probably could be considered an ultratrace element. However, it is only required in the form of vitamin B<sub>12</sub>, and thus its requirement is usually presented in this form. Iodine and selenium, in addition to chromium, an ultratrace element that has not been established as essential, are discussed elsewhere in this encyclopedia.

In the last 30 years of the 20th century, numerous ultratrace elements received some limited recognition as being essential based on a less rigorous definition of essentiality. The essentiality definition was that a dietary deficiency of a substance had to consistently and adversely change a biological function from optimal, and this change was preventable or reversible by physiological or nutritional amounts of the substance. For the ultratrace elements, this definition became questionable because of concerns about possible suboptimal diets and environments in studies reporting possible essentiality. Instead of overcoming a suboptimal function, it was considered possible that mineral element supplementation was having a pharmacological effect such as alleviating a pathology caused by a poor diet or environment, substituting for another essential nutrient provided in a deficient amount, or having an effect on intestinal microorganisms in a manner that was beneficial to the host. Minerals that once were suggested to be essential in ultratrace amounts based mostly on an apparent beneficial action in animals and essential functions in lower forms of life included aluminum, arsenic, boron, bromine, cadmium, fluoride, germanium, lead, lithium, nickel, rubidium, silicon, strontium, tin, and vanadium. These elements will be the focus of this article. Also included is the established essential ultratrace element molybdenum which is given very little nutritional attention apparently because a human nutritional deficiency has not been unequivocally identified other than in an individual nourished by total parenteral nutrition.

## Aluminum

In the 1990s, it was reported that a dietary deficiency of aluminum in goats increased abortions, depressed growth, caused incoordination and weakness in the hind legs, and decreased life span (Angelow et al., 1993). It was also reported that aluminum deficiency depressed growth in chicks (Carlisle and Curran, 1993). Neither of these reports have been confirmed. In both these studies, the diet and environment were not optimal, which suggests that the effect of aluminum may have been something other than that of an essential function. There is no question that aluminum can be bioactive. *In vitro* studies show that it can activate the enzyme adenylate cyclase, enhance calmodulin activity, stimulate DNA synthesis, and upregulate the parathyroid calcium-sensing receptor (Nielsen, 1996). However, aluminum is not required to perform these functions in living organisms. Most evidence indicates that for humans the body attempts to minimize the exposure of aluminum. Intestinal absorption is estimated to be 0.005% of intake. Any absorbed aluminum entering circulation is excreted by the kidney or becomes complexed to cellular components such as citrate, glutamic acid and entities containing phosphate molecules without disrupting cellular biochemistry. Thus, although it is found in the body in ultratrace amounts, there is insufficient evidence to support aluminum as being essential or indicate it having beneficial bioactivity in humans, which makes it inappropriate to give a suggested beneficial intake. If aluminum has a beneficial activity, the typical daily dietary intake of aluminum of 2–25 mg likely provides an adequate amount to accomplish it.

Aluminum toxicity is not of concern for healthy individuals. However, high intakes of aluminum by susceptible individuals (e.g., impaired kidney function, low-birth weight infants) can lead to aluminum accumulation in various organs including bone, parathyroid, brain, liver, and kidney. Bypassing natural barriers to the entry of aluminum in the body such as intravenous infusion of parenteral solutions high in aluminum also is another risk for aluminum accumulation in these organs. This accumulation can lead to pathology such as osteomalacia, hypoparathyroidism, and microcytic anemia (Klein, 2019), and perhaps exacerbate neurodegenerative disease such as Alzheimer's disease (Exley and Mold, 2019). For most healthy individuals, an aluminum intake of 125 mg day<sup>-1</sup> should not result in toxicological consequences.

## Arsenic

Arsenic is unquestionably a bioactive element in higher animals and humans. However, most studies of its bioactivity have been directed toward demonstrating that some forms of arsenic in amounts found in food and water are toxic. The concept that arsenic has beneficial activity in nutritional intakes is not well accepted, although numerous reports have purported that feeding a diet low in arsenic (e.g., <12 µg kg<sup>-1</sup> diet for rats, chicks, and hamsters, and <35 µg kg<sup>-1</sup> for goats and minipigs) resulted in an arsenic deficiency in animals that was overcome by low microgram quantities of supplemental arsenic (Uthus, 1992; Anke, 2005). The most consistent signs of the reported arsenic deprivation signs were depressed growth and abnormal reproduction characterized by impaired fertility and increased perinatal mortality. Death with myocardial damage also was reported for lactating goats. Many of these obtained deficiency findings were affected by various dietary manipulations and perhaps environmental conditions. For example, many reported signs of arsenic deprivation were changed and generally enhanced by nutritional stressors that affected sulfur amino acid or labile methyl metabolism. Because the "deprivation" findings might be the result of arsenic supplementation alleviating a suboptimal status caused by factor/s other than an arsenic deficiency, the findings are not sufficient to support essentiality. However, they indicate that arsenic could be beneficial in ultratrace amounts.

Interestingly, although considered to be carcinogenic, some studies indicate that certain amounts and forms of arsenic may be beneficial through reducing the risk for cancer. In one human study, both low exposure (<50 µg L<sup>-1</sup>) and high exposure (>100 µg L<sup>-1</sup>) in drinking water were associated with increased cancer incidence (Kayajanian, 2003). A similar finding was obtained by a study involving rats fed diets containing 0.1, 0.5, or 50 µg kg<sup>-1</sup> arsenic with dimethylhydrazine induced aberrant colon crypts.

More aberrant crypts and aberrant crypt foci, a relative DNA hypomethylation, and increased activity of DNA methyltransferase was found in rats fed the 0.1 and 50  $\mu\text{g kg}^{-1}$  diets than those fed the 0.5  $\mu\text{g kg}^{-1}$  diet (Uthus and Davis, 2005). Another human study found decreased serum arsenic concentrations in individuals undergoing hemodialysis treatment was correlated with cancer, in addition to vascular diseases and central nervous system injury (Mayer et al., 1993). Consistent with arsenic sometimes having beneficial bioactivity against cancer is the finding that pharmacological amounts of arsenic trioxide are effective treatments for some forms of cancer, especially promyelocytic leukemia (Liu et al., 2021).

A plausible mechanism for the bioactivity of arsenic is an effect on the methylation of metabolically or genetically important molecules. This suggestion is supported by the finding that global DNA methylation in cultured Caco-2 cells was significantly decreased when the culture contained low (25  $\mu\text{g L}^{-1}$ ) or high (175  $\mu\text{g L}^{-1}$ ) arsenic than when it contained 100  $\mu\text{g L}^{-1}$  (Davis et al., 2000).

Dietary Reference Intakes (DRIs) have not been set for arsenic. Several studies indicate that human arsenic intakes range from 20 to 70  $\mu\text{g day}^{-1}$ . This intake is similar to intakes found beneficial in animals and epidemiological studies. Animal data suggest that a beneficial intake of arsenic could be 12–25  $\mu\text{g day}^{-1}$  (Nielsen, 1996).

Despite the findings above, any measurable intake arsenic not in the arsenobetaine form is mostly considered a toxicological concern. This occurs although humans have enzymes that convert absorbed inorganic arsenic into a methylated form that is readily excreted in the urine (Thomas et al., 2007). Organic forms of arsenic that are readily absorbed, such as arsenobetaine and arsenocholine that is mostly converted to arsenobetaine, are found in significant amounts in seafoods; arsenobetaine passes through the body without transformation and is virtually nontoxic (Nielsen, 2006). A standard known as the reference dose (RfD; lifetime exposure that is unlikely to cause adverse health effects) of 0.3  $\mu\text{g kg}^{-1}$  body weight per day, or 21  $\mu\text{g day}^{-1}$  for a 70 kg human has been suggested for inorganic arsenic (Chappell et al., 1994). This intake conforms with the beneficial intakes indicated above.

The finding that arsenic might have beneficial effects in ultratrace amounts suggests that the human response curve to arsenic intakes is U or J shape where increasing or decreasing, respectively, very low or excessive intakes would be beneficial. Only limited concern about low intakes is needed because most reported intakes through water and diet exceed this amount, especially if the diet is high in cereal grains. On the other hand, excessive intakes of inorganic arsenic, especially trivalent arsenic (arsenite), is a significant global concern. Signs of subacute and chronic excessive intakes of inorganic arsenic include various dermatoses (hyperpigmentation, hyperkeratosis, desquamation, and hair loss) liver damage characterized by jaundice, portal cirrhosis, and ascites; peripheral neuritis; and hematopoietic depression. Excessive intakes have also been linked to increased risk for skin, lung, liver, kidney, and bladder cancers (Stoeppler, 2004). Excessive intakes inducing such pathologies are found in specific areas of countries where drinking water is high in inorganic arsenic, including Argentina, Bangladesh, Bolivia, Chile, China, Hungary, India, Mexico, Nepal, Romania, Taiwan, Thailand, Peru, United States, and Vietnam (Stoeppler, 2004).

Consuming foods from plants high in inorganic arsenic because of uptake from arsenic contaminated soil and water also can result in excessive intakes of arsenic. Of major concern is rice which is grown on soils throughout the world that favor the uptake of inorganic arsenic to amounts 10–20 times that usually are found in grains such as wheat. Rice in many parts of the world is a food staple and rice and rice products are commonly consumed in other countries in significant quantities other than just rice such as in ready-to-eat cereals, baked goods, rice cakes, and rice-based snacks in the daily diet. Of special concern are foods for infants and toddlers whose first foods are often rice-based. The European Commission (European Food Safety Authority et al., 2021) has given a limit of 100  $\mu\text{g/kg}$  for inorganic arsenic in rice-based foods for infants and young children. The United States Food and Drug Administration in 2016 proposed a limit of 100  $\mu\text{g/kg}$  arsenic in cereal and baby food. It should be noted that arsenic in rice varies greatly based on the variety and where grown, so not all rice and its products are a substantial source of arsenic. For example, rice grown in Asia has been found to be higher in inorganic arsenic than rice grown in the United States. Moreover, if rice and its products are not a major component of the diet, inorganic trivalent arsenic intake likely would not exceed suggested safe dietary intakes (Uthus, 1994).

## Boron

Boron has been shown to be essential for the completion of the life cycle for organisms in all phylogenetic kingdoms. Frogs and zebra fish are animals for which boron has been found essential. Boron has been found to be needed for cleavage of zebra fish zygotes to the two and four cell preblastula stage of development (Eckhart and Rowe, 1999), and for the normal morphogenesis of the frog *Xenopus laevis* (Fort et al., 2002). Boron has not been established as nutritionally essential for humans because it does not have a defined biochemical function. However, an increasing number of cell culture, animal, and human studies indicate that boron in nutritional amounts has beneficial effects in human health.

The beneficial effects of boron have been suggested to occur because boric acid and borates form ester complexes several biologically important sugars, especially ribose (Hunt, 2002). Through the formation of these esters, boron may modify the functions of biochemical entities containing ribose such as S-adenosylmethionine, diadenosine phosphate, oxidized nicotinic adenine dinucleotide ( $\text{NAD}^+$ ), and the  $\text{NAD}^+$  metabolite cyclic adenosine diphosphate c(ADP) ribose (cADPR), which are involved in bone formation and maintenance, cardiovascular health, cancer risk, and neurological function (Nielsen and Eckhart, 2020). Boron has been shown to beneficially affect these processes in animals and humans.

Boron also has been suggested to be beneficially bioactive through forming complexes with phosphoinositide, glycoproteins, and glycolipids that contain *cis*-hydroxyl groups in membranes (Nielsen and Meacham, 2011). This apparently is the basis for boron influencing cellular membrane transport in plants (Bolaños et al., 2004). Thus, boron might have beneficial effects in animals and humans through affecting membrane function such that it influences transmembrane signaling or transmembrane movement of anions, cations, and regulatory molecules. This may be the basis for boron supplementation after boron deprivation beneficially affecting numerous cell and organ functions.

Boron supplementation of animals fed diets made very low in boron (generally  $<0.2 \text{ mg kg}^{-1}$ ) and cells in culture media ( $<0.02 \text{ ng mL}^{-1}$ ) has been found to improve trabecular and alveolar bone growth and maintenance (Nielsen, 2012). Among the cell culture studies, it was found that four mineralization genes and five genes involved in cell proliferation and differentiation were upregulated by boron in osteoblastic cells. Boron also has been found to have a regulatory effect on tuftelin 1 gene that is of primary importance in formation of mineralized structures such as enamel and alveolar bone (Hakki et al., 2021). Cell culture studies have shown the boron can activate transcription factor 4 (ATF4) which is required for the differentiation of osteoblasts, osteogenesis, and thus bone remodeling (Nielsen and Eckhart, 2020).

Since 2008, numerous studies have shown that boron can modulate the response to inflammatory stress. These studies were with animals and cultured cells with induced oxidative or inflammatory stress, and supplementation and epidemiological of individuals with oxidative or inflammatory stress. Because inflammatory and oxidative stress are considered risk factors for atherosclerosis and cardiovascular disease, boron has been implicated as being a beneficial element in respect to these pathologies. In cultured human prostate cells, boron acts as a reversible noncompetitive inhibitor of cADPR leading to decreased endoplasmic  $\text{Ca}^{2+}$  (Kobylewski et al., 2016). The increased  $\text{Ca}^{2+}$  activates nuclear factor erythroid 2 like 2 (Nrf2) which increases mRNA antioxidant response genes. Nrf2 directly regulates the induction of *anti*-inflammatory genes and indirectly counteracts inflammation by modulating reactive oxygen and nitrogen species (Yamada and Eckhart, 2019). Several human studies have shown that boron supplementation reduced serum C-reactive protein (CRP) in individuals with concentrations  $>3.0 \text{ mg L}^{-1}$ , which is considered an indicator of inflammatory stress (Nielsen, 2020). For example, in a double-blind, placebo-controlled clinical study of healthy individuals with serum CRP concentrations  $>3.0 \text{ mg L}^{-1}$ , supplements of 3 or 6  $\text{mg day}^{-1}$  of boron as calcium fructoborate significantly decreased the serum concentrations of inflammatory markers CRP, interleukin-6, and monocyte chemoattractant protein-1 (Rogoveanu et al., 2015).

Modulation of inflammatory and oxidative stress also might be the basis for some of the other beneficial bioactivity reported for boron (Nielsen, 2012). Occasional reports have indicated that boron supplementation can alleviate the symptoms of arthritis. Boron has been inversely associated with prostate, cervical, lung, and breast cancer. Boron has been found to inhibit the growth or proliferation of some types of cultured cancerous prostate cells.

Findings indicating boron can affect cell signaling and calcium ion cellular transport, release and utilization likely explains reports that boron increases insulin sensitivity in chicks and rats, exacerbates gross bone abnormalities in chicks and rats fed low vitamin D diets, made oocytes responsive to progesterone in frogs, and enhanced the estrogen response in rats and humans (Nielsen, 2014). Alteration in cell membrane function also might be the basis for the finding that boron supplementation after boron deprivation resulted in electroencephalograms indicating less drowsiness and increased mental alertness, improved motor speed and dexterity skills, and improved attention and short-term memory in humans (Nielsen, 2014).

Neither a Recommended Dietary Allowance (RDA) nor an AI has been established for boron. Human depletion-repletion experiments found a response to boron supplementation after the consumption of a diet supplying only  $0.2\text{--}0.4 \text{ mg day}^{-1}$ . Human findings indicate that a fasting serum concentration  $<34 \text{ mg L}^{-1}$  and dietary intake of  $<1.0 \text{ mg day}^{-1}$  could be an indication that a person would benefit from an intake of boron of  $\geq 1.0 \text{ mg day}^{-1}$ . Good sources of boron are foods and drinks obtained from plants, including fruits, leafy vegetables, and nuts. Avocados, dried fruits such as raisins, peanuts, pecans, prune juice, grape juice, wine, and chocolate powder are especially rich sources of boron.

The Upper Intake levels (ULs) set by various official bodies indicate boron is a relatively nontoxic element. The United States ULs are, for children aged 1–3 years,  $3 \text{ mg day}^{-1}$ ; and aged 4–8 years,  $6 \text{ mg day}^{-1}$ . The UL for adolescents aged 9–18 years is  $17 \text{ mg day}^{-1}$ , and for adults,  $20 \text{ mg day}^{-1}$  (Institute of Medicine, Food and Nutrition Board, 2001). The World Health Organization, International Program on Chemical Safety (1998) has indicated that a safe UL would be  $0.4 \text{ mg kg}^{-1}$  body weight or  $\sim 28 \text{ mg day}^{-1}$  for a 70 kg person. The European Food Safety Authority (2013) established an Acceptable Daily Intake for boron at  $0.16 \text{ mg day}^{-1}$ , or  $\sim 11.2 \text{ mg day}^{-1}$  for a 70 kg person. The past use of boric acid and borates as food preservatives provides further evidence of the low order of toxicity for boron.

## Bromine

There is evidence that indicates bromine could be considered an essential ultratrace element because a defined biochemical function that occurs in humans has been identified in *Drosophila*; bromide deficiency is lethal to *Drosophila* (McCall et al., 2014). Bromide has been identified as a required co-factor for the peroxidase-catalyzed formation of sulfilimine crosslinks of the collagen IV scaffold in basement membranes needed for tissue development (McCall et al., 2014). A bromoester, 2-octyl 4-bromo-3-oxobutanoate, in cerebrospinal fluid (Gribble, 1999) has been found to induce rapid eye movement sleep and to have *anti*-cholinesterase activity. Insomnia exhibited by some hemodialysis patients has been suggested to be caused by a bromide deficiency (Oe et al., 1981). One laboratory has reported bromide deficiency depresses growth, fertility, hematocrit, hemoglobin, and life expectancy, and increases abortions in goats (Anke et al., 1993b). These findings have not been confirmed in another laboratory. Bromide also

can have beneficial activity by affecting essential halogen metabolism. Bromide has been found to alleviate growth retardation caused by hyperthyroidism in mice and chicks (Huff et al., 1956; Bosshardt et al., 1956), and to substitute for part of the chloride requirement of chicks (Leach, 1963). Bromine apparently is essential to lower forms of life. A bromoperoxidase has been found in marine algae that oxidizes bromide to facilitate the formation of the carbon-bromine bond in bromine-containing compounds (Vilter, 1995), which apparently are essential to the algae.

Because it has not been firmly established an essential ultratrace element, neither a RDA nor an AI has been established for bromide. If bromide is required by humans, the requirement likely would be very low because of its limited number of functions in the body. A low requirement similar to iodine or  $<300 \mu\text{g day}^{-1}$  would be easily met by the typical human bromine intake of  $2\text{--}5 \text{ mg day}^{-1}$ . Bromine ingested as bromide has a low order of toxicity for humans and thus is not of toxicological concern in nutrition. Pharmacological bromide intakes of  $500 \text{ mg--}1.0 \text{ g day}^{-1}$  have been found to cause toxicity.

## Cadmium

Very limited evidence exists to indicate that cadmium can be a beneficial element for humans. In the 1970s, it was reported at scientific conferences that cadmium supplementation to rats fed  $>4 \mu\text{g kg}^{-1}$  diet (Schwarz and Spallholz, 1979) and goats fed  $<20 \mu\text{g kg}^{-1}$  diet (Anke et al., 1978) improved growth. These findings have not been confirmed in a peer reviewed publication. Other isolated reports that suggest cadmium can have positive bioactivity include the finding a cadmium-containing carbonic anhydrase in a marine diatom (Lane et al., 2005). Cadmium can substitute for zinc to maintain optimal growth in marine organisms, which may be related to cadmium having nutrient-like behavior in oceans. If cadmium has any beneficial action in humans and higher animals, it will have to occur at extremely low amounts. Cadmium has a long half-life in the body. Thus, it does not take much of an elevated intake to result in an accumulation that leads to pathology in some organs, especially the kidney. In addition to renal dysfunction, high cadmium intakes have been associated with hypertension, some types of cancer and osteomalacia. The European Food Safety Authority has concluded that a tolerable weekly intake for cadmium is  $2.5 \mu\text{g kg}^{-1}$  body weight, or about  $25 \mu\text{g day}^{-1}$  for a 70 kg person. The typical daily intake is about  $20 \mu\text{g day}^{-1}$ , which would be a safe intake and would easily provide any beneficial effects of cadmium.

## Fluorine

There are no reported unequivocal or specific signs of fluoride deficiency that provide evidence that it is an essential nutrient. Except for unconfirmed studies with goats showing that fluoride deficiency decreased life expectancy and caused pathological changes in the kidney and endocrine organs (Anke et al., 1991; Avtsyn et al., 1993), evidence that has been used to suggest a need for fluoride have come from studies using pharmacological intakes. Pharmacological or supra nutritional doses of fluoride have been shown to prevent tooth caries and bone loss in humans (Jenkins, 1990); improve fertility, hematopoiesis and growth in iron-deficient mice and rats (Messer et al., 1974; Wegner et al., 1976); and prevent phosphorus-induced nephro-calculinosis in rats (Fransbergen et al., 1991).

Although fluoride should not be considered an essential element, it still is accepted as an important beneficial bioactive element for humans. On the basis that it can reduce dental caries without adverse effects, the United States and Canada set AIs for fluoride (Institute of Medicine, Food and Nutrition Board, 1997). These are per day: infants 0–6 months, 0.01 mg and 6–12 months, 0.5 mg; children 1–3 years, 0.7 mg and 4–8 years, 1 mg; adolescents 9–13 years, 2 mg and 14–18 years, 3 mg; and adult women, 3 mg and in men 4 mg. These are supra nutritional intakes that do not generally result in undesirable mottling of teeth. The prevention of dental caries should not be considered an essential function of fluoride because they are not preventing a nutritional deficiency.

Chronic fluoride toxicity through excessive intake mainly through drinking water and industrial exposure has been reported throughout the world. Chronic intakes through water and food providing not much more than  $2.0 \text{ mg day}^{-1}$  can result in barely discernible dental fluorosis or mottled enamel; much higher amounts can result in stained and pitted enamel. Crippling skeletal fluorosis apparently occurs in individuals who ingest  $10\text{--}25 \text{ mg day}^{-1}$  for 7–20 years. The UL ( $\text{mg day}^{-1}$ ) is for ages 0–6 months, 0.7; 7–12 months, 0.9; 1–3 years, 1.3, 4–8 years, 2.2; and  $>8$  years, 10 mg (Institute of Medicine, Food and Nutrition Board, 1997).

## Germanium

Most evidence indicating that germanium has beneficial biological activity has been obtained with supra nutritional or pharmacological amounts. Compared to diets containing about  $1.0 \text{ mg kg}^{-1}$ , a germanium supplement of  $30 \text{ mg kg}^{-1}$  altered bone and liver mineral composition and decreased tibial DNA in rats (Seaborn and Nielsen, 1994), and a germanium dioxide supplement of  $10 \text{ mg kg}^{-1}$  stimulated growth in rats (Venugopal and Luckey, 1978) and chicks (Li et al., 1993). These findings suggest that the beneficial activity of germanium occurs not through an essential function but through substituting or enhancing the function of another essential nutrient or through modification of them at the intestinal level. Pharmacological amounts of some organic germanium compounds have been promoted in the dietary supplement industry as having *anti-tumor* activity in addition to having therapeutic effects on rheumatoid arthritis, osteoarthritis, and osteoporosis (Cho et al., 2020). These effects have been attributed to the

organic supplements having *anti*-inflammatory and immune stimulating effects. Although the published reports indicate that inorganic and some organic germanium compounds may have beneficial activity in higher animals and humans, they do not provide evidence that germanium is an essential nutrient.

Although germanium is thought to have a low order of toxicity because of its diffusible state and rapid elimination from the body, inappropriate intakes can cause toxicity. Rats fed  $5 \mu\text{g mL}^{-1}$  of water for 36 months exhibited impaired kidney and liver function. Although organic forms of germanium touted in the supplement industry are less toxic than inorganic forms, some individuals consuming high amounts of organic germanium supplements contaminated with inorganic germanium have died from kidney failure (Tao and Bolger, 1997). Until more knowledge is obtained about the intakes of various forms of germanium that are toxic, they probably should not routinely greatly exceed those found in a typical diet. The typical daily dietary intake of germanium is 0.4–1.5 mg.

## Lead

One research group has suggested that lead may be essential in ultratrace amounts because  $30 \text{ ng g}^{-1}$  versus  $30 \mu\text{g g}^{-1}$  in the diet resulted in apparent deficiency signs in pigs (Kirchgessner et al., 1991) and rats (Reichlmayr-Lais and Kirchgessner, 1991). These signs were depressed growth; anemia; elevated serum cholesterol, phospholipids, and bile acids; disturbed iron metabolism; decreased liver glucose triacylglycerols, LDL-cholesterol and phospholipids; increased liver cholesterol; and altered blood and liver enzymes. Most of these findings have not been confirmed by another laboratory. Another group did report that lead alleviated iron deficiency in young rats (Uthus and Nielsen, 1988). Thus, many of the deficiency signs reported for lead might have been the result of a beneficial effect of on a disordered iron metabolism or deficiency, not through an unfilled essential function.

Although lead may be beneficial at low intakes under certain conditions, the concern about lead toxicity inhibits it from being recommended at any intake. Lead is considered a significant environmental pollutant because the past use of lead in paints, plumbing, food can solder, and fuel additives have resulted in it still being present in the environment. When blood concentrations reach  $10 \mu\text{g dL}^{-1}$ , lead adversely affects bone and mental development and blood pressure (Agency for Toxic Substances and Disease Registry, 2021). Anemia, nephrotoxicity, and more overt neurological impairments occur when concentrations exceed  $30 \mu\text{g dL}^{-1}$ .

## Lithium

In the early 1990s, two reports of induced lithium deficiency appeared. Rats deprived of lithium exhibited depressed fertility, birthweight, litter size, and weaning weight (Pickett and O'Dell, 1992). Goats exhibited depressed fertility, birthweight, and life span in addition to alteration in activity of several liver and blood enzymes (Anke et al., 1990). These findings are not sufficient to ascribe lithium as essential, but they do indicate that lithium could have beneficial biological action in nutritional amounts. In vitro findings supporting this conclusion are lithium stimulating growth of some cultured cells (Rybak and Stockdale, 1981), and having insulin mimetic action (Rossetti et al., 1990). Lithium is best known as a pharmacological agent in treating manic-depressive psychosis. Its ability to affect mental function might be the basis for the finding that the incidence of violent crimes is lower in areas with high-lithium drinking water (Schrauzer and Shrestha, 1990; Schrauzer et al., 1992).

The amount of lithium needed to be beneficial in animal experiments suggest that less than  $25 \mu\text{g day}^{-1}$  would provide these benefits to humans, which is much less than the usual dietary intake of  $200\text{--}600 \mu\text{g day}^{-1}$ . Lithium is not a particularly toxic element, but the therapeutic dose ( $\sim 500 \text{ mg day}^{-1}$ ) needed to treat psychiatric disorders is close to concentrations to that inducing mild toxicity signs. These signs include gastrointestinal disturbances, muscular weakness, tremor, drowsiness, and a dazed feeling. Severe toxicity results in coma, muscle tremor, convulsions, and death.

## Molybdenum

The evidence for the essentiality of molybdenum is substantial and conclusive. Molybdenum functions as a cofactor in enzymes aldehyde oxidase, sulfite oxidase, xanthine oxidase, and mitochondrial amidoxime-reducing component (Belaidi and Schwarz, 2016). However, only an isolated human case of nutritional molybdenum deficiency has been reported (Abumrad et al., 1981). A patient with Chron's disease receiving long-term parenteral nutrition exhibited high methionine and low uric acid in blood, high oxypurines and low uric acid in urine, and very urinary sulfate excretion. The patient had mental disturbances that progressed to coma. Intravenous administration of ammonium molybdate alleviated the mental disturbances and reversed the sulfur handling and uric acid defects. Other than this case, there have been no reports of a molybdenum deficiency induced through a low dietary intake. However, rare mutations in genes causing encoding errors involved in molybdenum cofactor synthesis can result in a severe deficiency syndrome (Belaidi and Schwarz, 2016). These genetic mutations result in the loss of all molybdenum cofactor enzymes. The deficiency usually diagnosed shortly after birth results in a marked loss of white matter in the brain. Biochemical changes include elevated urinary sulfite and S-sulfocysteine, hypouricemia, elevated plasma S-sulfonated transthyretin and deficient

molybdoenzyme activity in fibroblasts. Most patients die in childhood; some survive only a few days. Mild cases have been reported, perhaps because of a low residual activity of a mutant protein.

Although a dietary molybdenum deficiency in a healthy individual has not been reported, DRIs have been set ([Institute of Medicine, Food and Nutrition Board, 2001](#)) for this element based on balance studies performed in 1995. These studies found that adults achieve molybdenum balance on an intake of  $25 \mu\text{g day}^{-1}$  ([Turnland et al., 1995](#)). Because some foods might inhibit the bioavailability of molybdenum, a bioavailability of 75% was used to set an EAR of  $34 \mu\text{g day}^{-1}$  for adults. The RDA was set as the EAR+30% to get  $45 \mu\text{g day}^{-1}$  for adults. DRIs for children were extrapolated from the adult values using metabolic weight ( $\text{kg}^{0.75}$ ). The RDAs set in  $\mu\text{g day}^{-1}$  were for infants 0–6 months, 2, and 7–12 months, 3; children 1–3 years, 17, and 4–8 years, 22; for adolescents 9–13 years, 34, and 14–18 years, 34 (females) and 43 (males).

Pulses, especially various forms of beans, are rich sources of molybdenum. Whole grains, cereals, and organ meats also are good sources. Moderate sources include dark leafy and Brassica vegetables and milk and milk products. Daily intakes have been found to usually exceed the RDAs for molybdenum ([Novotny and Peterson, 2018](#)). In the United States, mean intakes of  $76 \mu\text{g day}^{-1}$  for women and  $109 \mu\text{g day}^{-1}$  for men have been reported. Higher mean intakes in other countries have been found, including  $225 \mu\text{g day}^{-1}$  in Japan and  $275 \mu\text{g day}^{-1}$  in France.

Molybdenum is a relatively low toxicity element, which results in a lack of toxicity data for humans. Most relevant toxicity data have come from nonruminant animal studies that used milligram doses instead of nutritional microgram doses of molybdenum. Based largely on animal findings, an UL of  $2000 \mu\text{g}$  ( $2.0 \text{ mg}$ )  $\text{day}^{-1}$  was set for adults in the United States ([Institute of Medicine Food and Nutrition Board, 2001](#)). The UL (in  $\mu\text{g day}^{-1}$ ) set for children was: 1–3 years, 300, and 4–8 years, 600; for adolescents 9–13 years, 1100, and 14–18 years, 1700.

## Nickel

Nickel is essential for plants and some bacteria. In these lower forms of life, nickel is an essential component of eight enzymes; seven of these enzymes are involved in the use or production of the gases ammonia, hydrogen, carbon monoxide, carbon dioxide, methane and oxygen ([Ragsdale, 2009](#)). The other enzyme converts methylglyoxal to lactate ([Fabiano et al., 2015](#)). A mammalian nickel-dependent enzyme has not been identified. Thus, nickel has not been established as an essential nutrient for higher animals and humans. However, nickel deprivation studies with several experimental animal models have shown that nickel has beneficial biological activity, and possibly an essential function ([Nielsen, 2006](#)). Reported effects of deprivation include impaired reproduction (decreased conception rate and sperm production and motility), impaired bone health (decreased strength and altered composition), altered carbohydrate and lipid metabolism (increased plasma lipids and decreased serum glucose), impaired iron status and utilization, altered thyroid metabolism, exacerbated vitamin B<sub>12</sub> deficiency with high blood homocysteine, exacerbated renal damage and high blood pressure induced by a high-salt diet, and impaired special senses of vision, olfaction, and taste.

Several suggestions have been given for the beneficial biological activity of nickel ([Nielsen, 2021](#)). These include affecting the formation or action of a functional gaseous molecule, performing actions normally done by iron, influencing intracellular calcium content and its signaling, and affecting the intestinal microbiome. Support for these suggestions include the following ([Nielsen, 2020](#)). Nickel has a stabilizing effect on hypoxia-inducible factor-1 $\alpha$  protein and activates hypoxia-inducible gene expression, which affects glucose metabolism and osteogenesis. Nickel also potently induces the activity of heme oxygenase that produces carbon monoxide, an activator of guanylate cyclase that produces cyclic guanylate monophosphate (cGMP). The cGMP signal transduction system has a role in vision, taste, smell, blood pressure control, kidney function, and sperm motility, all which are affected by nickel deprivation. The essential role of nickel in some microorganisms that may exist in the intestinal microbiome possibly results in the formation or function of substances that are beneficial to higher animals and humans.

Neither RDAs or AIs have been established for nickel. Based on animal findings, a beneficial intake for humans could be  $<100 \mu\text{g day}^{-1}$  and has been suggested to be as low as  $25\text{--}35 \mu\text{g day}^{-1}$  ([Nielsen, 2021](#)). Most individuals achieve this intake because typical daily dietary intakes for nickel are  $70\text{--}400 \mu\text{g day}^{-1}$ . Foods of plant origin are generally high in nickel while foods of animal origin are low. Rich sources of nickel include chocolate, nuts, dried beans, and peas, and grains. Diets high in these foods could supply  $>900 \mu\text{g day}^{-1}$ .

Life-threatening toxicity of nickel through oral intake is unlikely because intestinal absorption with food is low and absorbed nickel is rapidly excreted in the urine. Nickel has little tendency to accumulate in tissues of animals and humans. Based on extrapolation from animal studies, the ULs set for nickel as soluble nickel salts ( $\text{mg day}^{-1}$ ) in the United States are for children aged 1–3 years, 0.2; 4–8 years, 0.3; and 9–13 years, 0.6; and for adults, 1.0 ([Institute of Medicine, Food and Nutrition Board, 2001](#)).

## Rubidium

In the 1990s, it was reported that rubidium supplementation alleviated depressed food intake, milk production, growth, and life expectancy in goats fed a diet low in rubidium ([Anke et al., 1993a](#)). Also, it was reported that rubidium supplementation of rats fed a low rubidium diet exhibited tissue mineral concentrations in a manner suggesting an effect on potassium, phosphorus, calcium, and

magnesium (Yokoi et al., 1996). Neither of these reports have been confirmed. Rubidium can substitute for some roles performed by potassium. This might have been the basis for the limited reports about the beneficial effects of rubidium, which do not support it being essential. Based on animal experiments, any beneficial intake of rubidium would be less than  $200 \mu\text{g day}^{-1}$ , which would be easily met by the typical daily dietary intake of  $1\text{--}5 \text{ mg day}^{-1}$ . Rubidium is a relatively non-toxic element and thus is not of toxicological concern from the nutritional point of view. Increasing the normal body content of rubidium (0.36 g) by 50–100 times does not have any noticeable adverse effect.

## Silicon

Silicon is nutritionally essential for some lower forms of life, including diatoms, radiolarians, some sponges, and some plants (Carlisle, 1997). Silicon has not been established as essential for humans because it lacks a clearly defined biochemical function, and a deficient intake has not shown to prevent the life cycle. However, cell culture, animal, and human studies indicate that silicon in nutritional amounts can be beneficial, especially for bone and connective tissue function. Beneficial effects of silicon likely occur because it easily forms stable complexes with polyols that have at least four hydroxyl groups (Kinrade et al., 1999). Such polyols include hexosamines, and ascorbate used to form glycosaminoglycans, mucopolysaccharides, and collagen, which are involved in connective tissue formation and stabilization and bone formation. The complexing of silicon with hydroxylated molecules in the bone growth region apparently attracts calcium to form apatite. After calcification, silicon is lost, which explains the finding that silicon is much higher in under-mineralized than mineralized bone (Jugdaohsingh et al., 2015). Silicon in nutritional amounts may also be beneficial by inhibiting detrimental effects of other minerals such as aluminum, which has been associated with impaired cognitive function and bone health. This apparently occurs through the formation of non-metabolizable aluminosilicates.

Human studies indicating that silicon in nutritional amounts can have beneficial effects include the finding that hip bone density was higher in men and premenopausal women with intakes of  $>40 \text{ mg day}^{-1}$  than those with intakes  $<14 \text{ mg day}^{-1}$  (Jugdaohsingh et al., 2004). Also, energy-adjusted silicon intakes have been found to be negatively associated with urinary markers of bone resorption and positively associated with a marker of bone formation in a study where the lowest quartile of silicon intake was  $16 \text{ mg day}^{-1}$  and the highest quartile was  $31.5 \text{ mg day}^{-1}$  (Macdonald et al., 2012). Support for silicon having a beneficial effect on connective tissue is the finding that a silicon supplement of  $10 \text{ mg day}^{-1}$  as choline-stabilized orthosilicic acid for 20 weeks improved photodamaged skin and decreased hair and nail brittleness (Spector et al., 2008).

Animal and human data have been judged too limited to establish DRIs for silicon. In the Framingham Offspring Cohort study (Jugdaohsingh et al., 2004), the highest hip bone mineral density occurred in premenopausal women and men, respectively, with quintiles ranging from  $30.2$  to  $63.2 \text{ mg day}^{-1}$  and  $34.4$ – $118.0 \text{ mg day}^{-1}$  compared to the lowest quintile intakes ranging from  $7.1$  to  $16.7 \text{ mg day}^{-1}$  and  $18.8 \text{ mg day}^{-1}$ . These findings, in addition to extrapolation from animal data and questionable balance data suggest that a beneficial intake of silicon may be near  $25 \text{ mg day}^{-1}$  (Nielsen, 2006). The highest concentrations of silicon are found in cereals and cereal products, especially those less refined. Substantial amounts are also found in beans, spinach, dried fruits, bananas, and red lentils. The silicon in barley and hops is solubilized during the brewing process, which makes beer a rich source of silicon. Silicon is added to processed foods for anticaking, thickening, and stabilizing purposes. These forms of silicon are not readily absorbed by the gastrointestinal tract and should not be considered providing beneficial intakes of silicon. There are no reports of silicon toxicity through excessive dietary intake for people with normal renal function.

## Strontium

There is no conclusive evidence that strontium is essential for higher animals and humans. Strontium deprivation has been reported to depress growth, impair calcification of bones and teeth, and increase dental caries in rats and guinea pigs (Rygh, 1949), but these findings have not been confirmed. The findings might be explained by strontium, like fluoride, in supplemental or pharmacological amounts having beneficial effects on teeth and bone (Marie et al., 2001). Strontium ranelate in pharmacological amounts has been found to promote bone growth, prevent fractures in both spine and hip, and increase bone mineral density in the spine and femur of humans (O'Donnell et al., 2006). It is thought that the beneficial effects of strontium result from replacing or substituting for calcium in some of its biological roles.

Unfortunately, strontium ranelate in therapeutic doses increases the risk for venous thromboembolism, pulmonary embolism, and myocardial infarction, which has restricted its use (O'Donnell et al., 2006). There is no evidence that strontium provided by other forms in nutritional amounts by dietary means evoke such toxicological effects.

DRIs have not been established for strontium. Because beneficial effects of strontium have been found using non-nutritional amounts, it is difficult to give a dietary intake recommendation for this element. However, because strontium has been associated with bone and teeth health, assuring the consumption of foods relatively rich in strontium, such as whole grains and unpeeled fruits and vegetables would be prudent action. The typical daily dietary intake of strontium of  $1.5\text{--}3 \text{ mg day}^{-1}$  probably provides the possible benefits of nutritional amounts of strontium.

## Tin

In 1970, it was reported that tin deprivation depressed growth in rats (Schwarz et al., 1970); the diet used in this study was subsequently found to be inadequate in other nutrients including riboflavin. In 1990, another report appeared in which rats fed  $17 \text{ ng g}^{-1}$  tin versus  $1.99 \text{ } \mu\text{g g}^{-1}$  tin in the diet exhibited depressed growth, response to sound, and feed efficiency (Yokoi et al., 1990). The tin deprivation of the rats also altered copper, iron, manganese and zinc concentrations in the heart, muscle, and tibia. These findings have not been subsequently confirmed. Thus, the limited data available do not support tin essentiality and make it uncertain whether tin can have beneficial biological activity in nutritional amounts in humans. In addition, it is difficult to indicate a beneficial intake. However, any such intake is likely to be easily met by the usual dietary intake of  $1\text{--}40 \text{ mg day}^{-1}$  by humans. Tin is a relatively nontoxic element. However, because  $50 \text{ mg day}^{-1}$  of tin was found to detrimental to zinc and copper metabolism, routine intakes near this amount probably should be avoided.

## Vanadium

Vanadium is essential for some lower forms of life (algae, seaweeds, a lichen, and a fungus) where it is a component of the enzymes bromoperoxidase, iodoperoxidase, and chloroperoxidase (Crans et al., 2004). Vanadium reacts with  $\text{H}_2\text{O}_2$  to form a dioxygen species, which is an intermediate in the formation of the carbon-halogen bond. Vanadium has not been found to meet the criteria for essentiality for higher animals or humans but does have beneficial effects in supra nutritional or pharmacological and perhaps nutritional intakes. Animals deprived of vanadium ( $2\text{--}10 \text{ ng kg}^{-1}$  diet) responded to vanadium supplements of  $1\text{--}2 \text{ } \mu\text{g kg}^{-1}$  diet. The deprivation signs in goats were swollen joints, skeletal deformations, and decreased life span (Anke et al., 1989) and in rats were altered thyroid hormone metabolism, impaired reproduction and altered bone morphology (Uthus and Nielsen, 1990; Nielsen, 1998). These findings have not been subsequently confirmed. The supra nutritional or pharmacological beneficial action of vanadium that has received the most attention is its ability to mimic insulin (Marzban and McNeill, 2003). The inhibition of protein tyrosine phosphatase enzymes may be the basis for many of the reported beneficial responses to nutritional and supra nutritional intakes of vanadium (Hulley and Davison, 2003). However, vanadium affects other phosphorous associated enzymes including glucose-6-phosphate dehydrogenase, adenosine triphosphatase, phosphodiesterases, and phosphomutases in metabolic diseases (Treviño et al., 2019).

No studies have defined an intake at which nutritional intakes would have a beneficial effect in humans. As a result, neither an RDA nor AI has been established for vanadium. Based on animal findings, a daily intake of  $10 \text{ } \mu\text{g}$  probably would provide any nutritional benefits of vanadium. The typical daily dietary intake of vanadium is  $12\text{--}30 \text{ } \mu\text{g day}^{-1}$ . Good sources of vanadium include grains, mushrooms, parsley, and shellfish. An UL has been set for vanadium in the United States (Institute of Medicine, Food and Nutrition Board, 2001). Based on evidence for renal toxicity in animals, the UL for adults was set at  $1.8 \text{ mg day}^{-1}$ ; no UL was set for other age groups.

## Summary

The current knowledge about the essentiality, biochemical function, beneficial biological activity, possible deprivation signs, beneficial or required intakes, toxicity and nutritional importance of 16 ultratrace elements are presented. Emerging evidence indicates that several of these elements, including boron, molybdenum, nickel, silicon, vanadium, have beneficial bioactivity in nutritional amounts. This bioactivity may have ameliorative or preventive effects on chronic diseases such as cardiovascular disease, cancer, diabetes, and osteoporosis. Some elements, including fluoride and lithium in supra nutritional amounts have beneficial bioactivity. Other ultratrace elements, including bromine, germanium, molybdenum, rubidium, strontium, and tin might have beneficial activity in nutritional amounts that are normally provided by the typical diet. Although there is evidence for beneficial activity in ultratrace amounts for elements aluminum, arsenic, cadmium, and lead, they are of more concern about their toxicity. Thus, based on usual or typical intakes and strength of evidence for beneficial activity, only boron, molybdenum, nickel, silicon, and vanadium are ultratrace elements that presently should receive attention about achieving intakes needed for optimal beneficial effects. Because of reports that it is not uncommon for individuals not achieving beneficial intakes of boron (Nielsen and Meacham, 2011) and silicon (Jugdaohsingh et al., 2004), most attention should be directed toward boron and silicon. These individuals most likely have diets low in fruits, vegetables, and whole grains. If dietary modification cannot achieve beneficial intakes, these amounts of boron and silicon could be achieved by using supplements. Individuals with diets containing recommended amounts of pulses, nuts, and grains should have no concern about achieving beneficial intakes of molybdenum, nickel, and vanadium. For those with difficulty in consuming those types of foods, multi-mineral and vitamin supplements are available that provide molybdenum in recommended amounts and small amounts of nickel and vanadium.

### Key points

- Vitamin A (VA) deficiency results from inadequate intake of foods rich in preformed VA or its provitamin A (proVA) carotenoid precursors, often combined with inadequate breastfeeding and frequent infections.
- Approximately 30% of young children and ~15% of pregnant women in low-to-middle income countries are affected by VA deficiency.
- VA deficiency increases the risk of severe infection and consequent mortality and, when severe, can cause xerophthalmia—the eye disease of VA deficiency.
- VA deficiency can be prevented by several, complementary interventions: semi-annual supplementation with a large, oral dose of VA; fortification of staple food items; biofortification of staple crops with carotenoids; promotion of adequate and extended breastfeeding; and dietary diversification.

### Introduction

Vitamin A (VA) is an essential nutrient in the human diet. Deficiency can develop when its intake is chronically low and, when sufficiently severe, manifest as eye disease. Night blindness, the mildest ocular stage of xerophthalmia, has been recognized since antiquity, as depicted in *bas-relief* on the wall of the Egyptian pyramid in Saqqara. Hippocrates in the 4th century BC recognized and treated the condition with animal liver (a major dietary source of VA). In the 18th and 19th centuries, eye signs of VA deficiency were linked to a poor diet, as cod liver oil emerged for treatment, but the active compound remained unknown. After years of animal research, “fat soluble factor A” was described in 1913, an ether-soluble compound in butter and egg yolk essential for

growth, general health and vision; thus, launching a century of discovery, leading to the vitamin's chemical synthesis, advances in learning its metabolic, morphological, epithelial, immune, hematopoietic and osteoid functions, and a global pursuit to assess and prevent VA deficiency and its public health consequences.

### Vitamin A deficiency

Multiple methods are available to assess VA status (Tanumihardjo et al., 2016). Deficiency in populations is most often determined by plasma concentrations of retinol, or its carrier retinol binding protein (RBP4), or less often via indirect estimation of hepatic or total body nutrient stores, that likely precede functional consequences of deficiency. In uncomplicated hypovitaminosis A, plasma or serum retinol is homeostatically controlled until body (primarily liver) stores become lower, after which the plasma retinol concentration declines. Plasma retinol also decreases in response to an acute inflammatory response or chronic inflammation, in parallel with raised concentrations of positive acute phase proteins, increased tissue VA delivery, reduced hepatic mobilization via retinol-binding protein, and increased urinary loss. Plasma retinol gradually normalizes during recovery from infection in the presence of adequate hepatic stores. If VA is deficient, infection can further deplete stores. VA deficiency is generally diagnosed at a serum retinol concentration below  $0.70 \mu\text{mol L}^{-1}$  (or  $20 \mu\text{g dL}^{-1}$ ), below which often 15% to >50% of concentrations lie among individuals sampled in a VA-deficient population, compared to <2% in well-nourished societies. A serum retinol level  $<0.35 \mu\text{mol L}^{-1}$  ( $10 \mu\text{g dL}^{-1}$ ) indicates severe deficiency, while concentrations between  $0.70$  and  $1.05 \mu\text{mol L}^{-1}$  is often characterized as marginal or low status. Decrements in serum retinol below  $0.70 \mu\text{mol L}^{-1}$  can be expected to increase the severity of xerophthalmia and infectious illness. Breast milk retinol may also serve as an indicator, with low milk retinol serving as a measure of both maternal status and intake inadequacy of breastfed infants. Dried blood retinol, determined to provide reasonably comparable data to serum, has periodically been collected and analyzed to assess population prevalence of VA deficiency. A test, occasionally deployed, that indirectly assesses total liver retinol reserves, called a modified (from an earlier version) relative dose response test, involves measuring the dehydroretinol (VA<sub>2</sub>-acetate, a different form of VA) concentration in serum collected 5 h following a small challenge dose. As the orally administered form of VA<sub>2</sub> is released from the liver carried by RBP4 that accrues in the liver during VA deficiency, a high concentration relative to serum retinol provides a qualitative indication of a population that is depleted. Increasingly, stable isotopes of VA (e.g., <sup>2</sup>H- or <sup>13</sup>C-labeled retinyl acetate) are being employed to assess total body stores of VA of both individuals and groups. Retinol isotope dilution is a method that involves the administration of a small dose of the isotope, followed by a blood draw 4–14 days later to measure the ratio of labeled to unlabeled VA.

### VA deficiency disorders (VADD)

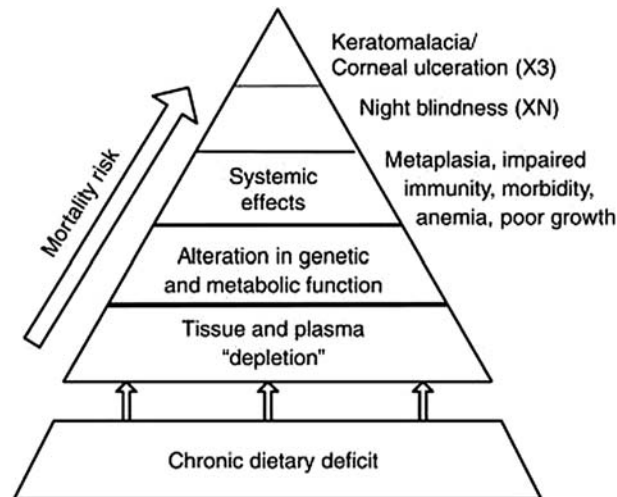

VA deficiency disorders (VADD) can be defined as pathophysiological consequences attributed, in part or whole, to inadequate VA nutriture, as illustrated in Fig. 1. As VA is essential to maintain normal retinal function, and in regulating cellular proliferation, differentiation and energy utilization, VADD can range from deficiency-induced tissue, organ or system dysfunction to disease conditions. Given VA is essential for photoreceptor function, night blindness represents a VADD. As effects of deficiency readily occur in rapidly dividing, bipotential cells such as epithelial linings leading to metaplasia and keratinization of mucosal surfaces, disorders include conjunctival and corneal xerosis, as well as metaplasia and mucociliary and immune defects throughout the respiratory, genitourinary and gastrointestinal tracts that may increase risk of infection (Sommer and West, 1996). Exposure to deficiency during the embryonic and fetal periods may effect epigenetic changes that permanently alter developing cell populations and organ systems that may impair lung, innate and adaptive immune or other organ systems with adverse health effects later in life.

### Xerophthalmia

Conjunctival and corneal epithelia deprived of VA undergo keratinizing metaplasia (Sommer, 1995; Sommer and West, 1996). Columnar epithelial cells on the ocular surface become squamous and mucus-producing goblet cells disappear, providing the histopathologic mechanisms for deficiency-induced xerotic (drying) changes to the ocular surfaces. VA deficiency is also required for rod vision in dim light. VA deficiency-induced night blindness often occurs with histopathologic changes on the ocular surface. Thus, night blindness and clinical eye signs both are listed under one xerophthalmia classification scheme (Table 1).

### Night blindness (XN)

VA, as retinaldehyde, is an essential photosensitive pigment in rod cells of the retina that respond to light (become “bleached”) by releasing the VA ligand from the protein rhodopsin, thereby initiating neural impulses to the brain that permits vision under conditions of low illumination. The utilization and recycling of VA in this process is known as the visual (or retinoid) cycle. Hypovitaminosis A restricts rhodopsin production that, in turn, raises the scotopic (low light) visual threshold. Gradually, a perceptive threshold is reached that leads to recognition of XN, the earliest symptom of xerophthalmia. It is marked by an inability to move about in the dark. Young children between 1 and 5 years of age and pregnant women appear to be at greatest risk of XN. Where VA deficiency is endemic, there is often a local term for XN that translates into “evening” or “twilight” blindness or “chicken

**Fig. 1** Concept of VADD, due primarily to underlying chronic dietary deficit in preformed VA and proVA carotenoids. Reproduced from West (2002).

**Table 1** World Health Organization (WHO) Classification and minimum prevalence criteria for xerophthalmia and VA deficiency as a public health problem.

Definition (code)	Minimum prevalence (%)	Highest-risk period
<b>Children 1–5 years of age</b>		
Night blindness (XN)	1.0	2–6 yr
Conjunctival xerosis (X1A)	–	–
Bitot's spots (X1B)	0.5	2–6 yr
Cornea xerosis (X2)/corneal ulceration (X3A)/keratomalacia (X3B)	0.01	1–3 yr
Xerophthalmic corneal scar (XS)	0.05	>1 yr
Deficient serum retinol ( $<0.70 \mu\text{mol L}^{-1}$ )	15.0	<5 yr
<b>Pregnant/lactating women</b>		
XN during most recent pregnancy	5.0	Third trimester
Low serum retinol ( $<1.05 \mu\text{mol L}^{-1}$ )	20.0	Third trimester

Source: Adapted from Sommer and Davidson (2002). Alpha-numeric characters in ( ) denote the WHO classification scheme for xerophthalmia.

eyes" (chickens lack rod cells and also cannot see at night), making the condition readily detectable by history. XN typically disappears within 24–48 h of VA treatment, while gestational XN resolves spontaneously shortly after child birth and expulsion of the placenta, likely due to reduced metabolic demands for VA.

#### Conjunctival xerosis (X1A) and Bitot's spots (X1B)

Early xerosis of the conjunctiva can be detected by filter paper impression cytology, showing distorted, enlarged, and noncontiguous sheaths of epithelial cells, and disappearance of goblet cells. In advanced VA deficiency, confluent xerosis appears clinically as a dry, unwettable surface of the bulbar conjunctiva (X1A). The affected areas are usually overlaid with superficial white, cheesy, or foamy patches of triangular or oval shape that consist of desquamated keratin and bacteria (often *Bacillus xerosis*). These are known as Bitot's Spots (designated X1B). They are nearly always bilateral, found temporal (and, in more advanced cases, also nasal) to the corneal limbus and is a sign more reliably diagnosed than X1A. X1B are not blinding but are reflective of chronic moderate-to-severe systemic depletion of VA (Sommer and West, 1996).

#### Corneal xerophthalmia (X2/X3)

Corneal xerophthalmia is an ocular manifestation of severe VA deficiency. The earliest corneal lesions appear as superficial punctate defects, evident with a slit lamp, that with advanced deficiency become more numerous and concentrated. The cornea is considered xerotic (X2) when the keratopathy covers large areas of its surface rendering a hazy, nonwettable, lusterless, and irregular appearance on handlight examination. Stromal edema may be present. In more severe cases, thick, elevated X2 plaques may form. Usually both eyes are affected. X3A can be sharply demarcated, round, or oval defects that are usually shallow but may also perforate the cornea. Healed ulcers form a leukoma (scar) or adherent leukoma if the iris has plugged the perforated ulcer. Most

**Fig. 2** Keratomalacia. Reproduced from [Sommer \(1995\)](#).

ulcers occur peripheral to the visual axis and, thus, may not threaten central vision if promptly treated. X3B refers to a full-thickness softening and necrosis of the corneal stroma that can cause protruding, opaque, yellow-to-gray lesions (**Fig. 2**). These may reduce or slough off leaving a descemetocoele following VA treatment. X3B usually impairs vision in the involved eye although the degree of visual loss depends on the location, thickness, and extent of corneal necrosis and the resultant scar. Owing to the generally malnourished and ill state of children with corneal xerophthalmia, fatality of hospitalized cases ranges from 4% to 25%.

### Other VADD: infection, anemia and poor growth

#### Infection

A synergism exists between hypovitaminosis A and infection, each exacerbating the other, representing a classic “vicious cycle.” In this context, infection may be considered both a cause of VA deficiency and, in terms of severity and sequelae, a consequence, or “disorder.” Xerophthalmia or severe hyporetinolemia have been consistently associated in cross-sectional assessment with higher risks of diarrhea, fever, and other infections though an acute phase reaction to infection can lower the circulating retinol level and directionality can be difficult to establish.

VA deficiency presumably raises risk of infection by compromising “barrier” epithelial defenses and impairing regulatory innate, cell-mediated and antibody-mediated immune mechanisms. Retinoic acid is also involved in suppressing pathological and autoimmune responses to inflammation, which could underlie its role in controlling severity of infection ([Stephensen and Lietz, 2021](#)). Epidemiological corollary evidence exists. For example, Indonesian preschoolers with mild xerophthalmia were twice as likely to develop acute respiratory infection and three times more likely to develop diarrhea over subsequent 3–6-month periods. VA-deficient children are also more likely to die, as seen in Indonesia (**Fig. 3**), where risk of mortality rose with increased severity of mild eye signs ([Sommer and West, 1996](#); [Palmer et al., 2017](#)). Measles is an illness that can deplete VA nutriture which, in malnourished children, can lead to corneal xerophthalmia, more severe complications, and a high risk of death. VA deficiency may exacerbate severity of middle ear infection that may consequently increase the risk of hearing loss ([Schmitz et al., 2012](#)).

#### Anemia and poor growth

Children with xerophthalmia tend to be anemic relative to peers without eye disease. VA supplementation can often improve hematological indicators of iron status and reduce anemia. Mechanisms involved in this interaction are not clear but could involve enhanced iron absorption, storage, and transport as well as direct effects on hematopoiesis in the presence of adequate iron stores.

VA deficiency decelerates growth in animals and has been observed to be associated with both stunting and wasting malnutrition in children, possibly reflecting plausible roles for the vitamin in osteogenesis and energy metabolism. Trials, however, have failed to show consistent effects of VA supplementation on child growth, possibly due to variations in the extent of infectious morbidities, seasonality in dietary protein and energy adequacy across populations studied, exclusion of xerophthalmic (most VA deficient) children in growth studies, or other nutritional deficiencies limiting growth.

### Epidemiology

The epidemiology of VA deficiency is mostly understood in relation to hyporetinolemia and xerophthalmia (**Table 1**), especially the more prevalent, milder stages of XN and X1B. Preschool children and women of reproductive age are at highest risk of being VA

**Fig. 3** Risk of mortality among ~3500 Indonesian preschool children by ocular status at the outset of each 3-month interval. RR, relative risk of mortality. Adapted from Sommer et al. (1983).

deficient, affecting an estimated ~30% and ~15%, respectively, based on population-based estimates of serum retinol (or surrogate RBP4) concentrations  $<0.70 \mu\text{mol L}^{-1}$  (or  $20 \mu\text{g dL}^{-1}$ ), respectively, best understood in terms of how deficiency distributes by person, place, and time (World Health Organization, 2009; Stevens et al., 2015).

#### Person (high-risk groups)

Despite uncertainty about an appropriate cutoff for hyporetinolemia in the 1st months of life, infants in all settings are born with low VA stores. Infants and young children rely on VA intake from breast milk and complementary foods to build stores. If these are inadequate, as they are in many low-income settings, deficiency can persist throughout early childhood. Most recent global estimates suggest that VA deficiency (serum retinol  $<0.70 \mu\text{mol L}^{-1}$ ) afflicts approximately 30% of preschool-aged children in the developing world. An estimated 1% of these exhibit XN.

The current extent of xerophthalmia is less known, as few national ophthalmological surveys have been conducted since the 1990s, although case and local area reports serve as reminders that VA deficiency can recur. Milder stages of xerophthalmia typically affect children beyond the 1st year of age, as breast milk is replaced by less nutritious food from the household diet. Boys tend to be at higher risk, possibly reflecting gender differences in dietary practices. Risk of corneal xerophthalmia (Fig. 2) peaks in the second through 4th years of life, typically following epidemics of acute infection such as severe measles. Informally, it appears that numbers of severe xerophthalmia cases globally have dropped in high-risk populations, likely due to the broad reach of semiannual VA supplementation, which reduces risk of corneal disease by ~90%, and decades of steadily increasing coverage of vaccination against measles (Sommer and West, 1996). Effects of the COVID-19 pandemic on corneal xerophthalmia are unknown, though could be a concern amid widespread suspension of measles vaccinations and calls in recent years to limit semi-annual VA supplementation campaigns.

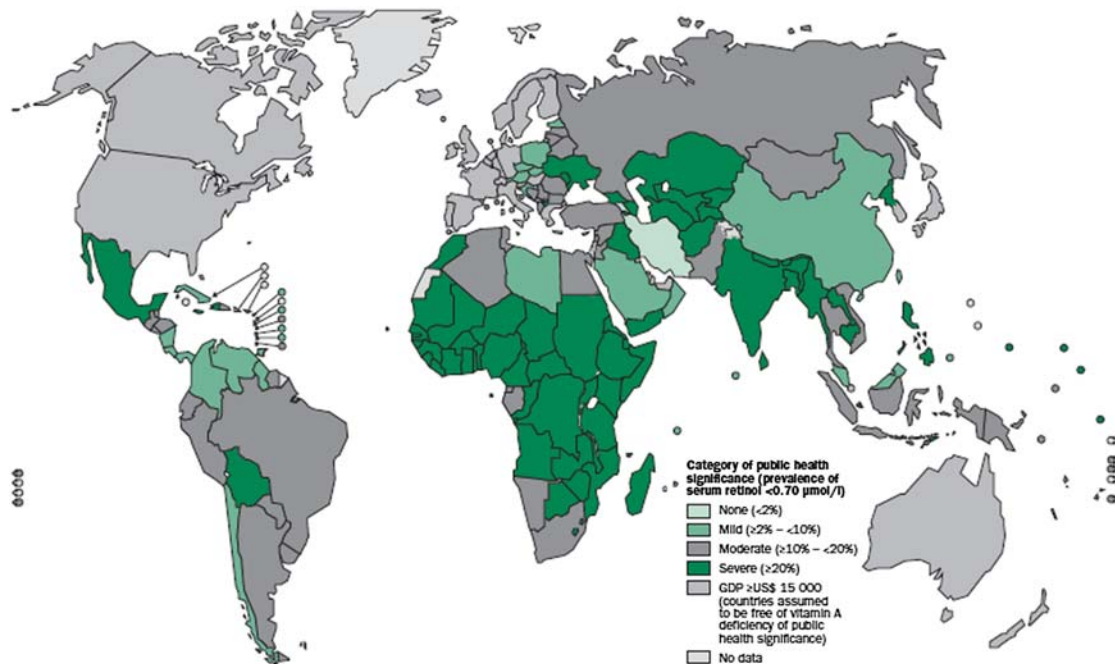

VA deficiency can affect women, especially during pregnancy, in undernourished settings, appearing to be driven by heightened nutrient demands of gestation. Globally, some 19 million pregnant women are estimated to be VA deficient (serum retinol concentration  $<0.70 \mu\text{mol L}^{-1}$ ), of whom nearly 10 million are estimated to become night blind (World Health Organization, 2009). Maternal XN not only identifies women at high risk of hyporetinemia but also anemia, wasting malnutrition, offspring mortality, and maternal morbidity and mortality (Fig. 4). Widespread maternal VA deficiency has been observed to coexist with HIV infection and AIDS throughout sub-Saharan Africa. However, modest, absent, or inconsistent effects of maternal VA supplementation on infant and maternal health, survival, or HIV transmission suggest the deficiency may be a consequence more than determinant of disease severity. Host-HIV competition for VA has also been implicated from intervention trials in Africa.

#### Place (geographic clustering)

Southern Asia and sub-Saharan Africa remain regions with the greatest burden of VA deficiency (Fig. 5) (World Health Organization, 2009; Stevens et al., 2015). Within a region, risk of deficiency can vary by local risk factors, especially, where diets are chronically inadequate and infectious disease burden high (Palmer et al., 2017). Clustering of xerophthalmia has been observed in surveys in Africa and Asia, where preschool children have been shown to incur a ~2-fold higher risk of xerophthalmia in villages where another child has been diagnosed compared to villages free of previous xerophthalmia (Table 2). More striking is a 7–13-fold higher risk of xerophthalmia described in siblings of cases compared to children at home with no history of xerophthalmia (Katz et al., 1993). Maternal XN and childhood xerophthalmia often coexist in household and community clusters, where spatial clustering appears to arise mostly from a shared, inadequate diet.

**Fig. 4** Mortality rates of rural Nepalese women (per 100,000 pregnancies) during and for up to 2 years following pregnancy according to whether mothers experienced night blindness ( $n = 361$ ) or not ( $n = 3052$ ) during pregnancy. Reproduced from [Christian et al. \(2000\)](#).

**Fig. 5** Global geographic distribution and public health significance of the prevalence of VA deficiency, based on serum retinol concentrations  $<0.70 \mu\text{mol L}^{-1}$  in preschool-aged children. Reproduced from the [World Health Organization \(2009\)](#).

### Time (periodicity)

Occurrence of xerophthalmia can follow predictable, though not parallel, seasonal peaks in different parts of the world, appearing to emerge from a convergence of factors. In South Asia, for example, absent VA interventions mild xerophthalmia peaks in the hot dry/early monsoon seasons (April–July), following a postharvest growth spurt in the preceding cool dry season. Peak risk also coincides with a general scarcity of proVA-rich vegetables and fruits and a seasonal rise in diarrhea, respiratory infections and measles, that interestingly tends to decline abruptly midway through the beta-carotene-rich mango season. Periodicity, where it exists, can help identify not only causes but specific times of the year for targeting interventions.

### Causal agents (diet and infection)

Deficiency results from consuming a diet chronically inadequate in VA in relation to need, that can be exacerbated by infection. A low dietary fat intake (e.g.,  $<5\%$  of calories) may restrict absorption of proVA carotenoids from vegetables and fruits and thus also predispose certain poor populations to deficiency.

**Table 2** Age-adjusted village and household odds ratios for risk of xerophthalmia among preschool children.

	<i>Malawi</i>		<i>Zambia</i>		<i>Indonesia</i>		<i>Nepal</i>	
	n	OR	N	OR	n	OR	N	OR
Village	50	1.2 (1.0–1.5)	110	1.7 (0.9–3.2)	460	1.8 (1.4–2.2)	40	2.3 (1.6–3.4)
Household	2899	7.3 (3.2–16.7)	2449	7.9 (3.5–17.8)	16,337	10.5 (7.0–15.7)	2909	13.2 (6.0–29.0)

Source: Adapted from Katz et al. (1993). Numbers of children <6 years of age in each country: Malawi ( $n = 5441$ ); Zambia ( $n = 4316$ ); Indonesia ( $n = 28,586$ ); and Nepal ( $n = 4764$ ). Figures are pairwise odds ratios (OR) based on alternating logistic regression (95% confidence intervals).

### Breastfeeding and diet

Breast milk is an infant's most important initial dietary source of VA. Commonly, breast milk from marginally nourished mothers contains  $\sim 500 \mu\text{g}$  of retinol activity equivalents (RAE) per liter, thereby delivering  $325 \mu\text{g}$  RAE per day to infants typically consuming  $\sim 650 \text{ mL day}^{-1}$ . An "adequate intake" of  $400\text{--}500 \mu\text{g}$  RAE has been set as a dietary guide for infants, making this common level of VA intake from breast milk marginal during the 1st year and, beyond infancy, marginally above an estimated deficient intake threshold of  $210 \mu\text{g}$  RAE, but usually sufficient to prevent clinical signs. Studies in Asia and Africa show breastfed infants and toddlers to be 65–90% less likely to develop xerophthalmia than nonbreast-fed peers of the same age. In Malawi, children who developed xerophthalmia had begun weaning  $\sim 1$  month earlier and completed breastfeeding  $\sim 6$  months earlier than nonxerophthalmic children. Even among breastfed children, in rural Nepal a higher daily frequency of feeding was associated with added protection against xerophthalmia.

The choice of foods offered to complement breast feeding may also affect risk of VA deficiency. Indonesian preschoolers were at a 2- to 6 fold higher risk of xerophthalmia if food sources of VA such as dark green leaves, mango or papaya, egg, meat or fish with liver, and milk, and other dairy products were not routinely given during their 1st year of complementary feeding, likely initiating a dietary exposure pattern that increases throughout the preschool years. Across undernourished regions, less frequent intakes of preformed VA and proVA-rich foods are observed by children with a history of xerophthalmia (Fig. 6). Similar dietary inadequacy is more likely to be reported among women with, versus without, a history of XN during a previous pregnancy.

### Infection

Evident as a vicious cycle, infection can be viewed as a cause of VA deficiency, consequent to impaired VA absorption, increased metabolism, and urinary losses of the vitamin (Stephensen and Lietz, 2021). Prospective studies show that severe infections such as measles, chicken pox, diarrhea, and acute respiratory illness decrease serum retinol, as well as apparent hepatic retinoid stores, and increase risk of xerophthalmia. In some settings, severe measles has been observed to increase by more than 13-fold the risk of precipitating corneal xerophthalmia. In Indonesia, young children with diarrhea and acute respiratory infections were twice as likely to develop mild xerophthalmia (XN or X1B) than disease-free children. Similar temporality between infection and incident XN have been observed in undernourished pregnant women. Explanations for a role of infection as a cause of VA deficiency include decreased absorption of VA, impaired retinol transport, increased metabolic requirements, greatly increased renal excretion during the acute-phase response, and immunodeficiency.

**Fig. 6** Foods that protect against xerophthalmia in early childhood, based on numerous studies. Dark line, strong evidence; dashed line, suggestive evidence. Reproduced from Sommer and West (1996).

## Impact of interventions

VA deficiency can be prevented through direct supplementation, fortification of common food items in factories or at “point of consumption” (in the home) and other food-based approaches that include biofortification of staple crops with proVA carotenoids, home gardening, small animal husbandry, and nutrition education. Evaluations to date—mostly of supplementation, and both industrially fortified and biofortified foods—have focused on VA status, xerophthalmia, mortality, and morbidity.

### On vitamin A status

The impact of VA interventions on population status can vary by indicator, dosage, and mode of delivery, as well as population status and health, including severity of deficiency and dominant infectious diseases (e.g., malaria, HIV, possibly COVID). Despite its limitations in reflecting liver reserves, except at their lowest concentrations, serum retinol, historically to the present day, remains the most widely employed indicator of VA status. Serum concentrations of retinol binding protein (RBP4), the major nutrient carrier in circulation may be substituted, with limitations, for retinol status. Methods that rely on use of stable isotopes or time-dependent response-to-therapy to VA supplementation can approximate body nutrient stores, valuable for metabolic nutrition research, are more rarely deployed for population use due to technical difficulty, requisite assumptions, cost and, thus, sample size.

A single, large oral dose of VA (210  $\mu$ mol, 60 mg RAE, or 200,000 IU) as routinely given semiannually to young children in undernourished populations of low-middle income countries can elevate serum retinol to near adequacy for up to a few weeks to months before declining (Palmer et al., 2012). Reasons for the transient response to a supplemental bolus remain poorly understood. Routine intake of a third to full recommended dietary allowance of VA through fortified food items, such as vegetable oil, sugar and wheat flour, gradually improves and sustains adequate serum and breast milk retinol concentrations and liver stores, assessed indirectly. Regular consumption of proVA, either as natural food sources (dark green leaves, yellow vegetables and fruits) or via biofortified crops, generally improves VA status in undernourished populations, although not to adequacy, as the response can be affected by many factors including food matrix, methods of storage and preparation, amounts of preformed VA and fat in the diet, gut integrity and function, host protein energy and VA status and genetic predisposition (e.g., single nucleotide polymorphisms in beta-carotene oxygenase 1, the intestinal enzyme responsible for cleaving beta-carotene to retinaldehyde that subsequently forms retinol metabolites). Despite variable responses, and multisectoral challenges in effecting food-based interventions, there is unanimity in the public health nutrition community in striving toward assuring a steady, adequate and safe dietary supply of VA and proVA foods to improve VA status of populations.

### On xerophthalmia

A large dose VA given to preschool children as a capsule or in syrup (in India) every 6 months is ~90% efficacious in preventing both corneal and noncorneal xerophthalmia. Prophylactic failure (~10% non-response or recurrence) may reflect inadequacy of dosage for some children who are severely VA-deficient or become ill. Xerophthalmia, on the other hand, virtually disappears in societies routinely consuming adequate dietary VA through fortified foods. Supervised treatment with proVA-rich vegetables and fruit has been reported to cure or improve noncorneal xerophthalmia.

### On mortality and morbidity

A synergism between infection and VA deficiency leading to more severe morbidity and risk of death has been shown experimentally in animals for the past century. In the 1980s and 90s, the efficacy of VA in reducing preschool child mortality was firmly established by eight controlled, community trials designed and executed to assess this outcome. In six trials, children 6 months to 6 years of age received an oral supplemented with 200,000 IU of VA every 4–6 months. A half-dose was provided to children 6–11 months of age. One study, in India (Vijayaraghavan et al., 1990), provided a small weekly dose of 15,000 IU to young children and another, in Indonesia, supplied one-third of a recommended dietary allowance of VA to children in treatment villages via fortified monosodium glutamate product (flavor enhancer) that was routinely added to meals (Muhilal et al., 1988). Six of the eight trials showed reductions of 19%–54% in child mortality beyond either 6 or 12 months of age, with meta-analyses of data from all eight trials revealing an overall mortality reduction of 23%–34% (Beaton et al., 1993), depending on inclusion criteria.

Causes of death likely impacted by VA include severe measles, diarrhea, dysentery, and febrile illnesses. In Ghana, where child mortality was reduced 19%, VA supplementation also significantly decreased childhood clinic visits for illness by 12% and hospitalization rates for severe disease by 38%; among children hospitalized over the course of the trial, diarrheal illness was less severe among VA versus placebo recipients (Ghana VAST Study Team, 1993). In a trial in Papua New Guinea (Shankar et al., 1999), VA supplementation reduced febrile, falciparum parasitemic episodes by 30% accompanied by lowered risk of an enlarged spleen, suggesting VA may plausibly reduce malaria case fatality. VA has consistently been shown to reduce measles case fatality, by ~50%. A lack of effect on fatality from acute lower respiratory infection (unrelated to measles) has been a consistent and perplexing finding across trials, reasons for which remain uncertain (Stephensen and Lietz, 2021). Overall, data suggest VA has little impact on prevalence of common childhood morbidities, but rather holds the potential to attenuate severity of infections, supporting the effect of the nutrient on mortality in undernourished populations.

Over the decades regularly updated meta-analyses have added data from nearly another 40 trials of VA on mortality and infectious disease outcomes in child populations of widely varying risks, including Australia, China and India, among other countries in

South Asia, Africa and Latin America (Imdad et al., 2022). While adding studies not designed, powered or executed to assess child mortality can dilute the overall effect size, these analyses continue to sustain evidence VA interventions can reduce severe infection and child mortality in undernourished settings.

Other trials have extended the assessment of VA supplementation shortly after birth on infant mortality, requiring different designs than for children. In all, five trials in Southern Asia (Indonesia, Bangladesh, India and Pakistan) and six in sub-Saharan Africa (Tanzania, Zimbabwe, Ghana and Guinea Bissau) have examined the efficacy of a 50,000 IU dose of VA in oil, expressed from a capsule into the mouth of newborns (Neonatal Vitamin A Supplementation Evidence Group, 2019). In Southern Asia, newborn VA significantly consistently reduced mortality in the first half of infancy, by an average of 13% (risk ratio of 0.87) but had no significant effect in African settings. Plausible explanations for the observed impact may include rapid maturational effects of VA on immature, newborn intestinal, airway and systemic immunity that could enhance resistance to infection months later, especially in cultures where prelacteal feeding may impair intestinal immunity. Reasons for a lack of effect in Africa remain speculative, with overall differences in maternal VA deficiency, more common in Asian settings, and mediating effects of HIV, which was endemic in some African populations, among them.

A third high risk group among whom VA interventions may affect health and survival is pregnant women. An initial trial, in rural Nepal where maternal XN routinely affected ~10% of pregnant women, women were provided a weekly capsule containing the equivalent of a recommended dietary allowance of VA, either preformed or as proVA beta-carotene, or placebo prior to conception through the 1st few years postnatally. Maternal VA or beta-carotene supplementation lowered all-cause, pregnancy-related mortality through twelve weeks postpartum by ~40%, plausibly mediated by improved resistance to severe infections, as may occur in the puerperium, and hematopoietic effects leading to less severe complications related to less anemia (West et al., 1999). Infant mortality was only lower in mothers prone to developing night blindness. Interestingly, when offspring were followed up between 10 and 13 years of age, children born to VA-supplemented mothers exhibited improved lung function (Checkley et al., 2010), expressed by forced expiratory volume at 1 s and forced vital capacity measures, and improved immunity as indicated by greater natural antibody concentrations than children born to mothers receiving placebo during pregnancy (Palmer et al., 2015). Despite the multiple effects of antenatal VA supplementation on mothers and children in Nepal, pregnancy intervention trials in Bangladesh and Ghana failed to reduce maternal mortality (Kirkwood et al., 2010; West et al., 2011), although risk of bacterial vaginosis was markedly lower among VA supplemented mothers in Bangladesh. Discrepant findings on maternal survival may have been related to lower maternal risks of mortality, population differences in VA deficiency and general nutritional status, as well as better primary health care systems in the latter two country settings.

## Management

### Treatment

WHO recommendations for treating clinical VA deficiency have remained the same for 25 years (Sommer, 1995; Ross, 2002). Children with xerophthalmia and measles should be treated immediately with oral, high-potency VA (200,000 IU), summarized in Table 3, and provided other supportive nutritional and medical therapy, as indicated. Corneal lesions should be topically treated with a suitable antibiotic (e.g., tetracycline or chloramphenicol) to prevent bacterial infection. Corneal xerophthalmia typically improves with VA treatment within a week, and resolves within 4 weeks, depending on size, thickness and location of the lesion, and nutritional and health status of the patient. Corneal xerosis (X2) typically resolves without sequelae; ulceration (X3A) will typically heal leaving a scar (leukoma), with location, size and depth in relation to the visual axis being key determinants of vision. Healed keratomalacia (X3B), mostly leaves the cornea severely scarred, possibly shrunken (phthisis) or bulging (staphyloma), and the eye blind. Mild xerophthalmia is non-blinding. XN typically disappears within 24–48 h of treatment with VA. Most Bitot's spots start to resolve within 2–5 days of VA treatment, and disappear within 2 weeks, though in older children X1B (underlying keratinized metaplasia) may persist for months, for unclear reasons. Importantly, any signs of xerophthalmia may recur if individuals become VA-deficient again.

**Table 3** VA treatment and prevention schedules.

Age	Treatment at diagnosis	Prevention	
		Dosage	Frequency
<6 mo	50,000 IU	50,000 IU	Once within 3 days after birth
6–11 mo	100,000 IU	100,000 IU	Every 4–6 months
12–59 mo	200,000 IU	200,000 IU	Every 4–6 months
Women	By severity of eye signs	200,000 IU	2 doses 24 h apart ~6 weeks after delivery

Source: Reproduced from Ross (2002) and Sommer (1995). Treat all cases of xerophthalmia and measles on days 1 and 2; give an additional dose for xerophthalmia on day 14. For severe malnutrition give 1 dose on day 1. For women of reproductive age, give 200,000 IU only for corneal xerophthalmia on days 1, 2, and 14; for night blindness or X1B give 10,000 IU per day or 25,000 IU per week for >3 months. Newborn prevention schedule is based on authors' recommendation for newborns in Southern Asia, where multiple trials have yielded an average reduction of 13% in infant mortality, but not in Africa where no effect has been observed (Neonatal Vitamin A Supplementation Evidence Group, 2019).

Severely wasted children should be given a single large oral dose (200,000 IU) for prophylaxis. It is also judicious to treat children with severe diarrhea, dysentery, respiratory infection, and measles a single, large oral dose of VA. Large-dose VA is indicated for women of reproductive age with corneal disease. For XN, smaller daily (10,000 IU) or weekly (25,000 IU) doses are recommended for at least 3 months.

### Prevention

The above health consequences, or disorders, of VA deficiency can be prevented via direct supplementation of target groups, food fortification at production facilities or by adding nutrient-dense powders with VA to meals at home, proVA carotenoid biofortification of staple crops, and other agricultural or dietary approaches, including gardening and education programs that encourage exclusive and extended breast-feeding and improved dietary quality (Palmer et al., 2017). Indirectly, public health interventions that reduce infection, inflammation and environmental stress can help to improve VA status in a population.

Administration of large-dose, oral VA (200,000 IU), adjusted to age (Table 3), on a ~6 monthly basis is a common preventive in most undernourished societies. A half-dose is dispensed to infants 6–11 months of age. Periodically providing a large dose of VA is thought to increase nutrient liver stores from where it is mobilized into circulation, as needed. Supplements can be provided during routine health care (e.g., for growth monitoring, immunization, and other extension services) or more extensively and systematically on a regular (e.g., semiannual) “universal” basis, especially through national campaigns often called Child Health Days, which routinely achieve 80% or greater coverage. Nearly five decades of distributing billions of large-dose VA supplements for prevention, coupled with marked declines in mortality attributed to the intervention, attests to the acceptance, likely continued effectiveness, and safety of this approach. Gastrointestinal side effects may occur in ~5% of recipient children.

Commercial fortification of foods with VA is a longer-term strategy, aiming to increase dietary intakes and sustainably increase VA status by offering a quarter to a full day's recommended allowance of VA. Food vehicles currently being used include sugar, vegetable oils, nonfat milk powder, wheat flour (for bread or noodles), and nonrefrigerated margarine. These share the common traits of being technically fortifiable at planned levels and consumed within a range that could be both effective in deficient groups while remaining safe for nutritionally adequate or overconsuming segments of a population. The decline of VA deficiency as a nutritional concern in Central America is largely attributed to successful sugar fortification in that region. Programs in Africa have had more limited success, with evaluations underscoring the need for strict quality control procedures at the production level to achieve targeted VA levels.

Biofortification of major staple grains and tubers, such as maize, cassava, and sweet potatoes, with proVA carotenoids has the potential to improve VA status in deficient populations, or at the minimum offer a “dietary safety net” that delivers a minimum amount of bioconvertible carotenoid to prevent deficiency during years of economic or agricultural downturn. Dietary diversification is widely held to be the most culturally appropriate and potentially sustainable approach to preventing VA deficiency. Although pilot trials show efficacy of a variety of dietary approaches in improving VA intake and status, data on effectiveness and cost of population food-based interventions remain lacking. Dietary intakes can be improved through home and school gardening initiatives, nutrition education, and social marketing of locally available food sources of VA. However, effective dietary change requires a thorough understanding of local cultural, food system, and behavioral factors that increase the risk of VA deficiency.

## Key points

- Both preformed vitamin A (retinol) and provitamin A (carotenoids) serve as the nutritionally necessary forms of vitamin A
- Metabolism occurring in the intestine, liver, and peripheral organs is essential to produce the bioactive forms of vitamin A
- The retina of the eye utilizes a unique form of vitamin A, 11-*cis*-retinal, to form the visual pigment rhodopsin, required for vision
- Both vitamin A deficiency and excess have profound consequences on embryonic development, as well as affecting the immune system and other essential physiological processes

## Glossary

**Retinol-binding protein** The transport protein for vitamin A (retinol) in plasma

**Retinol Activity Equivalent (RAE)** The unit of dietary vitamin A quantification

**Retinoic acid** The active metabolite of vitamin A in most tissues of the body

**Visual cycle** The reactions that recycle retinol and 11-*cis*-retinal in the rods and cones of the retina

## Introduction

Vitamin A (retinol) physiology comprises reactions that take place in the intestine (absorption), liver (uptake, storage, metabolism, secretion and elimination), and numerous target organs and epithelial cells throughout the body, especially the eye, immune system, and reproductive systems. Metabolism in the small intestine converts dietary forms of vitamin A, either retinyl esters or beta-carotene, into functionally active metabolites. In the retina, specific metabolic reactions generate 11-*cis*-retinal for vision. All-*trans*-retinoic acid is produced and catabolized by well-controlled metabolic processes in nearly all tissues. As vitamin A is not naturally water-miscible, its metabolism depends on various binding proteins that increase solubility and direct the vitamin A compounds to specific enzymes for metabolism. The nuclei of cells in nearly all tissues contain nuclear retinoic acid receptors that function to regulate vitamin A homeostasis and the many physiological functions of vitamin A throughout the body. This chapter elucidates these processes and discusses the nutritional values of various molecules in the vitamin A family, as well as the physiological consequences of a deficiency or excess of vitamin A.

Vitamin A (retinol) is a fat-soluble micronutrient that is essential for the life of all vertebrates. Its many functions include roles in vision, immunity, skin health, and reproduction. "Fat-soluble A" was discovered in 1913 as a dietary factor required for growth and survival, and shown to be present in very small amounts in the lipid fraction of certain foods of animal origin, including eggs, butter, whole milk, and fish liver, all of which contain preformed vitamin A in the form of retinol and its esters (Wolf, 1996). These precursors are metabolized *in vivo* into compounds that, in turn, exert the biological effects of vitamin A. A second form of vitamin A was soon discovered in certain foods of plant origin, especially green and deep-yellow vegetables, and characterized as beta-carotene. These "provitamin A" molecules can be cleaved and converted to retinol during intestinal absorption (von Lintig, 2012). Therefore, the nutritional requirement for vitamin A can be met by either preformed retinol, provitamin A carotenoids, or a mixture of both, providing vitamin A in forms that are useful to carnivorous, herbivorous, and omnivorous mammals (Ross and Harrison, 2014).

The true biological activities attributed to vitamin A are due to metabolites that are formed intracellularly in a well-regulated series of processes (Dawson, 2000). After retinol is absorbed and distributed to tissues, its activation takes place in step-wise oxidative reactions. In the case of provitamin A carotenoids, they must first be cleaved and then enzymatically reduced to produce retinol before they can undergo activation. Two of the best known metabolites are crucial to two of the major physiological functions of vitamin A: 11-*cis*-retinaldehyde (retinal), which is a component of the visual pigment required for vision, rhodopsin (Saari, 2016); and all-*trans*-retinoic acid, a carboxylic acid derivative, which is required in essentially all tissues for the regulation of gene expression, and thereby exerts a wide range of biological effects (Kedishvili, 2016; Ghyselinck and Duester, 2019).

In addition to the natural forms of vitamin A, there are now numerous synthetic compounds, termed retinoids (although the term is often used inclusively for the natural as well as synthetic compounds). Some retinoids are used as drugs, mainly in the treatment of certain disorders of the skin and cancers. Synthetic retinoids must be used with great caution and monitoring due to their potential for causing serious side effects.

## Major molecules in vitamin A biochemistry and physiology

Vitamin A and its metabolites comprise numerous molecules that differ in isomeric form and/or oxidation state. The major physiological forms are retinol, including its long-chain fatty acid esters, retinal, and retinoic acid. Additional polar metabolites of retinol and retinoic acid are often formed as end-products.

All-*trans*-Retinol is considered the parent molecule of the vitamin A family (Fig. 1). It is comprised of a beta-ionone ring, a methyl-substituted conjugated side chain, and a terminal hydroxyl functional group. Both all-*trans* and *cis* isomers of retinol and retinoic acid have been isolated from human tissues. In general, the all-*trans* forms are the most abundant. However, in the

R<sup>5</sup> = COO-glucuronide

**Fig. 1** Structure of all-*trans*-retinol and several related forms.

rods and cones of the retina, 11-*cis*-retinal is the most abundant form, acting as an essential light-sensing component of rhodopsin (see section on **Vision**). Tissues and plasma may also contain low concentrations of 9-*cis* and 13-*cis* isomers. In foods and most of the body's tissues where vitamin A is stored, retinol is esterified with a long-chain fatty acid such as palmitic acid to form retinyl ester, an extremely hydrophobic form that is usually contained within a lipid droplet or lipoprotein. Retinol in nutritional supplements may also be in the esterified form, which improves stability. Vitamin A compounds are sensitive to light and oxygen, so supplements should be kept out of light in closed containers.

Some naturally-occurring, variant forms of retinol are present in certain foods and human tissues, generally in small amounts, these include vitamin A<sub>2</sub>, (3,4 didehydroretinol) found in tissues of freshwater fish and produced metabolically in human skin, and  $\alpha$  (alpha)-retinol, a structural and less active isomer of all-*trans*-retinol.

### Metabolites formed through oxidation

Oxidative metabolism is essential for the physiological functions of vitamin A (Kedishvili, 2016). Fig. 2 illustrates key processes in retinol metabolism. Retinol is oxidized within cells to generate retinal, which is generally a transient metabolite that can either be reduced back to generate retinol, allowing for cycling between these two molecular forms of vitamin A, or it can be further oxidized in an irreversible reaction to form retinoic acid. All-*trans*-retinoic acid is the major acidic form of vitamin A and the form with wide-spread effects on gene expression. 9-*cis*-Retinoic acid has also been proposed to function in gene regulation although its in vivo activity remains unproven. 13-*cis*-Retinoic acid another *cis* isomer found naturally in plasma and skin, as well as being used clinically.

### Polar compounds

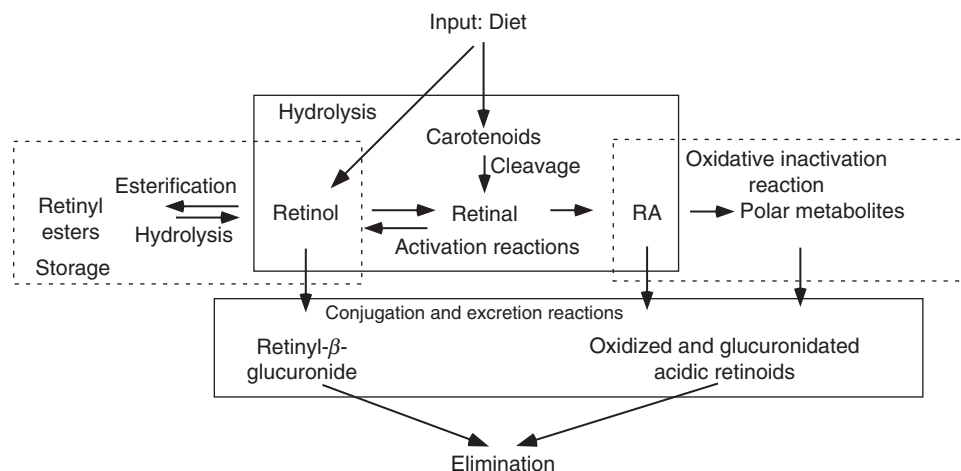

Polar metabolites of retinol or retinoic acid are formed by the addition of hydroxyl or keto groups to the ionone ring structure, generally at ring positions 4 or 18, or by formation of epoxides such as 5,6 epoxy-retinoic acid (Isoherranen and Zhong, 2019). Retinol, retinoic acid and their more polar metabolites may be conjugated with glucuronic acid, forming retinyl and retinoyl-beta-glucuronide. These derivatized forms generally have lower biological activity and a short half-life in vivo; they are readily eliminated in bile and urine.

### Transport

Due to the low aqueous solubility of most retinoids, their transport in plasma and cells depends on their association with specific proteins (reviewed in Ross and Harrison, 2014; Blaner et al., 2016; Honarbakhsh et al., 2021). Major forms include:

### Retinol-binding protein (RBP4)

RBP (gene name RBP4) is the major transporter of retinol in plasma. RBP is a 21-kDa protein of the lipocalin family, it is synthesized mostly in the liver (see later). It is filtered from plasma in the renal glomerulus, and recovered to a significant extent by binding to a multi-ligand receptor, megalin, which facilitates reuptake. Each RBP molecule binds noncovalently with a single molecule of all-

**Fig. 2** Schematic of principal reactions of vitamin A metabolism.

*trans*-retinol; this complex is referred to as holo-RBP. Holo-RBP itself circulates in non-covalent association with another co-transport protein, transthyretin (TTR), to form a molecular complex of retinol-RBP-TTR having a molecular weight of about 75 kDa. TTR is also a transporter for thyroxine.

### Cellular retinoid binding proteins

Several proteins referred to as cellular retinoid-binding proteins are members of the gene family of fatty acid binding proteins. These proteins exist in the cytosol of various cell types, each specific protein differing in its preferred ligand and cell-type distribution. The two most abundant forms of cellular retinoid binding proteins are CRBP-I and CRBP-II, each of which binds a molecule of all-*trans*-retinol, with CRBP-I predominant in liver, eye, and several other tissues, and CRBP-II predominant in the enterocytes of the small intestine. CRBP-II can also bind retinal. Similar proteins that are specific for binding all-*trans*-retinoic acid are called CRABP-I and -II. The CRBPs and CRABPs function as chaperones that confer aqueous solubility on their lipophilic retinoid and facilitate their trafficking to specific enzymes that catalyze their metabolism. In the retina, (see [Vision](#)), there are additional specialized retinoid binding proteins for transporting retinal, which is abundant in the retina, within and between cells of the retina.

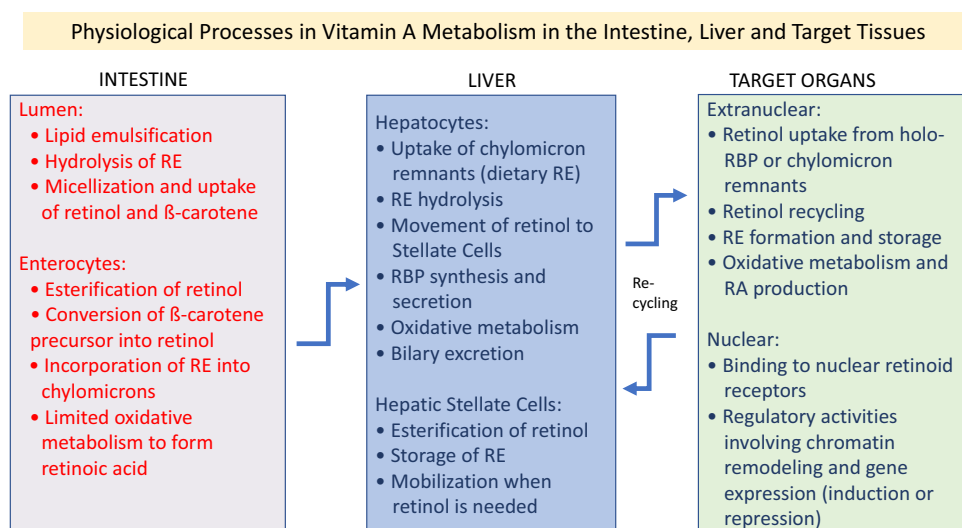

### Nuclear retinoid receptors

The nuclear retinoid receptor proteins RAR and RXR are specialized forms of retinoid chaperone proteins that reside mainly in the nucleus of cells where they function as regulators of gene transcription ([Ghyselinck and Duester, 2019](#)). The RAR (RAR $\alpha$ ,  $\beta$  and  $\gamma$ ) and RXR (RXR $\alpha$ ,  $\beta$  and  $\gamma$ ) possess a ligand binding domain and a DNA binding domain; these domains determine their specificity with respect to the ligand they prefer to bind, and the specific DNA sequences, termed RARE, that they bind to in retinoid-responsive genes. The binding of all-*trans*-RA to the ligand-binding domain of RARs and, potentially, of 9-*cis*-retinoic acid to the ligand-binding domain of RXRs, alters the receptor's conformation and hence its interactions with transcriptional regulatory complexes. Additionally, numerous post-translational protein modifications of the RAR and RXR have been described which further modulate their gene-regulatory activity. Several hundred genes have been shown to be responsive to retinoic acid in a manner mediated by nuclear receptor signaling.

## Absorption and metabolism

### Intestinal metabolism

Numerous similarities exist between the absorption of vitamin A and of dietary fat ([Ross and Harrison, 2014](#); [Blaner et al., 2016](#); [Honarbakhsh et al., 2021](#)). Beginning in the lumen of the small intestine, dietary retinyl esters must be emulsified with bile salts and phospholipids, incorporated into lipid micelles, and hydrolyzed to free retinol before retinol itself can be absorbed into the mucosa ([Fig. 3](#)). Hydrolysis is catalyzed by retinyl ester hydrolase enzymes secreted in pancreatic juice or bound to the brush border of duodenal and jejunal enterocytes. Efficient absorption of vitamin A requires that dietary fat is consumed concomitantly, as would

**Fig. 3** Legend to [Fig. 3](#). Major physiological processes in the intestine, liver and various target organs, which include the skin, immune, respiratory, reproductive and immune systems, and epithelial cells throughout the body. RE, retinyl ester, RBP, retinol-binding protein.

typically occur in most meals. Once released, the retinol molecules diffuse into the enterocytes and are bound to CRBP-II, then chaperoned to the esterifying enzyme lecithin:retinol acyltransferase (LRAT) before becoming incorporated as retinyl esters within the lipid core of the chylomicrons, the intestinally-produced lipoproteins that transport newly absorbed dietary fat to the circulation. Animals lacking LRAT absorb vitamin A inefficiently. Usually, about 70–90% of intestinal vitamin A is absorbed, and this fraction is not significantly down-regulated when vitamin A consumption increases. Intakes of vitamin A that are acutely very high or chronically excessive are still highly absorbable and thus can result in hypervitaminosis A (toxicity). Conversely, conditions that cause fat malabsorption may reduce the bioavailability of vitamin A.

Beta-Carotene is absorbed less efficiently than retinol, on the order of only 9–22%, and, moreover, efficiency falls as the ingested dose increases. Like preformed vitamin A, the provitamin A carotenoids also require dietary fat for their absorption, but, unlike retinyl esters, they are absorbed into the enterocytes intact and then undergo metabolism within these cells. Beta-Carotene is first cleaved at its central 15, 15' double bond by carotene monooxygenase (BCO-I), generating retinal which is then rapidly metabolized to retinol; CRBP-II facilitates this process as well as the esterification of retinol by LRAT (Von Lintig, 2012). An analogous enzymatic process involving acentric cleavage of beta-carotene yields a variety of products referred to as apo-carotenals, only some of which may be converted into retinol. About one-third of beta-carotene in the human small intestine escapes cleavage and is absorbed intact, becoming incorporated unchanged into chylomicrons and then exchanging onto serum lipoproteins that transport carotenoids in plasma. The central cleavage enzyme BCO-1 is feedback regulated at the transcriptional level by retinoic acid such that, when vitamin A is abundant and its metabolism generates higher levels of retinoic acid, the retinoic acid activates nuclear receptor signaling which down-regulates the production of BCO-1, reducing beta-carotene cleavage and the production of retinol (von Lintig et al., 2020).

### Retinoic acid in the intestine

Retinoic acid is produced in small quantities during the absorption of vitamin A and beta-carotene. It is either absorbed into the portal vein and transported to the systemic circulation or used locally in its gene-regulatory capacity by epithelial and immune system cells within the intestinal epithelium and submucosal layers.

### Hepatic vitamin A uptake, storage and release

The liver plays no fewer than 5 essential roles in the metabolism of vitamin A: (1) uptake of the dietary retinyl esters carried in partially metabolized chylomicrons (remnants); (2) conversion of dietary retinyl esters into new retinyl esters for storage in hepatic stellate cells (HSC); (3) production of RBP and release of holo-RBP to the circulation; (4) oxidative catabolism of excess retinoids (often taken up from plasma) into polar forms that can be excreted; (5) biliary excretion of various retinoids into the intestinal tract for removal from the body (Ross and Harrison, 2014; Blaner et al., 2016). Firstly, the retinyl esters contained in chylomicron remnants are cleared rapidly from plasma, with the greatest uptake into liver parenchymal cells (hepatocytes) (Fig. 3), wherein the ester bond is hydrolyzed and after which retinol is transferred into hepatic HSC. The HSC are enriched in CRBP-I which facilitates the esterification of retinol by LRAT, forming the major products retinyl palmitate and retinyl stearate. These esters, along with other lipids, are stored in the numerous small lipid droplets present within the cytoplasm of the HSC. When vitamin A nutriture is adequate, greater than 90% of the body's total vitamin A resides in HSC as retinyl esters. Interestingly, a similar process involving smaller quantities of retinol exists in several extrahepatic tissues that also contain cells resembling HSCs, suggesting the presence of a network of vitamin A-storing cells throughout the body.

When peripheral tissues need retinol, retinyl esters in HSCs are hydrolyzed. Exactly which metabolic signals initiate this hydrolytic process is not clear. However, it has been shown that the liberated retinol combines with newly synthesized RBP and is secreted through the Golgi apparatus into plasma. Either shortly before or after the secretion of holo-RBP into plasma, the complex binds noncovalently with a tetramer of TTR to form the larger holo-RBP-TTR transport complex described earlier. The liver's role in oxidative metabolism will be considered later.

### Plasma concentrations

In the fasting condition, holo-RBP is the major form of circulating vitamin A. The concentration of plasma retinol is maintained within a narrow range of around about 2  $\mu\text{mol/L}$  in adults, and somewhat lower in children. RBP is normally 80–90% saturated with retinol. Apo-RBP (i.e., RBP without retinol) has reduced affinity for TTR and the free apo-RBP protein is readily filtered in the kidneys and lost in urine.

In the postprandial state, a significant proportion of total plasma retinol is present as retinyl ester in the lipid-rich chylomicrons described above, or associated with higher-density lipoproteins. This postprandial peak in concentration of retinyl esters depends directly on the amount of dietary vitamin A that was consumed. They are typically clearly within 6–8 h after their consumption. When blood specimens for clinical analysis are collected in the fasting state, postprandial retinyl esters will be missed.

Several other retinoids are present in plasma in minor concentrations, including retinoic acid (all-*trans* and some *cis* isomers), ring-oxidized forms of retinoids, and glucuronides thereof.

**Relationship of plasma retinol to liver retinol concentration**

The quantitative relationship between plasma vitamin A and liver vitamin A has been studied in humans and animals (Tanumihardjo et al., 2016). As noted above, nearly steady-state levels of plasma retinol are generally maintained even though hepatic vitamin A concentrations often vary widely. In general, the body's vitamin A reserves are sufficient to maintain plasma retinol at its normal level; however, if intake is not sufficient and liver vitamin A reserves fall below a concentration of about 20–30 µg retinol/g liver, then the secretion of holo-RBP from the hepatocytes into plasma is compromised, and apo-RBP levels fall. This decline occurs slowly, over weeks or months, and continues until nearly all of the vitamin A in liver is used up. As plasma retinol falls, a state of marginal vitamin A deficiency occurs first, which may be detected biochemically but isn't apparent otherwise. Clinical signs of vitamin A deficiency take longer to appear and will begin to become manifest after the point where liver reserves have been exhausted and plasma retinol concentrations have become too low to maintain the normal functions of vitamin A in peripheral tissues.

If retinol is consumed again, either by consuming vitamin A-rich foods or by taking a vitamin A-containing supplement, retinol will be rapidly absorbed, taken up into the liver, and secreted back into plasma as holo-RBP. Whereas depletion is slow, repletion is rapid such that plasma retinol levels return to near normal in a matter of hours.

**Metabolic disturbances that affect plasma retinol**

Several disturbances are known to affect the levels of retinol and RBP in plasma. These include intestinal conditions causing fat and fat-soluble vitamin malabsorption; deficiencies of protein or calories that are severe enough to affect the synthesis of RBP and TTR in liver; and inflammation, wherein the cytokines associated with tissue damage, including interleukin-6, decrease the synthesis of RBP and TTR in the liver and therefore plasma levels fall. In inflammatory states, laboratory values for plasma retinol must be interpreted cautiously because it may appear that the person is deficient in vitamin A, whereas the true cause of hyporetinolemia is inflammation (Rosales et al., 1996). Other causes of impaired uptake, transport and metabolism of vitamin A include excessive alcohol consumption, which affect metabolism in the liver and thereby the delivery of retinol to target tissues by RBP. Although it is much more rare, inadvertent exposure to environmental toxicant, has also been shown to significantly reduce plasma retinol concentrations (Grignard et al., 2020).

**Hypervitaminosis A**

This term is used to describe the condition caused by excessive consumption, which, if high enough, causes overt toxicity. Hypervitaminosis A is dose-dependent and may develop slowly due to ingestion of too much vitamin A over a period of time, or it may be very acute after intake of extremely large doses (Tanumihardjo et al., 2016). Biochemical findings include liver levels >300 µg retinol/g liver, and the presence of retinyl esters in plasma lipoproteins in the fasting state. Manifestations of severe hypervitaminosis A are noted below. In order to provide dietary guidance to the public for the prevention of nutrient-related toxicity, the Tolerable Upper Intake Level, known as the UL, has been established (see later section on Recommended Dietary Allowances).

**Vitamin A kinetics**

RBP and TTR each have a relatively short half-life in the circulation, ~0.5 and 2–3 d, respectively. Due to their rapid turnover, the maintenance of stable plasma concentrations requires continuous synthesis and secretion of holo-RBP by the liver.

Based on kinetic studies, each molecule of retinol circulates through the plasma compartment several times before becoming irreversibly degraded (see **Tissue retinoid metabolism**, below). More retinol passes through plasma per day than is actually degraded, indicative of extensive recycling. In contrast to retinol, RBP itself is not significantly recycled, implying that new RBP molecules must be synthesized in order for the continued recycling of retinol from peripheral tissues back to liver. Several extrahepatic tissues including kidney and adipose, contain RBP mRNA at levels about ~5–10% that in liver, and thus may be active in RBP production. The kidney plays a critical role in the recycling and conservation of retinol as, following the glomerular filtration of holo-RBP the protein binds to megalin, the multi-ligand receptor mentioned earlier which is present on the surface of renal tubular epithelial cells. After uptake, retinol crosses the epithelium and is returned to plasma. This conservation mechanism is important for efficient utilization of vitamin A, for when megalin is lacking RBP and retinol are lost in the urine (Nielsen et al., 2016).

Adipose tissue may be another source of plasma RBP. Additionally, adipose-derived RBP has been reported to have adipokine-like activity. Overall, numerous studies have shown that the body is very efficient at conserving retinol. In contrast, it is relatively inefficient in degrading and eliminating excess retinoids.

**Tissue retinoid metabolism**

Vitamin A is distributed on holo-RBP to tissues throughout the body (Ross and Harrison, 2014). The uptake mechanism is best elucidated for the retina, where a receptor for holo-RBP known as Stra6 is present on the plasma membrane surface of retinal pigment epithelial (RPE) cells. Some other tissues also express the Stra6 gene. However, as the liver does not appreciably express Stra6 yet is involved in retinol recycling, this suggests there must be other uptake mechanisms for the reuptake of retinol into the liver.

Numerous organs play a role in retinoid uptake and oxidation (Kedishvili, 2016). As noted earlier, the active forms of vitamin A are 11-*cis*-retinal (in the eye only) and all-*trans*-retinoic acid, occurring in many tissues. Several enzymes of the alcohol dehydrogenase, the short-chain dehydrogenase/reductase, and aldehyde dehydrogenase gene families participate in these oxidative reactions. Retinoic acid is generally present in tissues at nanomolar concentrations, far lower than that of retinol—suggesting that its formation is closely regulated and that much of the retinol taken up into peripheral tissues is released back to plasma and recycled. The half-life of retinoic acid is short, on the order of minutes to a few hours. Some tissues, such as brain, derive most of their retinoic acid through their own metabolism while other tissues such as liver obtain retinoic acid mostly by uptake from plasma.

As noted above, polar metabolites of both retinol and retinoic acid are formed by oxidation of their ring structure, usually at carbon 4, to yield hydroxy and oxo metabolites. The process is partially auto-regulated by retinoic acid itself, as retinoic acid through its nuclear receptors induces the expression of cytochrome P450 enzymes of the CYP26 family, which are retinoic acid 4-hydroxylases (Isoherranen and Zhong, 2019). Normally, tissue retinoid levels are maintained at low concentrations by the balance between retinoid production (activation) and retinoid oxidation (inactivation). Nevertheless, it is possible for homeostatic mechanisms to be overwhelmed when vitamin A or other retinoids are consumed in excess (see section on Hypervitaminosis A and retinoid toxicity).

## Physiological actions

### Vision

The retina functions as the light-sensing organ of the body (Table 1). It is organized into several specific cell layers. The layer of RPE cells proximal to the choroid capillaries takes up retinol from RBP. Some of this retinol is esterified by LRAT into retinyl esters for local storage in the RPE, where these esters will ultimately be used in hydrolysis and isomerization processes to generate 11-*cis*-retinal (Saari, 2016). The rod and cones cells comprise the next layer of photoreceptor cells, just in front of the RPE cells. The photoreceptor cells contain the highest concentrations of 11-*cis*-retinal, which is bound to specific opsin proteins. Axonal-like processes projecting from the photoreceptor cells are connected to those from the next cell layer comprised of neuronal ganglion cells that signal to the brain. As 11-*cis*-retinal is needed by the photoreceptor cells, it is transported from the RPE to the photoreceptor cells by a novel interstitial retinoid-binding protein, IRBP. After uptake by the rods and cones, 11-*cis*-retinal combines covalently with opsin in rods to generate the visual pigment rhodopsin, and, similarly, with iodopsin proteins in cones to form red-, green- and blue-sensitive pigments. These photoreceptor pigments (e.g., rhodopsin) are very efficient in absorbing visible light. The outer segment portion of the rod cell is densely packed with membrane disks that contain some  $10^8$  molecules of rhodopsin per cell. Much research has been conducted to elucidate a specific visual cycle which constitutes a recycling process in which 11-*cis*-retinal is converted by photons of light into all-*trans*-retinal, which then is transported back to the RPE and regenerated by an enzymatic cascade into 11-*cis*-retinal again. This regeneration process is referred to as the visual cycle, and is related to the physiological process of dark adaptation. Because dark adaptation is relatively slow (on the order of minutes) as compared to the very rapid process of photoisomerization, retinyl esters stored in the RPE are quickly recruited through hydrolysis and isomerization to generate new 11-*cis*-retinal, which is passed by IRP to the rods where rhodopsin is regenerated. However, when the RPE's supply of retinyl esters is low, then the visual cycle slows. The clinical outcome of slow visual pigment regeneration is referred to as night blindness, which is one of the first clinical signs of vitamin A deficiency (see Chapter on Hypovitaminosis A).

### Vitamin A and the cornea

The cornea of the eye is composed of epithelial cells that also require vitamin A, but in this case, it is in the form of retinoic acid for maintenance of normal cell differentiation (Table 1). Although the cornea is avascular, holo-RBP is present in the lacrimal glands and tears, and this vitamin A is likely to provide retinol for the local formation of retinoic acid. In states of prolonged retinoid deficiency, the mucin-secreting goblet cells within the cornea lose their function, resulting in corneal xerosis and Bitôt spots (foamy

**Table 1** Forms and functions of vitamin A in vision.

	Part of eye

Major active form of retinoid	11- <i>cis</i> -retinal	All- <i>trans</i> -retinoic acid
Major cell types	Photoreceptors (rods and cones); Retinal pigment epithelium	Epithelial cells and mucus-secreting goblet cells
Major function	Light sensing and neural transmission	Barrier and antimicrobial
Signs of retinoid deficiency	Night blindness	Xerosis, Bitôt spots

deposits of cells and bacteria, usually at the outer quadrants of the eye), which indicate severe vitamin A deficiency (see chapter on Hypovitaminosis A). Persons with these signs need repletion with vitamin A immediately to prevent further damage resulting in life long blindness.

### Functions in cell differentiation

The entire body's epithelial tissues (skin, respiratory tract, immune system, reproductive organs, etc.) are sensitive to vitamin A, both deficiency and excess (Tanumihardjo et al., 2016). The systemic effects of vitamin A deficiency include dryness of the skin (follicular hyperkeratosis), loss of goblet cells in the trachea and respiratory tract, as well as the cornea as mentioned earlier; the morphological appearance is often of a flattening, dry epithelia referred to as squamous metaplasia, (sometimes with keratinization). The hematopoietic system is also affected which results in multiple impairments in the immune response (see below). Reproduction is abnormal, including impaired spermatogenesis in vitamin A deficient males and abnormal fetal development, which is manifest in both vitamin A deficiency and excess. During embryonic development, retinoids are required from the post-gastrulation stage and formation of the neural tube, continuing throughout the stages of organogenesis (Ghyselinck and Duester, 2019; Schubert and Gibert, 2020). Retinoic acid concentration is very tightly controlled as it is a key determinant of the expression of several developmentally important genes, particularly *Hox* genes that are critical for the formation of the body pattern, and genes necessary for formation of the circulatory and nervous systems. Both a deficiency of vitamin A and an excess of vitamin A and an excess of either natural or synthetic retinoids are known to cause developmental defects of the head, face, limbs, and organ systems.

### Immunity

Well-regulated retinoid signaling is necessary for the maintenance of normal immune cell populations and immune responses (Larange and Cheroutre, 2016). A lack of vitamin A results in reductions in mucosal epithelial lymphocyte numbers and functions, reduced T cell counts and altered T-cell subsets, and abnormalities in natural killer cells and macrophages. The production of the cytokines that are required for the normal regulation of T-cell immunity and B-cell antibody production becomes dysregulated. Often, antibody responses are low. Mucosal immunity affecting the intestine is impaired and gut infections are altered (Chai et al., 2021). The function of the lungs and body's ability to generate antibody responses are impaired (Penkert et al., 2020). Although specific studies of vitamin A deficiency and SARS-2/Covid-19 infection are not yet available, the similarities between infections caused by the SARS-2 virus and measles virus have been reviewed, and the data suggest that adequate vitamin A is an important factor for maintaining the mucosal and systemic immune functions necessary to combat both of these viruses (Stephensen and Lietz, 2021). As noted earlier, inflammation, which is common in many infectious and non-infectious diseases, is itself a cause of hyporetinolemia.

### Dietary sources and nutritional equivalency

Preformed vitamin A is present at highest concentration in liver and fish oils; it is present at lower concentrations in non-organ meats and eggs. Vitamin A, usually as retinyl palmitate for improved stability, is also used in food fortification and supplement preparation. In the US, about two-thirds of vitamin A consumption is in the form of preformed vitamin A consumed in foods of animal origin, and the rest is consumed as carotenoids. However, the proportions vary widely depending on dietary patterns. In low-income countries, provitamin A is the major source. Importantly, a variety of dietary patterns can provide adequate vitamin A nutriture.

### Units of nutritional activity

Because vitamin A exists in multiple forms and since the efficiency of utilization of some of its forms—including carotenoids—is lower than that of preformed vitamin A, it is necessary to have a unit that expresses the total bioactivity of vitamin A. The currently accepted nutritional equivalents, established in 2001 by the Institute of Medicine (2001), are expressed in terms of Retinol Activity Equivalents (RAE), where 1 µg RAE has equivalent activity to 1 µg of all-*trans*-retinol. It is now considered that, on average, carotenoids must be ingested in the following amounts to provide the equivalent nutritional value of 1 µg of all-*trans*-retinol (1 RAE):

- \* 2 µg of supplemental beta-carotene (in an oily, easily absorbed solution)
- \* 12 µg of beta-carotene, or 24 µg of  $\alpha$ -carotene or beta-cryptoxanthin in fruits and vegetables (due to association of carotenoids with the food matrices, and therefore reduced digestibility)

A still older unit, the international unit (IU), is sometimes still in use. This unit does not account for newer knowledge about carotenoid bioavailability and equivalency. One IU is defined as 0.3 µg of all-*trans*-retinol.

### Recommended Dietary Allowances (RDA) and tolerable upper intake levels (UL) for vitamin A

RDA for the US and Canada were updated in 2001 (Institute of Medicine, 2001). Guidelines were also established for a Tolerable Upper Intake Level (UL). The RDA and UL for vitamin A for various life stages are listed in Table 3. The UL is defined as the highest intake of a nutrient that is likely to pose no risk of adverse health effects in nearly all healthy individuals. It is important to recognize that for vitamin A the UL applies specifically to preformed vitamin A (e.g., retinol, but not carotenoids), including intake from foods, fortified foods, and supplements (Table 2). The IOM committee set the UL based on epidemiological evidence of increased risk of

**Table 2** Food sources of vitamin A.

<i>Food</i>	<i>Micrograms (mcg) RAE per serving</i>	<i>Percent DV*</i>
Beef liver, pan fried, 3 ounces	6582	731
Sweet potato, baked in skin, 1 whole	1403	156
Spinach, frozen, boiled, ½ cup	573	64
Pumpkin pie, commercially prepared, 1 piece	488	54
Carrots, raw, ½ cup	459	51
Ice cream, French vanilla, soft serve, 1 cup	278	31
Cheese, ricotta, part skim, 1 cup	263	29
Herring, Atlantic, pickled, 3 ounces	219	24
Milk, fat free or skim, with added vitamin A and vitamin D, 1 cup	149	17
Cantaloupe, raw, ½ cup	135	15
Peppers, sweet, red, raw, ½ cup	117	13
Mangos, raw, 1 whole	112	12
Breakfast cereals, fortified with 10% of the DV for vitamin A, 1 serving	90	10
Egg, hard boiled, 1 large	75	8
Black-eyed peas (cowpeas), boiled, 1 cup	66	7
Apricots, dried, sulfured, 10 halves	63	7
Broccoli, boiled, ½ cup	60	7
Salmon, sockeye, cooked, 3 ounces	59	7
Tomato juice, canned, ¾ cup	42	5
Yogurt, plain, low fat, 1 cup	32	4
Tuna, light, canned in oil, drained solids, 3 ounces	20	2
Baked beans, canned, plain or vegetarian, 1 cup	13	1
Summer squash, all varieties, boiled, ½ cup	10	1
Chicken, breast meat and skin, roasted, ½ breast	5	1
Pistachio nuts, dry roasted, 1 ounce	4	0

\*DV = Daily Value. FDA developed DVs to help consumers compare the nutrient contents of foods and dietary supplements within the context of a total diet. The DV for vitamin A is 900 mcg RAE for adults and children age 4 years and older, where 1 mcg RAE = 1 mcg retinol, 2 mcg beta-carotene from supplements, 12 mcg beta-carotene from foods, 24 mcg alpha-carotene, or 24 mcg beta-cryptoxanthin. FDA does not require food labels to list vitamin A content unless vitamin A has been added to the food. Foods providing 20% or more of the DV are considered to be high sources of a nutrient, but foods providing lower percentages of the DV also contribute to a healthful diet.

birth defects with intakes >10,000 IU/day, as well as on minimizing the risk of liver damage due to hypervitaminosis A. For children, the RDA and UL values were scaled down based on body weight.

For consumer information purposes, the labels present on food items use the term % Daily Value (%DV), which is a less quantitative means to conveniently compare the nutritional value of various foods. It provides the relative contribution that a serving of that food makes to daily vitamin A intake, assuming a reference intake. Unlike the RDA and UL, the %DV is not scaled to different values for adults and children.

## Conditions of excess

### Hypervitaminosis A

Hypervitaminosis A is a rare but serious condition, where the severity depends on dose and frequency of intake (Tanumihardjo et al., 2016). It can arise acutely, within hours or days, after consumption of very large amounts of preformed vitamin A, causing serious illness and death. Or, it can develop slowly due to a persistent intake of lower but still excessive amounts of preformed vitamin A. Carotenoids are not a cause of vitamin A toxicity. Most clinical cases of toxicity are the result of excessive intake of retinol-containing supplements, or in patients taking prescription retinoids. The clinical signs of vitamin A toxicity include nausea and vomiting, headache, dizziness, blurred vision, lack of muscular coordination, abnormal liver function, and pain in weight-bearing bones and joints. The offspring of women of child-bearing age who consume excess vitamin A (over the UL on a regular basis), or use retinoids for therapeutic reasons, are at increased risk of birth defects. For this reason, the Food and Drug Administration (FDA) closely regulates the prescription of medicinal retinoids (FDA, 2012). Similarly, dietary supplements that contain amounts of vitamin A over the UL, which may be advertised as having health effects, should be avoided by women of child-bearing age, as the safety of intakes about the UL is not certain. Diets high in vitamin A-rich foods, such as liver and sausages prepared with organ meats, if consumed frequently, could pose a risk to developing fetus. As teratogenic effects on the fetus occur very early in development, even before pregnancy may be detected, women capable of becoming pregnant should avoid high intakes of these foods (Van den Berg et al., 1996).

There is no antidote for vitamin A toxicity, and little that can be done besides eliminating the intake of vitamin A or use of retinoids, and waiting for the body to clear the excess to the extent possible. Therefore, prevention is imperative. The overconsumption of preformed vitamin A, including that in supplements, should be avoided. As noted above, the UL, which applies to only preformed vitamin A, is meant to provide guidance to the public and health care workers for what is a safe upper level of intake on a chronic basis.

### Excessive carotene intake

Individuals who consume large amounts of carotenoid-rich foods or juices may develop yellowing of the skin (carotenoderma), especially in fatty tissues and the palms of the hands. This condition is considered benign and the yellow color will gradually subside after intake of carotene is reduced to a normal level. Regarding beta-carotene supplementation and cancer, although results have been somewhat controversial, the data from large clinical trials of high-dose supplemental beta-carotene in men who smoked showed adverse effects, with higher incidence of lung cancer in the supplement arm of the trial. It is therefore prudent for persons who smoke to avoid taking extra supplemental beta-carotene. Based on these studies, the "AREDS" formula to reduce risk of age-related macular degeneration was modified to eliminate beta-carotene, substituting other non-provitamin A carotenoids instead (Gorusupudi et al., 2017). Diets high in beta-carotene have not been shown to have adverse effects, and it is difficult to obtain very high intakes from dietary sources. Additionally, as noted above, the efficiency of absorption of dietary beta-carotene is physiologically regulated.

## Vitamin A supplementation in public health

Even at the present time, vitamin A deficiency is a significant public health concern, focused in low- and middle-income countries. A report (Stevens et al., 2015) described that despite improvements in vitamin A status overall during the past 3 decades, vitamin A deficiency remains prevalent in south Asia and sub-Saharan Africa. In public health settings such as in low-income parts of the world where children are at risk of developing vitamin A deficiency, large doses of vitamin A are often administered on a periodic basis as prophylaxis, or vitamin A may be administered therapeutically in cases of severe illnesses such as measles (Bello et al., 2011). Vitamin A supplementation in children ages 6 months to 5 years, living in at-risk settings, has significantly reduced disease severity and child mortality (Sommer, 2008) (see Chapter on Hypovitaminosis A).

## Conclusion/summary/outlook

As reviewed in this chapter, the human body makes use of both preformed vitamin A (retinol and its esters) and provitamin A (mainly beta-carotene) to produce the physiologically necessary forms of vitamin A, particularly 11-*cis*-retinal and all-*trans*-retinoic acid. Through the extensive processing of these dietary precursors, a vitamin A-adequate diet can be achieved through a variety of dietary patterns. These processing reactions begin during intestinal metabolism, when retinol is absorbed and beta-carotene is absorbed and then cleaved. They continue in the liver and in the many peripheral organs that utilize vitamin A, mainly through reactions that are part of oxidative metabolism. The transport of retinol between tissues is mediated by holo-RBP, the retinol component of which is extensively recycled. The kidneys are especially important in recapturing retinol from the renal filtrate and returning it to plasma. Nearly all cells of the body contain nuclear retinoic acid receptors that target the actions of vitamin A in gene expression. The retina is unique in utilizing 11-*cis*-retinal, which, in protein-bound form as rhodopsin, is required for vision. Vitamin A deficiency is a public health problem due to poor nutrition, linked to poor immune outcomes and loss of vision.

In contrast, vitamin A excess occurs much less commonly, is often due to excessive use of supplements, and can be very acute. Nutritional recommendations such as the RDA are set to provide an adequate allowance of vitamin A for all its physiological functions and to provide for some storage in tissues, whereas the UL is set as public health guidance to avoid excessive intake and the occurrence of hypervitaminosis A and, in its most severe form, vitamin A toxicity.

## Glossary

**Cobalamins** Compounds that are collectively known as vitamin B<sub>12</sub> and contain cobalt in a corrin ring. The cobalt can be attached to one of several sidegroups, including cyanide. Cyanocobalamin is the stable form of the vitamin manufactured for use as supplements and a food fortificant

**Macrocytosis** When red blood cells (erythrocytes) are larger than normal

**Transcobalamins** Carrier proteins which bind and transport vitamin B<sub>12</sub>

## Introduction

The cobalamins are a group of closely related and interconvertible compounds with a complex structure that are collectively known by the common name of vitamin B<sub>12</sub>. Recommended biochemical nomenclature restricts the term “vitamin B<sub>12</sub>” for the particular form of cobalamin known as cyanocobalamin. All cobalamins belong to the broader family of corrinoids, which share the characteristic of consisting of a planar four-membered pyrrole ring (corrin ring) containing a central cobalt atom. Cobalamins are distinguished from other corrinoids by possessing both alpha (lower) and beta (upper) axial ligands that are attached to the central cobalt atom (Fig. 1). The lower ligand consists of a base (5,6-dimethylbenzimidazole) attached to a sugar (ribose), which in turn is attached to a phosphate and an amino-propyl group that ultimately is tethered back to the corrin ring. In the naturally occurring cobalamins the upper ligand is variably a cyano-, hydroxo-, aquo-, methyl-, or adenosylgroup, giving rise to the correspondingly named chemical forms of the vitamin. Of these, methylcobalamin and deoxyadenosylcobalamin are the forms that function as coenzymes for metabolic reactions. All chemical forms of B<sub>12</sub> are highly sensitive to destruction by light; cyanocobalamin, as a synthetic naturally not occurring form, is a more stable form and is therefore used in therapeutic preparations. Hydroxo- or aquo-cobalamin are intermediates during the synthesis of the coenzyme forms. Other forms including sulphito-, nitrito-, and glutathionyl derivatives of cobalamin have also been described, but their precise role in metabolism is not known.

## Biochemistry and metabolic functions

Only two reactions in humans and other animals are known to require cobalamin (Fig. 2). One, isomerization of methylmalonyl CoA, which requires deoxyadenosylcobalamin, catalyzed by the enzyme methylmalonyl CoA mutase and is mitochondrial. The other reaction is the transmethylation of homocysteine by 5-methyl-tetrahydrofolate to methionine, catalyzed by the enzyme methionine synthase (N<sup>5</sup>-methyl homocysteine methyl transferase), which requires methylcobalamin as coenzyme and is located in the cytosol. It is through their essential roles in this important metabolic reaction that cobalamin and folate interact and are linked with respect to their importance in nutrition. In addition, there are major similarities in the effects of their deficiencies in humans.

Considering this “metabolic crossroad” for the two vitamins, it may be pointed out that without adequate supplies of both nutrients, the synthesis of methionine and its derivative S-adenosylmethionine (SAM) is disrupted, with consequent profound effects on normal cellular function. Methionine is an essential amino acid and normal supply depends critically on recycling through the remethylation pathway (Fig. 3). Moreover, SAM is the universal methyl donor, essential for more than 100 transmethylation reactions involving amino acid, nucleotide, neurotransmitter, and phospholipid metabolism as well as detoxification reactions.

**Fig. 1** Chemical structure of cobalamin.

Apart from methionine the other product of the methionine synthase reaction, which is almost completely irreversible, is tetrahydrofolate (THF). This constitutes the first step by which folate enters bone marrow and other cells from plasma, for its conversion into the various intracellular forms of reduced folate containing a series of one-carbon substituents (Fig. 3). The active forms of these folate congeners are all polyglutamated by an enzyme, folate polyglutamate synthetase, which cannot use methyl-THF as substrate. THF is the obligate substrate for polyglutamate addition. Consequently, when the methionine synthase reaction is blocked as a result of cobalamin deficiency, there is "THF starvation". Methyl-THF accumulates in the plasma, although intracellular folate concentrations fall due to failure of formation of the critical intracellular folate polyglutamates because of "methyl-folate trapping." This theory explains the abnormalities of folate metabolism, which occur in cobalamin deficiency (high concentrations of serum folate, low red blood cell folate), and also why the anemia that occurs in cobalamin deficiency will temporarily or partially respond to folic acid in large doses. The explanation of why the serum cobalamin falls in folate deficiency may also be related to impairment of the methionine synthase reaction resulting from reduced formation of methylcobalamin, the predominant circulating form of cobalamin in plasma.

**Fig. 2** Mammalian intracellular reactions requiring cobalamin. Conversion of methylmalonyl CoA to succinyl CoA is mitochondrial and requires cobalamin in the form of adenosyl-B<sub>12</sub>. Conversion of homocysteine to methionine is cytosolic and requires cobalamin in the form of methyl-B<sub>12</sub>.

**Fig. 3** The remethylation and transsulfuration pathways of homocysteine metabolism showing the role of cobalamin in the form of methyl-B<sub>12</sub> (CH<sub>3</sub>-B<sub>12</sub>) in the production of methionine. Other B vitamins (B<sub>6</sub>, folate) and required enzymes for related pathways are shown. MS, methionine synthase; MTHFR, methylene tetrahydrofolate reductase; TS, thymidylate synthase; DHFR, dihydrofolate reductase; CBS, cystathionine beta synthase; THF, tetrahydrofolate.

## Physiology

The recommended dietary allowance (RDA) for cobalamin in adults, proposed by the Food and Nutrition Board of the Institute of Medicine in 1997, is 2.4 µg/d for men and women, 2.6 µg/d and 2.8 µg/d during pregnancy and lactation, respectively. Cobalamins do not occur in plants and are synthesized by certain bacteria, fungi, and algae, which constitute the ultimate source of all cobalamins found in nature. Cobalamins enter the food chain through herbivorous animals that harbor cobalamin-producing microorganisms in their upper gastrointestinal tract (e.g., the “first stomach” of ruminants). Consumption of the meat or products of these animals supplies cobalamin in the diet for other animals. Dietary sources of cobalamin in humans are restricted to meat, poultry, fish, shellfish, eggs, and dairy products. Cobalamin is relatively resistant to destruction by cooking and depends besides others also on the cooking technique (frying leads to the highest losses), unlike the heat labile folates. On account of the exceedingly small daily requirement for cobalamin, in the order of 2–3 µg, and the relatively large body store of the vitamin (3000–5000 µg in individuals in developed countries), complete absence of intake or absorption of cobalamin is preceded by a long lag of up to 3–5 years before depletion of body cobalamin stores reaches a critical point that begins to result in the manifestations of cobalamin deficiency. This is not the case in developing countries where the onset of depletion may be much more rapid because of initially lower stores. Still, complete lack of dietary intake of cobalamin is somewhat rare and occurs only in strict vegans who shun all animal foods, including dairy products and eggs.

Cobalamin absorption is a complex mechanism that consists of several steps and involves several protein chaperones and receptors, defects of which can result in reduced or absent uptake of dietary cobalamin. The related and continuous processes of ingestion, digestion, and absorption of cobalamin comprising the assimilation of the vitamin are arbitrarily divided into six steps. During the first step of mastication and swallowing of food, dietary cobalamin becomes mixed with a binding protein derived from saliva belonging to the family of cobalamin-binding proteins known as haptocorrins. Cobalamin in foods is generally complexed to proteins that must first be digested to release the bioavailable vitamin. In the second step release of cobalamin takes place largely in the stomach, under the influence of gastric hydrochloric acid and proteolytic digestion by pepsin. It is during this process and in the acid environment of the stomach that salivary haptocorrin preferentially binds and protects food cobalamin. Another specific cobalamin-binding protein, known as intrinsic factor, is secreted by the parietal cells of the stomach, but is unable to bind the cobalamin still tightly complexed to haptocorrin. During the third step, which occurs in the duodenum, cobalamin is released from its complex with haptocorrin through the combined effects of pancreatic bicarbonate, which neutralizes the gastric acid, and the proteolytic action of the enzymes trypsin and chymotrypsin that digest haptocorrin and thus enable the binding of the free cobalamin by gastric intrinsic factor. In the fourth step, the intrinsic factor-cobalamin complex, having traversed the full length of the small intestine, arrives at the luminal surface of the terminal ileum. There, it comes in contact with specialized receptors. In the presence of calcium, the complex attaches to the receptor consisting of two distinct proteins coded by the genes cubulin and amnionless that is necessary to complete the assimilation process. Both proteins are essential for the internalization of the intrinsic factor-B<sub>12</sub> complex through the process of receptor-mediated endocytosis. Through this process, cobalamin together with intrinsic factor is escorted by the receptor and taken into lysosomes. Here the intrinsic factor-cobalamin complex is released and intrinsic factor is degraded through the action of acid hydrolysis by lysosomal peptidases. The final fifth step is poorly understood but first

**Table 1** Properties of human plasma cobalamin binding proteins.

	<i>Haptocorrins (TC I + III)</i>	<i>Transcobalamin (TC II)</i>
Source	Granulocytes	Endothelial cells
Transport functions	Storage, excretion of B <sub>12</sub> analogs, antimicrobial	Cellular B <sub>12</sub> uptake
Binding specificity	Low specificity, binds B <sub>12</sub> analogs	Binds B <sub>12</sub> with higher specificity
Membrane receptors	Nonspecific asialoglycoprotein receptors on hepatocytes	Specific receptors on most cells
Saturation	High (mainly "holo")	Low (mainly "apo")
Fraction of total B <sub>12</sub>	70–90%	10–30%
Plasma clearance	Slow ( $t_{1/2}$ ~10 days)	Rapid ( $t_{1/2}$ ~6 min)
Molecular weight	60,000	38,000–45,000

involves the release from lysosomes and then the metabolism of cobalamin to its methyl and deoxyadenosyl derivatives. It is currently believed that cobalamin enters the plasma in the form of methylcobalamin. The assimilation of food containing vitamin B<sub>12</sub> is a lengthy process, as evidenced by the 6–8 h taken for orally administered cobalamin to first appear in the plasma and several additional hours for the process to be completed. Recent evidence indicates that cobalamin leaves the cell through an exit portal that is part of the ABC drug transport system, ABCC1 (also known as the Multidrug Resistance Protein, MRP1), present in the basolateral membrane of the intestinal epithelium as well as in other cells.

After cobalamin enters the plasma via the MRP1 it becomes bound to the cobalamin binding protein, transcobalamin (previously known as transcobalamin II to distinguish it from transcobalamins I and III which, together with the salivary cobalamin binding protein and other cobalamin binders present in secretions are now referred to collectively as the haptocorrins). The properties of transcobalamin and the haptocorrins are summarized in **Table 1**. The fraction of cobalamin bound to transcobalamin accounts for only 10–30% of the total plasma cobalamin. The major residual fraction of the plasma cobalamin is attached to haptocorrin. The function of haptocorrins is not known, but rapidly proliferating cells including bone marrow precursors can obtain cobalamin only from transcobalamin. Consequently, the critical fraction of the serum cobalamin is the transcobalamin-bound portion, known as holotranscobalamin. Conditions that alter the amount or distribution of cobalamin on these binding proteins can critically affect delivery and transport. Therefore, conditions that lead to an increase in haptocorrins, such as chronic granulocytic leukemia, characterized by markedly increased numbers of granulocytes (haptocorrins are produced in granulocytes), can give rise to an apparently normal serum cobalamin level even in patients who have severe underlying cobalamin deficiency, through redistribution of reduced body cobalamin stores. Conversely, insufficient holotranscobalamin can result in cobalamin deficiency even if the total serum cobalamin level is apparently normal. This occurs in infants and children affected by congenital transcobalamin deficiency, which is associated with severe megaloblastic anemia. Levels of transcobalamin may be affected by a number of factors. Lowering of holotranscobalamin can result in tissue cobalamin deficiency with a normal total serum cobalamin level. Now that sufficiently sensitive and robust methods are available to measure holotranscobalamin levels in serum, several studies have reported that there is a good inverse correlation between serum holotranscobalamin concentration and serum levels of the metabolites methylmalonic acid and homocysteine, which are described below.

### Causes, mechanisms, and effects of cobalamin deficiency

There are several causes of cobalamin deficiency that range in severity and frequency of occurrence. These are summarized in **Table 2**. In general, causes of cobalamin deficiency can be divided into those caused by absent or markedly reduced dietary intake and those caused by malabsorption, either gastric or ileal. The most frequent cause of severe cobalamin deficiency is pernicious anemia, caused by an autoimmune destruction of the gastric mucosa with consequent failure of intrinsic factor production. Less common causes include chemical inactivation and inherited defects in cobalamin absorption or metabolism.

In all situations resulting from impairment of cobalamin absorption, the time to onset of deficiency depends on several factors, including the size of the body store, the extent of impairment of absorption (partial or complete), and, in diseases like pernicious anemia and others affecting the small intestine, the rate of progression of the disease. In general, however, cobalamin deficiency resulting from malabsorption develops sooner than is the case in the dietary deficiency encountered among vegans. This difference may be explained by the existence of a considerable enterohepatic recirculation of cobalamin. Biliary cobalamin is efficiently reabsorbed in vegans compared with patients with pernicious anemia or other forms of malabsorption, because the intrinsic factor-dependent mechanism is intact.

Deficiency of cobalamin, when severe, affects all rapidly growing (DNA-synthesizing) tissues. After the marrow, the next most affected tissues are the epithelial cell surfaces of the gastrointestinal tract (mouth, stomach, and the small intestine). Affected cells are large, with increased numbers of multinucleated and apoptotic dying cells. The gonads are also affected and infertility occurs in patients with cobalamin deficiency. Cobalamin deficiency may cause bilateral peripheral neuropathy or degeneration

**Table 2** Causes of vitamin B<sub>12</sub> deficiency.

1. Dietary<sup>a</sup>
  - a. Veganism or very low intake of animal source foods
2. Gastric
  - a. Atrophic gastritis and food B<sub>12</sub> malabsorption
  - b. Autoimmune gastritis/gastric atrophy (classical pernicious anemia)
  - c. Extensive gastric disease or resection (including bariatric surgery)
3. Ileal
  - a. Extensive ileal disease (Crohn disease, inflammatory bowel disease, tuberculous enteritis), or resection for these diseases
  - b. Luminal disturbances (chronic pancreatic disease and gastrinoma) and parasites (giardiasis, bacterial overgrowth, and fish tapeworm).
4. Chemical/drug
  - a. Nitrous oxide
  - b. PAS, metformin, colchicine, proton pump inhibitors, H<sub>2</sub>-receptor antagonists
5. Congenital/inherited
  - a. Intrinsic factor deficiency/defect ("Juvenile" pernicious anemia).
  - b. Intrinsic factor receptor deficiency/defect (Immerslund-Gräsbeck disease).
  - c. Transcobalamin (TC) II deficiency or polymorphisms<sup>a</sup>
  - d. Cobalamin mutants (C-G).

<sup>a</sup>Suboptimal cobalamin status caused by lowered intake or TC polymorphisms can predispose to more rapid onset of deficiency when other pathological causes of cobalamin deficiency occur.

(demyelination) of the posterior and pyramidal tracts of the spinal cord and, less frequently, atrophy of the optic nerve or cerebral symptoms. Cobalamin-deficient patients typically display sensory disturbances (paraesthesiae), muscle weakness, difficulty in walking and sometimes dementia, psychotic disturbances or visual impairment. Long-term nutritional cobalamin deficiency in infancy leads to poor brain development and impaired intellectual development. The effects of cobalamin deficiency on the blood and on the nervous system may occur separately or in combination and their severity is often inversely rather than directly correlated. The biochemical basis for cobalamin neuropathy, however, remains obscure. Its occurrence in the absence of methylmalonic aciduria in TCII deficiency, and in monkeys given the anesthetic agent nitrous oxide, suggests that the neuropathy is related to a defect in homocysteine-methionine conversion. Accumulation of S-adenosylhomocysteine in the brain, resulting in inhibition of transmethylation reactions has been suggested as the mechanism.

Psychiatric disturbance is common in cobalamin deficiencies. Like the neuropathy, this has been attributed to a failure of the synthesis of SAM, due to reduced conversion of homocysteine to methionine. SAM is needed for methylation of biogenic amines (e.g., dopamine), as well as of proteins, phospholipids, and neurotransmitters in the brain.

### Diagnosis of cobalamin deficiency

Cobalamin deficiency is suspected in individuals who display the typical manifestations of deficiency of the vitamin as described in the Section above, Causes, Mechanisms and Effects of Cobalamin Deficiency. In addition to the symptoms that may be experienced related to anemia (easy fatigue, shortness of breath, palpitations) and neuropathy (sensory and motor disturbances and memory loss) there are features that may be detected by a physician, including skin pallor (from anemia), abnormalities in neurological examination (sensory loss, abnormal balance and reflexes, and mental changes), and epithelial changes (skin pigmentation and smooth tongue). On the basis of any combination of such changes, cobalamin deficiency may be suspected but confirmation is necessary using laboratory tests because other conditions may give rise to effects that closely resemble cobalamin deficiency. The need to confirm suspected cobalamin deficiency applies also to individuals who have abnormalities in their blood count measurements.

The standard screening test for cobalamin deficiency consists of direct measurement of circulating levels of cobalamin. Serum levels less than 150 pmol L<sup>-1</sup> (<200 ng/L) are considered deficient and levels 150–250 pmol L<sup>-1</sup> are considered borderline. Serum or plasma cobalamin concentration can be measured in several ways and this has evolved from early microbial growth assays through competitive binding assays that were first radioisotopic and are now enzyme linked or based on chemiluminescence detection. The sensitivity and specificity of these assays are imperfect, such that measurement of serum cobalamin levels does not always detect the presence of deficiency, nor does the finding of a low serum cobalamin always connote true deficiency. There are several reasons for this including the distribution of cobalamin between the binding proteins in circulation (Table 1), imperfections in the assays for its measurement, and various poorly understood factors relating to exchange of cobalamin between cellular and circulatory compartments. Regarding the distribution of cobalamin between plasma-binding proteins, because transcobalamin is responsible for cobalamin delivery to cells, the fraction of the total cobalamin that is associated with transcobalamin (holoTC), even though small in comparison with the haptocorrin-associated fraction, is more likely to be indicative of cobalamin status than is the total serum cobalamin. Serum vitamin B<sub>12</sub> assays measure the sum of vitamin B<sub>12</sub> bound to haptocorrin (i.e., holohaptocorrin) and the fraction bound to transcobalamin (i.e., the holotranscobalamin). However, only the fraction of vitamin B<sub>12</sub> bound to

**Table 3** Laboratory identification of cobalamin deficiency.

<i>Test</i>	<i>Finding</i>	<i>Major limitations</i>
Serum/plasma cobalamin concentration	Low (<150 pmol L <sup>-1</sup> )	Normal levels in some deficient subjects; slight to moderately low levels may not connote deficiency
Serum/plasma holotranscobalamin (holo TC II)	Low (<35 pmol L <sup>-1</sup> )	Holo-TC assays show a rather wide coefficient of variation according to the used assay methods and thus variable interpretation of the results; assay interference due to autoantibodies or vitamin B12 supplements
Serum/plasma or urine methylmalonic acid	Raised (>350 nmol L <sup>-1</sup> )	Considerable inter-assay variability, levels raised in renal insufficiency, increased levels during pregnancy
Plasma homocysteine	Raised (>12 μmol L <sup>-1</sup> )	Levels raised in folate and in vitamin B <sub>6</sub> deficiencies, renal insufficiency, hypothyroidism

transcobalamin is taken up by the cells to cover their metabolic requirements (thus often named as “active B12”), suggesting that this biochemical parameter would represent a more suitable index. Despite still ongoing controversy in clinical practice the measurement of holotranscobalamin is favored as the first line assay, although serum/plasma levels as well as the holotranscobalamin levels do show a rather large gray zone for a clear interpretation of the results so that the measurement of the concentration of methylmalonic acid as a second line assay becomes often inevitable.

Since there is still no gold standard to assess vitamin B12 nutriture in a fully reliable and cost-efficient manner a combination of parameters might be applied. Cobalamin deficiency can be identified indirectly, based on the detection of raised levels of compounds in the blood or urine that require adequate tissue levels of cobalamin for their metabolic disposal. The compounds most commonly measured for identification of possible cobalamin deficiency are methylmalonic acid and homocysteine. These are the substrates in two cobalamin-dependent reactions shown in Fig. 2. Because of the identification of these metabolic roles for cobalamin, it has been apparent that deficiency of cobalamin or disturbances in its metabolism would result in accumulation of these substances and clinical assays for these metabolites is now available. Of the two compounds, elevation of the levels of methylmalonic acid is more specific for identification of cobalamin deficiency; however, renal insufficiency can cause raised levels of methylmalonic acid in the blood. In addition to cobalamin deficiency, several other conditions also can cause raised homocysteine levels in the blood, including deficiencies of folate and vitamin B<sub>6</sub>, lowered levels of thyroid hormone, and renal insufficiency.

Table 3 shows the idealized usefulness of the various tests commonly employed for the detection of cobalamin deficiency. Despite the lack of a reliable single parameter approach to assess deficiency, the main clinical issue is to assure high plasma/serum levels of vitamin B12 (>300 pmol L<sup>-1</sup>) in any patient. This pragmatic approach is supported by recent evidence that the presence of a “high-folate-low-vitamin B12” status (as is frequently occurring due to the fortification of cereals with folate) might be a correctable cause of vitamin B12 depletion.

### Inborn errors of cobalamin metabolism

There are several known but rare inherited molecular defects resulting in absence or structural defects of proteins required for normal absorption, transport, or metabolism of cobalamin. These include the intestinal binding proteins, gastric intrinsic factor and its ileal receptor complex cubulin and amnionless, the plasma binders transcobalamin and haptocorrin, the enzymes that are required for conversion of cobalamin to its coenzymatically active methyl and deoxyadenosyl forms, and enzyme complexes involved in the catalysis of the two cobalamin-dependent reactions responsible for conversion of homocysteine to methionine and methylmalonate to succinate, respectively. Individuals who inherit a defective gene from each parent for any one of the proteins that are critical for cobalamin metabolism suffer from varying degrees of impairment of normal cobalamin-related status (see Table 4), closely mimicking the various manifestations of cobalamin deficiency described above. These disorders usually become manifest at an early age.

**Table 4** Inherited disorders affecting cobalamin metabolism and their effects.

<i>Cobalamin protein</i>	<i>Effects of deletion or mutation</i>
Intrinsic factor	Cobalamin malabsorption (juvenile pernicious anemia)
Cubulin/amnionless complex	Selective malabsorption of cobalamin, autosomal recessive megaloblastic anemia (MGA1, Immerslund-Gräsbeck disease)
Transcobalamin	Severe cobalamin deficiency
Haptocorrin	No apparent abnormality
Cobalamin reducing and activating enzymes (mut <sup>+</sup> and mut <sup>-</sup> , cobalamin mutants C-G)	Varying degrees of disruption in one or both cobalamin-dependent pathways

### Key points

To explain:

- How the various forms of vitamin B<sub>6</sub> in the diet are converted to pyridoxal phosphate (PLP) in our organs and tissues
- How PLP acts as a cofactor for numerous enzymes, particularly those involving amino acids
- How dietary constituents and drugs that bind PLP can increase the amount of B<sub>6</sub> an individual needs to avoid symptoms of PLP deficiency
- How inborn errors of metabolism can have a similar effect.

To show how dietary deficiency of B<sub>6</sub> and the effects of drugs and inborn errors of metabolism have taught us that:

- The principal effects of PLP deficiency are neurological including seizures, movement disorder and polyneuropathy
  - Deficiency can, however, also cause other disorders such as anemia
  - These effects can be traced to reduced activity of PLP-dependent enzymes
- To indicate to the reader that:

- Vitamin B<sub>6</sub> has functions in the body in addition to its role in supplying the PLP cofactor for PLP-dependent enzymes
- PLP plays a role in many common diseases including infection and inflammation, cancer and neurodegenerative disorders such as Parkinson disease

## Introduction

Vitamin B<sub>6</sub> refers collectively to a group of related compounds, namely pyridoxine (PN), pyridoxamine (PM) and pyridoxal (PL), free, or as phosphates or glycoside esters. Most unicellular organisms and plants are capable of synthesizing vitamin B<sub>6</sub> de novo. *Escherichia coli* synthesizes PLP via the deoxyxylulose-5-phosphate (DXP)-dependent pathway utilizing erythrose-4-phosphate, glyceraldehyde-3-phosphate and pyruvate. Other bacteria, fungi, and plants use an alternative pathway that does not involve DXP, referred to as the DXP-independent pathway (Raschle et al., 2009). Animals, however, are not able to synthesize vitamin B<sub>6</sub> and are therefore reliant on the forms available in their diet, despite a contribution from gut microbiota, or that are recycled from protein turnover via a salvage pathway. One of the forms of vitamin B<sub>6</sub>, pyridoxal 5'-phosphate (PLP), is catalytically active functioning as a cofactor for more than 4% of all known cellular enzymes. Increasingly, it is being recognized that B<sub>6</sub> vitamers also have nonenzymatic roles; having been shown to be effective antioxidants, regulating activity of steroid hormone receptors and modulating gene expression, and playing a role in brain glucose regulation. Because of such a wide spectrum of functions, vitamin B<sub>6</sub> is implicated in many common and rare disorders. A severe deficiency of PLP is rare and manifests as an epilepsy, believed to occur as a result of neurotransmitter imbalance. Milder deficiencies are more common, it has been suggested that 24–31% of the elderly have a B<sub>6</sub> intake below the estimated average requirement (EAR) (Porter et al., 2016). These have been implicated in disordered sleep, behavior, cardiovascular function and a loss of hypothalamus pituitary control of hormone excretion as well as having been reported to be associated with cognitive deficits and structural brain changes. Conversely, very high levels of vitamin B<sub>6</sub> may have toxic effects and cause peripheral neuropathy or induce seizures.

## Chemical structures of B<sub>6</sub> vitamers and dietary sources

B<sub>6</sub> vitamers (Fig. 1) are derivatives of 2-methyl-3-hydroxy-5-hydroxymethyl-pyridine. The C4 substituent of the pyridine ring is an aldehyde group in pyridoxal, a hydroxymethyl group in pyridoxine and an aminomethyl group in pyridoxamine. The 5' alcohol group is esterified to phosphate in pyridoxal phosphate (PLP), pyridoxine phosphate (PNP) and pyridoxamine phosphate (PMP) and linked to glucose in pyridoxine β-glucoside (PNG). The principal forms of vitamin B<sub>6</sub> in meat and fish are PLP and PMP, in breast milk PLP and pyridoxal and, in fruit and vegetables pyridoxine, PNP and PNG. PNG provides about 15% of the total vitamin B<sub>6</sub> in a mixed diet, however, the bioavailability of PNG is only about 50–60% that of pyridoxine ((Mackey et al., 2004); see Digestion and Absorption below). PLP in the diet may be bound to the ε-amino group of lysine residues proteins as a Schiff base (aldimine) and excessive heating of food can lead to reduction of the aldimine to produce phosphopyridoxyllysine (Gregory, 1980); this was implicated in dietary deficiency of B<sub>6</sub> in infants (see below). Vitamin B<sub>6</sub> can be synthesized by the gut flora and this may make a significant contribution to our B<sub>6</sub> intake (see below).

## Digestion and absorption

Prior to absorption phosphorylated B<sub>6</sub> vitamers must be dephosphorylated by intestinal phosphatases and PNG must also be hydrolyzed to release pyridoxine. The latter reaction is catalyzed by two enzymes, the brush border membrane β-glucosidase, lactase phlorizin hydrolase and the cytosolic β-glucosidase, pyridoxine 5'-β-D-glucosidase (Mackey et al., 2004). Individuals with relative lactase deficiency may be at risk for a degree of pyridoxine deficiency (Mackey et al., 2002).

## Bacterial metabolism

The gut flora is capable of synthesizing vitamin B<sub>6</sub> that can be used the host; indeed it has been suggested that the gut microbiota may be able to synthesis enough pyridoxine to supply 86% of the recommended dietary intake of B<sub>6</sub> although this needs to be

**Fig. 1** Chemical structures of the B<sub>6</sub> vitamers. The B<sub>6</sub> vitamers are based on a pyridine ring structure. Pyridoxine, pyridoxamine and pyridoxal differ by the substituent at the 4-position and when phosphorylated at position 5 form pyridoxine 5'-phosphate, pyridoxamine 5'-phosphate and pyridoxal 5'-phosphate, respectively. Numbering of the ring positions is shown in blue for pyridoxine.

verified experimentally (Magnúsdóttir et al., 2015). However, some bacteria also catabolize B<sub>6</sub> vitamers (McCulloch et al., 2010) and this may become important when individuals with inborn errors of metabolism are treated with very high doses of PLP given orally.

## Metabolism and transport

Pyridoxal, pyridoxamine and pyridoxine absorbed from the gut are mainly converted to PLP in the liver (Fig. 2), although this can occur in other tissues. Phosphorylation by pyridoxal kinase (PK) produces PLP, PMP and PNP and conversion of PMP and PNP to PLP is catalyzed by pyridox(am)ine 5'-phosphate oxidase (PNPO) which utilizes flavin mononucleotide (FMN) as cofactor (Wilson et al., 2019). PLP produced in the liver is exported into the circulation bound to lysine 190 of albumin. Studies have also shown (Albersen et al., 2013) that B<sub>6</sub> vitamers can be converted to PLP by a Caco-2 cell line, an in vitro intestinal model derived from a colon carcinoma, with PL being the predominant vitamer excreted.

PK and PNPO are both inhibited by PLP. Regulation of enzyme activities also occurs at the transcriptional level (at least in experimental animals). Three transcription factors, DBP (albumin D-site-binding protein), HLF (hepatic leukemia factor), and TEF (thyrotroph embryonic factor), increase transcription of PK leading to a circadian rhythm of PK expression and PLP levels in mice (Gachon et al., 2004). Knockout of these 3 transcription factors leads to brain PLP deficiency and epilepsy. Transcription of PNPO can be affected by knockout of a non-coding microRNA, miR324 and this also leads to increased hippocampal excitability (Hayman et al., 2021).

When the intake of B<sub>6</sub> vitamers exceeds the body requirement, PLP is catabolized, mainly in the liver, by phosphatases with subsequent conversion of the pyridoxal to pyridoxic acid which is excreted in the urine. It is not certain whether the oxidation of pyridoxal to pyridoxic acid is catalyzed by an aldehyde dehydrogenase or an aldehyde oxidase.

The main form of B<sub>6</sub> in plasma is PLP bound to albumin. To supply B<sub>6</sub> to the brain, PLP must dissociate from albumin, and undergo dephosphorylation to pyridoxal which then crosses the blood brain barrier and/or the blood CSF barrier of the choroid plexus (Wilson et al., 2019). Dephosphorylation is catalyzed by the ectoenzyme tissue non-specific alkaline phosphatase (TNSALP) which is tethered to the blood facing membrane by a glycoposphatidylinositol (GPI anchor). Once inside neurons and glia, pyridoxal is rephosphorylated by pyridoxal kinase. PLP regenerated from pyridoxal, by pyridoxal kinase, in the choroid plexus can be

**Fig. 2** Interconversion of dietary B<sub>6</sub> vitamers to the active cofactor, pyridoxal 5'-phosphate. Enzymes involved in the interconversion given in blue text. Pyridoxal 5'-phosphate (PLP); pyridoxamine 5'-phosphate (PMP); pyridoxal (PL); pyridoxine (PN); pyridoxine 5'-phosphate (PNP); pyridoxine-5'-β-D-glucoside (PNG); intestinal phosphatases (IP); pyridoxal kinase (PK); pyridox(am)ine 5'-phosphate oxidase (PNPO); tissue non-specific alkaline phosphatase (TNSALP); pyridoxal-phosphatase (PLPase); GPI anchor (glycosylphosphatidylinositol anchor); AOX/DH (Aldehyde oxidase [Mo cofactor]/β-NAD dehydrogenase); E-PLP (enzyme-PLP); E-PMP (enzyme-PMP).

secreted into the CSF bound to albumin. Uptake of B<sub>6</sub> from the CSF requires dephosphorylation by TNSALP. Supply of B<sub>6</sub> to other tissues of the body from plasma PLP is also dependent on TNSALP.

The body conserves B<sub>6</sub> by means of a salvage pathway. PMP generated when PLP-dependent enzymes catalyze a partial reaction (e.g., the first half reaction of a transamination) or when they are catabolized can be converted back to PLP by PNPO. Free vitamers can be rephosphorylated by pyridoxal kinase (Wilson et al., 2019).

## Cellular homeostasis

All cells in the body require PLP bound to their PLP-dependent enzymes, however, concentrations of free PLP over 10 μM can inhibit enzymes (Christmann-Franck et al., 2007) and to avoid unwanted reactions of PLP the free PLP is maintained at 1 μM (di Salvo et al., 2011). Mechanisms for controlling the free PLP concentration are thought to include: (i) inhibition of pyridoxal kinase and PNPO by PLP; (ii) transfer of newly formed PLP from either enzyme to apo-B<sub>6</sub>-enzymes by direct channeling; (iii) hydrolysis of excess PLP by phosphatases; (iv) binding of PLP to abundant intracellular proteins e.g., glycogen phosphorylase in muscle and hemoglobin in red cells; (v) binding of PLP to the pyridoxal phosphate homeostatic protein (PLPHP aka PLP-binding protein, PLPBP, PROSC). Deficiency of the latter was found to be a cause of impaired cellular PLP homeostasis and B<sub>6</sub>-dependent epilepsy in 2016 (Darin et al., 2016) but the exact function of PLPHP is not known.

## Reactions catalyzed by PLP enzymes

PLP enzymes in the body, in their resting state, have the PLP bound covalently via an imine bond to the ε-amino group of the active site lysine forming a Schiff base or "internal aldimine" (Eliot and Kirsch, 2004). The largest group of PLP-catalyzed reactions act on

amino acid substrates. The amino group of the substrate displaces the lysine  $\epsilon$ -amino group forming a new aldimine with the PLP ("external aldimine/external Schiff base"). This increases the reactivity of the  $\alpha$ ,  $\beta$  and  $\gamma$  carbons of the amino acid. The reactions that are catalyzed at the  $\alpha$ -carbon include transamination, decarboxylation, racemization and elimination and replacement of an electrophilic group. Reactions catalyzed at the  $\beta$ - and  $\gamma$ - carbons include eliminations and replacements (Eliot and Kirsch, 2004).

The notable exception to the general rule that PLP-catalyzed reactions occur through the formation of an external aldimine of PLP and an amino acid is glycogen phosphorylase. This enzyme catalyzes the transfer of a phosphate group to glycogen generating glucose-1-phosphate (Takagi et al., 1982).

The consequences of reduced activity of some specific PLP enzymes and PLP-dependent pathways are discussed below:

### Glutamate decarboxylase (GAD)

This PLP enzyme is required for the synthesis of GABA, the major inhibitory neurotransmitter. Deficiency of the GAD65 isoform in rats causes low GABA levels in the brain, epilepsy and premature lethality (Kakizaki et al., 2021). Animal models with PLP deficiency causing seizures have low brain GABA levels (Ciapaite et al., 2020; Johnstone et al., 2019; Pena et al., 2017). In children with pyridoxine-dependent epilepsy there is evidence of low GAD activity and low brain and CSF GABA (Gospe et al., 1994).

### Aromatic amino acid decarboxylase

This PLP enzyme catalyzes the production of dopamine from L-Dopa and of serotonin from 5-hydroxytryptophan. Isolated AADC deficiency leads to deficiency of dopamine and serotonin most easily detected by reduced CSF concentrations of their metabolites, homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5HIAA) respectively. The clinical phenotype is a severe movement disorder with particularly prominent oculogyric crises (Hyland et al., 1992; Saudubray et al., 2016). Inborn errors of metabolism causing PLP deficiency can also demonstrate low CSF HVA and 5HIAA and the dominant feature of the phenotype can be a movement disorder resembling AADC deficiency (Johnstone et al., 2019).

### Glycine and serine metabolism, 1-carbon and folate metabolism

The glycine decarboxylase component of the glycine cleavage enzyme is a PLP-dependent enzyme. Isolated deficiency of the glycine cleavage enzyme (GCE) causes non-ketotic hyperglycinaemia which presents with neonatal hypotonia, severe seizures and raised plasma and CSF glycine. Thus, it is likely that reduced glycine decarboxylase activity contributes to the high plasma and CSF glycine, and possibly to the seizures seen in PLP deficiency. Serine reacts with tetrahydrofolate in a reaction catalyzed by the PLP-dependent enzyme, serine hydroxymethyl transferase (SHMT), to produce glycine and 5,10-methylenetetrahydrofolate. Serine levels in plasma are elevated in B<sub>6</sub> deficiency; mathematical modeling suggests that this is due more to reduction in the activity of GCE than SHMT (Nijhout et al., 2009).

When neuronal cells are cultured in B<sub>6</sub>-deficient medium, their content of serine and glycine is reduced as is their content of 5-methyltetrahydrofolate. This suggests that the PLP deficiency is affecting the PLP-dependent steps involved in serine synthesis from glycolytic intermediates and this together with the direct effect on GCE and SHMT is causing impaired function of the folate cycle (Ramos et al., 2017). In some individuals with inborn errors of metabolism leading to PLP deficiency, folinic acid-responsive seizures have been described (Johnstone et al., 2019; Gallagher et al., 2009). In *C. elegans* rendered profoundly PLP deficient by ensuring that the *E. coli* that formed the diet as well as the gut flora could not synthesize B<sub>6</sub>, dysfunction of the folate cycle and 1-carbon metabolism was clearly demonstrated (Scott et al., 2017).

It has been suggested that the neuropathology of folate and B<sub>12</sub> disorders could be caused by deficiency of S-adenosyl-methionine (Bottiglieri et al., 1994); the same may be true of features of B<sub>6</sub> disorders such as peripheral and optic neuropathies.

### Sulfur amino acid metabolism

B<sub>6</sub> deficiency can contribute to hyperhomocysteinemia. The PLP-dependent enzyme cystathionine  $\beta$ -synthase provides one route for metabolism of homocysteine i.e., conversion to cystathionine. Individuals with cystathionine  $\beta$ -synthase deficiency have considerably elevated plasma homocysteine levels and in about 50% the hyperhomocysteinemia can be effectively treated with large doses of pyridoxine (Saudubray et al., 2016). However reduced activity of CBS may be only one factor that leads to hyperhomocysteinemia in B<sub>6</sub> deficiency. The folate cycle generates 5-methyl-tetrahydrofolate which is required for the B<sub>12</sub>-dependent conversion of homocysteine to methionine and as indicated above the folate cycle may be impaired in B<sub>6</sub> deficiency. Folic acid supplementation can ameliorate the hyperhomocysteinemia induced in rats by B<sub>6</sub> deficiency and methionine supplementation (Yamamoto et al., 2012). Finally, PLP is required for cystathionine  $\gamma$ -lyase activity and PLP deficiency can lead to raised plasma cystathionine, however, this may not contribute to disease as individuals with cystathionine  $\gamma$ -lyase deficiency are asymptomatic (Saudubray et al., 2016).

Cysteine supplies the sulfur in the iron/sulfur clusters that are essential for oxidative phosphorylation and this is achieved through the action of cysteine desulfurase, a PLP-dependent enzyme. Individuals with cysteine desulfurase deficiency have defective oxidative phosphorylation (Farhan et al., 2014) and inborn errors of metabolism that cause severe PLP deficiency can show marked lactic acidosis, for which cysteine desulfurase deficiency may be one cause.

### Tryptophan metabolism

The catabolism of tryptophan and its conversion to nicotinamide require the PLP-dependent enzyme, kynureninase, which converts 3-hydroxykynurenine to 3-hydroxyanthranilic acid. If 3-hydroxykynurenine builds up it is converted to xanthurenic acid. PLP deficiency leads to increased excretion of xanthurenic acid especially if the individual is given a tryptophan load. Deficiency of nicotinamide is probably unusual in PLP deficiency, but it has been described in isoniazid-induced deficiency (Prabhu et al., 2021).

### Glyoxylate metabolism

The B<sub>6</sub>-dependent enzyme alanine glyoxylate aminotransferase catalyzes the conversion of alanine and glyoxylate to pyruvate plus glycine. Reduced activity of this enzyme leads to increased production of oxalate increasing the risk of formation of oxalate stones in the urinary tract. This can occur in B<sub>6</sub>-deficient rats (Nishijima et al., 2003).

### Glucose homeostasis

Hypoglycaemia has been described in inborn errors of metabolism causing PLP deficiency. The following enzyme deficiencies may play a role: glycogen phosphorylase (rate limiting step for release of glucose from glycogen); transaminases and other PLP dependent reactions of amino acids (required for gluconeogenesis from amino acids); AADC deficiency (impaired catecholamine synthesis) and others.

### Heme synthesis

PLP is needed by the enzyme that catalyzes the first step in heme synthesis i.e.,  $\delta$ -aminolaevulinic acid synthase. Isolated deficiency of this enzyme causes a sideroblastic anemia which can be effectively treated with pyridoxine, plus folic acid (Saudubray et al., 2016). Anemia is a feature of PLP deficiency of various causes and deficiency of  $\delta$ -aminolaevulinic acid synthase may contribute.

### Reactivity of PLP

The reactive aldehyde group of PLP allows it to act as the cofactor for enzyme-catalyzed reactions as indicated above. However some reactions of PLP have adverse or potentially adverse effects if the reacting molecule is present in sufficiently high concentration (see Table 1 for small molecules). PLP can also have adverse effects on proteins if present at high concentration (Kajita et al., 2013; Christmann-Franck et al., 2007). Finally, as an endogenous aldehyde, PLP may in some circumstances damage chromosomes and mutate stem cells (Garaycochea et al., 2018).

### Roles of B<sub>6</sub> vitamers other than as an enzyme cofactor

B<sub>6</sub> vitamers can act as antioxidants; they can quench singlet oxygen at rates comparable to vitamin C and E (Bilski et al., 2000).

PLP can affect the expression and action of steroid hormone receptors (Tully et al., 1994). It can inhibit the binding of the transcription factor HNF1 to DNA (Oka et al., 2001). The action of a corepressor for many nuclear factors, RIP140, is enhanced by conjugation of Lys613 to PLP (Huq et al., 2007). This may affect the function of RIP141 in adipocyte differentiation.

PLP can act as an antagonist of ATP at the purinergic receptor P2X7 (Thériault et al., 2014). Activation of P2X7 receptors by ATP is thought to be a mechanism for the genesis of epilepsy in neuroinflammation (Beamer et al., 2017). Antagonism by PLP may explain why it acts as an anticonvulsant even when there is no evidence of PLP deficiency.

In the immune system, PLP binds tightly to the D1 domain of CD4 and this may interfere with the reaction of CD4 with MHC II (Salhany and Schopfer, 1993).

Using *Drosophila* as a model system, Marzio et al. (2014) obtained evidence that PLP plays a crucial role in maintenance of the integrity of the genome. Mutations in the gene encoding pyridoxal kinase (*dPdxk*) produce chromosome aberrations (CABs) in larval neuroblasts; this can be prevented by PLP. CABs can also be induced by PLP antagonists such as 4-deoxypyridoxine hydrochloride; penicillamine, cycloserine and isoniazid also increase the frequency of CABs. The authors suggest that, since CABs are precursors of cancer, low levels of PLP may predispose to initiation of cancer. In the same *Drosophila* model, Marzio et al. (2014) found that *dPdxk*<sup>1</sup> mutants have increased levels of glucose in their hemolymph attributable to insulin resistance. They suggested that this might indicate a susceptibility to diabetes and that DNA damage is caused by high glucose levels in PLP deficient cells.

**Table 1** Molecules that react with PLP.

Molecule	Reason for build-up	Consequence of reduced PLP
Δ <sup>1</sup> -piperidine-6-carboxylate (P6C)	ALDH7A1 deficiency (OMIM 266100)	Pyridoxine-responsive epilepsy
Δ <sup>1</sup> -pyrroline-5-carboxylate (P5C)	ALDH4A1 deficiency (OMIM 239510)	Pyridoxine responsive seizures
Sulfite and P6C	Molybdenum cofactor deficiency (OMIM 603708)	Pyridoxine-responsive seizures
1-Amino-D-proline (Linatine)	Ingestion of linseed/oil	Seizures in rats
Isoniazid	Treatment of tuberculosis	Peripheral neuropathy. Increased urinary xanthurenic acid Pellagra (decreased nicotinamide synthesis from tryptophan) Overdose: Seizures, lactic acidosis
D-cycloserine	Treatment of tuberculosis	Seizures Psychosis
Hydralazine	Treatment of hypertension <sup>a</sup>	Peripheral neuropathy
Monomethylhydrazine	Poisoning with <i>Gyromitra</i> mushrooms (false morel) <sup>b</sup>	Seizures, coma
Penicillamine	Treatment of Wilson disease <sup>c</sup>	Optic neuropathy Epilepsy Increased urinary xanthurenic acid
L-Dopa	Treatment of Parkinson disease	Reduced PLP and reduced L-Dopa may both contribute to reduced effectiveness of L-Dopa Contribution to peripheral neuropathy <sup>d</sup>

## Dietary deficiency

The main symptoms of dietary B<sub>6</sub> deficiency in infancy are neurological. In 1954, Coursin described 300 infants who were fed on an infant formula that had been heated excessively and only contained 60 µg/L of available B<sub>6</sub>; heat converts protein bound PLP to pyridoxyllysine. After between 6 weeks and 4 months the unfortunate infants developed a triad of hyperacusis, irritability and convulsions; these symptoms worsened when protein intake was increased and improved with a high carbohydrate diet. All symptoms were abolished by increasing the dietary vitamin B<sub>6</sub> intake.

Adults fed diets deficient in B<sub>6</sub> also develop neurological symptoms—confusion, irritability and convulsions associated with an abnormal electroencephalogram—but they also develop a microcytic anemia and skin and mouth symptoms (eczema, seborrheic dermatitis, cheilosis, glossitis and angular stomatitis (Berger et al., 2022).

Dietary deficiency of vitamin B<sub>6</sub> will respond to treatment with oral supplementation. This is readily available and 50–100 mg for one to two weeks is safe (Berger et al., 2022). The no-observed-adverse-effect level (NOAEL) is 100 mg/day.

## Assessment of vitamin B<sub>6</sub> status

Historically a number of biochemical parameters have been used to assess B<sub>6</sub> status. These have included measurement of erythrocyte alanine and aspartate transaminases before and after addition of PLP and measurement of urinary excretion of xanthurenic acid and kynurenic acid after a tryptophan load. Nowadays, vitamin B<sub>6</sub> status is usually assessed by direct measurement of plasma PLP and urinary pyridoxic acid. An increase in dietary B<sub>6</sub> intake leads to an immediate increase in pyridoxic acid excretion, plasma PLP levels rise more slowly and plateau at about 7–10 days after the increase in intake. It has been suggested that urinary pyridoxic acid excretion is an index of recent B<sub>6</sub> intake whereas plasma PLP is a marker of body stores. However, it is also useful to look at a range of indirect biomarkers that indicate the effect of B<sub>6</sub> status on individual enzymes/pathways e.g., kynurenine pathway, one-carbon metabolism, transsulfuration (cystathionine), and glycine decarboxylation (serine and glycine) (Ueland et al., 2015). Normal values of plasma PLP are 20–200 nmol/L (5–50 µg/L) (Berger et al., 2022).

## Recommended daily intake

The Reference Nutrient Intake (RNI, European Food Safety Authority) and Recommended Dietary Allowance (RDA, United States), i.e., estimates of the amount of B<sub>6</sub> that is enough to ensure requirements of 97.5% of the population are being met, have been

**Table 2** Recommended dietary allowance of vitamin B<sub>6</sub> for infants, children and adolescents.

Age	Male	Female
0–6 months <sup>a</sup>	0.1 mg	0.1 mg
7–12 months <sup>a</sup>	0.3 mg	0.3 mg
1–3 years	0.5 mg	0.5 mg
4–8 years	0.6 mg	0.6 mg
9–13 years	1.0 mg	1.0 mg
14–18 years	1.3 mg	1.2 mg

<sup>a</sup>Adequate intake.

Institute of Medicine (1998).

determined by depletion-repletion studies using either plasma PLP or the tryptophan load as measures of B<sub>6</sub> sufficiency. Because PLP is central to the reactions of amino acid catabolism, it is not surprising that vitamin B<sub>6</sub> depletion was shown to occur more rapidly in individuals on a high protein intake compared to those on a low intake (Canham et al., 1969).

The recommended daily allowance (RDA) for vitamin B<sub>6</sub> is 1.3–1.7 mg/day, irrespective of gender for 14–70-year-olds, although one study has suggested that the over 60s may have a requirement of 1.96 mg for men and 1.9 mg for women (Ribaya-Mercado et al., 1991). In pregnant women this can increase to 2 mg/day. The upper advised limit for pyridoxine intake is 80 mg/day for 14–18 year olds; 100 mg/day for those over 19 years old (Berger et al., 2022). The RDA for infants, children and adolescents is presented in Table 2 (Institute of Medicine, 1998).

### Dietary constituents that can cause PLP deficiency

Ginkgo nuts contain 4-O-methyl pyridoxine which is an inhibitor of pyridoxal kinase. The seizures induced by eating too many Ginkgo nuts can be effectively treated with pyridoxine (Hasegawa et al., 2006).

Sulfite is present in many foods and in wine as a preservative. As it forms a complex with PLP, it may reduce the availability of B<sub>6</sub> (Gould and Russell, 2003).

Chicks and turkey poults show poor growth and signs of B vitamin deficiency when reared on linseed meal. The signs of vitamin deficiency can be prevented by the addition of 20 ppm of pyridoxine to the linseed-containing diet (Kratzer and Williams, 1948). Klosterman et al. identified the vitamin B<sub>6</sub> antagonist as 1-amino-proline (“linatine”) (Klosterman et al., 1967). Administration of linatine to rats causes seizures (Sasaoka et al., 1976). Many people consume linseed (flax seed) as a dietary supplement. However, the known side effects in man (gastrointestinal and clotting) do not include seizures.

Poisoning with *Gyromitra* mushrooms (False morel) can cause refractory seizures because they contain monomethyl hydrazine which forms a complex with PLP (Lheureux et al., 2005).

### Drug-induced deficiency

Drugs can lead to deficiency of PLP either by forming a complex with it or by inhibiting an enzyme required for its synthesis from dietary B<sub>6</sub> vitamers and its recycling.

Examples of drugs forming a complex with PLP are included in Table 1. Consequences include peripheral neuropathy with isoniazid and hydralazine (Raskin and Fishman, 1965), seizures and psychosis with D-cycloserine, optic neuropathy and seizures with penicillamine (Gibbs and Walshe, 1969). These side effects can be prevented by coadministration of pyridoxine. Treatment of Parkinson’s disease with L-Dopa and carbidopa can lead to peripheral neuropathy and B<sub>6</sub> deficiency is a contributory factor (Romagnola et al., 2018). An example of a drug that inhibits synthesis and recycling of PLP is theophylline, a non-competitive inhibitor of pyridoxal kinase (Ubbink et al., 1990). An overdose of theophylline can induce seizures and pyridoxine treatment has been shown to be beneficial in animals (Glenn et al., 1995).

### Toxicity of vitamin B<sub>6</sub>

Similar to Vitamin B<sub>6</sub> deficiency states, the predominant symptoms of B<sub>6</sub> toxicity are neurological. Toxicity of vitamin B<sub>6</sub> is not observed through dietary intake alone, however it is reported following the intake of supraphysiological doses of both pyridoxine and pyridoxal phosphate (PLP) used for various indications in clinical practice and in some instances, individuals self-treating with over-the-counter supplements.

## Pyridoxine

### Acute toxicity

In animal studies very high doses of pyridoxine (2–6 g/kg) induce ataxia and seizures and may be lethal (Unna, 1940). Administration of such high doses is not reported in human studies, however B<sub>6</sub> appears to have low acute toxicity in man with doses up to 357 mg/kg used for a short time period in isoniazid overdose without any adverse events (Lheureux et al., 2005).

### Chronic toxicity

Typical symptoms of chronic pyridoxine toxicity include peripheral sensory neuropathy which manifests as symmetrical paresthesia in the extremities and difficulty in walking due to ataxia and disequilibrium (Albin et al., 1987). Other symptoms reported less frequently in a large study of patients include hyperesthesia, muscle weakness, fasciculations and bone pains (Dalton and Dalton, 1987).

Clinical and electrophysiological evidence of sensory neuropathy is observed in healthy volunteers and patients taking pyridoxine for a variety of indications. A single case reports evidence of sensory and motor neuropathy following a prolonged course of high intake (1 g/day for 10 years) (Morra et al., 1993). In the majority of cases, symptoms are reversible on stopping pyridoxine intake (although residual nerve damage remains in some patients) (Schaumburg et al., 1983) and shows a clear relationship to pyridoxine dose and in some instances to length of administration (Cohen and Bendich, 1986; Bender, 1999). Regular clinical examination and nerve conduction studies are recommended for all patients receiving long term high dose pyridoxine therapy.

Rarely, high doses of pyridoxine have been reported to cause serious life-threatening complications such as convulsions and apnea which have both been reported in the neonate. It appears that this age group may respond differently to large doses of pyridoxine and it is recommended that the lowest possible doses should be used alongside adequate monitoring in this age group.

Ames et al. (2020) report a newborn infant treated with 100 mg pyridoxine daily (31 mg/kg/d) for one week followed by 200 mg daily (54 mg/kg/d) for a second week as part of the protocol for management of newborn screen positive for classical homocystinuria. After approximately 2 weeks of pyridoxine treatment the infant developed dyspnea, cyanosis and apnea requiring resuscitation and intensive care admission. She was also found to have elevated liver transaminase and creatine kinase (CK). No other cause for her deterioration was found and her condition improved within 72 h of pyridoxine cessation and did not recur when she was recommenced on a low dose pyridoxine (10 mg/kg).

Another case of pyridoxine toxicity is described in a neonate whose mother received pyridoxine antenatally and was then treated with pyridoxine from birth (33 mg/kg/day) due to familial risk of pyridoxine dependent epilepsy—ALDH7A1-deficiency (Hartmann et al., 2011). From day 14 the infant began to feed poorly and had abnormal breathing. On Day 15 he required admission to hospital for repeated apnea and seizure activity with abnormal EEG. A further increase in pyridoxine dose to 60 mg/kg/day resulted in the need for ventilatory support. He was noted to have elevated CK, AST with plasma PLP grossly elevated >3000 µg/L (normal range up to 18 µg/L). Treatment with vitamin B<sub>6</sub> was stopped when ALDH7A1-deficiency was excluded, and the infant made a full recovery.

The mechanism of pyridoxine toxicity is incompletely understood. Studies of chronic, long-term pyridoxine administration in animals have shown the potential neurotoxicity of vitamin B<sub>6</sub> with doses of 200 mg/kg causing ataxia, peripheral neuropathy and muscle weakness. Histological examination demonstrates widespread neuronal damage with loss of myelin and degeneration of sensory fibers in peripheral nerves, dorsal columns of the spinal cord and descending tract of the trigeminal nerve (Phillips et al., 1978). Studies in dogs (Yun et al., 2020) demonstrate neuropathological changes in dorsal root ganglia following large doses of pyridoxine (150 mg/kg) which are reversible. Neurotoxicity of injected pyridoxine may be enhanced by a protein deficient diet. This is perhaps due to decreased protein binding in serum and decreased urinary excretion of the toxin secondary to oliguria which is evident in these animals because of reduced water consumption (Levine and Saltzman, 2004).

A recent *in vitro* study showed that pyridoxine can induce cell death in a dose dependent manner and that it also inhibits pyridoxal-phosphate dependent enzymes, thus partly explaining why symptoms of pyridoxine toxicity are similar to those of deficiency (Vrolijk et al., 2017).

### Pyridoxal phosphate

Less is known about PLP toxicity as clinical experience is comparatively limited. Hammen et al. (1998) report a newborn with intractable epilepsy who showed an increase in seizure frequency and EEG alterations after administration of vitamin B<sub>6</sub>. Wang et al. (2005) also describe a paradoxical seizure increase during treatment with PLP. PLP may also cause tonic-clonic convulsions in immature mice possibly secondary to degeneration of GABA-ergic neurotransmission (Ishioka et al., 1995).

PLP at a dose of 1800 mg/day induced hepatotoxicity in a child with homocystinuria (Yoshida et al., 1985) and liver cirrhosis has developed in at least two children with pyridoxamine 5'-phosphate oxidase (PNPO) deficiency while on treatment with oral PLP (Coman et al., 2016; Sudarsanam et al., 2014). The mechanism of toxicity is unknown however, preparation of PLP immediately prior to administration may prevent deterioration of the vitamin to toxic intermediates in UV light on standing.

**Table 3** Disorders in which vitamin B<sub>6</sub> preparations may be used therapeutically where metabolites accumulate that inactivate pyridoxal 5'-phosphate.

Disorder (OMIM reference)	Enzyme	Gene; location	Vitamin B <sub>6</sub> preparation; dose	Clinical aim or biochemical effect
Pyridoxine dependent epilepsy (266100/107323)	$\alpha$ -Aminoadipic semialdehyde dehydrogenase EC 1.2.1.31	<i>ALDH7A1</i> 5q31	PN; 50–100 mg IV single dose(s), 5–15 mg/kg/d oral maintenance	Cessation and prevention of seizures and improvement of IQ
Hyperprolinaemia type II (239510/606811)	L- $\Delta^1$ -Pyrroline-5-carboxylic acid dehydrogenase EC 1.5.1.12	<i>ALDH4A1</i> 1p36	PN; 50 mg/d, subsequent reduction to 10 mg/d	Cessation and prevention of seizures (particularly during intercurrent infection)

PN - pyridoxine.

### Genetic disorders affecting vitamin B<sub>6</sub> metabolism and other disorders which may be treated with vitamin B<sub>6</sub>

There are several rare genetic metabolic disorders which affect vitamin B<sub>6</sub> metabolism in differing ways, ultimately resulting in a common endpoint; cellular deficiency of pyridoxal phosphate, the active form of vitamin B<sub>6</sub> (Tables 3 and 4).

Due to the critical role of PLP as an enzyme cofactor in the central nervous system, these disorders manifest with a neurological phenotype and the majority present with epilepsy early in life, often soon after birth. These disorders are characteristically responsive to treatment with vitamin B<sub>6</sub> (pyridoxine or pyridoxal phosphate) and lifelong treatment is required.

Table 5 summarizes other disorders which may benefit from treatment with vitamin B<sub>6</sub> whereby the treatment aim is to augment the residual enzyme activity of a B<sub>6</sub> dependent enzyme.

### The role of vitamin B<sub>6</sub> in common diseases

While a severe isolated deficiency of vitamin B<sub>6</sub> is rare, suboptimal levels have been reported in smokers and alcoholics, users of oral contraceptives and some drugs, pregnant women, and in individuals with chronic renal failure, diabetes and inflammatory bowel disease. Low plasma PLP is associated with an increased risk of more common chronic disorders including cardiovascular diseases, stroke, diabetes and cancer and has also been linked to rheumatoid arthritis. Inflammation is believed to play a pivotal role in the pathogenesis or progression of these conditions.

**Table 4** Disorders in which vitamin B<sub>6</sub> preparations (pyridoxine or pyridoxal 5'-phosphate) may be used therapeutically where there is inadequate production of the active cofactor (in the correct location) due to an inborn error affecting B<sub>6</sub> interconversion or due to disruption in cellular PLP homeostasis.

Disorder (OMIM reference)	Enzyme/protein	Gene; location	Vitamin B <sub>6</sub> preparation; dose	Clinical aim or biochemical effect
Pyridoxal phosphate dependent epilepsy (603287/610090)	Pyridox(am)ine 5'-phosphate oxidase EC 1.4.3.5	<i>PNPO</i> ; 17q21.32	PLP; 30–50 mg/kg/d orally In some PN; 6–55 mg/kg/d	Cessation and prevention of seizures
Hypophosphatasia (infantile) (241500/171760)	Tissue nonspecific alkaline phosphatase EC 3.1.3.1	<i>ALPL</i> / <i>TNSALP</i> / <i>TNAP</i> ; 1p36.1-34	PN; 100 mg IV PLP; 30 mg/kg/d	Cessation and prevention of seizures
Hyperphosphatasia (239300/610274)	Phosphatidyl-inositol glycan class V	<i>PIGV</i> ; 1p36.11	PN; 100 mg/day	Cessation of seizures, paradoxical change in electroencephalogram
Pyridoxal phosphate-binding protein deficiency (604436/617290)	Pyridoxal phosphate binding protein	<i>PLPBP</i> ; 8p1123	PLP is superior treatment for seizure control; 10–45 mg/kg/d	Cessation of seizures
Pyridoxal kinase deficiency (179020/618511)	Pyridoxal kinase EC 2.7.1.35	<i>PDXK</i> ; 21q22.3	PLP; 50 mg/day	Improve polyneuropathy—improve motor function and neuropathic pain

PLP—pyridoxal 5'-phosphate, PN—pyridoxine.

**Table 5** Disorders in which vitamin B<sub>6</sub> preparations (pyridoxine or pyridoxal 5'-phosphate) may be used therapeutically to augment residual enzyme activity in inborn errors affecting a PLP-dependent enzyme.

Disorder (OMIM reference)	Enzyme	Gene; location (B <sub>6</sub> responsive mutations)	Vitamin B <sub>6</sub> preparation; dose	Clinical aim or biochemical effect
Homocystinuria (236200) (B <sub>6</sub> responsive subgroup)	Cystathionine β-synthase EC 4.2.1.22	<i>CBS</i> ; 21q22.3 (I278T, 114V, R266K, 336H, K384E, L539S)	<sup>a</sup> PN; 100 mg/d	Biochemical parameters normalize. Prevention of thromboembolic events
Gyrate atrophy of the choroid and retina (258870)	Ornithine δ-aminotransferase EC 2.6.1.13	<i>OAT</i> ; 10q26 (V332M, A226V, 318K)	PN; 500–1000 mg/d	Decrease in plasma ornithine. Unknown effect on chorioretinal degeneration
Aromatic amino acid decarboxylase deficiency (608643/107930)	Aromatic L-amino acid decarboxylase EC 4.1.1.28	<i>AADC</i> ; 7p11	<sup>b</sup> PN; 400–800 mg/day <sup>c</sup> PLP; 200 mg/day	Improvement of Parkinsonian movement disorder
Pyridoxine responsive anemia (X-linked sideroblastic anemia) (300751/301300)	Δ-aminolevulinatase δ-ALA synthase EC 2.3.1.37	<i>ALAS2</i> ; Xp11.21	PN; 50–400 mg/d	Resolution of anemia
Primary hyperoxaluria type I (259900/604285)	Liver-specific alanine/glyoxylate aminotransferase EC 2.6.1.44	<i>AGXT</i> ; 2p37.3 (c.508G>A)	PN; 5–10 mg/kg/day	Reduction/normalization of hyperoxaluria. Urinary tract stone formation and subsequent renal failure reduced
Cystathioninuria (219500/607657)	γ-cystathionase EC 4.4.1.1	<i>CTH</i> ; 1p31.1	PN; 100 mg/d	Reduction of cystathioninaemia/uria
Phosphoserine aminotransferase deficiency (610936/610992)	Phosphoserine aminotransferase EC 2.6.1.52	<i>PSAT1</i> ; 9q21.31	PN; 120 mg/d	No effect observed in single case reported
McArdle's disease; glycogen storage Disease type V (232600/608455)	Muscle glycogen phosphorylase EC 2.4.1.1	<i>PYGM</i> ; 11q13	PN; 50–100 mg/d	Reduced exercise intolerance and cramp

PN—pyridoxine, PLP—pyridoxal 5'-phosphate.

<sup>a</sup>Ensure patient is folate replete.

<sup>b</sup>Effective to augment L-dopa treatment (not as single therapeutic agent). Some cases report no improvement.

<sup>c</sup>In twin patients being treated with tranlycypromine, pergolide and pyridoxine, substitution of pyridoxine with pyridoxal phosphate led to improved symptom control.

Saudubray, J.M., Baumgartner, M.R., Walter, J., 2016. Inborn metabolic diseases: diagnosis and treatment. sixth ed. Berlin, Heidelberg, New York: Springer-Verlag.

## Inflammation

The anti-inflammatory properties of vitamin B<sub>6</sub> are involved in maintaining a normal immune response (Du et al., 2020). B<sub>6</sub> helps prevent excessive inflammation in macrophages by inhibiting lipopolysaccharide-induced expression of COX-2 and iNOS thereby suppressing the NF-KB signaling and mitogen-activated protein kinase (MAPK) signaling pathways which when activated cause release of inflammatory factors e.g., interleukin-1 beta, tumor necrosis factor alpha, Il-6 and nitric oxide. The exact mechanisms involved are unclear although plasma and liver PLP show an inverse association with inflammatory markers (Ueland et al., 2017). A possible mechanism is mobilization of B<sub>6</sub> to sites of inflammation so that it is available as a cofactor for enzymes involved in pathways that modulate the immune response. Recently it has been shown that B<sub>6</sub> supplementation enhances the activity of sphingosine-1-phosphate (S1P) lyase, a PLP-dependent enzyme, reducing accumulation of S1P and suppressing excessive inflammation. S1P affects the activation of NF-KB signaling and mitogen-activated protein kinase (MAPK) signaling pathways. Other relevant B<sub>6</sub>-dependent inflammatory pathways include the kynurenine, serine, glycine and transulfuration pathways (Ueland et al., 2017). Vitamin B<sub>6</sub> also has antioxidant properties, which are likely to also play a role in its anti-inflammatory properties, hydroxyl and amine substituents of the pyridine ring directly reacting with peroxy radicals (Contestabile et al., 2020).

## Cardiovascular disease

Several studies have shown that vitamin B<sub>6</sub> deficiency is associated with atherosclerosis, stroke and thrombosis and is a risk factor for cardiovascular outcomes and mortality in coronary artery disease. Prospective studies have also shown that a higher dietary intake of vitamin B<sub>6</sub> is inversely associated with cardiovascular disease (CVD) and that high-risk patients scheduled for a coronary artery bypass graft benefitted from oral administration of PLP. However, epidemiological studies have yielded controversial results, with meta-analysis of several randomized control trials having suggested that vitamin supplements, including B<sub>6</sub>, are ineffective at preventing cardiovascular outcomes (Kumrungsee et al., 2022; Stach et al., 2021; Jeon and Park, 2019).

Proposed cardioprotective mechanisms of vitamin B<sub>6</sub> include: (i) lowering of homocysteine, a risk factor for CVD and stroke, through the B<sub>6</sub>-dependent transsulfuration pathway; (ii) lowering of chronic inflammation through modulation of the B<sub>6</sub>-dependent kynurenine pathway, kynurenine-related metabolites may have beneficial anti-inflammatory effects; (iii) suppression of NF- $\kappa$ B activation (as described above) and (iv) inhibition of inflammation through B<sub>6</sub> inhibiting the nucleotide-binding oligomerization domain-like receptor family pyrin domain-containing 3 (NLRP3) inflammasome. Vitamin B<sub>6</sub> may also suppress oxidative stress, by increasing levels of cardiac imidazole dipeptides and regulate Ca<sup>2+</sup> influx into cells via voltage-gated ATP-dependent purinergic receptors (Kumrungsee et al., 2022; Stach et al., 2021).

### Infection

Vitamin B<sub>6</sub> is involved in the production of interleukins and T lymphocytes. A deficiency of B<sub>6</sub> is associated with lower immune function and increased susceptibility to viral infection. It leads to decreased production of IL-2 and increase in IL-4. In conditions of chronic inflammation there is an inverse association of B<sub>6</sub> with IL-6 and TNF- $\alpha$  levels (Stach et al., 2021). In mice, vitamin B<sub>6</sub> had beneficial effects against pneumonia, inhibiting macrophage activation and preventing lipopolysaccharide-induced systemic inflammation (Kumrungsee et al., 2020). Mice fed a B<sub>6</sub>-deficient diet were more susceptible to murine pneumonia virus.

### Cancer

A deficiency of B<sub>6</sub> not only leads to an increased risk of developing certain types of tumors, including those affecting the lungs and gastrointestinal tract, but is also observed in patients with other forms of cancer. The latter may be due to increased biosynthesis requirements of proliferating tumor cells, with PLP being involved as a cofactor in several biosynthetic pathways. Enzymes involved in B<sub>6</sub> metabolism are differentially expressed in cancer tissues (Contestabile et al., 2020). PNPO expression is upregulated significantly in most cancer types and has been proposed as a prognostic factor, although is down-regulated in adrenocortical and kidney renal clear cell carcinomas, acute myeloid leukemia and testicular germ cell tumors (Zhang et al., 2022). PDXK is also upregulated in non-small cell lung cancer and is abundantly expressed in myeloid leukemia cells and when depleted causes anti-proliferative effects (Contestabile et al., 2020). However, the role of vitamin B<sub>6</sub> in cancer is multifaceted as it can also stimulate an immune response and it is an effective inhibitor of the formation of advanced glycation end products. It also functions as an antioxidant protecting DNA from damage, having singlet oxygen quench capacity comparable to antioxidants vitamin C and E (Shen, 2015). The hydroxyl and amine substituents on the pyridine ring of vitamin B<sub>6</sub> directly react with peroxy radicals (Contestabile et al., 2020). B<sub>6</sub> is also involved in the generation of glutathione, a key regulator of redox state within cells, through its role as a cofactor in the transsulfuration pathway. However, it can also lead to elevated homocysteine levels, which in turn result in ROS generation. In *Drosophila*, a deficiency of PLP causes chromosome aberrations which can be rescued by PLP suggesting that B<sub>6</sub> is also important for maintaining chromosomal integrity (Contestabile et al., 2020).

### Parkinson's disease

While the number of studies that have looked at vitamin B<sub>6</sub> intake and Parkinson's Disease (PD) are limited, meta-analysis suggests that higher dietary intake may be associated with a decreased risk of Parkinson's disease (Shen, 2015). Patients with PD have also been reported to have increased levels of homocysteine which may lead to dopaminergic cell death. Given that PLP is required as a cofactor by two of the enzymes in homocysteine metabolism, increased B<sub>6</sub> intake may decrease plasma homocysteine and the risk of PD. PLP is also required as a cofactor for the final step in dopamine synthesis where L-DOPA is converted to dopamine by the enzyme aromatic L-amino acid decarboxylase; PD is characterized by the degeneration of dopaminergic neurons resulting in decreased levels of the neurotransmitter dopamine. Pyridoxine has been shown recently to induce synthesis of GSH, an important antioxidant in the brain which is generated from homocysteine, in a PD mouse model and to reduce dopaminergic neuron loss (Wei et al., 2020). Besides its role as a cofactor, the antioxidant properties of B<sub>6</sub> may also contribute to the protective effects proposed.

Symptomatic treatment of PD is usually achieved using L-DOPA, which is typically co-administered with a DOPA decarboxylase inhibitor, such as carbidopa, to prevent peripheral breakdown. Plasma vitamin B<sub>6</sub> levels should be monitored in PD patients receiving treatment with high levodopa (L-DOPA)/carbidopa doses as carbidopa binds covalently and irreversibly to PLP and can cause B<sub>6</sub> depletion (Rojo-Sebastián et al., 2020).

### Conclusion/summary/outlook

B<sub>6</sub> vitamins in the diet are converted to intracellular pyridoxal phosphate (PLP) which is the cofactor for at least 70 enzyme-catalyzed reactions. Within the cell, the concentration of PLP must be kept low to avoid unwanted reactions of this reactive cofactor while at the same time ensuring its efficient transfer to apoenzymes. This intracellular homeostasis is the subject of current research.

Deficiency of PLP in the brain can give rise to seizures (probably attributable, at least in part, to reduced activity of glutamate decarboxylase and hence reduced levels of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid [GABA], and to a movement disorder (probably due to reduced activity of aromatic amino acid decarboxylase leading to low levels of dopamine).

In the peripheral nervous system, lack of PLP can cause a sensory-motor neuropathy. Paradoxically ingestion of large doses of pyridoxine also causes a neuropathy, perhaps because pyridoxine or pyridoxine phosphate inhibits PLP-dependent enzymes.

In the hematopoietic system, PLP deficiency can cause anemia because heme synthesis is disrupted by reduced activity of  $\delta$ -aminolaevulinic acid synthase.

PLP-enzymes play important roles in inflammation and the immune response and a B<sub>6</sub> deficient diet predisposes to viral pneumonia in the mouse.

B<sub>6</sub> vitamers have roles in addition to supplying PLP to PLP-dependent apo-enzymes. They have antioxidant properties, bind to some transcription factors and corepressors, affect the expression and function of steroid hormone receptors and contribute to genome stability.

The optimum personalized intake of B<sub>6</sub> for individuals with a common disease cannot easily be determined currently but should be a focus of future research. Deficiencies of specific PLP-dependent enzymes can, in some cases, be very effectively treated with supra-physiological doses of B<sub>6</sub>. Disorders of the synthesis and recycling of PLP may also respond dramatically to treatment with pyridoxine or pyridoxal phosphate.

Deficiency of PLP because of insufficient B<sub>6</sub> in the diet is rare probably because, at least after infancy, the gut flora can synthesize significant amounts of B<sub>6</sub>. PLP deficiency can, however, occur if we ingest something that binds PLP e.g., large amounts of Ginkgo nuts or hydralazine.

### Key points

- To learn the processes of absorption, transport, storage, metabolism and excretion of vitamin C.
- To understand the metabolic functions of ascorbic acid.
- To have information about the requirements and the assessment of vitamin C status.
- To know the main dietary sources of this vitamin.
- To know the recent discovered role of ascorbate as an epigenetic regulator.
- To recognize the relationship between ascorbate and disease.

### Glossary

**Carnitine**  $\beta$ -Hydroxy- $\gamma$ -trimethylammonium butyrate, biosynthesized by methylation of lysine, important for the transport of fatty acids into the mitochondrion for oxidation

**Epigenetics** The study of how cells control gene activity without changing the DNA sequence. “Epi-” means on or above in Greek, and “epigenetic” describes factors beyond the genetic code. Epigenetic changes are modifications to DNA that regulate whether genes are turned on or off

**Flavoprotein** Any enzyme (or other protein) with a prosthetic group formed from riboflavin (vitamin B<sub>2</sub>) or one of its derivatives

**Glutathione** A tripeptide,  $\gamma$ -glutamyl–cysteinyl–glycine that acts as a major redox cofactor, being oxidized to yield the hexapeptide lined by a disulfide bridge

**Granulocytes** A class of white blood cells characterized by conspicuous cytoplasmic granules

**Hydroxymethylglutaryl CoA reductase** The first and rate-limiting enzyme of cholesterol biosynthesis. The target of statin drugs for the treatment of hypercholesterolemia

**Hypercholesterolemia** Elevated blood concentration of cholesterol

**Leukocytes** White blood cells of various kinds

**Teleost fish** Bony, as opposed to cartilaginous, fishes

## Introduction

Ascorbic acid is a vitamin (vitamin C) for only a limited number of species: human beings and other primates, bats, the guinea pig, a number of birds, and teleost fishes. In other species ascorbic acid is not a vitamin but is an intermediate in glucuronic acid catabolism, and its rate of synthesis bears no relation to physiological requirements for ascorbate (Combs and McClung, 2016). Species for which ascorbate is a vitamin lack the enzyme gulonolactone oxidase (EC 1.1.3.8) and have an alternative pathway for glucuronic acid metabolism, via reduction and the pentose phosphate pathway (Bender, 2003; Rodwell et al., 2018).

Ascorbic acid functions as a relatively nonspecific, radical-trapping antioxidant, and also reduces the tocopheroxyl radical formed by oxidation of vitamin E. It has a specific metabolic function as the coenzyme for dopamine  $\beta$ -hydroxylase and peptidyl glycine hydroxylase, and it is required to maintain the iron of 2-oxoglutarate-dependent hydroxylases in the reduced state. It also enhances the absorption of inorganic iron from foods (Ross et al., 2014; Stipanuk and Caudill, 2018).

## Chemical structure

The term vitamin C encompasses all compounds with the biological activity of L-ascorbic acid (2,3-enediol gulonic acid or 2-oxo-L-threo-hexono-1,4-lactone-2,3-enediol). It is a chemically simple compound although it presents an atypical structure, whose empirical formula is C<sub>6</sub>H<sub>8</sub>O<sub>6</sub>. It is a lactonic derivative of hexuronic acid and corresponds to an oxidized form of glucose. Specifically, it is a  $\delta$ -ketolactone of six carbon atoms showing a five-membered lactone ring and a bifunctional enediol group with an adjacent carbonyl group. The enediol group is essential for its biological activity (Fig. 1).

## Absorption, transport, and storage

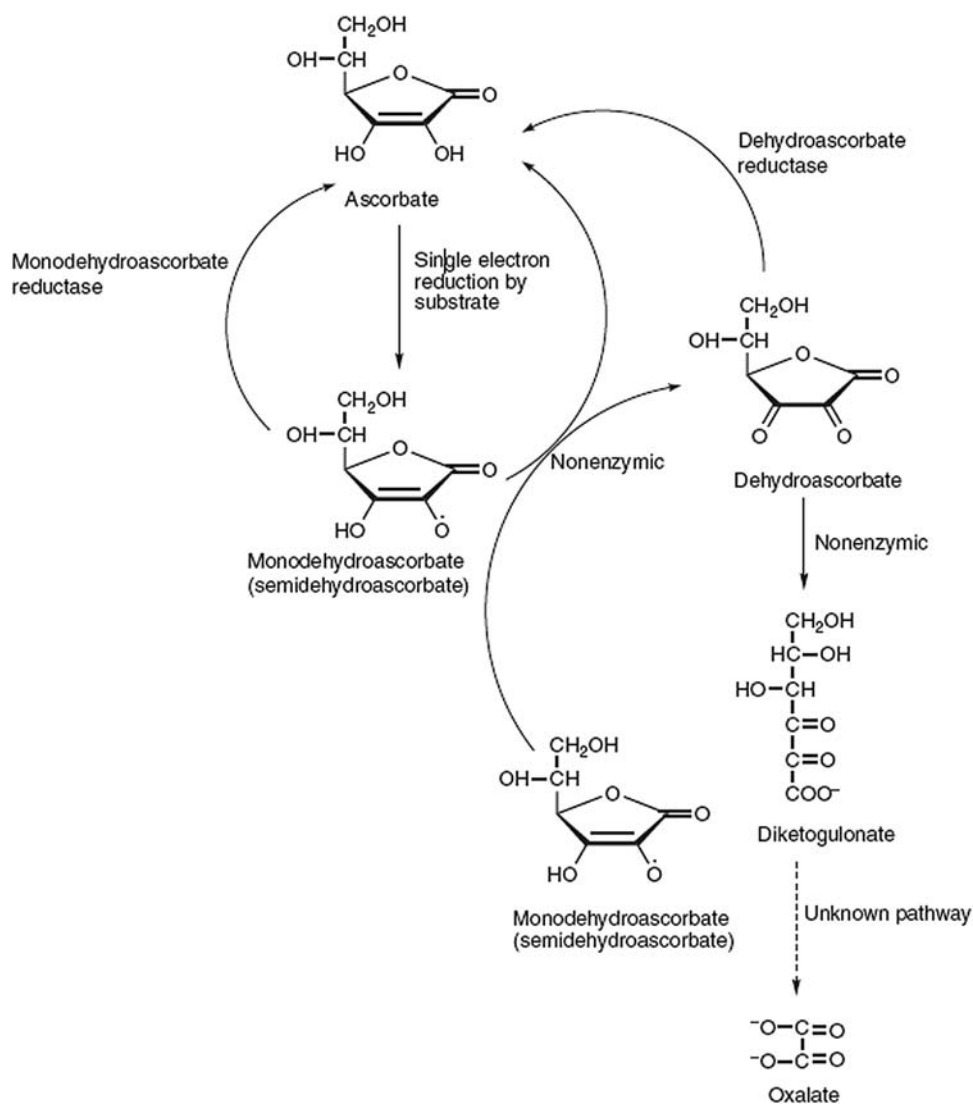

In species for which ascorbate is not a vitamin, intestinal absorption is by sodium-independent facilitated diffusion, whereas in human beings and guinea pigs there is sodium-dependent active transport of the vitamin at the brush border membrane, with a sodium-independent mechanism at the basolateral membrane. Dehydroascorbate is absorbed passively in the intestinal mucosa, and is reduced to ascorbate before transport across the basolateral membrane (Bender, 2003).

At intakes up to about 100 mg day<sup>-1</sup>, 80–95% of dietary ascorbate is absorbed, falling from 50% of a 1 g to 25% of a 6 g and 16% of a 12 g dose. Unabsorbed ascorbate is a substrate for intestinal bacterial metabolism.

Ascorbate and dehydroascorbate circulate in the bloodstream both in free solution and bound to albumin. Approximately 5% of plasma vitamin C is normally in the form of dehydroascorbate. Ascorbate enters cells by sodium-dependent active transport; dehydroascorbate is transported by insulin-dependent glucose transporters and is accumulated intracellularly by reduction to ascorbate. In poorly controlled diabetes mellitus, tissue uptake of dehydroascorbate is impaired because of competition by glucose, as well as insulin resistance or lack of insulin, which is required for activity of the transporters, and there may be functional deficiency of vitamin C despite an apparently adequate intake.

Approximately 70% of blood-borne ascorbate is in plasma and erythrocytes (which do not concentrate the vitamin from plasma). The remainder is in white cells, which have a marked ability to concentrate ascorbate; mononuclear leukocytes achieve 80-fold concentration, platelets 40-fold, and granulocytes 25-fold, compared with the plasma concentration.

There is no specific storage organ for ascorbate; apart from leukocytes (which account for 10% of total blood ascorbate), the only tissues showing a significant concentration of the vitamin are the adrenal and pituitary glands. Although the concentration of ascorbate in muscle is relatively low, skeletal muscle contains much of the body pool of 5–8.5 mmol (900–1500 mg) of ascorbate.

**Fig. 1** The metabolism of ascorbate.

### Metabolism and excretion

As shown in **Fig. 1**, oxidation of ascorbic acid proceeds by a one-electron process, forming monodehydroascorbate, which disproportionates to ascorbate and dehydroascorbate. Most tissues also contain monodehydroascorbate reductase (EC 1.6.5.4), a flavoprotein that reduces the radical back to ascorbate. In the cytosol dehydroascorbate is reduced by either reduced nicotinamide adenine dinucleotide (NADH) or reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent enzymes; in mitochondria it is reduced by complex 3 of the electron transport chain. It is also reduced nonenzymatically by reaction with glutathione. At neutral pH dehydroascorbate is unstable and is rapidly hydrated to diketogulonate, but little is lost in this way.

Both ascorbate and dehydroascorbate are filtered at the glomerulus, then reabsorbed by the same transporters as are involved in intestinal absorption; the sodium-dependent vitamin C transporter for ascorbate and the glucose transporter for dehydroascorbate. When glomerular filtration exceeds the capacity of the transport systems, at a plasma concentration of ascorbate above about  $85 \mu\text{mol L}^{-1}$ , the vitamin is excreted in the urine in amounts proportional to intake.

Approximately 1.5% of dietary ascorbate is excreted as oxalate; this may be a factor in development of oxalate renal stones. The pathway of oxalate formation from ascorbate is not known, and it is likely that there is nonenzymic cleavage of diketogulonate to oxalate. Ascorbate also increases the intestinal absorption of dietary oxalate.

## Metabolic functions of ascorbic acid

Ascorbic acid has specific and well-defined roles in two classes of enzymes: copper-containing hydroxylases and the 2-oxoglutarate-linked, iron-containing hydroxylases. It also increases the activity of a number of other enzymes *in vitro*—a nonspecific reducing action rather than reflecting a metabolic function of the vitamin. In addition, ascorbic acid has a number of less specific effects due to its action as a reducing agent and oxygen-radical quencher. There is also evidence that ascorbate has a role in regulating the expression of connective tissue protein (and some other) genes (Bender, 2003).

### Copper-containing hydroxylases

Dopamine  $\beta$ -hydroxylase (EC 1.14.17.1) is a copper-containing enzyme involved in the synthesis of the catecholamines noradrenaline and adrenaline from tyrosine in the adrenal medulla and central nervous system. The active enzyme contains  $\text{Cu}^+$ , which is oxidized to  $\text{Cu}^{2+}$  during the hydroxylation of the substrate; reduction back to  $\text{Cu}^+$  specifically requires ascorbate, which is oxidized to monodehydroascorbate. In the chromaffin granules, monodehydroascorbate is reduced by transmembrane electron transport via cytochrome  $b_{561}$ , with electrons provided by ascorbate in the cytosol. The resultant monodehydroascorbate in the cytosol is reduced back to ascorbate by a mitochondrial outer membrane reductase.

More than half of the peptide hormones undergo postsynthetic modification to form a carboxyl terminal amide, which is essential for biological activity. One function of this amidation is to render the peptides more hydrophobic, and so enhance receptor binding. The amide group is derived from a glycine residue that is to the carboxyl side of the amino acid that will become the amidated terminal of the mature peptide. The reaction is catalyzed by peptidyl glycine hydroxylase (peptidyl  $\alpha$ -amidase, EC 1.14.17.3).

The first step in the reaction is hydroxylation of the glycine residue to yield hydroxyglycine. The hydroxylase is a copper-containing oxygenase that uses ascorbate to reduce the two copper ions to  $\text{Cu}^+$ ; these then activate oxygen, with incorporation of one atom into hydroxyglycine and reduction of the other to water. This is followed by the cleavage of the peptide bond, with amidation of the amino acid to the amino side of the hydroxyglycine residue, and release of glyoxylate. These two activities occur in a single bifunctional protein.

### 2-Oxoglutarate-linked, iron-containing hydroxylases

A number of iron-containing hydroxylases (listed in Table 1) share a common reaction mechanism, in which hydroxylation of the substrate is linked to decarboxylation of 2-oxoglutarate. Ascorbate is required for the activity of all of these enzymes, but it does not function as either a stoichiometric substrate or a conventional coenzyme (which would not be consumed in the reaction).

Proline and lysine hydroxylases are required for the postsynthetic modification of osteocalcin in bone and the  $\text{Cl}_q$  component of complement, as well as a number of other proteins that have a collagen-like domain.

Aspartyl  $\beta$ -hydroxylase catalyzes hydroxylation of aspartyl and asparaginyl residues in epidermal growth factor (EGF) and a number of other proteins that have an EGF-like domain, including several of the vitamin K-dependent blood clotting factors.

Trimethyllysine and  $\gamma$ -butyrobetaine hydroxylases are required for the synthesis of carnitine, and many of the early signs of scurvy may be due to carnitine deficiency.

The best studied of this class of enzymes is procollagen proline hydroxylase; it is assumed that the others follow essentially the same mechanism. As shown in Fig. 2, the first step is the binding of oxygen to the enzyme-bound iron, followed by attack on the 2-oxoglutarate substrate, resulting in decarboxylation to succinate, leaving a ferryl radical at the active site of the enzyme. This catalyzes the hydroxylation of proline, restoring the free iron to undergo further reaction with oxygen.

It has long been known that ascorbate is oxidized during the reaction, but not stoichiometrically with hydroxylation of proline and decarboxylation of 2-oxoglutarate. The purified enzyme is active in the absence of ascorbate, but after some 5–10 s (approximately 15–30 cycles of enzyme action) the rate of reaction falls. The loss of activity is due to a side-reaction of

the highly reactive ferryl radical in which the iron is oxidized to  $\text{Fe}^{3+}$ , which is catalytically inactive—so-called uncoupled decarboxylation of 2-oxoglutarate. Activity is only restored by ascorbate, which reduces the iron back to  $\text{Fe}^{2+}$ .

### The role of ascorbate in iron absorption

Inorganic dietary iron is absorbed as  $\text{Fe}^{2+}$ , and not as  $\text{Fe}^{3+}$ ; ascorbic acid in the intestinal lumen not only maintains iron in the reduced state but also chelates it, increasing absorption considerably. A dose of 25 mg of vitamin C taken together with a meal increases the absorption of iron approximately 65%, whereas a 1 g dose gives a ninefold increase. This is an effect of ascorbic acid present together with the test meal; neither intravenous administration of vitamin C nor supplements several hours before the test meal affects iron absorption, although the ascorbate secreted in gastric juice should be effective. This is not a specific effect of ascorbate; a variety of other reducing agents including alcohol and fructose also enhance the absorption of inorganic iron. In addition, ascorbate is the electron donor for the intracellular ferric reductase in intestinal mucosal cells.

### Inhibition of nitrosamine formation

Oral bacteria can reduce nitrate to nitrite which, under the acidic conditions of the stomach, can react with amines in foods to form carcinogenic *N*-nitrosamines. In addition to dietary sources, a significant amount of nitrate is formed endogenously by the metabolism of nitric oxide—1 mg per kg bodyweight per day (about the same as the average dietary intake), increasing 20-fold in response to inflammation and immune stimulation, and nitrate is secreted in saliva.

Ascorbate reacts with nitrite forming NO,  $\text{NO}_2$ , and  $\text{N}_2$ , so preventing the formation of nitrosamines. In addition to ascorbate in foods, there is considerable secretion of ascorbate in the gastric juice, and inhibition of gastric secretion for treatment of gastric ulcers, as well as reducing vitamin B<sub>12</sub> absorption, also inhibits this presumably protective gastric secretion of ascorbate.

However, although ascorbate can deplete nitrosating compounds under anaerobic conditions, the situation may be reversed in the presence of oxygen. Nitric oxide reacts with oxygen to form  $\text{N}_2\text{O}_3$  and  $\text{N}_2\text{O}_4$ , both of which are nitrosating reagents, and can also react with ascorbate to form NO and monodehydroascorbate. It is thus possible for ascorbate to be depleted, with little or no significant effect on the total concentration of nitrosating species.

### Antioxidant and prooxidant actions of ascorbate

Chemically, ascorbate is a potent reducing agent, both reducing hydrogen peroxide and also acting as a radical-trapping antioxidant, reacting with superoxide and a proton to yield hydrogen peroxide, or with the hydroxy radical to yield water. In each case the product is monodehydroascorbate, which, as shown in Fig. 1, undergoes dismutation to ascorbate and dehydroascorbate. In studies

of ascorbate depletion in men there is a significant increase in abnormalities of sperm deoxyribonucleic acid (DNA), suggesting that vitamin C may have a general, nonspecific radical-trapping antioxidant function.

Ascorbate also acts to reduce the tocopheroxyl radical formed by the oxidation of vitamin E in cell membranes and plasma lipoproteins. It thus has a vitamin E sparing antioxidant action, coupling lipophilic and hydrophilic antioxidant reactions.

The antioxidant efficiency of ascorbate is variable. From the chemistry involved, it would be expected that overall 2 mol of tocopheroxyl radical would be reduced per mole of ascorbate, because of the reaction of 2 mol of monodehydroascorbate to yield ascorbate and dehydroascorbate. However, as the concentration of ascorbate increases, the molar ratio decreases, and only at very low concentrations of ascorbate it tends toward the theoretical ratio. This is because, as well as its antioxidant role, ascorbate can be a source of hydroxyl and superoxide radicals.

At high concentrations, ascorbate can reduce molecular oxygen to superoxide, being oxidized to monodehydroascorbate. Both  $\text{Fe}^{3+}$  and  $\text{Cu}^{2+}$  ions are reduced by ascorbate, again yielding monodehydroascorbate; the resultant  $\text{Fe}^{2+}$  and  $\text{Cu}^+$  are reoxidized by reaction with hydrogen peroxide to yield hydroxide ions and hydroxyl radicals. Thus, as well as its antioxidant role, ascorbate has prooxidant action; the net result will depend on the relative rates of formation of superoxide and hydroxyl radicals by autooxidation and metal-catalyzed reactions of ascorbate, and the trapping of these radicals by ascorbate.

It seems likely that the prooxidant actions of ascorbate are of relatively little importance *in vivo*. Except in cases of iron overload there are almost no transition metal ions in free solution, they are all bound to proteins, and because the renal transport system is readily saturated, plasma and tissue concentrations of ascorbate are unlikely to rise to a sufficient extent to lead to significant radical formation.

## Assessment of vitamin C status

The early method of assessing vitamin C nutritional status was by testing the extent of saturation of the body's reserves, by giving a test dose of 500 mg (2.8 mmol), and measuring the amount excreted in the urine. In a subject with high status, more or less all of the test dose is recovered over a period of 5–6 h.

More sensitive assessment of status is achieved by measuring the concentration of the vitamin in whole blood, plasma, or leukocytes (Bender, 2003; Card, 2019). Criteria of adequacy are shown in Table 2. The determination of ascorbate in whole blood is complicated by nonenzymic oxidation of the vitamin by hemoglobin, and most studies rely on plasma or leukocyte concentrations of ascorbate.

A problem arises in the interpretation of leukocyte ascorbate concentrations because of the different capacity of different classes of leukocytes to accumulate the vitamin. Granulocytes are saturated at a concentration of approximately 530 pmol per  $10^6$  cells, whereas mononuclear leukocytes can accumulate 2.5-times more ascorbate. A considerable mythology has developed to the effect that vitamin C requirements are increased in response to infection, inflammation, and trauma, based on reduced leukocyte concentrations of ascorbate in these conditions. However, the fall in leukocyte ascorbate can be accounted for by an increase in the proportion of granulocytes in response to trauma and infection (and hence a fall in the proportion of mononuclear leukocytes). Total leukocyte ascorbate is not a useful index of vitamin C status without a differential white cell count.

There is increased formation of 8-hydroxyguanine (a marker of oxidative radical damage) in DNA during (short term) vitamin C depletion, and the rate of removal of 8-hydroxyguanine from DNA by excision repair, and hence its urinary excretion, is affected by vitamin C status. This suggests that measurement of urinary excretion of 8-hydroxyguanine may provide a biomarker of optimum status, as a basis for estimating requirements.

## Requirements

Ascorbate requirements are estimated from the plasma and leukocyte concentrations. Although the minimum requirement for ascorbate is firmly established, there are considerable differences between the reference intakes published by different national and international authorities. Depending on the chosen criteria of adequacy, and assumptions made in interpreting experimental

**Table 2** Plasma and leukocyte ascorbate concentrations as criteria of vitamin C nutritional status.

		<i>Deficient</i>	<i>Marginal</i>	<i>Adequate</i>
Whole blood	mmol L <sup>-1</sup>	<17	17–28	>28
	mg L <sup>-1</sup>	<3.0	3.0–5.0	>5.0
Plasma	mmol L <sup>-1</sup>	<11	11–17	>17
	mg L <sup>-1</sup>	<2.0	2.0–3.0	>3.0
Leukocytes	pmol per 10 <sup>6</sup> cells	<1.1	1.1–2.8	>2.8
	μg per 10 <sup>6</sup> cells	<0.2	0.2–0.5	>0.5

results, it is possible to produce arguments in support of reference intakes ranging from 30 to 100 mg day<sup>-1</sup>. Average ascorbate requirements published by The Institute of Medicine of the National Academies (USA) (2006) and the European Food Safety Administration (2017) appear on [Table 3](#).

### Requirements estimated from maintenance of the body pool of ascorbate

An alternative approach to estimating requirements is to determine the fractional rate of catabolism of total body ascorbate; an appropriate intake would then be that required to replace losses and maintain the body pool.

Clinical signs of scurvy are seen when the total body pool of ascorbate is below 1.7 mmol (300 mg). The pool increases with intake, reaching a maximum of approximately 8.5 mmol (1500 mg) in adults—114  $\mu$ mol (20 mg) per kg bodyweight. The basis for the 1989 United States Recommended Daily Amount (US RDA) of 60 mg was the observed mean fractional turnover rate of 3.2% of a body pool of 20 mg per kg bodyweight per day, with allowances for incomplete absorption of dietary ascorbate and individual variation.

It has been argued that a total body pool of 5.1 mmol (900 mg) is adequate; it is threefold higher than the minimum required to prevent scurvy, and there is no evidence that there are any health benefits from a body pool greater than 600 mg. The observed body pool of 8.5 mmol in depletion/repletion studies was found in subjects previously consuming a self-selected diet, with a relatively high intake of vitamin C, and therefore might not represent any index of requirement. Assuming a total body pool of 5.1 mmol and catabolism of 2.7% per day, allowing for efficiency of absorption and individual variation gives a reference intake of 40 mg day<sup>-1</sup>.

Because the fractional turnover rate was determined during a depletion study, and the rate of ascorbate catabolism varies with intake, it has been suggested that this implies a rate of 3.6% per day before depletion. On this basis, and allowing for incomplete absorption and individual variation, various national authorities arrive at a reference intake of 80 mg.

The rate of ascorbate catabolism is affected by intake, and the requirement to maintain the body pool cannot be estimated as an absolute value. A habitual low intake, with a consequent low rate of catabolism, will maintain the same body pool as a habitual higher intake with a higher rate of catabolism.

### Dietary sources and high intakes

It is apparent from the list of rich sources of vitamin C in [Table 4](#) that the major determinant of vitamin C intake is the consumption of fruits and vegetables; deficiency is likely in people whose habitual intake of fruit and vegetables is very low. However, clinical signs of deficiency are rarely seen in developed countries. The range of intakes by healthy adults reflects fruit and vegetable consumption: the 2.5 percentile intake is 19 mg day<sup>-1</sup> (men) and 14 mg day<sup>-1</sup> (women), whereas the 97.5 percentile intake from foods (excluding supplements) is 170 mg day<sup>-1</sup> (men) and 160 mg day<sup>-1</sup> (women). Smokers may be at increased risk of deficiency; there is some evidence that the rate of ascorbate catabolism is twofold higher in smokers than in nonsmokers.

Intakes in excess of approximately 80–100 mg day<sup>-1</sup> lead to a quantitative increase in urinary excretion of unmetabolized ascorbate, suggesting saturation of tissue reserves. It is difficult to justify a requirement in excess of tissue storage capacity.

A number of studies have reported low ascorbate status in patients with advanced cancer—perhaps an unsurprising finding in seriously ill patients. One study has suggested, on the basis of an uncontrolled open trial, that 10 g daily doses of vitamin C resulted in increased survival. Controlled studies have not demonstrated any beneficial effects of high dose ascorbic acid in the treatment of

**Table 3** Average requirements of vitamin C by life stage groups.

advanced cancer (see section “**Vitamin C and disease**”). On the contrary, large doses of vitamin C supplements have been shown to cause diarrhea, nausea, vomiting, heartburn, stomach cramps, headache and nephrolithiasis.

High doses of ascorbate are popularly recommended for the prevention and treatment of the common cold. The evidence from controlled trials is unconvincing, and meta-analysis shows no evidence of a protective effect against the incidence of colds. There is, however, consistent evidence of a beneficial effect in reducing the severity and duration of symptoms (see section “**Vitamin C and disease**”). This may be due to the antioxidant actions of ascorbate against the oxidizing agents produced by, and released from, activated phagocytes, and hence a decreased inflammatory response.

## Vitamin C and gene expression

The first genes whose transcription was shown to be modulated (particularly up-regulated) by ascorbic acid were procollagen and other extracellular matrix genes. Later on, ascorbic acid was shown to revert in part the Charcot-Marie-Tooth 1A disease in transgenic mice. This disease is due to the overexpression of a major myelin gene, *PMP22*, in humans and ascorbic acid treatment lowered *PMP22* expression in the mice ([Belin et al., 2010](#)). Results in humans, however, indicate that ascorbic acid does not improve the course of the disease, according to the last available Cochrane systematic review ([Gess et al., 2015](#)).

Other genes up-regulated by ascorbic acid in mice implanted with cancer cells are Raf kinase inhibitory protein (RKIP) and annexin A5. Among the genes whose transcription is down-regulated by ascorbate are those belonging to the families of tRNA synthetases and translation initiation factors ([Belin et al., 2010](#)).

Recent discoveries have provided evidence that ascorbate is an important epigenetic regulator through various mechanisms, which has repercussions on genomic stability.

## Vitamin C and demethylation of DNA

In mammals, DNA methylation in the form of 5′methylcytosine (5 mC) is the major form of DNA modification and plays a key role in development and in the control of gene transcription under normal and pathologic conditions. *De novo* 5′methylation of cytosine is induced by DNA methyltransferase 3A (DNMT3A) and DNMT3B; 5 mC is maintained by methyltransferase DNMT1. DNA methylation is a reversible process and 5 mC can be converted back to unmodified cytosine (C) by TET (Ten-Eleven Translocation) proteins (TETs).

The mechanism of TET-mediated demethylation is complex: 5 mC is converted to C by TET mediated oxidation to 5-hydroxy methylcytosine (5hmC), 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC), followed by the process of active modification-

active removal (AM-AR): by excision of 5 fC or 5caC-mediated thymine DNA glycosylase (TDG) coupled with base excision repair (BER) or the process of active modification-passive dilution (AM-PD): replication-dependent dilution of 5hmC, 5 fC or 5caC.

Three TET enzymes have been discovered in mammalian cells, TET1, TET2 and TET3, all possessing DNA-demethylating activity. TET enzymes are iron (II)/ $\alpha$ -ketoglutarate (Fe(II)  $\alpha$ -KG)-dependent dioxygenases ( $\alpha$ -KGDD) and have a typical structure. They contain a carboxy-terminal core catalytic domain that comprises a cysteine-rich domain and double-stranded  $\beta$ -helix domain (DSBH). Within the DSBH domain, there are some essential catalytic residues, interacting with 2OG and Fe (II): upon cofactor binding, molecular oxygen oxidizes Fe (II) in the catalytic pocket and induces the oxidative decarboxylation of 2OG and substrate oxidation. Within the DSBH domain there is low complexity insert, whose deletion increases the activity of the catalytic domain. Finally, TET1 and TET3, but not TET2, have a DNA-binding domain called the CXXC domain, composed by two Cys4-type zinc finger motifs and located at the amino-terminal region. Vit C increases the enzymatic activity of TET enzymes. Thus, various studies have shown that ascorbate drives DNA methylation in cultured cells in a TET-dependent manner. For instance, In embryonic stem cell cultures, incubation in the presence of 0.25 mM ascorbate elicited a marked loss of 5 mC levels, associated with a moderate increase of 5hmC levels (Mastrangelo et al., 2018; Brabson et al., 2021).

Two mechanisms have been proposed to explain the stimulatory effect of ascorbate on TET enzymatic activity. A first set of studies suggests that ascorbate acts as an enzyme cofactor, able to directly interact with the catalytic domain of TET proteins to increase their enzymatic activity; furthermore, Vit C could promote TET folding to improve the recycling of Fe (II). This hypothesis is supported by the observation that antioxidants other than ascorbate have no effects on TET activity in cultured cells (Mastrangelo et al., 2018).

The second hypothesis challenges the role of ascorbate as a cofactor of TET enzymes and proposes that the stimulatory role of vitamin C on TET activity is related to its capacity to promote the reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ . This conclusion is also supported by the observation that redox-active quinone stimulate TET activity by reducing iron-free  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  (Mastrangelo et al., 2018).

Interestingly, physiologic ascorbate concentrations (i.e., 0.1 mM) increase 5hmC content in human melanoma cell lines to levels comparable to those observed in normal melanocytes and reduced the malignancy of these cells, without affecting their proliferation. Ascorbate at these low and almost physiologic concentrations (100–200  $\mu\text{M}$ ) elicited apoptosis of some melanoma cell lines through a mechanism involving epigenetic downregulation of clusterin, responsible in turn for Bax activation and Bcl-XL sequestering in the mitochondria, with consequent induction of apoptosis (Mastrangelo et al., 2018).

### Vitamin C and demethylation of histones

In addition to DNA methylation, also histone molecules at the levels of lysine and arginine residues can be methylated. Histone methylation is a key event at the level of the epigenetic mechanisms of chromatin control and can result in either gene activation or in gene repression. Histone methylation is a dynamic process and involves methyltransferases, such as MLL, that operate histone methylation and several demethylases that demethylate mono-, di- and tri-methylated histones. Two groups of histone demethylases have been identified: lysine-specific histone demethylases (LSD1 and LSD2), promoting the demethylation of mono- and di-methylated lysine residues; and JmjC domain-containing histone demethylases, promoting the demethylation of mono-, di- and tri-methylated histone lysine/arginine residues (Mastrangelo et al., 2018; Brabson et al., 2021).

Vitamin C accelerates and enhances somatic cell reprogramming (generation of induced pluripotent stem cells) with exogenous factors, through a mechanism not simply ascribable to its antioxidant activity alone. This effect of ascorbate is mediated by its capacity to enhance histone demethylase function of JhdM 1a/1b (Mastrangelo et al., 2018).

Vitamin C also promotes pluripotency of human induced pluripotent stem cells through the induction of increased expression of the histone demethylase JARID1A, and facilitates dopamine neuron differentiation in fetal mid brain through modulation of TET1 and JMJD3 activity (Mastrangelo et al., 2018).

Finally, vitamin C can participate as a cofactor to enhance and maintain the activity of other  $\alpha$ -KGDD family members, such as hypoxia inducible factor (HIF) prolyl hydroxylases, and ALKB homologs (ALKBHs), in addition to TET proteins, that in combination can influence genomic stability (Brabson et al., 2021).

### Vitamin C and disease

Vitamin C has been and is the subject of much research, and has been implicated in the cure and prevention of numerous diseases. The truth of the matter is that, according to Cochrane Database Systematic Reviews, there is not scientific evidence nowadays to support the use of ascorbate as a preventive or therapeutic agent with the exception of scurvy.

#### Scurvy

Observations on scurvy first appeared in Egyptian medical scrolls 3500 years ago, and continued through to the discovery of vitamin C and the modern research on the physiological role of ascorbic acid. The observations of great navigators during the 15th and 16th centuries, when scurvy plagued ships' crews, played an important role in clarifying scurvy's etiology. Among the personalities in the history of the disease, James Lind and Albert Szent-Györgyi are most noteworthy, the first for conducting the first clinical trial on the

treatment of scurvy with lemon and orange juices, and the second for discovering and identifying vitamin C (Magiorkinis et al., 2011).

### Common cold

The most recent systematic reviews and meta-analyses conclude that the consumption of vitamin C does not prevent the incidence of common cold, so routine vitamin C supplementation is not justified. Yet vitamin C may be useful for people exposed to brief periods of severe physical exercise. Regular supplementation trials have shown that vitamin C reduces the duration of colds, but this was not replicated in the few therapeutic trials that have been carried out. Nevertheless, given the consistent effect of vitamin C on the duration and severity of colds in the regular supplementation studies, and the low cost and safety, it may be worthwhile for common cold patients to test on an individual basis whether therapeutic vitamin C is beneficial for them (Gómez et al., 2018; Hemilä and Chalker 2013).

### Cardiovascular disease

The evidence available on the effect of vitamin C supplementation and the risk of cardiovascular disease is of low- and very low-quality. Currently, there is no evidence to suggest that vitamin C supplementation reduces the risk of cardiovascular disease in healthy participants and those at increased risk, but evidence is limited to one trial of middle-aged and older male physicians from the USA (Al-Khudairy et al., 2017).

### Cancer

Well-designed randomized controlled trials have shown no beneficial effect of vitamins A, C, D and E supplements for the prevention of lung cancer and lung cancer mortality in healthy people. On the contrary, vitamin C increases lung cancer incidence in women (Cortés-Jofré et al., 2020). Vitamin C supplements do not exert significant effects on gastrointestinal cancers (Bjelakovic et al., 2008).

### Cataracts

There is no evidence from randomized controlled trials that supplementation with vitamin C prevents or slows the progression of age-related cataracts (Mathew et al., 2012).

### Asthma

There is no indication currently that vitamin C can be recommended as a therapeutic agent in asthma (Milan et al., 2013).

### Pneumonia

The current evidence is too weak to advocate prophylactic use of vitamin C to prevent pneumonia in the general population. Nevertheless, therapeutic vitamin C supplementation may be reasonable for pneumonia patients who have low vitamin C plasma levels because its cost and risks are low (Padhani et al., 2021).

### Pregnancy complications

The data do not support routine vitamin C supplementation alone or in combination with other supplements for the prevention of fetal or neonatal death, poor fetal growth, preterm birth or pre-eclampsia (Rumbold et al., 2015).

### Conclusions

Vitamin C is widely distributed in nature, but it is found mainly in vegetable foods, where occurs naturally in two interconvertible chemical forms: ascorbic acid (reduced form) and dehydroascorbic acid (oxidized form). Both forms have similar biological action. Although its biological functions have been known for a long time, its role in the regulation of gene expression and its epigenetic effects are more novel.

Vitamin C has been implicated in the cure and prevention of numerous diseases. However, the scientific evidence available nowadays only clearly supports the use of this vitamin to prevent scurvy and reduce the duration and severity of colds.

### Glossary

**Clinical deficiency** Often results from severe prolonged tissue (nutrient) deficiency, which may in turn result from inadequate (nutrient) intake, but may also arise from impaired absorption, increased turnover and/or excretion; increased tissue demand, etc. Deficiency signs are directly observable; symptoms can be elicited by testing, and the response of these to intervention (e.g., nutrient supplementation) can help to confirm a diagnosis of deficiency.

**Deficiency (clinical or biochemical)** Arises when the amounts of an essential nutrient in (tissues of) the body falls below a critical minimum level. Biochemical (tissue) depletion then occurs, and may be followed by clinical (i.e., pathological) signs and symptoms of deficiency. Deficiency of an essential nutrient in the diet may lead to tissue- and clinical-deficiency, but impaired absorption, increased losses, increased tissue demands, etc., may also lead to a functional (tissue) deficiency, even when the diet-content is adequate.

**Nutrient (e.g., vitamin) status** Commonly assessed by measuring the concentration of the nutrient in an accessible body fluid such as serum or urine, or else the functionality of an enzyme or biochemical pathway (functional status). Published 'normal ranges' enable the results to be classified as (e.g.,) deficient, low, normal, or high.

### Scurvy: The History and Discovery of Vitamin C

Scurvy is traditionally associated with long sea voyages, which often lasted for several years; the seamen's diets were confined to whatever could be stored at room temperature for long periods. In the absence of refrigeration, their diets typically consisted of dried biscuits and other dry cereal foods (wheat flour and oatmeal), salted meat, dried peas, cheese, butter, and ale, i.e., whatever could be dried and preserved in adverse tropical climates. The signs and symptoms described in classical accounts of scurvy, written long before its cause was understood, included lassitude, swollen joints, putrid and bleeding gums, failure of wound healing and the opening of old wounds and sores, intradermal bleeding due to capillary fragility, heart failure, and sudden death (**Table 1**). Although nowadays we distinguish the symptoms of true scurvy (now known to be produced specifically by vitamin C deficiency) from conditions such as beriberi (thiamin deficiency, associated with edema of the lower limbs), vitamin A deficiency (associated with night-blindness and corneal lesions), and rickets (vitamin D deficiency caused mainly by a lack of exposure to sunlight in children), in the older literature these conditions were often not recognized as distinct. Signs and symptoms of scurvy occurred on land in times of siege or during prolonged military campaigns where accesses to fresh foods were severely restricted. Although some medical practitioners and political leaders became convinced that scurvy had a dietary cause, and that its cure or prevention were possible by including fresh plant materials such as curvy grass, decoctions of evergreen needles, etc., in the diet (**Table 2**), many believed, right up to the beginning of the twentieth century, that factors such as 'foul vapours or infections were to be blamed. Indeed, before the recognition and discovery of essential micronutrients in the early years of the twentieth century, which confirmed that small amounts of certain complex organic molecules are needed in the diet to maintain health; it was thought that food is needed to supply only energy, protein, certain minerals, and water.

Although treatments for scurvy stretch back over many centuries, a definitive dietary cure is attributable to James Lind, whose controlled intervention trial on board HMS Salisbury, followed by 'A Treatise of the Scurvy' in 1753, provided decisive evidence that persuaded the British Admiralty to insist on the inclusion of citrus fruit regularly in the British naval diet (**Table 2**). Lind showed that a 'rob' or decoction of oranges could rapidly cure the disease, and his discovery rapidly brought about dramatic reductions in the incidence and mortality due to scurvy.

In the first decade of the twentieth century, two Norwegian scientists, Holst and Frohlich, found that guinea pigs, like humans, reproducibly become scorbutic if fed a diet that lacks the 'antiscorbutic principle' which was, by now, known to be abundantly

**Table 1** Signs, symptoms, and biochemical indicators of vitamin C deficiency*Signs of clinical scurvy:*

Bleeding gums and looseness of teeth.  
 Skin petechiae (intradermal bleeding due to capillary fragility); perifollicular hemorrhages; larger sheet hemorrhages, especially of the skin of the limbs and trunk; hematomas; purpura; bruising.  
 Ecchymoses (failure of eruption of hair from hair follicles); hyperkeratosis of hair follicles.  
 Breakdown and bleeding from previously healed wounds.  
 Swollen painful joints, with effusions and arthralgia; hemarthrosis; myalgia  
 Edema (especially pedal); dyspnea; dry eyes and mouth.  
 Abnormal long bone development in children; swelling ('beading') of rib cage; swelling of long-bone joints.  
 Intracranial hemorrhages in children; 'bulging eyes'; gums often affected if teeth already erupted.

*Clinical symptoms of scurvy:*

Fatigue, lassitude, joint pain, 'pithed frog' appearance in babies, for example, after prolonged feeding of condensed milk.  
 Abnormal X-ray appearance of long bones in children, especially at the epiphyses; subperiosteal bleeding; osteolysis; osteonecrosis.  
 Capillary fragility, as measured by the Hess test (pressure cuff on limb); nonspecific anemia in many cases.  
 Heart failure in severe cases, potentially leading to death.

*Biochemical indicators of vitamin C deficiency:*

Plasma vitamin C (ascorbate) concentrations  $<11 \mu\text{mol/l}$   
 Buffy coat vitamin C concentrations  $<15 \mu\text{g}/10^8$  cells  
 Suggested, but not yet verified, functional tests, for example, abnormalities of hydroxylation and cross-links of nascent collagen; of carnitine formation, of vitamin E recycling; of purine oxidation, etc.

**Table 2** Historical timeline of investigations into scurvy and discovery of vitamin C (ascorbic acid)

*Tudor England:* Leaders on certain long naval voyages successfully made use of plant foods (e.g., scurvy grass; young pine needles) as an *ad hoc* remedy for the prevalent scourge of scurvy.  
*Mid-eighteenth century:* James Lind (a Scottish physician) carried out the first controlled trial of scurvy remedies at sea; he demonstrated efficacy of citrus fruit (oranges, lemons) and published 'Treatise of the Scurvy', 1753. Sir Gilbert Blane (end of eighteenth century) caused British naval diets to be supplemented with citrus (lemons, limes), thereby reducing prevalence of scurvy and greatly improving sailors' health – although limes eventually proved less effective than lemons, and scurvy reappeared as a result of failure to realise this.  
*Nineteenth century:* Emergence of 'Barlow's disease' – scurvy in babies mainly fed with condensed milk.  
 Early twentieth century: Holst and Frohlich developed a guinea-pig model of scurvy, permitting investigation of the antiscorbutic potency of various foods.  
 1929: Albert Szent-Gyorgyi in Cambridge isolated 'hexuronic acid' from adrenal extracts, which proved identical to 'ascorbic acid', or 'vitamin C', the elusive antiscorbutic substance present in citrus fruit and plants, then being studied by Charles Glen King in Pittsburgh. 'Vitamin C' was thus isolated and named.  
 1930s: Norman Haworth and Tadeus Reichstein achieved chemical synthesis of vitamin C (ascorbic acid) from common sugars (glucose, galactose), thereby proving its chemical structure and elucidating its unique chemical and physiological (nutritional) properties.  
 1940s: Wartime studies showed that 10 mg vitamin C per day is sufficient to prevent and cure clinical scurvy in adult males.  
*Mid-twentieth century:* Biochemical studies in several laboratories elucidated multiple roles of vitamin C: (1) as a cofactor for certain key enzymes, involved in specific oxidation and hydroxylation pathways of intermediary metabolism; (2) as a redox-modulator and provider of protection against certain types of (especially oxygen-radical-mediated) oxidative damage.

present in fresh fruit and vegetables. Few other mammals share this unusual dietary requirement, which, we now know, is solely attributable to the lack of a key enzyme, L-gulonolactone oxidase, which is needed in the multistep biosynthetic pathway for the synthesis of ascorbic acid from common sugars such as glucose and galactose. This animal model of dietary-induced scurvy provided a very important tool for the study of the disease.

Paradoxically, crystalline ascorbic acid (vitamin C) was first isolated, not from a well-established antiscorbutic plant source such as fruit or green leaves, but instead from an animal source, namely adrenal glands, where high concentrations of the vitamin are also found. Indeed, the original motivation for the isolation of the crystalline material (by Albert Szent-Gyorgyi in Gowland Hopkins' laboratory in Cambridge) was a serendipitous accident, arising out of his attempts to isolate a new adrenal hormone. Charles Glen King in Pittsburgh then showed that this easily-oxidized sugar derivative (initially named 'hexuronic acid') was indeed the long-sought antiscorbutic principle, i.e., vitamin C or L-ascorbic acid.

The vitamin was isolated in 1928, and its chemical structure was proven by de novo synthesis from common sugars a few years later (Table 2).

## Degradation, Turnover, and Factors that Induce Increased Requirements for Vitamin C

The instability of vitamin C in air, and especially in neutral or alkaline aqueous solution, is attributable to the fact that in the presence of oxygen or other oxidizing agents it readily undergoes two successive one-electron oxidation steps to produce (reversibly, see below) another unstable product, dehydroascorbate, which readily undergoes an irreversible lactone ring-hydrolysis to yield 2,3-diketogulonic acid. Thus the vitamin is readily destroyed, both in foods during storage and (at a lower rate because of efficient recycling mechanisms) in the body. Diketogulonic acid is one of several degradation products of vitamin C that cannot be reconverted to the vitamin and are further degraded to stable excretory products, such as oxalic acid, by oxidative catabolism. Of all the micro-nutrients that are essential for human health and survival, vitamin C is the most easily destroyed during drying and other traditional methods of preserving food. Citrus fruits contain other organic acids that inhibit this process of oxidation by lowering the pH of the fruit juice. This enables them, and extracts of them, to preserve at least some of their vitamin content for several weeks and even months of storage and thereby helps them to prevent and cure scurvy.

It remains largely a mystery why some people succumb to scurvy after a modest period of very low intake, whereas others survive for much longer. It has been speculated that some people may be able to produce all of the enzymes of the vitamin C synthetic pathway, including gulonolactone oxidase. However, this now seems unlikely and it is more probable that the retention and recycling mechanisms for the vitamin are more efficient in some people than in others. For example, smokers have a higher turnover of endogenous vitamin C than nonsmokers, mainly because of the free-radical oxidant species in cigarette smoke. People with infections also have increased vitamin C turnover, which is associated with the liberation of pro-oxidant substances (such as hypochlorous acid) that are used by the body to kill bacteria. Some people have genetic variants of the vitamin C transporters (see the following section); others have isoforms of certain blood proteins such as haptoglobins, both of which may be associated with relatively low levels of vitamin C in the blood. Very occasionally, there arise nonlethal mutations of vitamin C-dependent pathways whose abnormalities can be treated with high vitamin C intakes. A well-characterized example is Ehlers–Danlos syndrome, type VI, which is associated with impaired collagen lysyl hydroxylation and presents a variety of clinical and biochemical connective-tissue (collagen-related) defects. However, much more research is needed to determine, which of many possible genetic and environmental factors modulate the turnover of vitamin C in the body and to determine individual requirements and hence relative resistance to scurvy. Although 100–200 mg of the vitamins per day is needed to approach saturation of the tissues of humans, the amount needed to prevent or cure scurvy is less than 10 mg day<sup>-1</sup>, as was shown by experiments involving prolonged periods of feeding with depleted diets in the middle of the twentieth century (Table 2). Today, overt clinical scurvy is rare. It is occasionally seen in refugee camps or in elderly people with poor diets that are devoid of the usual sources of the vitamin. The latter high-risk group contains many individuals who are unable to chew fresh fruit and vegetables because of poorly-fitting dentures or poor gastric tolerance of acidic or fibrous foods (see final section).

An essential dietary requirement for vitamin C is shared by only a small number of vertebrates, including most primates, guinea pigs and agoutis, and some birds and fishes. Most mammals synthesize the vitamin in their livers from hexose sugars; birds synthesize it in their kidneys. The final enzyme in the pathway, L-gulonolactone oxidase, has been lost in several unrelated species, suggesting a vulnerable and easily mutated locus on the genome. Presumably this mutation was neutral or advantageous during the natural selection of man's ancestors, when human and related-primate diets were rich in plant sources of the vitamin.

## Well-Established Metabolic Functions of Vitamin C that are Impaired by Deficiency

Studies of guinea pigs (and other species that require a dietary source of vitamin C) have revealed that, when deprived of the vitamin, characteristic lesions of growing bones, failure of wound-healing of skin and bones, capillary defects, and other lesions arise, all of which point to a failure of the new synthesis of or repair processes for, connective tissues and especially the protein collagen, which is the major extracellular protein and comprises a third of all the protein in the body (Table 2). As the biochemical pathway of collagen biosynthesis became better understood, during the middle years of the twentieth century, it became clear that hydroxylated amino-acids, comprising two different hydroxylated forms of proline and one of lysine, occurred uniquely in collagen. These were not coded by the genome or inserted by the amino-acid-assembly machinery of the cell but instead were created by 'post-translational' amino-acid hydroxylation processes that took place after the nascent procollagen polypeptide chain had been synthesized on the polysomal messenger RNA. Some of the prolyl residues of the procollagen molecule were then hydroxylated to hydroxyprolyl residues, and some of the lysyl residues were hydroxylated to hydroxyllysyl residues. The hydroxylated prolyl residues are essential for subsequent collagen triple-helix formation and hence for the secretion of nascent collagen; the hydroxylated lysyl residues form part of the essential pyridinoline-type crosslinks that stabilize the collagen fibers, especially those in bone. In the absence of sufficient vitamin C, these hydroxylation reactions rapidly fail, because the ferrous iron at the active center of the 'mixed function oxidase' enzymes that catalyze them is rapidly inactivated by oxidation. Vitamin C, specifically, is needed to keep the essential ferrous residues at the hydroxylase-enzyme active centers in the reduced, active, form. In the absence of the vitamin, these enzymes are inactivated only after a few cycles of hydroxylation. Hydroxyproline formation in the C1q component of complement, an important component of the immune system, is also vitamin C-dependent.

The essential function of vitamin C in collagen maturation can go a long way toward explaining many of the clinical lesions of scurvy (Table 1). However, the vitamin may also act directly on the transcription and translation of collagen mRNA and on the synthesis of other parts of the cell machinery that are needed for the formation of normal connective tissues.

Vitamin C plays a cofactor-like role in the reactions of several other enzymes that split molecular oxygen, notably members of the group of enzymes that are classified as 'mixed-function oxidases.' Two enzymes containing ferrous iron that are involved in carnitine biosynthesis (trimethyl lysine hydroxylase and  $\gamma$ -butyrobetaine hydroxylase) fall into this category. Aspartate  $\beta$ -hydroxylase, which is needed for the postsynthetic modification of protein kinase C, also requires vitamin C. Another enzyme that requires vitamin C is the copper-containing dopamine  $\beta$ -hydroxylase, and in the reaction that it catalyzes, ascorbic acid reduces cupric to cuprous copper at the active site. Peptidyl glycine hydroxylase (peptidyl  $\alpha$ -amidase) is also a copper-containing enzyme requiring vitamin C as cosubstrate. Vitamin C can increase the activities of several other enzymes, usually by a nonspecific reducing or protective action that is also shared by some other cellular reductants. Newly identified roles for the vitamin include cell-signaling; nucleic acid and histone dealkylation, and proteoglycan deglycanation (e.g., via turnover of glycan-1, which is involved in cell growth and differentiation). One such newly identified ascorbate-dependent reaction is a dioxygenase-dependent hydroxylation of prolyl and asparaginyl residues in the  $\alpha$ -subunit of hypoxia-inducible transcription factor 1 (HIF-1). The asparagine-hydroxylation modulates interaction with other activators, whereas the proline-hydroxylation targets HIF-1 for destruction in proteasomes; the unhydroxylated HIF-1 increases expression of most glycolytic enzymes and two glucose transporters (which also transport dehydroascorbate).

During its function, ascorbic acid is oxidized in two successive reversible one-electron steps, and most, if not all, of its essential biological actions are centered around this redox cycle. The first oxidation product is the free-radical form of the vitamin, which is known variously as 'monodehydroascorbate,' 'semidehydroascorbate,' or 'ascorbate free radical' (AFR). Although this intermediate shares with most other free radicals, the properties of having a relatively short half life and a high degree of chemical reactivity, it is more stable than many other free radicals, contrasting with the highly reactive and damaging radicals such as hydroxyl or superoxide radical that arise from molecular oxygen. By reacting with, and thus quenching, these damaging oxygen free radicals, ascorbate can act as a free-radical chain terminator and can thereby protect vulnerable macromolecules such as DNA, lipids, and proteins from oxidative damage by free-radical chain reactions. Such reactions would otherwise cause extensive damage, including genetic damage (to DNA), the formation of potentially atherogenic oxidized lipids, and oxidative inactivation of enzymes. For this reason, ascorbic acid is thought to possess important 'protective' antioxidant properties that are not directly connected with its other cofactor-like or cosubstrate-like roles in enzyme reactions. Ascorbate probably also protects host tissues against damage by oxidants such as hypochlorous acid that are produced in the normal course of bacterial-killing action of white cells.

The second one-electron oxidation step in ascorbate oxidation produces dehydroascorbate from the free-radical intermediate AFR. Both of these oxidized forms can be recycled to ascorbate either by nonenzymatic reactions with glutathione as the reductant (electron acceptor) or by pyridine nucleotide-dependent enzymatically catalyzed reactions. Thus, the two sequential one-electron oxidation steps from ascorbate to dehydroascorbate are fully reversible *in vivo*. However, the subsequent spontaneous nonenzymatic reaction comprising of hydrolysis of the 1,4-lactone ring is not reversible, so that the product of this reaction, diketogulonic acid, has no provitamin activity. Normally, approximately 3% of the vitamin C in the body is degraded every day and this loss must be replaced from the diet. Nevertheless, many weeks at or near zero intake are usually needed to reach scorbutic levels.

An important aspect of functional adequacy of nutrients is their efficient transport across cell membranes and hence between tissue pools. Reduced ascorbic acid is transported by two distinct sodium-vitamin C transporters, SVCT1, which is found mainly in epithelial tissue such as intestine, liver, and kidney and SVCT2, which is widely distributed among tissues. Naturally-occurring genetic variants affecting SVCT1 have recently been shown to affect circulating concentrations of the vitamin in human populations, and thus, presumably, vitamin C status and requirements. The oxidized form, dehydroascorbate, is transported by the glucose transporter systems, GLUT1 and GLUT2, and glucose and other sugars that share these transporters compete with it, a fact that is relevant for some diseases, such as diabetes, in which glucose transport and concentrations are abnormal.

### Measurement of Vitamin C Status; Biochemical Tests for Adequacy and Deficiency

In species (such as humans) that cannot synthesize vitamin C in their bodies, the vitamin concentration in tissues and blood compartments (plasma, erythrocytes, and white blood cells) varies characteristically with the dietary intake of the vitamin. Because the blood-compartment concentrations mirror the concentrations in most other cells and tissue compartments, tissue vitamin C status can be monitored by measuring the concentration in plasma or blood, even though the blood intracellular concentrations are generally lower than those in most tissues. The concentration ratios between extracellular and various intracellular compartments are determined by active transport systems (SVCT 1 and 2, see previous section), that concentrate the vitamin inside many cell types. At high intakes of the vitamin, the intestinal absorption process is overwhelmed, so that some of the ingested vitamins remain unabsorbed and is destroyed in the lower intestine by intestinal bacteria. The maximum steady-state level in plasma can be temporarily exceeded following a high bolus intake, but the excess vitamin is rapidly excreted in the urine once the renal threshold for filtration and reabsorption is exceeded. These safety mechanisms limit the maximum concentration of the vitamin to which the tissues are normally exposed.

For many years, the best biochemical measure of vitamin C status was considered to be the buffy coat, or total white-cell concentration of the vitamin (Table 1), expressed as micrograms or micromoles per  $10^8$  white cells, the cell count in the assay sample being estimated by an electronic cell counter. This status index varied predictably with total body vitamin C stores during controlled (e.g., animal) depletion studies. However, in practice it has proved to be a difficult test to use in human studies and especially in surveys, as it requires complex laboratory operations to be performed immediately after collecting the blood. It is also difficult to harmonize

this test between laboratories, and, because it measures the average vitamin C content across several different white-cell types, whose individual proportions and relative vitamin C contents may vary considerably, its interpretation was not always straightforward. In addition, infection affects the values obtained. For all of these reasons, this assay has fallen out of favor and is now rarely used. The concentration of the vitamin in erythrocytes or whole blood is not an ideal alternative, partly because hemoglobin can catalyze the oxidative destruction of the vitamin *in vitro* and partly because erythrocyte concentrations do not mirror other body compartments in a simple manner.

Serum or plasma vitamin C has therefore become the most commonly used status assay. To avoid short-term fluctuations caused by recent bolus intakes from food or supplements, it is preferable to collect an overnight-fasting blood sample. Because the vitamin is extremely easily oxidized, the sample must be carefully preserved unless the assay can be performed immediately. The usual approach is to add freshly prepared metaphosphoric acid, usually at between 2 and 5% w/v, which precipitates plasma proteins, chelates transition-metal ions, and provides a protective acidic environment of a suitable pH. If stored, the samples must be kept at a low temperature, for example, at  $-25^{\circ}\text{C}$  for not more than a week or two or at  $-80^{\circ}\text{C}$  for up to 1–2 years. There are many alternative physicochemical and chemical assay methods for measuring vitamin C in extracts of plasma or serum. These include (1) the measurement of its chemical reducing action on reducible dyes such as dichlorophenol indophenol or (2) the formation of either a colored osazone, or a fluorescent derivative with orthophenylene diamine, after conversion to dehydroascorbate. Quantitation by absorbance or by electrochemical detection after separation by high-performance liquid chromatography is favored by many workers. This procedure has the advantage of being relatively specific (i.e., free from most forms of interference) and highly sensitive, but it is more time-consuming than the simpler nonchromatographic methods. Different methods may differ with respect to their specificity and their sensitivity to problems of interference as well as in the precautions that are needed to avoid oxidative destruction of the vitamin during the assay. Careful validation and robust quality-control procedures are essential.

Plasma or serum levels below  $11\ \mu\text{mol l}^{-1}$  ( $<0.2\ \text{mg per } 100\ \text{ml}$ ) are considered to be evidences of biochemical deficiency, and if this is severe and prolonged, the risk of clinical deficiency, i.e., scorbutic signs and symptoms, gradually increases. Intakes below  $20\ \text{mg day}^{-1}$  are likely to result in plasma levels in this range. Studies of human volunteers in the middle of the twentieth century showed clearly that an intake of  $10\ \text{mg}$  vitamin C per day in a healthy adult is sufficient to prevent clinical scurvy, and this small amount is also sufficient to cure scorbutic signs and symptoms (Table 2).

Assay methods based on urinary excretion of vitamin C have been used to study status, but they are too cumbersome and difficult to interpret to be useful in population studies. There are no well-established functional assays available to define vitamin C status and requirements at present. An older method known as the 'Hess test,' which measures relative capillary fragility under pressure or suction (Table 1), is useful only if subclinical scurvy is present and is rarely attempted today. Studies of collagen crosslinks or oxidative damage to macromolecules such as DNA or lipids may yield evidences about functional status in the future, but this remains a research challenge and is not yet an available option for routine studies or surveys.

## Occurrence of Low Intakes and Poor Biochemical Status in Present-Day Societies

Although scurvy is rare, biochemical evidence of poor vitamin C status is not uncommon in certain high-risk groups in different human populations. Studies in The Gambia in West Africa, for instance, have shown that there is a regular seasonal cycle of availability of foods rich in vitamin C, with a good availability in the dry season alternating with a severe shortage during the rainy season. Plasma, buffy-coat, and breast-milk concentrations are all, on average, adequate in the dry season but are severely reduced during the rains. Functional and health-related parameters also deteriorate during the rains, but it has so far proved to be difficult to

**Table 3** Prevalence of low vitamin C intakes and low plasma vitamin C concentrations in Britain at the end of the twentieth century

Age group	LRNI( $\text{mg day}^{-1}$ )	Intake less than LRNI	Less than $11\ \mu\text{mol l}^{-1}$ plasma vitamin
Preschool 1.5–4.5 years	8	8/723=1.1%	24/723=3.3%
Young people 4–18 years			
4–10 years	8	1/423=0.2%	6/422=1.4%
11–14 years	9	0/307=0%	4/307=1.3%
15–18 years	10	1/271=0.4%	8/271=3.0%
Adults 19–64 years			
19–24 years	10	1/212=0.5%	11/151=7.3%
25–34 years	10	0/429=0%	8/307=2.6%
35–49 years	10	0/571=0%	8/414=1.9%
50–64 years	10	0/512=0%	8/366=2.2%
Adults 65 years and above			
Free-living 65–79 years	10	8/606=1.3%	88/606=14.5%
Free-living 80+ years	10	7/274=2.5%	45/274=16.4%
Institution-living	10	2/248=0.8%	98/248=39.5%

The LRNI is the Lower Reference Nutrient Intake, deemed to be sufficient for only that 2.5% of the population who have the smallest requirements, and a plasma concentration of  $11\ \mu\text{mol l}^{-1}$  is the cut-off for biochemical deficiency.

reverse this deterioration by vitamin C supplements alone. Therefore robust evidence of health consequences of this seasonal availability cycle has not yet been obtained.

From recent surveys in the UK, **Table 3** shows the prevalence of low intakes of vitamin C (estimated from the proportion of participants receiving less than the lower reference nutrient intake (LRNI), which is the amount deemed to be sufficient for only a few people in a population group, namely the 2.5% with the lowest requirements). Also shown in **Table 3** is the prevalence of plasma concentrations below the lower cut-off in normality, set at  $0.2 \text{ mg dl}^{-1}$  or  $11 \text{ } \mu\text{mol l}^{-1}$ . This is shown for several subgroups of the British population of different ages, from data collected in three nationally representative population surveys during the decade 1990s. It is clear from these results that a very few people were getting less than the LRNI for vitamin C over a 4 days or 7 days period of weighed-intake estimates of their diets. Low plasma levels were likewise relatively uncommon in the younger age groups; however, they were more common in older people and were especially prevalent, at almost 40%, in older people living in institutions such as nursing homes. Many of these relatively low plasma levels seen in frail older people are likely to be caused by factors other than very low intakes of the vitamin, such as reduced efficiency of the vitamin C transporters, especially SVCT1 or increased vitamin turnover. In the UK, unlike The Gambia, there was relatively little evidence of a major seasonal variation in vitamin C intake or status at the end of the twentieth century.

Vitamin C absorption does not appear to be abnormally low in healthy older people. However, the multiple pathologies associated with old age (and with debility at any age) are associated with increased turnover of the vitamin. Older people with very low levels of vitamin C are at higher risk of dying sooner than those with high levels, although short-term vitamin supplements generally fail to reverse this increased risk. It thus appears that vitamin C status can act as a barometer of health as well as being a marker of adequacy of vitamin C intake. Further research is needed to determine the key mechanisms that affect the rate of vitamin C turnover and its control in different age groups and different metabolic states. Because frail older people are at high risk of developing pressure sores and of needing surgery for a variety of ailments, there seems to be a potential public-health advantage in protecting vitamin C stores, especially in this vulnerable older age group.

## Key points

- Understand how vitamin D is produced in the skin during sunlight exposure.
- Appreciate that a variety of factors including time of day, season, latitude, skin pigmentation and aging can have a dramatic influence on the cutaneous production of vitamin D.
- Recognize a major cause of rickets is due to vitamin D deficiency.
- Increase knowledge about the many noncalcemic benefits of vitamin D for reducing risk of chronic illnesses including autoimmune disorders, type 1 and type 2 diabetes, neurocognitive function, some deadly cancers, neurocognitive dysfunction and acute infection including COVID 19.
- Understand the definition of vitamin D deficiency, insufficiency and sufficiency and vitamin D requirements for all 3 groups.
- To convert  $\text{ng mL}^{-1}$  to SI unit  $\text{nmol L}^{-1}$  multiply  $\text{ng mL}^{-1}$  by 2.5

## Introduction

Vitamin D is a fat-soluble vitamin that is recognized for its importance for bone health. Vitamin D is neither a vitamin nor a nutrient. It is a hormone because exposure to sunlight can produce vitamin D in the skin (Wacker and Holick, 2013). There are two major forms of vitamin D (Holick, 2007). Vitamin D<sub>2</sub> originates from ultraviolet irradiated yeasts, mushrooms and plants. Vitamin D<sub>3</sub> is produced in the skin during sun exposure and is also found in oily fish including salmon, mackerel and herring. We take vitamin D for granted because it was casual exposure to sunlight that provided most humans with their vitamin D requirement when they were hunter gatherers. Due to our civilized lifestyle and concerns about skin cancer we no longer are able to get an adequate amount of vitamin D from sun exposure. The fortification of milk and other foods including some margarines and cereals with vitamin D have eradicated vitamin D deficiency rickets as a significant health problem for most children in the US and countries that practice this fortification process (Holick, 2006). India has now begun a fortification program where cooking oil and milk are fortified with vitamin D<sub>2</sub>. Although there is some debate as to whether vitamin D<sub>2</sub> is as effective as vitamin D<sub>3</sub> in raising blood concentrations of 25(OH)D several studies have reported that physiologic doses of either form will raise blood concentrations of 25(OH)D to essentially the same degree (Holick et al., 2011).

It is now recognized that both children and adults worldwide are at risk for developing vitamin D deficiency and sufficiency. The Endocrine Society Guidelines defines deficiency and insufficiency as a serum concentration of 25-hydroxyvitamin D [25(OH)D] of  $<20 \text{ ng mL}^{-1}$  ( $<50 \text{ nmol L}^{-1}$ ) and  $21\text{--}29 \text{ ng mL}^{-1}$  ( $51\text{--}74 \text{ nmol L}^{-1}$ ) respectively. Vitamin D sufficiency is defined as a serum 25(OH)D of between  $30$  ( $75 \text{ nmol L}^{-1}$ ) and  $100$  ( $250 \text{ nmol L}^{-1}$ )  $\text{ng mL}^{-1}$  ( $\text{nmol L}^{-1}$ ). The guidelines suggested that vitamin D intoxication is not usually seen until a circulating serum concentration of 25(OH)D is greater than  $150 \text{ ng mL}^{-1}$  ( $375 \text{ nmol L}^{-1}$ ) (Holick et al., 2011). In 2010 the Institute of Medicine recommended that to achieve a circulating blood level of 25(OH)D of at least  $20 \text{ ng mL}^{-1}$  required the daily intake of  $400 \text{ IU day}^{-1}$  for children 0–1 year,  $600 \text{ IU day}^{-1}$  for children over 1 year and all and adults  $<70$  years old, and  $800 \text{ IU day}^{-1}$  for those  $>70$  years (Ross et al., 2011). The Endocrine Society recommended that to achieve and maintain a circulating serum concentration of 25(OH)D of at least  $30 \text{ ng mL}^{-1}$  ( $75 \text{ nmol L}^{-1}$ ) required the daily ingestion of  $400\text{--}1000 \text{ IUs}$ ,  $600\text{--}1000 \text{ IUs}$  and  $1500\text{--}2000 \text{ IUs}$  for infants up to 1 year of age, children 1 year of age and older and all adults of normal weight respectively. Obese adults ( $\text{BMI} > 30$ ) require 2–3 times more vitamin D to satisfy their requirement compared to a normal weight adult (Table 1) (Holick et al., 2011).

Once vitamin  $\text{D}_3$  is formed in the skin or vitamin  $\text{D}_2$  and/or vitamin  $\text{D}_3$  are ingested from the diet or supplements, vitamin D (D represents  $\text{D}_2$  and/or  $\text{D}_3$ ) enters the bloodstream and travels to the liver and kidneys where it is hydroxylated on carbons 25 and 1 to form [25(OH)D] and 1,25-dihydroxyvitamin D [1,25(OH) $_2$ D] respectively (Holick, 2007; Bouillon et al., 2019). 25-Hydroxyvitamin D is the major circulating form of the vitamin that is measured to determine the vitamin D status of patients (Holick et al., 2011). 1,25(OH) $_2$ D is the biologically active form of vitamin D that is responsible for maintaining calcium homeostasis and bone health (Holick, 2007). It is now recognized that vitamin D deficiency may increase the risk of many acute and chronic diseases, including some deadly cancers including cancer of the breast, prostate, and colon, type I diabetes mellitus, multiple sclerosis, rheumatoid arthritis, neurocognitive dysfunction including Alzheimer's disease and depression, type 2 diabetes, cardiovascular disease and infectious diseases including influenza and COVID-1 (Grant, 2002; Bouillon et al., 2019; Charoenngam and Holick, 2020; Kaufman et al., 2020; Charoenngam et al., 2021; Seal et al., 2022).

**Table 1** Sources of vitamin  $\text{D}_2$  and vitamin  $\text{D}_3$ .

Source	Vitamin D content (IU = 25 ng)
<b>Natural sources</b>	
Cod liver oil	~400–1000 IU/tsp vitamin $\text{D}_3$
Salmon, fresh wild caught	~600–1000 IU/3.5 oz vitamin $\text{D}_3$
Salmon, fresh farmed	~100–250 IU/3.5 oz vitamin $\text{D}_3$ , vitamin $\text{D}_2$
Salmon, canned	~300–600 IU/3.5 oz vitamin $\text{D}_3$
Sardines, canned	~300 IU/3.5 oz vitamin $\text{D}_3$
Mackerel, canned	~250 IU/3.5 oz vitamin $\text{D}_3$
Tuna, canned	~236 IU/3.5 oz vitamin $\text{D}_3$
Shiitake mushrooms, fresh	~100 IU/3.5 oz vitamin $\text{D}_2$
Shiitake mushrooms, sun dried	~1600 IU/3.5 oz vitamin $\text{D}_2$
Egg yolk	~20 IU/yolk vitamin $\text{D}_3$ or $\text{D}_2$
Sunlight/UVB radiation	~20,000 IU equivalent to exposure to 1 minimal erythral dose (MED) in a bathing suit. Thus, exposure of arms and legs to 0.5 MED is equivalent to ingesting ~3000 IU vitamin $\text{D}_3$
<b>Fortified foods</b>	
Fortified milk	100 IU/8 oz usually vitamin $\text{D}_3$
Fortified orange juice	100 IU/8 oz vitamin $\text{D}_3$
Infant formulas	100 IU/8 oz vitamin $\text{D}_3$
Fortified yogurts	100 IU/8 oz usually vitamin $\text{D}_3$
Fortified butter	56 IU/3.5 oz usually vitamin $\text{D}_3$
Fortified margarine	429/3.5 oz usually vitamin $\text{D}_3$
Fortified cheeses	100 IU/3 oz usually vitamin $\text{D}_3$
Fortified breakfast cereals	100 IU/serving usually vitamin $\text{D}_3$
<b>Pharmaceutical sources in the US</b>	
Vitamin $\text{D}_2$ (ergocalciferol)	50,000 IU/capsule
Drisdol (vitamin $\text{D}_2$ ) liquid	8000 IU/cc
<b>Supplemental sources</b>	
Multivitamin	400, 500, 1000 IU vitamin $\text{D}_3$ or vitamin $\text{D}_2$
Vitamin $\text{D}_3$	400, 800, 1000, 2000, 5000, 10,000, and 50,000 IU

Modified from Holick (2007) Vitamin D deficiency. *New England Journal of Medicine* 357: 266–281.

## Origin and structure of vitamin D

As the industrial revolution began to take hold in Northern Europe in the fifteenth century, it was quickly associated with a new disease that caused severe growth retardation and bony deformities in young children (**Fig. 1**) ([Holick, 2006](#)). This disease was commonly known as rickets or “English disease” and plagued the children of the industrialized cities in Europe and North America for more than 250 years. Although Sniadecki in 1822 and Palm in 1890 both recognized that it was lack of exposure to sunlight that was the likely cause of rickets in children, Huldschinsky, in 1919, was the first to prove that exposure of the skin to ultraviolet radiation could cure rickets. Within 2 years, Hess and Unger reported that exposure of several rachitic children to sunlight was adequate for curing this bone-deforming disease.

Steenbock and Black and Hess independently recognized that exposure of animals and their food to ultraviolet radiation imparted antirachitic activity. This led to the recommendation for the ultraviolet irradiation of foods as a means of fortifying them with vitamin D. This resulted in the addition of provitamin D to milk followed by ultraviolet irradiation. As soon as it was possible to commercially synthesize vitamin D<sub>2</sub> from yeast in large quantities, it was added directly to milk and other foods ([Wacker and Holick, 2013](#)).

The first vitamin D was isolated from the irradiation of the yeast sterol ergosterol (**Fig. 3**). This vitamin D was thought to be identical to that produced in the skin of animals and humans. However, studies revealed that when vitamin D produced from yeast was fed to chickens, they were unable to utilize it and developed rickets. When chickens were fed natural vitamin D from fish liver oil, rickets was prevented. This led to the conclusion that vitamin D originating from yeast was different from that in fish liver oil and animal and human skin. In 1937, this mystery was solved when the structure of provitamin D from pig skin was determined. A

**Fig. 1** This is a typical presentation of a child with rickets. The child is suffering from severe muscle weakness, has bony deformities including bowed legs, and knob-like projects in the middle of his ribcage called the rachitic rosary. Reproduced from Fraser D and Scriver CR (1979) Disorders associated with hereditary or acquired abnormalities of vitamin D function: Hereditary disorders associated with vitamin D resistance or defective phosphate metabolism. In: De Groot LJ. et al. (eds.) *Endocrinology*, pp. 797–808. New York: Grune and Stratton.

structural analysis revealed that provitamin D derived from ergosterol differed from that derived from pig skin. The provitamin D (ergosterol; provitamin D<sub>2</sub>) that came from yeast had a double bond between carbons 22 and 23 and a methyl group on carbon 24. The provitamin D in animal skin had a side chain that was identical to cholesterol, that is, it did not contain either a double bond or methyl group on carbons 22–23 and 24, respectively, and was identified as 7-dehydrocholesterol (provitamin D<sub>3</sub>) (Fig. 2). The vitamin Ds generated from ergosterol and 7-dehydrocholesterol were called ergocalciferol (vitamin D<sub>2</sub>) and cholecalciferol (vitamin D<sub>3</sub>), respectively (Wacker and Holick, 2013).

### Production of vitamin D in the skin

During exposure to sunlight, the ultraviolet B photons with energies between 290 and 315 nm are absorbed by provitamin D<sub>3</sub> (7-dehydrocholesterol) in the skin. This absorption results in a photolysis of the B-ring of provitamin D<sub>3</sub> resulting in the formation of previtamin D<sub>3</sub> (Fig. 3). However, because previtamin D<sub>3</sub> is thermodynamically unstable, it quickly undergoes an isomerization (rearrangement) of its triple bond system to form vitamin D<sub>3</sub>. This isomerization process is enhanced in skin cells because the previtamin D<sub>3</sub> is synthesized in the cell membrane, which restricts its movement thereby accelerating the transformation of previtamin D<sub>3</sub> to vitamin D<sub>3</sub>. Once vitamin D<sub>3</sub> is formed in the skin cell membrane, it is no longer restricted in its movement and freely translocates into the extracellular space to find its way into the dermal capillary bloodstream where it is bound to a specific vitamin D-binding protein (Fig. 3).

An increase in skin pigmentation and zenith angle of the sun (change in latitude, season, and time of day) and the topical application of a sunscreen can markedly diminish or even prevent the production of vitamin D<sub>3</sub> in the skin. Over the age of ~65 years, there is a three- to fourfold decline in the synthetic capacity of the skin to produce vitamin D<sub>3</sub>. Excessive exposure to sunlight cannot cause vitamin D<sub>3</sub> intoxication because once previtamin D<sub>3</sub> and vitamin D<sub>3</sub> are made in the skin, excessive quantities are rapidly destroyed by sunlight (Fig. 3) (Holick, 2007; Wacker and Holick, 2013).

**Fig. 2** Structures for 7-dehydrocholesterol (provitamin D<sub>3</sub>), ergosterol (provitamin D<sub>2</sub>), vitamin D<sub>3</sub> (cholecalciferol), and vitamin D<sub>2</sub> (ergocalciferol). The carbons are numbered and the ring systems are labeled. Reproduced with permission from Holick MF Copyright 2007.

**Fig. 3** Schematic representation of the synthesis and metabolism of vitamin D for skeletal and nonskeletal function. 1-OHase = 25-hydroxyvitamin D-1α-hydroxylase; 24-OHase = 25-hydroxyvitamin D-24-hydroxylase; 25(OH)D = 25-hydroxyvitamin D; 1,25(OH)<sub>2</sub>D = 1,25-dihydroxyvitamin D; CaBP = calcium-binding protein; CYP27B1, Cytochrome P450-27B1; DBP = vitamin D binding protein; ECaC = epithelial calcium channel; FGF-23 = fibroblast growth factor-23; PTH = parathyroid hormone; RANK = receptor activator of the NF-κB; RANKL = receptor activator of the NF-κB ligand; RXR = retinoic acid receptor; TLR2/1 = Toll-like receptor 2/1; VDR = vitamin D receptor; vitamin D = vitamin D<sub>2</sub> or vitamin D<sub>3</sub>. ## Absorption, metabolism, and excretion of vitamin D

Vitamin D (vitamin D without a subscript represents either vitamin D<sub>2</sub> or D<sub>3</sub>) is fat soluble and, therefore, once ingested vitamin D<sub>2</sub> and vitamin D<sub>3</sub> are incorporated into the chylomicron fraction and absorbed in the small intestine into the lymphatic system. Both dietary vitamin D<sub>2</sub> and vitamin D<sub>3</sub>, and cutaneous vitamin D<sub>3</sub> enter the circulation and are bound to a specific  $\alpha_1$ -globulin known as the vitamin D-binding protein (DBP). It is believed that this protein acts as a buffering system whereby it helps maintain circulating concentrations of 25(OH)D. The bound form of 25(OH)D can enter into the renal tubular cells via the membrane receptor megalin. Once inside the renal tubule 25(OH)D is dissociated from DBP and enters the mitochondria to be metabolized to 1,25-dihydroxyvitamin D [1,25(OH)<sub>2</sub>D](Fig. 3) (Hosseini-nezhad and Holick, 2013).

Neither vitamin D<sub>2</sub> nor vitamin D<sub>3</sub> possess any intrinsic biologic activity on calcium metabolism. They both require a hydroxylation on carbon 25 to form 25(OH)D (Fig. 4). When given as a 1000 or 2000 IU supplement, vitamin D<sub>2</sub> is as effective as vitamin D<sub>3</sub> in raising serum 25(OH)D levels. 25(OH)D is the major circulating form of vitamin D, and at physiologic concentrations, it too has little biologic activity on calcium metabolism. It must undergo a hydroxylation on carbon 1 in the kidney to form 1,25(OH)<sub>2</sub>D, the biologically active form of vitamin D (Fig. 3). The metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D is tightly regulated by parathyroid hormone (PTH), fibroblast growth factor 23 (FGF23), and serum phosphorus levels (Fig. 5). PTH and low serum phosphorus levels increase the production of 1,25(OH)<sub>2</sub>D, whereas FGF23 suppresses its production (DeLuca, 1988; Holick, 2007; Hosseini-nezhad and Holick, 2013; Charoenngam et al., 2021).

25(OH)D and 1,25(OH)<sub>2</sub>D act as substrate for a 24-hydroxylase (an enzyme that attaches a hydroxyl on carbon-24), which is found in the kidneys and other target tissues for 1,25(OH)<sub>2</sub>D. Once 1,25(OH)<sub>2</sub>D is hydroxylated on carbon 24, this is the first step in its degradation to a water-soluble acid, calcitroic acid (Fig. 4). Vitamin D and calcitroic acid are excreted in the bile (Holick, 2007; Hosseini-nezhad and Holick, 2013).

## Biologic functions of vitamin D on calcium metabolism

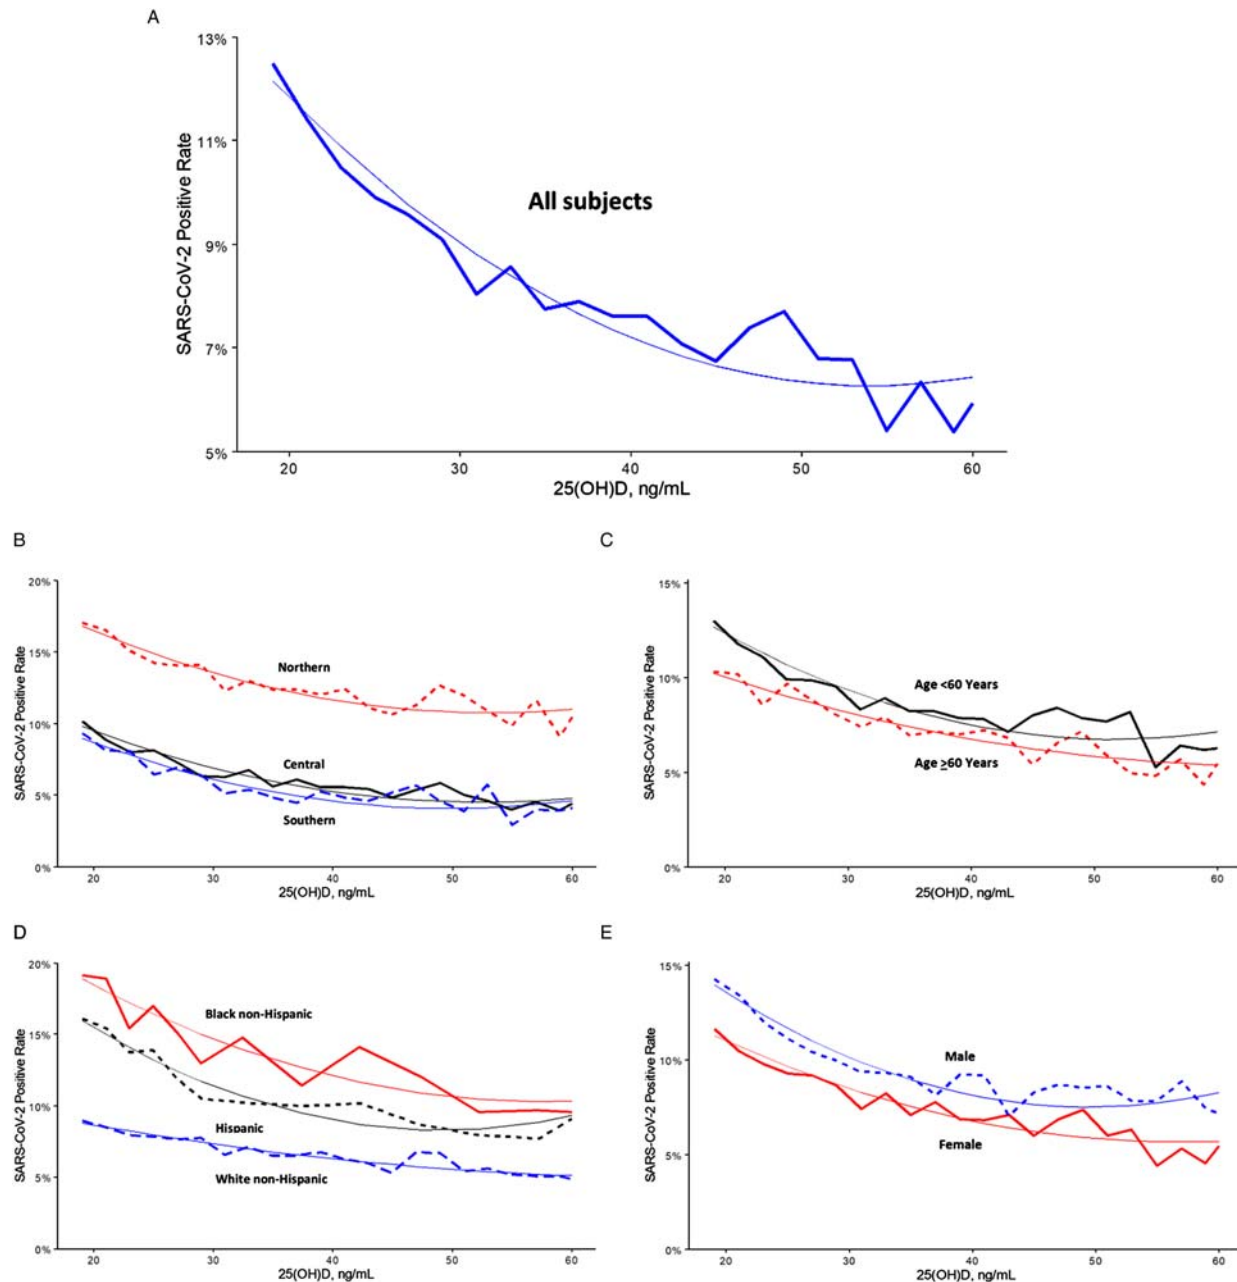

1,25(OH)<sub>2</sub>D interacts with a specific nuclear receptor that is commonly known as the vitamin D receptor (VDR) and is one of the many members of the super family of steroid hormone receptors that includes retinoic acid, thyroid hormone, glucocorticoids, and sex steroids. Once 1,25(OH)<sub>2</sub>D interacts with the VDR, the complex forms a heterodimer with retinoic acid X receptor (RXR) (Fig. 3). This new complex sits on specific segments of vitamin D responsive genes known as vitamin D responsive elements (VDREs) to either increase or decrease transcriptional activity of the vitamin D-sensitive genes such as osteocalcin, calcium binding protein (calbindin), PTH, calcium channel and osteonectin (Fig. 3) (Hosseini-nezhad and Holick, 2013).

In the intestine, 1,25(OH)<sub>2</sub>D enhances the absorption of dietary calcium (from ~15% to 30–40% in adults) and phosphorus (from ~60 to ~80%) across the microvilli of the small intestinal absorptive cells (Fig. 3). 1,25(OH)<sub>2</sub>D also interacts with osteoblasts to stimulate the expression for receptor activator NF $\kappa$ B ligand (RANKL) in the bone to initiate the transformation of monocytes into mature osteoclasts (Fig. 3). Thus, 1,25(OH)<sub>2</sub>D<sub>3</sub> regulates serum calcium levels by enhancing the efficiency of intestinal calcium absorption and stimulating resorption of calcium from the bone (Holick, 2007; Hosseini-nezhad and Holick, 2013).

There are a variety of other tissues including the brain, gonads, pancreas, stomach, activated T and B lymphocytes, monocytes, macrophages, and skin that have a nuclear VDR. Although the exact physiologic function of 1,25(OH)<sub>2</sub>D's interaction with these VDRs is not well understood, it is known that *in vivo* and *in vitro* 1,25(OH)<sub>2</sub>D<sub>3</sub> can inhibit proliferation and induce terminal differentiation of various normal and tumor cells including normal human keratinocytes. This is the reason why activated vitamin D compounds are now routinely used for the treatment of the hyperproliferative skin disorder psoriasis (Wacker and Holick, 2013). It has been estimated that at least 200 and as many as 2000 genes are influenced directly or indirectly by 1,25(OH)<sub>2</sub>D<sub>3</sub> (Carlberg and Haq, 2018; Shirvani et al., 2019; Charoenngam and Holick, 2020).

## Evaluation for and consequences of vitamin D deficiency

Vitamin D deficiency in infants and children causes rickets. As a child becomes vitamin D deficient, this results in a decrease in the efficiency of intestinal calcium absorption. There is a decline in blood-ionized calcium, which causes the parathyroid glands to produce and secrete more PTH. PTH tries to conserve calcium by enhancing tubular reabsorption of calcium in the kidneys. However, in the face of developing hypocalcemia, which could disturb neuromuscular function and a wide variety of metabolic and cellular processes, the body calls upon 1,25(OH)<sub>2</sub>D and PTH to stimulate the expression of RANKL in osteoblasts to mobilize monocytic stem cells to become functional osteoclasts, which, in turn, mobilize calcium from the skeleton (Fig. 3) (Aksenes and Aarskog, 1982; Holick, 2006; Hosseini-nezhad and Holick, 2013). In addition, PTH causes a loss of phosphorus into the urine causing hypophosphatemia (low blood phosphate concentration). Thus, in early vitamin D deficiency, the serum calcium is normal; it is the low serum phosphorus that causes the extracellular CaXPO<sub>4</sub> to be too low for normal mineralization of bone matrix. This causes a disruption in the orderly sequence of events in the differentiation of hypertrophied chondrocytes in the epiphyseal plates resulting in their disorganization causing a widening of the epiphyseal plates (end of long bones). PTH causes a demineralization of the skeleton, and newly laid down collagen matrix is unable to be mineralized. All of these in concert cause bony deformities seen in rachitic children (Fig. 1) (Holick, 2006; Hosseini-nezhad and Holick, 2013; Charoenngam and Holick, 2020).

**Fig. 4** SARS-CoV-2 nucleic acid amplification test positivity rates and circulating 25(OH)D levels in all subjects (A) and stratified by latitude region (B), predominately Black non- Hispanic, Hispanic and White non-Hispanic zip codes (C), age group (D), and sex (E). Smooth lines represent the weighted second order polynomial regression fit to the data associating circulating 25(OH)D levels (x-axis) and SARS-CoV-2 positivity rates (y-axis). 25(OH)D  $\frac{1}{4}$  25-hydroxyvitamin D; SARS-CoV-2  $\frac{1}{4}$  severe acute respiratory distress syndrome coronavirus 2. Once the epiphyseal plates are closed later in adolescence, vitamin D deficiency can no longer cause bone deformities. Instead, there is an inability to mineralize newly deposited bone matrix leading to wide osteoid seams within the trabecular and cortical bone causing the bone disease commonly known as osteomalacia. Although osteomalacia is not associated with bone deformities it is associated with aching throbbing bone pain and muscle weakness that can be misdiagnosed as fibromyalgia and chronic fatigue syndrome respectively. In addition, the secondary hyperparathyroidism that results from vitamin D deficiency results in the mobilization of precious calcium stores from the skeleton thereby exacerbating bone loss and causing osteoporosis. This can increase a person's risk for fracture (Holick, 2007; Hossain and Holick, 2013; Bouillon et al., 2019). A study by Priemel et al., (2010)

**Fig. 5** Vitamin D intakes recommended by the Institute of Medicine and the Endocrine Practice Guidelines Committee. 25(OH)D = 25-hydroxyvitamin D; AI = adequate intakes; RDA = recommended dietary allowance; SE = standard error; UL = tolerable upper intake level. reported that in a large cohort of adults ages 20 and above who had died unexpectedly that they found no evidence of osteomalacia when the circulating concentration of 25(OH)D was at least 30 ng mL<sup>-1</sup> (75 nmol L<sup>-1</sup>).

The hallmark for determining the vitamin D status is the measurement of the circulating concentration of 25(OH)D. The 25(OH)D is low or undetectable in vitamin D deficiency and markedly elevated in vitamin D intoxication. The Endocrine Society Practice Guidelines on Vitamin D defined vitamin D deficiency and insufficiency as a 25(OH)D of <20 ng mL<sup>-1</sup> (<50 nmol L<sup>-1</sup>) and 21–29 ng mL<sup>-1</sup> (51–74 nmol L<sup>-1</sup>) and vitamin D sufficiency is defined as a serum 25(OH)D of between 30 (75 nmol L<sup>-1</sup>) and 100 (250 nmol L<sup>-1</sup>) ng mL<sup>-1</sup> (nmol L<sup>-1</sup>) respectively. Vitamin D intoxication is normally not observed until the blood level of 25(OH)D > 150 ng mL<sup>-1</sup> (250 nmol L<sup>-1</sup>). Measurement of 1,25(OH)<sub>2</sub>D is of little value for determining the vitamin D nutritional status because its synthesis is tightly regulated. Indeed, as a person becomes vitamin D deficient, there is an increase in the secretion of PTH which, in turn, increases the production of 1,25(OH)<sub>2</sub>D. Thus, early in vitamin D deficiency one can see a normal fasting serum calcium, low-normal to low phosphorus, low 25(OH)D, and elevated PTH, 1,25(OH)<sub>2</sub>D and alkaline phosphatase. In chronic vitamin D deficiency, all the above are seen with the exception that serum calcium and 1,25(OH)<sub>2</sub>D are low-normal or low (Holick, 2007).

### Nonskeletal consequences of vitamin D deficiency

As early as 1941, it was appreciated that if you lived at higher latitudes in the US you were at higher risk of dying of cancer (Apperly, 1941). A multitude of epidemiologic studies clearly show that if you live at higher latitudes and are more prone to vitamin D deficiency, then you are at higher risk of dying of colon, prostate, breast, ovarian, and a variety of other cancers (Grant, 2002; Hosseini and Holick, 2013; Wacker and Holick, 2013). It is also known that living at higher latitudes increases risk of having high

blood pressure and heart disease as well as autoimmune diseases including multiple sclerosis and type I diabetes (Wacker and Holick, 2013).

Essentially every cell and organ in the body requires vitamin D, that is, they all have a VDR. It is also known that most tissues in the body can activate vitamin D (Hossain and Holick, 2013; Bouillon et al., 2019; Charoenngam and Holick, 2020). Thus, maintaining adequate concentrations of 25(OH)D in the circulation of at least 30 ng mL<sup>-1</sup> may be necessary for various organs including colon, breast, and macrophages and dendritic cells to convert it to 1,25(OH)<sub>2</sub>D, which in turn can help regulate various genes responsible for cell growth and differentiation (Fig. 3) (Hossein-nezhad and Holick, 2013; Bouillon et al., 2019; Shirvani et al., 2019; Charoenngam and Holick, 2020). This could be the explanation for how vitamin D sufficiency is protective against many common cancers (Grant, 2002; Hossein-nezhad and Holick, 2013). The immune cells also recognize 1,25(OH)<sub>2</sub>D<sub>3</sub>. This may explain why children who had received 2000 IU of vitamin D a day during their first year decreased their risk of developing type I diabetes by 88%. A study in Japanese children who received 1200 IU vitamin D<sub>3</sub>/d from December through March had a 42% reduced risk for developing influenza A infection compared to children who received a placebo pill (Hypponen et al., 2001; Ura-shima et al., 2010; Bouillon et al., 2019; Charoenngam and Holick, 2020). A study of more than 191,000 COVID 19 positive patients revealed a 54% reduced risk for those patients who had a blood level of 25(OH)D of 34 ng mL<sup>-1</sup> compared to patients with a blood level of less than 20 ng mL<sup>-1</sup> (Kaufman et al., 2020). The benefit of having less infection continued up to a blood level of 55 ng mL<sup>-1</sup> (Fig. 4). A major consequence of being infected with COVID 19 is the cytokine storm which increases risk for morbidity and mortality. Several studies have reported that patients who had a blood concentration of 25(OH)D of at least 30 ng mL<sup>-1</sup> significantly reduced risk of unconsciousness, intensive care admission and mortality (Charoenngam et al., 2021; Seal et al., 2022). Increasing intake of vitamin D and sun exposure has been associated with decreased risk of developing multiple sclerosis, rheumatoid arthritis, and even Crohn's disease (Moan et al., 2008; Wacker and Holick, 2013).

The relationship of vitamin D to cardiovascular disease is finally being understood. 1,25(OH)<sub>2</sub>D inhibits the production of the blood pressure hormone renin. It also alters cardiomyocyte growth and modulates the inflammatory response of atherosclerosis. Vitamin D deficiency has been associated with a 50% increased risk for having a heart attack and stroke, and 80% increased risk for developing peripheral vascular disease. When African-American teenagers were given 2000 IU vitamin D<sub>3</sub>/d for 4 months, they had a significant reduction in arterial wall stiffness, a prelude to hypertension and arteriosclerosis when compared to teenagers receiving 400 IU vitamin D<sub>3</sub>/d for four months (Melamed et al., 2008; Dong et al., 2010; Dobnig et al., 2008; Hossain and Holick, 2013; Dudenkov et al., 2018).

### Recommended dietary intake of vitamin D (Fig. 5)

Vitamin D is very rare in foods naturally, with the exception of fatty fish, some fish liver oils, and mushrooms exposed to UVR (Fig. 3). Milk and some dairy products in the United States are fortified with vitamin D<sub>3</sub>/8 oz or serving. Some orange juice and other juice products are fortified with calcium and 100 IU of vitamin D<sub>3</sub>/8 oz (Holick, 2007). In India milk and cooking oil is fortified with vitamin D<sub>2</sub>. Multivitamin preparations that contain vitamin D are a good source of vitamin D as are pharmaceutical preparations (Table 2).

In 2010, the Institute of Medicine and the National Academy of Sciences reviewed the recommended dietary intake for calcium and vitamin D. The recommended dietary allowance (RDA) was defined as the daily intake level that is sufficient to meet nutrient requirements for nearly all (97–98%) individuals in life-stage and gender group. The RDA was meant to apply to individuals and not groups. When sufficient scientific evidence was not available to calculate an estimated average requirement (EAR), that is, a nutrient value that was estimated to meet the requirement defined by a specified indicator of adequacy in 50% of individuals in a life-stage and gender group, the Committee recommended using an adequate intake (AI). The AI is based on the observation of experimentally determined approximations of average nutrient intake by a defined population or subgroup that appears to sustain a defined nutritional state such as normal circulation nutrient values or growth. Because sunlight played such an important role in providing humans with their vitamin D requirement and, therefore, was a variable that was difficult to quantify in studies in infants that were reviewed by the Committee, it was concluded that an AI rather than an RDA should be used for vitamin D (Fig. 5, Table 2) (Ross et al., 2011). At the same time the Endocrine Society formed a committee to evaluate how to treat and prevent vitamin D deficiency as it relates to skeletal health. The Endocrine Society Guidelines on Vitamin D was published in 2011 and the recommendations are included in Table 2 (Holick et al., 2011).

### Recommendations for adequate intake for ages 0–12 months

It is well documented that human and cows' milk has very little vitamin D naturally (Hollis and Wagner, 2004). Human milk contains on average between 10 and 50 IU L<sup>-1</sup> (0.25–1.25 µg). This is dependent on the mother's exposure to sunlight and her vitamin D intake. Several studies have suggested that infant intakes of vitamin D of between 8.5 (340 IU) and 15 µg (600 IU) day<sup>-1</sup> would provide the maximum effect on their linear growth. A study in infants from Northern China (40–47° N) found that vitamin D supplements of 2.5 (100 IU), 5 (200 IU), or 10 µg (400 IU) day<sup>-1</sup> resulted in 36, 29, and 2% of the infants being vitamin D deficient with 25(OH)D levels of less than 25 nmol L<sup>-1</sup> (10 ng mL<sup>-1</sup>). None of the infants, however, had overt manifestations of rickets i.e bony deformities. Chinese infants from two southern cities (22° N and 30° N) maintained normal vitamin D status on as little as 2.5 µg (100 IU) day<sup>-1</sup> of vitamin D (Holick, 2006; Hossain and Holick, 2013).

**Table 2** Adequate intakes (AI), daily allowance and tolerable upper limit (UL) for Vitamin D.

Life stage group	IOM recommendations				The current endocrine society practice guidelines

Recommended adequate intakes (AI), estimated average requirement (EAR), recommended dietary allowance (RDA) and tolerable upper limit (UL) by the Institute of Medicine (IOM) and Dr. Holick's recommendation for Daily Allowance and safe Upper Limit (UL) for vitamin D for children and adults who are not obtaining adequate vitamin D from sun exposure and who are at risk for vitamin D deficiency.

Modified from Holick et al. (2011) Evaluation, treatment, and prevention of vitamin D deficiency: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 96(7): 1911–1930.

There was a seasonal variation of vitamin D status of infants when they were fed human milk only and did not receive vitamin D supplements; their 25(OH)D levels decreased in the winter due to less exposure to sunlight. However, this decrease did not occur in infants receiving a vitamin D supplement of 10 µg (400 IU) day<sup>-1</sup> beginning at 3 weeks of age (Aksenes and Aarskog, 1982; Holick, 2006; Kumar et al., 2009; Grober et al., 2013).

Therefore, based on the available literature, it was concluded that a minimum intake of 2.5 µg (100 IU) day<sup>-1</sup> of vitamin D was adequate to prevent rickets. However, at this intake and in the absence of sunlight, infants are at risk for developing hypovitaminosis D; therefore, it was recommended by the Institute of Medicine (IOM) that an adequate intake of 10 µg day<sup>-1</sup> (400 IU) was prudent for infants during their first year of life (Ross et al., 2011). The American Academy of Pediatrics emphasized the importance of providing breast fed infants with 400 IUs daily since there is little if any vitamin D in human breast milk. An alternative is for mothers who are breast-feeding their infant to ingest 6400 IUs daily. This amount of intake places enough vitamin D in her milk to satisfy her infant's requirement. The Endocrine Society Practice Guidelines on Vitamin D recommended infants should receive 600–1000 IUs for maximum bone health (Holick et al., 2011).

### Recommendations for adequate intake for ages 1–18 years

There are no studies in the scientific literature that systematically evaluated the influence of different amounts of vitamin D on either serum 25(OH)D or bone mineral content in this age group. Sunlight exposure is very important for this age group to obtain its required vitamin D. In South Africa, children aged 1–8 years of mixed race showed no evidence of vitamin D deficiency (Holick et al., 2011).

During puberty, there is a need to increase the efficiency of dietary calcium absorption in order to satisfy the rapid growth of the skeleton. As a result, there is an increase in the metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D. Because the blood levels of 1,25(OH)<sub>2</sub>D are approximately 1000 times less than 25(OH)D, this increase in metabolism does not appear to increase the requirement of vitamin D for either boys or girls between the ages of 8 and 18 years. Girls of 9–17 years in Lebanon who took 2000 IU day<sup>-1</sup> for 1 year had better bone density and muscle strength compared to girls who received 400 IU vitamin D<sub>3</sub> per day. Therefore, based on the available literature, it appears that children between 1 and 18 years obtain some of their vitamin D from exposure to sunlight. The IOM recommended they ingest 15 µg (600 IU) day<sup>-1</sup>. The Endocrine Society Practice Guidelines on Vitamin D recommended 600–1000 IUs daily for maximum bone health (Ross et al., 2011; Holick et al., 2011).

### Recommended adequate intake for ages 19–70+ years

There is only sparse literature regarding the roles that sunlight and diet play in maintaining an adequate vitamin D status for men and women in this age group. This age group depends on sunlight for some of its vitamin D requirement (Wacker and Holick, 2013). There was strong evidence-based literature that demonstrated a decrease in the circulating concentration of 25(OH)D, and an increase in the PTH level correlated with an increased risk of skeletal fractures in both the hip and spine in this age group. Studies in both men and women supplemented with 10–25 µg day<sup>-1</sup> of vitamin D demonstrated reduced bone resorption, increased bone mineral content, and a decrease in vertebral and nonvertebral fractures. An evaluation of 333 ambulatory Caucasian women (mean age 58 ± 6 years) found that serum PTH concentrations were elevated in the winter (between March and May) in women consuming less than 5.5 µg (220 IU) day<sup>-1</sup> of vitamin D. There was no seasonal variation in serum PTH concentrations when vitamin D intakes were greater than 5.5 µg (220 IU) day<sup>-1</sup>. When bone loss was evaluated between seasons in women (62 ± 0.5 years) who had a usual vitamin D intake of 2.5 µg day<sup>-1</sup>, a dietary supplement of 10 µg day<sup>-1</sup> decreased spinal and hip-bone density loss. An analysis of the skeletons of German adults at autopsy revealed no evidence of vitamin D deficiency osteomalacia for those who had a 25(OH)D > 30 ng mL<sup>-1</sup>. Regardless of exposure to sunlight, it was estimated by the IOM that 15 µg (600 IU) day<sup>-1</sup> meets this age group's needs for bone health. They recommended for adults over the age of 70 years that they required 800 IUs daily (Ross et al., 2011). The Endocrine Society Practice Guidelines on Vitamin D recommended for all adults 19 years and above require the same amount of vitamin D for maximum bone health which was 1500–2000 IUs daily. They also recommended that for obese adults they require 2–3 times more vitamin D to satisfy their vitamin D requirement. This is because vitamin D be fat soluble and is diluted in the body fat and therefore not directly bioavailable to the body (Holick et al., 2011).

### Recommendations for adequate intake for pregnancy and lactation

Although there is an increase in the metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D, during the last trimester of pregnancy and during lactation, the IOM concluded there is nothing in the evidence-based literature to suggest that there is an increased vitamin D requirement for pregnant and lactating women. Therefore, it was recommended that the RDA of vitamin D for pregnancy and lactation follows that recommended for their age group, that is, 15 µg (600 IU) day<sup>-1</sup>. However, a study in Boston reported that 81% newborns and 76% of their mothers had a 25(OH)D < 20 ng mL<sup>-1</sup> even though they took a prenatal vitamin supplement containing 400 IU and drank two glasses of milk per day thereby ingesting 600 IU day<sup>-1</sup> (Lee et al., 2007). Several reports have suggested that pregnant women who maintain a serum concentration of 25(OH)D of at least 30 ng mL<sup>-1</sup> reduced their risk of preeclampsia, premature births and need for a Cesarean section. The Endocrine Society Practice Guidelines recommended that pregnant and lactating women require this same amount of vitamin D as all adults (Holick et al., 2011).

### Healthy vitamin D intakes

There have been a multitude of studies during the past decade that suggest that the RDAs recommended for vitamin D may still be inadequate if there is no exposure to sunlight. Based on a multitude of studies, it is reasonable for children and adults to increase their vitamin D intake to the concentrations recommended by the Endocrine Society Practice Guidelines (Table 1). In order to maintain a blood level of 25(OH)D > 30 ng mL<sup>-1</sup> and not to exceed 100 ng mL<sup>-1</sup> for all the potential health benefits of vitamin D (Fig. 6) (Holick et al., 2011; Charoenngam and Holick, 2020).

### Tolerable upper intake levels and vitamin D intoxication

An excessive intake of vitamin D can lead to vitamin D intoxication. This is characterized by a marked increase in serum concentration of 25(OH)D that is usually greater than 150 ng mL<sup>-1</sup> (375 nmol L<sup>-1</sup>) and is associated with hypercalciuria and hypercalcemia. There is a compensatory decrease in serum concentrations of PTH and often an increase in serum concentrations of phosphate. This can lead to soft tissue calcification of the kidneys (nephrocalcinosis) and arteries and increased risk of kidney stones. The safe upper limits for vitamin D, as recommended by the IOM and the Endocrine Society Guidelines on Vitamin D, are found in Table 1 (Holick, 2007; Ross et al., 2011; Holick et al., 2011).

Vitamin D intoxication usually occurs when a person ingests more than 100,000 IU of vitamin D daily for at least several months. A person does not need to be concerned about becoming vitamin D intoxicated if they take a multivitamin that contains

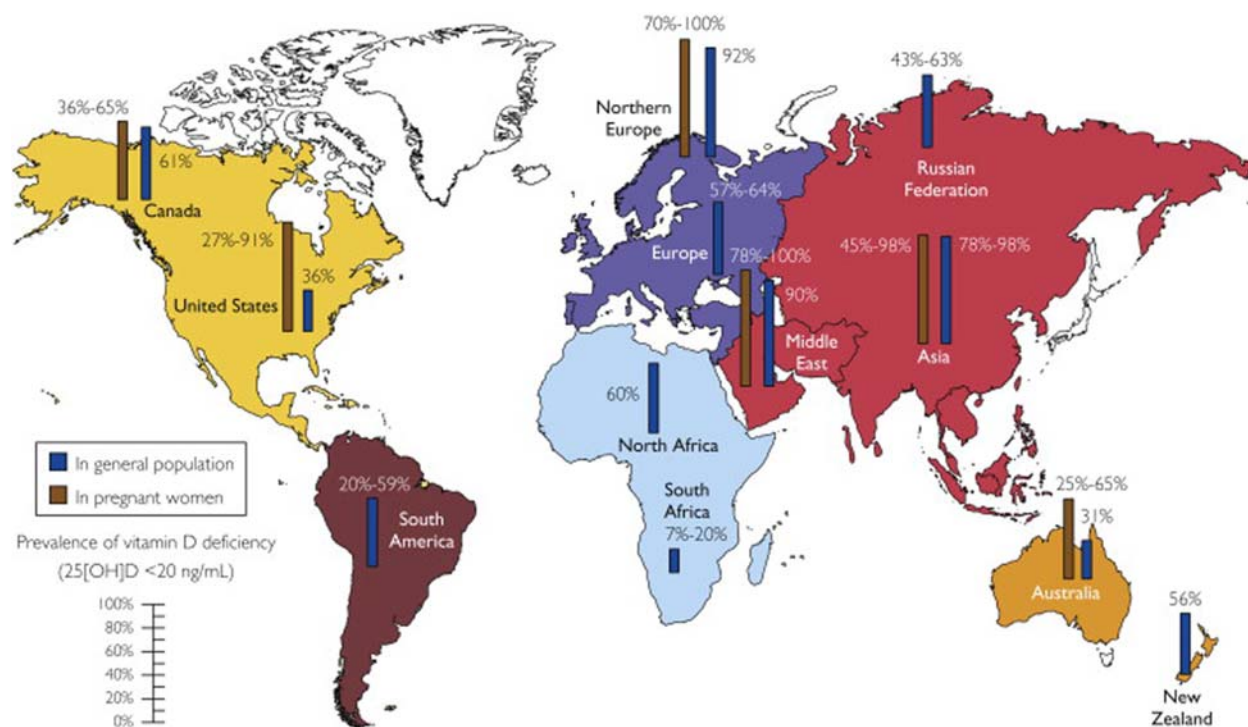

**Fig. 6** Summary of causes of vitamin D deficiency and diseases and disorders associated with vitamin D deficiency. 1000 IU of vitamin D or vitamin D supplementation as recommended by the Endocrine Society drink a quart of milk that contains 400 IU of vitamin D, and is exposed to sunlight. The IOM recognized that vitamin D is not as toxic as once believed and raised the upper limit (UL) for older children and adults up to 4000 IU day<sup>-1</sup>. Based on the evidence-based literature, these recommendations are conservative. Several studies have reported that healthy adults ingesting up to 10,000 IUs daily for at least 6 months did not have any toxicity and maintained serum concentrations of 25(OH)D less than 100 ng mL<sup>-1</sup> (Shirvani et al., 2019). A Canadian study reported healthy adults in Canada ingesting up to 20,000 IUs daily demonstrated no toxicity (Ekwaru et al., 2014). Based on all of the evidence the Endocrine Society Practice Guidelines on Vitamin D recommended a UL of 4000 and 10,000 IU day<sup>-1</sup> for children and adults respectively (Table 2) (Holick et al., 2011).

## Conclusion

Vitamin D deficiency continues to be a major health problem worldwide (Fig. 7) that is due to a variety of causes (Fig. 6). Sunlight exposure was the major source of vitamin D for our hunter gatherer forefathers since very few foods naturally contained vitamin D. A study of the Maasai and Hadzebe who are hunter gatherers revealed that their mean blood concentration of 25(OH)D was 46 ng mL<sup>-1</sup> (115 nmol L<sup>-1</sup>) (Luxwolda et al., 2013). In order for an adult to achieve this level would require ingesting 4000–5000 IUs daily (Ekwaru et al., 2014). Studies have shown that healthy adults who have a starting blood concentration of 25(OH)D of between 15 and 20 ng mL<sup>-1</sup> require 100 IUs to raise the blood level by approximately 0.6–1 ng mL<sup>-1</sup>. A multitude of studies have reported that maintaining a blood concentration of 25(OH)D of at least 30 ng mL<sup>-1</sup> and ideally as recommended by the Endocrine Society between 40 and 60 ng mL<sup>-1</sup> reduces risk of preeclampsia, premature births, autoimmune disorders, cardiovascular disease, neurocognitive dysfunction including Alzheimer's disease, type 2 diabetes and infectious diseases (Holick, 2010; Holick et al., 2011; Hossein-nezhad and Holick, 2013; Pludowski et al., 2013; Charoengnam and Holick, 2020). In the era of COVID 19 several studies have reported significant reductions in infectivity, morbidity and mortality associated with this highly infectious and deadly viral infection (Charoengnam and Holick, 2020; Kaufman et al., 2020; Charoengnam et al., 2021; Seal et al., 2022). It is unrealistic for most of the world's population to obtain an adequate amount of vitamin D from dietary sources and sensible sun exposure. Although in the lay press it is suggested that 5–15 min of sun exposure will produce enough vitamin D, this is highly unlikely unless you are fair skinned in a bathing suit and exposed to sunlight at noontime near the equator. Time of

**Fig. 7** Reported incidence of vitamin D deficiency defined as a 25-hydroxyvitamin D (25[OH]D) level below 20 ng mL<sup>-1</sup> around the globe in pregnant women and the general population. To convert 25(OH)D values to nmol L<sup>-1</sup>, multiply by 2.496. Copyright Holick (2013), reproduced with permission.

day, season, latitude, altitude, weather conditions, skin pigmentation and sunscreen use all influence the skin's production of vitamin D during sun exposure (Wacker and Holick, 2013). Therefore, institution of food fortification programs as has been done for almost 100 years in the United States and Canada and more recently in India, Sweden and Finland should be encouraged. To guarantee vitamin D sufficiency with all of its potential health benefits following the Endocrine Society Guidelines on Vitamin D is prudent.

## Key points

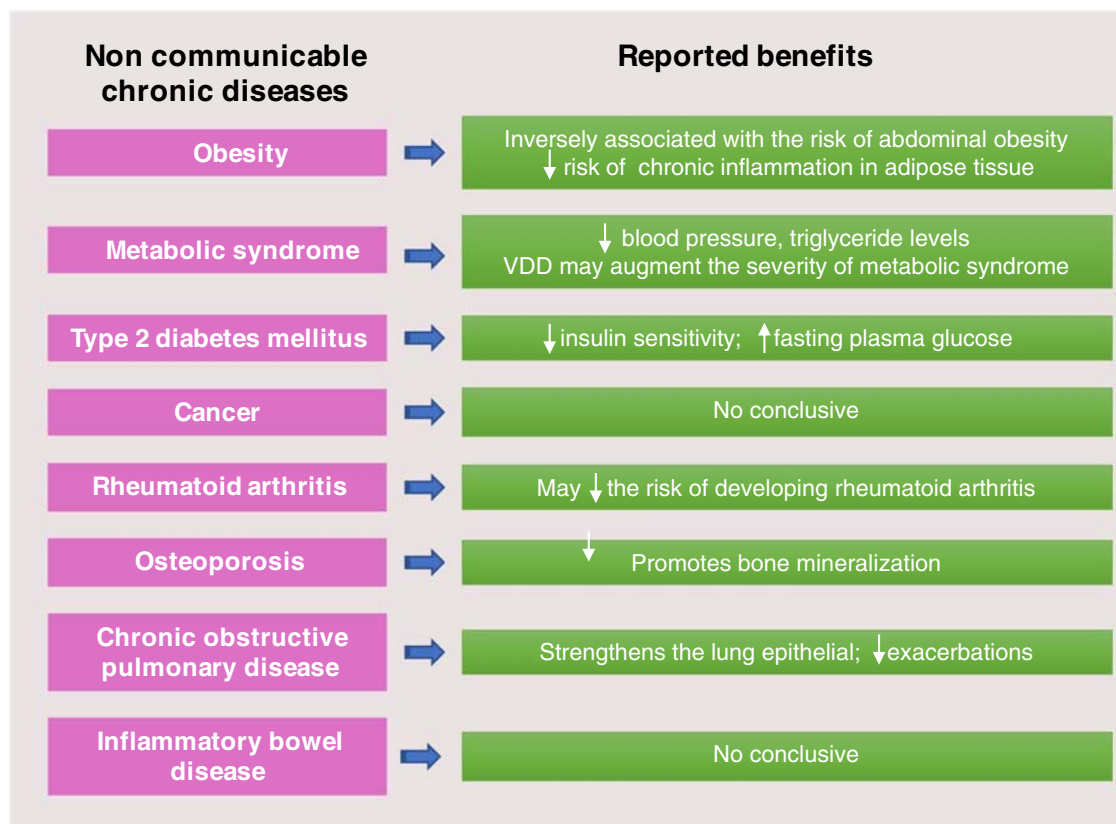

- To know the role of vitamin D in the prevention and treatment of non-communicable chronic diseases.
- To understand how vitamin D deficiency is related to obesity, insulin resistance and metabolic syndrome, type 2 diabetes, cancer, rheumatoid arthritis, osteoporosis, chronic pulmonary obstructive disease, and inflammatory bowel disease.
- To know the function of vitamin D in the prevention and treatment of acute infectious diseases of bacterial and viral origins, namely respiratory infections.
- To understand the role of vitamin D in the prevention of HIV and SARS-Cov2 infections
- To know how vitamin D status affects the course of critical illness diseases

## Introduction

Vitamin D is involved in bone health by promoting calcium absorption in the gut and maintaining serum calcium and phosphate concentrations, and by its action on bone growth and reorganization through osteoblasts and osteoclasts cells. Moreover, during the last three decades, novel actions of vitamin D have been discovered. Indeed, active vitamin D also regulates cell proliferation and differentiation and has a key role in the responses of the immune and nervous systems. Current effects of vitamin D include xenobiotic detoxification, oxidative stress reduction, neuroprotective functions, antimicrobial defense, immunoregulation, *anti-inflammatory/anticancer* actions, and cardiovascular benefits (Gil et al., 2018).

Several systematic reviews and meta-analyses have shown links between serum vitamin D levels and non-communicable diseases. In line with these findings, a wide number of studies have suggested associations of vitamin D deficiency (VDD) with respiratory tract infections, osteoporosis, and other chronic and metabolic diseases such as obesity, metabolic syndrome, type 2 diabetes mellitus (T2DM), cancer, rheumatoid arthritis (RA), and inflammatory bowel disease (IBD). Fig. 1 shows a summary of the benefits of vitamin D supplementation on main non-communicable chronic diseases.

Hence, clinical trials addressed to evaluate the efficacy of administration of vitamin D and its metabolites for the treatment of both chronic and acute diseases are of great interest, although variable outcomes are being reported. In this concern, evidence shows

**Fig. 1** Summary of reported benefits of vitamin D in non-communicable chronic diseases.

a notorious inter-individual difference in gene expression in human peripheral blood mononuclear cells in response to vitamin D supplementation, which suggests that some individuals might present a higher grade of benefits from vitamin D supplementation than others (Charoenngam, 2021) (Table 1).

Vitamin D also exerts important actions in the clinical course of infectious and other acute diseases, particularly respiratory bacterial infections, tuberculosis, and virus infections, e.g., those generated by human immunodeficiency and SARS-CoV-2 (COVID-19) viruses.

In humans, the recommended daily dietary allowance of vitamin D is 400–800 IU depending on age and sex. The circulating 25-hydroxy-vitamin D [25(OH)D] is the most used biomarker of VDD recommended by clinical guidelines and 1,25 dihydroxy-vitamin D [1,25 (OH)<sub>2</sub>D], named calcitriol, the active form-of vitamin D. Other biomarkers and immune assay methods are also being evaluated and compared, such as bioavailable and free 25(OH)D, 24,25 dihydroxy-vitamin D [24,25(OH)<sub>2</sub>D], other vitamin D metabolites, vitamin D binding protein or parathyroid hormone (Ganmaa et al., 2021).

According to the guidelines of the American Endocrine Society, serum levels of 25(OH)D below 20 ng/mL (50 nmol/L) are considered as VDD, while 25(OH)D serum levels between 21 and 29 ng/mL (52.5–72.5 nmol/L) are defined as vitamin D insufficiency (Holick et al., 2011). To maintain adequate levels in the preferred range of 40–60 ng/mL (100–150 nmol/L) (Ganmaa et al., 2021; Charoenngam, 2021) and thus avoid the risk of VDD, it is advisable to increase the intake of vitamin D and have adequate exposure to sunlight. However, it remains controversial what is the optimal serum level of 25(OH)D. For this, some professional societies recommend higher vitamin D intakes, and, in consequence, physicians sometimes prescribe more than 4000 IU to compensate for VDD. This can be biologically explained by: (1) the fact that the vitamin D receptor is expressed in the majority of human tissues; (2) vitamin D levels in northern latitudes are far lower than the hominids evolved in the equatorial Africa area and (3) the stimulation of vitamin D receptor by calcitriol alter the expression of over two hundred genes to support a large range of physiological responses with the potential to protect against the development of several pathologies (Ganmaa et al., 2021).

## Vitamin D and chronic diseases

### Obesity

Evidence shows that obesity negatively regulates circulating vitamin D levels. In fact, obesity decreases the detectable serum levels of 25(OH)D through the sequestration of vitamin D in body fat tissue (since vitamin D is a fat-soluble vitamin) or reduce skin synthesis of vitamin D because of limited outdoor activity and sun exposure (Al Anouti et al., 2020).

**Table 1** Doses of vitamin D recommended or administered in interventions studies with reported benefits in chronic diseases.

Disease	Dose
Obesity/MetS	Obese adults and the elderly obese adults and the elderly (BMI 30+ kg/m <sup>2</sup> ): (BMI 30+ kg/m <sup>2</sup> ):
T2DM	1250–1500 µg/week (prevention)
Cancer	400 IUs or 2000 IU/day (reduced cancer mortality but not cancer incidence)
Rheumatoid arthritis	25–75,000 IU (decrease in fatigue severity and in pain)
Osteoporosis	2000 IU/day
COPD	Keeping the <25 nmol/L but not higher levels reduced the rate of moderate/severe exacerbations
IBD	5000–10,000 IU/day

BMI, body mass index; COPD, chronic obstructive pulmonary disease; IBD, inflammatory bowel disease; IU, international units; MetS, metabolic syndrome; T2DM, type 2 diabetes mellitus.

Moreover, alternations in vitamin D metabolism in obese subjects manifesting low serum levels of 25(OH)D is well-recognized, while weight reduction with loss of adipose tissue is associated with improvement in circulating 25(OH)D. Additionally, patients with obesity and intestinal malabsorption require a two to three times higher intake of vitamin D to maintain the same serum 25(OH)D concentrations ([Charoengnam, 2021](#)). It has been also demonstrated that abdominal obesity is more prevalent in those individuals with lower serum vitamin D levels. By contrast, results from observational studies aimed to investigate the relationship between VDD and the risk of central obesity are inconsistent. However, a meta-analysis of epidemiologic studies revealed that serum vitamin D level was inversely associated, in a dose-response manner, with the risk of abdominal obesity, particularly in adults. Furthermore, vitamin D reduced the risk of chronic disease and chronic inflammation in adipose tissue. In addition, dose-response analysis showed that every 25 nmol/L increments in serum vitamin D were related to an 8% reduced risk of abdominal obesity, 10% decreased central adiposity risk in representative populations, and 13% lower risk of metabolic syndrome.

The entire mechanisms throughout vitamin D affect the lipid profile is still undeciphered, even though observational and interventional studies report conflicting evidence. Moreover, it has been suggested that the association between vitamin D and metabolic disorders may be confounded by obesity rather than being a causal relationship. Accordingly, usual chronic inflammatory processes in obese patients might decrease 25(OH)D levels and, at the same time, affect several metabolic parameters ([Al Anouti et al., 2020](#)).

### Metabolic syndrome

Metabolic syndrome is known as one of the most important risk factors of T2DM and cardiovascular disease and can increase the risk of myocardial infarction and stroke two-fold. According to the National Cholesterol Education Program's Adult Treatment Panel III (NCEP-ATP III) criteria of metabolic syndrome has six main components, namely obesity, dyslipidemia, high blood pressure, insulin resistance or glucose intolerance, pro-inflammatory state, and prothrombotic state ([Ganmaa et al., 2021](#)). Although this disease is a well-known and serious public health burden, the metabolic syndrome does not have any direct and ultimate treatment due to its multifactorial nature. In consequence, clinical management to reduce the risk factors is the most common intervention.

Results from randomized control trials (RCTs) suggest that vitamin D supplementation positively impacts blood pressure and abdominal obesity. However, most trials have revealed that vitamin D supplementation has no effect in reducing myocardial cardiovascular events, heart attack, death from cardiovascular disease, or in the treatment of chronic heart failure. In this concern, 1-year supplementation with 4000 IU/day vitamin D3 did not affect cardiovascular disease, lipid profiles, or C-reactive protein levels in T2DM patients, but reduced triglyceride levels. Another trial reported that supplementation with 150,000 IU bolus of vitamin D every 3 months was unable to alter inflammatory markers and lipids in adults with metabolic syndrome. In addition, a Cochrane review including 159 RCTs suggested that vitamin D supplementation may reduce all-cause mortality compared with placebo or no intervention; by contrast, vitamin D supplementation had no significant effect on mortality related to cardiovascular events ([Ganmaa et al., 2021](#)).

Despite the populations recruited for the study of the role of vitamin D in metabolic syndrome vary by sex, age, and country, data from observational studies highlight specific associations between vitamin D and individual components of this disease such as obesity, dyslipidemia and blood pressure, as well as with metabolic syndrome as a complete entity.

VDD or low levels of 25(OH)D is related to a higher risk of this disease. Additionally, suboptimal levels of vitamin D may augment the severity of the metabolic syndrome. Concentrations of 25(OH)D are lower in patients with metabolic syndrome than in those without it. The prevalence of metabolic syndrome is reduced by half if individuals have high 25(OH)D concentrations. Specifically, vitamin D might modulate the atherogenic components of metabolic syndrome ([Al Anouti et al., 2020](#)).

Considering that inflammation plays a key role in the development of the metabolic syndrome, and under the premise that the anti-inflammatory effect of vitamin D would decrease the risk of this disease, a dose-response analysis reported that an increase of 25 nmol/L in plasma 25(OH)D was associated with a 13% lower risk of metabolic syndrome.

### Type 2 diabetes mellitus

T2DM is a worldwide disease that grows in parallel with other diseases affecting multi-body systems. Thus, it is mandatory to develop strategies to treat T2DM effectively, maintaining glucose homeostasis to avoid complications such as diabetic nephropathy, peripheral neuropathy, and retinopathy.

Vitamin D has *anti*-inflammatory action, inhibiting cytokine production, which has an important role in suppressing the chronic low-grade inflammation present in T2DM. Vitamin D regulates insulin secretion by binding to vitamin D receptors present on pancreatic beta cells. Vitamin D increases insulin sensitivity by upregulating the expression of insulin receptors and binding to the vitamin D response element present in the human insulin receptor gene promoter. It also affects fatty acid metabolism in insulin-responsive tissues through the activation of its transcription factor. Hence, the role of vitamin D in glucose metabolism and fuel homeostasis is supported by several observational studies revealing an inverse relationship seen between vitamin D and T2DM.

Although not many studies address the relationship between insulin sensitivity and vitamin D, one study reported that serum 25(OH)D concentration is responsible for 21.2% of the variation of the insulin sensitivity index. In addition, serum 25(OH)D concentration accounted for 8.2% of the variation of beta-cell function.

Data from meta-analyses of RCTs showed favorable effects of vitamin D intervention in T2DM non-obese individuals [BMI < 30] but not in those with BMI  $\geq$  30. Furthermore, supplementation with vitamin D in pre-diabetic subjects prevented progression to T2DM, improved insulin sensitivity, decreased insulin resistance and systemic inflammation, and lowered fasting plasma glucose (Ganmaa et al., 2021).

Since vitamin D affects different organs and tissues in patients with T2DM a systematic review was conducted to evaluate the effect of vitamin D supplementation in glycemic homeostasis and its impact on the T2DM patients. This study was focused on how this vitamin influences effectively, maintaining glucose homeostasis to avoid its complications. The authors found an inverse relationship between vitamin D levels and neuropathy and diabetic retinopathy.

### Cancer

Biological functions of vitamin D include modulation of the immune system and *anti*-carcinogenic effects. The association of VDD with cancer (along with other effects), has been described because of its potential effect on cell differentiation and the suppression of cell proliferation. Consequently, recent studies have assessed the association between serum vitamin D and the risk of some types of cancer.

In a meta-analysis of RCTs, the authors reported that vitamin D supplementation significantly reduced total cancer mortality but did not reduce total cancer incidence (Ganmaa et al., 2021). On the other hand, a dose-response meta-analysis demonstrated that each five nmol/L increase in blood vitamin D levels was associated with a 6% decrease in the risk of breast cancer, while a 400 IU/day increase in vitamin D intake was not significantly correlated to this type of cancer. By contrast, other dose-response meta-analyses found that both serum vitamin D and vitamin D intake were inversely related to colorectal cancer. Further, another meta-analysis of RCTs showed a protective effect of vitamin D supplementation on cancer incidence and mortality. Additionally, a significant reduction in metastatic or fatal cancers has been reported in men  $\leq$  50 years and women  $\leq$  55 years (Ganmaa et al., 2021).

Given these controversial results, to date, neither 1,25(OH)<sub>2</sub>D nor its analogs have ever been successfully developed as a strategy to treat or prevent any type of cancer.

### Rheumatoid arthritis

RA is a chronic autoimmune condition resulting in synovial inflammation around joints, progressively leading to cartilage and bone destruction. Results from multiple observational studies have evidenced a link between a low level of serum 25(OH)D and the presence and/or severity of several rheumatic diseases (Charoenngam, 2021). Indeed, vitamin D is believed to play a role in modulating RA's pathogenesis and disease activity, based on the actions of 1,25(OH)<sub>2</sub>D on the adaptive immune response that suppresses the proliferation and activity of T helper 1 cells (Th1) and Th17, and enhances the T regulatory cells (Treg) activity. Furthermore, genomic studies have shown that certain polymorphisms of the gene encoding vitamin D receptor and vitamin D binding protein are associated with susceptibility to RA (Charoenngam, 2021). An inverse correlation between circulating vitamin D levels and RA incidence and disease activity is also known.

Despite these promising results, unfortunately, evidence from clinical trials demonstrating the impact of any form of vitamin D supplementation on most rheumatic diseases has not been established yet. Moreover, it is still unclear whether the association between vitamin D and these conditions are causal or more likely explained by confounders and reverse causation, such as limited physical activity or corticosteroid administration (Charoenngam, 2021).

Concerning studies about dose-response, it is recommendable that patients with rheumatic diseases should maintain a serum 25(OH)D level of at least 30 ng/mL (75 nmol/L) to prevent osteomalacia, secondary osteoporosis and fracture, and possibly 40–60 ng/mL (100–150 nmol/L) to reach the higher benefit of vitamin D (Charoenngam, 2021). In treatment-naïve RA patients, a significant negative association was observed between vitamin D levels and disease activity parameters. Notably, the association of vitamin D with the incidence and severity of RA is very well supported by evidence. However, due to heterogeneity in dosages and durations of supplementation, robust evidence supporting vitamin D supplementation in ameliorating clinical outcomes is still needed. In sum, observational studies suggest that increasing vitamin D intake to raise serum 25(OH)D may reduce the risk of

developing RA. However, there is no demonstration from a reliable clinical trial that vitamin D supplementation can reduce the risk of RA. In addition, there is moderate evidence that vitamin D supplements or the oral administration of 1,25(OH)<sub>2</sub>D can mitigate RA severity (Charoenngam, 2021).

### **Osteoporosis**

Vitamin D regulates the absorption of calcium and phosphorus and, thus, is universally accepted as an essential vitamin for bone strength and as a promotor of the immune system function; it has been reported to have an *anti-inflammatory* role and established benefits in osteoporosis and osteomalacia.

Accordingly, VDD is a well-recognized health problem and contributes to bone loss and calcium dysregulation, which causes or aggravates osteoporosis. 1,25(OH)<sub>2</sub>D regulates calcium and phosphate homeostasis by acting on the small intestine, kidneys, and bones. It passively promotes bone mineralization by inducing intestinal absorption of calcium and phosphate and renal tubular calcium reabsorption, which helps maintain adequate calcium-phosphate crystallizing in the collagen matrix.

However, multiple studies failed to demonstrate any benefit from vitamin D supplementation in patients with osteoporosis, and a systematic review and meta-analysis also were unable to confirm any beneficial effect on bone density or fracture prevention. Additionally, placebo-control RTCs revealed a threshold effect of vitamin D with no benefit observed on the subjects with baseline 25(OH)D level  $\geq 75$  nmol/L (30 ng/mL). Furthermore, possible detrimental effects on bone mineral density were observed in subjects who received a higher dose of vitamin D (250  $\mu$ g or 10,000 IU daily) with a mean 25(OH)D of 200 nmol/L or 80 ng/mL.

On the other hand, a maternal vitamin D osteoporosis study reported that daily vitamin D supplementation in pregnant women did not increase offspring whole-body bone mineral content above that of the placebo group (Ganmaa et al., 2021).

### **Chronic obstructive pulmonary disease**

Chronic obstructive pulmonary disease (COPD) is related to high mortality and morbidity worldwide, and its exacerbations cause significant morbidity, mortality, impaired quality of life, and costs (Lokesh et al., 2021). The main pathogenesis associated with COPD development is inflammation, oxidative stress, protease–antiprotease imbalance, and lung rebuilding (Ganmaa et al., 2021).

Having this into account, supplementation with vitamin D is particularly interesting due to its various effects on lungs, tissue remodeling, reduction of pro-inflammatory cytokines, and beneficial modulation of both innate and adaptive immune systems (Lokesh et al., 2021). In fact, lower vitamin D levels have been related to the regulation of typical characters associated with COPD (i.e., higher expression of proteases, modulation of inflammation and extracellular matrix turnover, and increased oxidative stress), their pathogenesis and severity. Some evidence suggests that vitamin D strengthens the lung epithelial. Accordingly, a recent meta-analysis of RCTs suggested that vitamin D supplementation may safely and substantially reduce the rate of moderate/severe COPD exacerbations in patients with baseline 25(OH)D levels  $< 25$  nmol/L, improve lung function and acute exacerbation. However, barrier studies focused on investigating a potential causal effect remain limited, and randomized trials report conflicting results for vitamin D supplementation and prevention (Ganmaa et al., 2021). Moreover, most of the studies focused on studying the relationship of vitamin D with COPD, its severity and exacerbations were performed in areas with sub-optimal sunlight and lack of sunlight throughout the year, or in cities where most residents spend time indoors (i.e., homes or offices). In consequence, reported data aimed to relate the association of vitamin D with the severity of COPD and its exacerbation in populations that are both adequately exposed to sunlight or keep higher levels of physical activity through the life course are quite limited (Lokesh et al., 2021).

On the other hand, it is deeply needed to perform longitudinal studies to evaluate whether young healthy subjects exposed to risk factors such as smoking or biomass fuel with low levels of vitamin D would present a higher risk of developing COPD, as well as whether vitamin D supplementation in these subjects would have the ability to prevent or delay the development of this disease (Lokesh et al., 2021).

### **Inflammatory bowel disease**

IBD is a chronic inflammatory condition of the gastrointestinal tract that includes ulcerative colitis and Crohn's disease (Myint et al., 2020). It has been observed that samples from colonic biopsies of patients with IBD present a decreased concentration of vitamin D receptors and have a higher level of pro-inflammatory cytokines such as TNF- $\alpha$  and IL-1 $\beta$ . The most important IBD pharmacological strategy is to reduce inflammation. Due to the immunomodulatory properties that possess vitamin D, it is considered a very appropriate candidate for modifying risk factors and preventing the development of IBD, as well as ameliorating its severity. In fact, vitamin D protects the intestinal mucosa by increasing the expression of the proteins responsible for tight junction creation and affects epithelial integrity by the inhibition of the intestine epithelial apoptosis, which contributes to intestinal inflammation and the healing process.

However, although epidemiological and clinical observational studies have demonstrated an association between vitamin D and IBD, it is necessary to identify whether VDD is a consequence or a cause of IBD (Myint et al., 2020). Despite being limited by issues with trial design such as small sample size, uncertain use of control groups, inconsistent definitions of VDD, and/or absence of clinical outcomes, vitamin D supplementation trials suggest a variable association between VDD and IBD activity (Myint et al., 2020). However, the mentioned inconsistencies indicate that data from trials to evaluate dosing strategies for treatment are not sufficiently reliable.

### Vitamin D and acute diseases

As mentioned previously, calcitriol is involved in the regulation of cell proliferation and differentiation and has a key role in the inflammatory and immune system response. This regulation confers an important role in the defense against bacterial and virus infections, which is mediated by its capacity to activate the innate defense response and to exert an *anti*-inflammatory action on the adaptive response, resulting in an overall immunotolerance effect (Gil et al., 2018).

The European Food Safety Authority (EFSA) considers vitamin D, within other vitamins and minerals, to be essential for the normal growth and functioning of the immune system. Impaired nutritional status or deficiencies of this vitamin is associated with increased risk and severity of many different types of infections. However, the immunomodulatory role of vitamin D against infections is complex and varies according to the nature of the pathogen. Moreover, the effectiveness of vitamin D is uncertain and appears to be highly dependent on the genetic polymorphisms of its receptor and epigenetic modifications. Fig. 2 shows a summary of the association of vitamin D with the main acute diseases.

### Vitamin D and the immune system

Innate immunity is the first defense against invading microorganisms, including bacteria, viruses, fungi and protozoa. These mechanisms recognize microorganisms or their products and trigger a cascade of events that will eliminate and/or destruct the invading agents through the release of cytokines and antimicrobial peptides. Adaptive immunity is the second defense mechanism that mediates an antigen-specific immune response through antigen presentation cells (APC), namely dendritic cells (DCs), and the antigen recognition cells, T and B lymphocytes. Their activation causes the production of various cytokines and antibodies and induces cell killing.

The roles of vitamin D in the regulation of immunity are particularly well known. Immune system cells express the vitamin D receptors (VDR) when activated by external stimuli, indicating that vitamin D is especially involved in regulating their defense mechanisms. The binding of vitamin D to its cellular VDR activates immunity surveillance signaling pathways that modulate gene expression of proteins, such as cathelicidins (LL37) and defensins, involved in inflammation, oxidation, cell proliferation and differentiation, in apoptosis, and the processes of autophagy and bacterial destruction of infected macrophages (Gil et al., 2018).

On the other hand, related to the antimicrobial defense, vitamin D can inhibit the Th1, Th2 and Th17 adaptive response directly on lymphocytes via VDR signaling, or indirectly through paracrine signaling on APC. Vitamin D decreases the maturation of DCs and their ability to present antigens and alters the profile of Th and Treg. Specifically, vitamin D inhibits Th1, Th17, and Th9 cells development and leads to immune tolerance, and suppresses T-cell-mediated inappropriate proinflammatory mediators production. On the other hand, vitamin D enhances differentiation and proliferation of Th2 and Treg cells, which stimulate the release of *anti*-inflammatory cytokines (IL-4, IL-5, and IL-10) to be a significant mechanism by which vitamin D could be advantageous in autoimmune diseases by promoting an *anti*-inflammatory vs. inflammatory response.

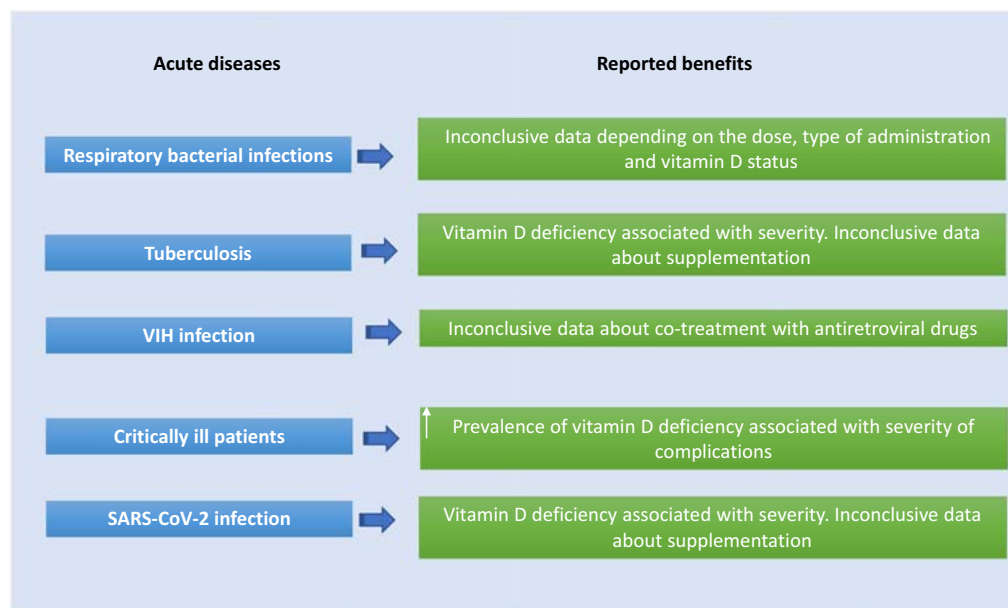

Fig. 2 Summary of reported benefits of vitamin D in acute diseases.

### Vitamin D and respiratory bacterial infections

A large number of studies have associated a deficit of vitamin D blood levels and increased risk and severity of acute respiratory infections in children, adolescents and adults. Randomized controlled trials exploring the potential of vitamin D to prevent acute respiratory infections have yielded mixed results. Meta-analysis has the potential to identify factors that may explain this heterogeneity. Vitamin D supplementation is safe, and it protects against acute respiratory infections overall. Very deficient individuals and those receiving continuous supplements and not bolus doses are the ones who experienced the benefits. Incorporation of additional individual participant data from ongoing trials will be useful to increase the knowledge in these fields.

Tuberculosis is one of the most common and devastating infectious diseases worldwide. Several systematic reviews have found low vitamin D blood levels in patients with tuberculosis compared to healthy controls. These works have concluded that VDD may be a risk factor for tuberculosis disease progression. Current studies have shown that vitamin D plays a significant role in the host immune defense against *Mycobacterium tuberculosis*, but clinical trials reported inconsistent results. In 2021, a systematic review and meta-analysis have concluded an association between low levels of vitamin D and tuberculosis infections in adults and children. However, this analysis showed considerable heterogeneity of included studies, and therefore, the findings should be applied with caution (Kafle et al., 2021).

VDD can predict the risk of tuberculosis in a dose-dependent manner and is more likely a risk factor for tuberculosis than its consequence. But unfortunately, the beneficial effect of vitamin D supplementation for treating *M. tuberculosis* infection in vitamin D-deficient patients is not still clear, and it seems that several factors such as genetic and the mode of administration, among others, may influence clinical outcomes. Intervention clinical trials have reported that vitamin D supplementation has no clinical benefits on tuberculosis therapy. However, it reduced the time to sputum culture conversion in patients with tt genotype of the TaqI vitamin D receptor gene polymorphism and improved the multidrug-resistant tuberculosis sputum culture conversion. Another meta-analysis has concluded that vitamin D administration together with *anti-tuberculosis* treatment may be well tolerated and effective, improving sputum smear conversion rate and chest radiological appearance, while exhibiting an inflammation resolution effect. In addition, meta-analyses of vitamin D supplementation in the prevention of tuberculosis and other acute respiratory conditions support the efficacy of daily low dose supplementation but not after intermittent bolus dosing. Indeed, the optimal dose to achieve benefits remains unclear; anyhow, it is suggested to continue studies since vitamin D has shown a synergistic benefit on the immune system. Therefore, long-term prospective cohort studies in tuberculosis endemic countries should be conducted to understand better the causal relationship between VDD and this disease as well as its possible therapeutical application.

1,25D<sub>3</sub> upregulates human cathelicidin from monocytes/macrophages infected with *M. tuberculosis*, resulting in autophagy, and upregulates nitric oxide synthase, suppressing mycobacterial growth. A meta-analysis has revealed a significant difference in vitamin D and cathelicidin LL-37 blood levels among tuberculosis and healthy subjects. It seems that active pulmonary tuberculosis infection is associated with hypovitaminosis D and elevated blood cathelicidin concentrations. In contrast, in local tissue lesions, cathelicidin LL-37 expression was lower in tuberculosis than in healthy subjects. Therefore, the mechanism involved in vitamin D-mediated immune regulation against *M. tuberculosis* needs to be further investigated.

### Vitamin D and virus infections

Virus infections have also been associated with VDD. Children with hand-foot-and-mouth disease have very low vitamin D levels, associated with a poor prognosis. Patients with atopic dermatitis are susceptible to microbial infection due to the decreased production of cathelicidin and other antimicrobial peptides, and they can be improved by vitamin D supplementation. In these cases, the participation of vitamin D in the regulation of the secretion of antimicrobial peptides is also altered. This occurs in cathelicidins (LL37) and defensins, molecules that through different mechanisms prevent the entry of viruses and their activity, by interacting with the viral coatings and limiting its replication directly or indirectly by modulating the immune cells, migration, activation, proliferation and differentiation, specifically neutrophils, monocytes-macrophages, and T lymphocytes. These antimicrobial peptides are also able to regulate autophagy and apoptosis of infected cells, thus contributing to the reduction of viral load. Indeed, vitamin D supplementation in healthy subjects appears to confer some protection against virus respiratory tract infection in healthy adults from the USA and Canada but not in other world regions. However, these conclusions cannot be generalized for all types of virus infections, and their potential effect must be demonstrated. For example, associations between vitamin D and herpesviruses remain inconclusive and further studies are needed in the general population.

Indeed, vitamin D-modulated immune response against viral infection is mediated by its VDR, which acts as a transcription factor modulating the expression of genes triggering the response against viruses. To date, six major VDR polymorphisms (*Cdx*, *A1012G*, *FokI*, *BsmI*, *Apal*, and *TaqI*) have been studied in the context of viral infection susceptibility. Reported studies show controversial results, probably due to statistical lack of power and population genetic differences. In this sense, *FokI* polymorphism is a relevant variant capturing the association of VDR polymorphisms with viral infections.

### Vitamin D and the human immunodeficiency virus infection

Human immunodeficiency virus (HIV) infection is a heavy burden worldwide. Observational studies have reported a high prevalence of VDD among people living with HIV compared with the general population. Low 25(OH)D is common in diverse HIV-infected populations and is an independent risk factor for clinical and virologic failure. It has been associated with increased HIV mortality, although it may also be influenced by other factors such as older age, lower body mass index, lower latitude, male sex and antiretroviral treatments.

The disagreement regarding the effect of antiretroviral therapy drugs on vitamin D metabolism is still unresolved. The Prospective Evaluation of Antiretrovirals in Resource Limited Settings (PEARLS) study (ACTG5175) is a large-scale, randomized controlled trial in diverse populations in many different settings from four continents. This study investigated whether simplified antiretroviral regimens (once daily) were as effective as standard twice-daily regimens, which may make it more suitable for low-income settings, and decrease adverse effects. It was observed that baseline VDD was associated with diminished CD4 recovery after combined antiretroviral therapy initiation, and that impaired CD4 recovery may contribute to the poor clinical outcomes observed in individuals with VDD (Ewald et al., 2019). Prospective studies assessing the potential benefit of vitamin D supplementation among HIV patients that initiate a combined antiretroviral therapy are lacking and therefore warranted, to demonstrate if vitamin D recommendation policies should be part of routine clinical practice.

### ***Vitamin D and critically ill patients***

It has been suggested that vitamin D insufficiency is a risk factor in intensive care and plays an essential role in infectious, immunologic, neurologic, cardiovascular, and respiratory complications. VDD has been hypothesized not only to be common but also to represent a potentially modifiable risk factor for greater illness severity and outcomes during critical illness. Observational studies have demonstrated an association between VDD and increased risk of morbidity and mortality in critically ill patients. Cohort studies and pilot trials have suggested promising beneficial effects of vitamin D replacement in critical illness, at least in patients with severe VDD. However, the results are inconclusive.

Vitamin D insufficiency is reported in up to 77% of critically ill patients. It is associated with increased mortality, length of stay in an intensive care unit (ICU) and hospital, as well as with respiratory disorders in prolonged ventilated patients (Langlois et al., 2018). In critically ill children, the status and the effect of VDD on the outcome are still unclear. In 2017, a systematic review and meta-analysis stated that approximately 50% of critically ill children have VDD (blood total 25(OH)D concentration under 50 nmol/L) at the time of pediatric ICU (PICU) admission. VDD was also associated with greater illness severity, multiple organ dysfunction, and mortality in the PICU setting. Another meta-analysis has confirmed that 25(OH)D deficiency is prevalent in critically ill children at PICU admission and seems to be associated with higher cardiovascular sequential organ failure assessment and pediatric risk of mortality III scores, sepsis, length of hospital stays, and duration of mechanical ventilation.

However, clinical trials are not consistent in confirming the beneficial effects of improving vitamin D status on patient outcomes. Studies are needed to determine if improving low 25OHD levels (to a level of about 30 ng/mL) is associated with reduced mortality and can improve the functional discharge status of ICU patients. Some studies have stated that vitamin D administration might be associated with reducing mortality without significant adverse events in critically ill patients. However, other studies concluded that vitamin D administration did not improve clinical outcomes and was not significantly associated with reduced mortality or with the length of ICU stay, although statistical imprecision could be explained by the sparse number of trials (Langlois et al., 2018). Therefore, the causal association between VDD and worse outcomes of the critically ill needs further investigations, and large multicenter randomized trials are necessary to conclusively establish the potential beneficial effect of vitamin D supplementation. Indeed, vitamin D supplementation does not provide additional advantages over placebo for critically ill patients and is not associated with reduced all-cause mortality in critically ill patients. Therefore, large-scale prospective studies are needed to validate these findings.

VDD has been related to the risk of sepsis. Different meta-analyses have evaluated the relationship between serum 25(OH)D at admission and mortality risk and concluded that severe VDD might be independently associated with increased mortality in septic adult patients and in septic children compared to those without sepsis. Even though a high prevalence of VDD was found in sepsis, it was not associated with greater severity of illness or other clinical outcomes.

A burn is a severe form of injury associated with severe altered pathophysiological immune-inflammatory responses. In addition, burn patients are a group of critically ill patients in which vitamin D skin synthesis is compromised. Therefore, burn patients suffer common complications that overlap with those reported by patients with VDD. Burn patients with low vitamin D are more susceptible to higher complication rates, including sepsis, pneumonia, cardiovascular complications, and graft loss. However, the literature regarding vitamin D status and its influence on clinical outcomes remains insufficient in this type of patient.

Sufficient vitamin D concentrations and vitamin D supplementation may be of benefit in burn-injured patients since this supplementation is the only means to avoid vitamin D insufficiency in burn victims. However, as in other critically ill situations, the adequate dose, formulation, and route of administration remain unknown, and there is limited data on the impact of vitamin D status on clinical outcomes. Indeed, the high incidence of low serum D25 levels 1 year after major burn injury indicates prolonged compromise of vitamin D metabolism. Therefore, continued treatment with vitamin D3 beyond the acute phase postburn is recommended to improve the abnormal blood levels and associated co-morbidities in adults and children.

Another critical situation that a vitamin D deficient state may impair is patients with traumatic injuries, in which inflammation is a consequence of the trauma. For example, traumatic brain injury is the most frequent trauma and a leading cause of injury-related death and disability, in which inflammation processes influence severity and mortality incidences. VDD may induce impaired immune responses and increase the risk of infections in these patients, and therefore, vitamin D intervention has been proposed as a good tool for preventing these complications. To date, there is no actual data on the effectiveness of vitamin D for the improvement of immune function in traumatic brain injury patients. 25(OH)D level measured within 24 h after admission to the trauma

ICU was unrelated to clinical outcomes. However, patients with increased 25(OH)D levels after 7 days of hospitalization had better clinical outcomes than those with decreased levels.

Since vitamin D supplements are inexpensive and safe, their use could potentially improve clinical outcomes in all critical ill situations by reducing inflammation and infection-associated morbidity and mortality rates. However, more clinical interventional trials are mandatory to ascertain its effectiveness and the appropriateness of its prescription.

### Vitamin D and SARS-CoV-2 infection

Special mention should be made of the effects of vitamin D against SARS-CoV2 infection. Vitamin D inadequacy may be involved in the mechanisms of SARS-CoV-2 infection and in potential risk factors for disease propagation or control of coronavirus disease 2019 (COVID-19). Several studies have been performed, but the inconsistency of results, due to heterogeneity of studies design and patients, do not allow to establish final conclusions. A Cochrane systematic review has concluded that at this moment, we cannot know whether vitamin D helps prevent death from COVID-19. However, it may reduce the need for assisted ventilation, although the evidence is still uncertain. This effect is most notable in vitamin D-deficient COVID-19 subjects (Stroehlein et al., 2021).

The discussion is open regarding the relationship between blood levels of calcitriol and SARS-CoV-2 infection severity. Most of the COVID-19 patients suffered from VDD or insufficiency. In addition, there is about a three times higher chance of getting infected with SARS-CoV-2 among vitamin D-deficient subjects, and about five times higher probability of developing the severe disease associated with VDD. Another meta-analysis has found strong evidence of low blood D3 as a predictor rather than just a side effect of this infection. Other meta-analysis has associated VDD with the risk of SARS-CoV-2 infection and with the severity of the disease but did not find any association with mortality rates.

Lower vitamin D levels have been related to key altered clinical and biochemical parameters during SARS-CoV-2 infection. In this type of critical patients, a vitamin D deficit has been recognized at admission and further deterioration after three days of stay. Given the different responses of the 25OHD3 and 25OHD2 forms, it would be useful to monitor them on the evolution of these critically ill patients. A meta-analysis has stated that relations between VDD and ICU admission, pulmonary complications, hospitalization, and inflammation were inconsistent and insufficient since although studies were heterogeneous in methodological and statistical approach, most of them showed a significant relation between 25(OH)D and SARS-CoV-2 infection, COVID-19 composite severity, and mortality. Regarding infection, caution should be taken for the interpretation of the results, due to intrinsic study limitations. Although the current findings indicate a potential role of vitamin D in improving COVID-19 severity in hospitalized patients, no significant difference with vitamin D supplementation on major health-related outcomes in COVID-19 patients has been found, and more robust data from randomized controlled trials are needed to verify its effects on mortality.

As it occurs with tuberculosis and other conditions, it is hypothesized that the administration mode may influence the outcomes, i.e., low daily doses may be more useful than intermittent bolus, and there is an urgent need for well-designed and sufficiently powered randomized controlled trials to address this matter.

## Conclusions

Vitamin D plays a key role in the regulation and maintenance of innate immunity. A poor vitamin D status is related to non-communicable chronic diseases, namely obesity, metabolic syndrome, T2DM, cancer, RA, COPD, and IBD. Also, a low vitamin D status is associated with an increased incidence of acute respiratory illnesses of both bacterial and viral origin. Likewise, low 25(OH)D levels are associated with a worse prognosis of patients with acute illness. Well-designed randomized intervention clinical trials addressed to evaluate the efficacy of administration of vitamin D and its metabolites for the treatment of both chronic and acute diseases are needed.

## Key points

- Vitamin E is a potent fat-soluble antioxidant
- Vitamin E functions to stop lipid peroxidation
- Vitamin E deficiency occurs in humans with gene defects in the  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP) or with fat malabsorption syndromes
- $\alpha$ -TTP and vitamin E catabolism function to maintain the body's preference for  $\alpha$ -tocopherol
- Vitamin E deficiency dysregulates energy metabolism, the methionine cycle, and thiol status
- $\alpha$ -TTP and  $\alpha$ -tocopherol are necessary for neurologic development in experimental models
- Vitamin E | Metabolism and Requirements

## Glossary

**$\alpha$ -tocopherol transfer protein** The hepatic  $\alpha$ -TTP preferentially facilitates secretion of  $\alpha$ -tocopherol, specifically 2R- $\alpha$ -tocopherols, not other tocopherols or tocotrienols, from the liver into the plasma

**Ataxia with Vitamin E Deficiency** Humans with a defect in the  $\alpha$ -TTP gene, who are not supplemented with vitamin E, display a syndrome called "Ataxia with Vitamin E Deficiency" (AVED)

**Fat Malabsorption Syndromes** Fat malabsorption syndromes are various disorders that cause an inability to absorb dietary fat. These can include cystic fibrosis, short bowel syndrome or cholestatic liver disease, as examples

## Introduction

Vitamin E was discovered in 1922 because it prevented fetal resorption in rats (Evans and Bishop, 1922). Vitamin E is the most potent, fat-soluble antioxidant in vivo. There are at least 8 different molecular forms with vitamin E antioxidant activity, yet the body preferentially retains  $\alpha$ -tocopherol. This preference was recognized in the 2000 Dietary Reference Intakes (DRIs) for vitamin E, which recommended that only  $\alpha$ -tocopherol, not the other forms, meets human vitamin E requirements (Food and Nutrition Board and Institute of Medicine, 2000). This recommendation was based on the observations that  $\alpha$ -tocopherol is maintained in the circulation by the hepatic  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP). Abnormalities in the  $\alpha$ -TTP gene leads to vitamin E deficiency in humans, a syndrome called "Ataxia with Vitamin E Deficiency" [(AVED) OMIM #277460] (Schuelke, 2005 May 20 [Updated 2016 Oct 13]). This demonstration of human vitamin E deficiency solidified the role of  $\alpha$ -TTP as a critical determinant of plasma  $\alpha$ -tocopherol concentrations.  $\alpha$ -TTP is also the key factor in the discrimination between  $\alpha$ -tocopherol and other forms of vitamin E, as well as between natural and synthetic  $\alpha$ -tocopherols. The other important factor in determining the retained form of vitamin E is metabolism. Specifically, catabolism increases excretion of non- $\alpha$ -tocopherol vitamin E forms, as well as excess  $\alpha$ -tocopherol and 2S- $\alpha$ -tocopherol (defined below).

## General description and scientific name

Dietary components with vitamin E antioxidant activity include  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherols and  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocotrienols. These compounds all have a chromanol ring with a varying (one to three) number of methyl groups and have either a saturated, phytyl tail (tocopherols) or an unsaturated tail (tocotrienols).  $\alpha$ -Tocopherol and  $\alpha$ -tocotrienol have three methyl groups,  $\beta$ - and  $\gamma$ - have two, and  $\delta$ - has one.

The naturally occurring form of  $\alpha$ -tocopherol is called *RRR*- $\alpha$ -tocopherol; or on supplement labels, *d*- $\alpha$ -tocopherol; or more formally, 2,5,7,8-tetramethyl-2*R*-(4'*R*,8'*R*,12 trimethyltridecyl)-6-chromanol (Fig. 1). Chiral carbon-centers are located at  $\alpha$ -tocopherol positions 2, 4' and 8' in the side chain. In naturally occurring  $\alpha$ -tocopherol, these carbons are in the *R*-conformation, but can be in either the *R*- or the *S*-conformation in synthetic. Chemical  $\alpha$ -tocopherol synthesis produces an equal mixture of eight different stereoisomers (*RRR*, *RSR*, *RSS*, *RSS*, *SRR*, *SSR*, *SRS*, *SSS*), or more formally 2,5,7,8-tetramethyl-2*RS*-(4'*RS*,8'*RS*,12 trimethyltridecyl)-6-chromanol. The first letter of the three-letter combination is the 2 position, which is the most important for biologic activity. Thus, only half of the synthetic  $\alpha$ -tocopherol is in the "active" 2*R*- $\alpha$ -tocopherol conformation. The dietary reference intakes (DRIs) for vitamin E are given in units of mg 2*R*- $\alpha$ -tocopherol (Table 1, see below for discussion). These same units are used for the updated food and supplement labeling, where the daily value or "reference dietary intake" (RDI) is 15 mg (Food and Drug Administration, 2016). To indicate that synthetic  $\alpha$ -tocopherol is a racemic mixture, it is called *all-rac*- $\alpha$ -tocopherol, or on supplement labels, *dl*- $\alpha$ -tocopherol. Table 2 lists the factors to convert IU to mg 2*R*- $\alpha$ -tocopherol. For example, if a vitamin E supplement is labeled 400 IU and it is *dl*- $\alpha$ -tocopheryl acetate, then 400 times 0.45 equals 180 mg 2*R*- $\alpha$ -tocopherol, but if it is labeled *d*- $\alpha$ -tocopheryl acetate, then 400 times 0.67 equals 268 mg 2*R*- $\alpha$ -tocopherol.

**Fig. 1** Vitamin E structures. (A) The tocopherols have a saturated, phytyl tail and the tocotrienols have an unsaturated tail. Chiral carbon-centers are located at  $\alpha$ -tocopherol positions 2, 4' and 8' in the side chain. Both tocopherols and tocotrienols have a chromanol ring with a varying (one to three) number of methyl groups. The location of the methyl groups on the chromanol ring is indicated by an X<sub>n</sub>. (B) The table shows either a methyl group (CH<sub>3</sub>) or a hydrogen (H) at the X location for each of the four tocopherols or tocotrienols. For example, both  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol have three methyl groups. (C) The  $\alpha$ -tocopherol stereochemical structure of natural *RRR*- $\alpha$ -tocopherol [2,5,7,8-tetramethyl-2*R*-(4'*R*,8'*R*,12 trimethyltridecyl)-6-chromanol] is shown on the right. Chemical  $\alpha$ -tocopherol synthesis produces an equal mixture of eight different stereoisomers (*RRR*, *RSR*, *RSS*, *RSS*, *SRR*, *SSR*, *SRS*, *SSS*), or more formally 2,5,7,8-tetramethyl-2*RS*-(4'*RS*,8'*RS*,12 trimethyltridecyl)-6-chromanol. *SRR*- $\alpha$ -tocopherol is shown with the *S*-conformation at the 2 position.

**Table 1** Estimated average  $\alpha$ -tocopherol requirements (EARs), recommended dietary allowances (RDAs), and average intakes (AIs) in mg/day for Adults and Children.

Life stage	EAR	RDA	AI
0–6 months			4
7–12 months			6
1–3 years	5	6	
4–8 years	6	7	
9–13 years	9	11	
14–18 years	12	15	
Adult (male or female)	12	15	
Pregnant	12	15	
Lactation	16	19	

Adapted from Food and Nutrition Board and Institute of Medicine (2000).

**Table 2** Factors to convert IU vitamin E on supplement labels to mg 2*R*- $\alpha$ -tocopherol.

	mg/IU <sup>a</sup>
<b><i>all rac</i>-<math>\alpha</math>-tocopherol and esters<sup>b</sup></b>	
<i>dl</i> - $\alpha$ -tocopheryl acetate	0.45
<i>dl</i> - $\alpha$ -tocopheryl succinate	0.45
<i>dl</i> - $\alpha$ -tocopherol	0.45
<b><i>RRR</i>-<math>\alpha</math>-tocopherol and esters<sup>b</sup></b>	
<i>d</i> - $\alpha$ -tocopheryl acetate	0.67
<i>d</i> - $\alpha$ -tocopheryl succinate	0.67
<i>d</i> - $\alpha$ -tocopherol	0.67

<sup>a</sup>Multiply the IU times the indicated factor to obtain the mg active vitamin E (2*R*- $\alpha$ -tocopherol).

<sup>b</sup>Note when the esters are synthesized the weight per IU is adjusted to include the molecular weight of the ester form. Thus, to calculate mg  $\alpha$ -tocopherol, this adjustment is not included in the calculation.

## Vitamin E actions

### Antioxidant activity

Vitamin E protects polyunsaturated fatty acids within membrane phospholipids, lipid droplets or in plasma lipoproteins. During lipid peroxidation, a peroxy radical forms in a lipid milieu. In the absence of vitamin E, lipid peroxidation is a chain reaction that continuously produces more radicals. When vitamin E is present in a phospholipid-containing membrane, for example, the peroxy radical is 1000 times more likely to attack the vitamin E molecule than a polyunsaturated fatty acid (Fig. 2). The vitamin E hydroxyl group on the chromanol ring reacts with the peroxy radical to form the corresponding lipid hydroperoxide and tocopheroxyl radical. The lipid hydroperoxide can be detoxified by other antioxidant systems, such as glutathione peroxidase. However, the vitamin E forms a radical itself, which could re-initiate lipid peroxidation. The tocopheroxyl radical has a number of possible fates. The tocopheroxyl radical can react with another radical to form non-reactive products. Alternatively, it can be further oxidized to the tocopheryl quinone, a two-electron oxidation product. Another possibility is “vitamin E recycling”, where the tocopheroxyl radical is restored to its unoxidized form by other antioxidants such as vitamin C or ubiquinol, or with thiols, such as glutathione. This process will deplete these other antioxidants. For this reason, it is important to maintain a good intake of other dietary antioxidants. Additionally, in a closed system, such as a vitamin E deficient zebrafish embryo, other metabolic pathways also become depleted in an effort to maintain phosphatidyl choline, choline, methionine and other methyl donors, as well as glucose-dependent energy systems, such as nicotinamide adenine dinucleotide phosphate [NAD(P)H], (McDougall et al., 2017; Zhang et al., 2021).

### Biologic activity

Biologic activity is a term that has been used historically to indicate a disconnect between vitamin E antioxidant activities and in vivo activities. Observations in rodent experiments carried out in the 1930s, formed the basis for determining the “biologic activity” of vitamin E. Although the various vitamin E forms have similar structures and antioxidant activities, they differ in their abilities to prevent or reverse specific vitamin E deficiency symptoms (e.g., fetal resorption, muscular dystrophy and encephalomalacia).  $\alpha$ -Tocopherol with three methyl groups and a free hydroxyl group on the chromanol ring with the phytyl tail meeting the ring in the *R*-orientation (Fig. 1) has the highest biological activity. This specific structural requirement for biological, but not chemical, activity is dependent upon the  $\alpha$ -TTP binding pocket structure (Min et al., 2003) and its hepatic function (Kono and Arai,

**Fig. 2** Lipid peroxidation and vitamin E. During lipid peroxidation (LPO), a peroxy radical (LOO•) forms when carbon centered radical (L•) reacts with oxygen (O<sub>2</sub>, a di-radical). In the absence of vitamin E, LPO is a chain reaction that continuously produces more radicals because LOO• reacts with polyunsaturated fatty acids (PUFA) to generate a lipid hydroperoxide (LOOH) and another lipid radical. When vitamin E is present (shown here as α-tocopherol, α-TOC-OH), the LOO• is 1000 times more likely to attack α-TOC-OH than the PUFA. The vitamin E hydroxyl group (OH) on the chromanol ring reacts with the peroxy radical to form the corresponding LOOH and tocopheroxyl radical (α-TOC-O•). The LOOH can be detoxified by other antioxidant systems, such as glutathione peroxidase, so long as glutathione (GSH) is available as a reductant. The α-TOC-O• can be restored to its unoxidized form by other antioxidants such as vitamin C (ascorbic acid, AA<sup>-</sup>), which is oxidized to the ascorbyl radical (A•<sup>-</sup>). The A•<sup>-</sup> is then reduced by GSH, in this example. GSH is oxidized to GSSG, which can be reduced by GSH reductase using the reduced form of nicotinamide adenine dinucleotide phosphate [NAD(P)H], as a co-factor. Adapted from [Cadenas et al. \(2016\)](#).

2015), as discussed below. α-TTP maintains plasma, and indirectly tissue, α-tocopherol concentrations. The antioxidant functions (described above) are not limited to α-tocopherol, but because the other forms are at much lower concentrations in vivo, α-tocopherol is the major lipid soluble antioxidant in the body.

### Molecular function

In addition to antioxidant activity, there have been claims that there are specific α-tocopherol-dependent functions that normalize cellular functions, are involved in cell signaling or in gene regulation. However, most of the information in this area has been obtained from in vitro studies in cell culture experiments. Various studies in vivo have demonstrated that α-tocopherol has no specific molecular transduction role in addition to its antioxidant activity, as reviewed ([Blaner et al., 2021](#)). However, α-tocopherol is reportedly necessary for intracellular vesicle formation ([Nell et al., 2007](#)), which appears to be important for membrane repair ([Howard et al., 2011](#)).

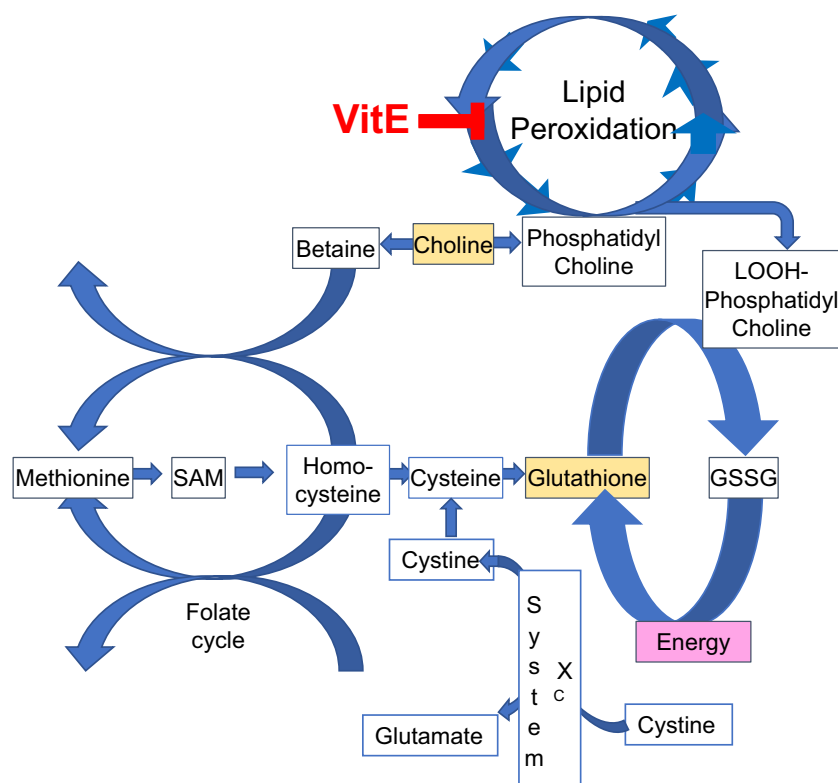

Knockdown of α-TTP in zebrafish is embryonically lethal and α-tocopherol deficiency also causes 80% of the embryos to die, while sufficient embryos during the same 5 day period become swimming fish. The α-TTP gene (*Ttpa*) is highly expressed in the zebrafish embryo, especially in the developing nervous system ([Head et al., 2020](#)). α-Tocopherol deficiency causes malformation of the brain and spinal cord, with defects reminiscent of neural tube defects, while simultaneously energy metabolism, thiol status and methylation pathways are dysregulated ([Fig. 3](#)) ([Head et al., 2021](#); [Zhang et al., 2021](#)). During α-tocopherol deficiency, various metabolic pathways become dysregulated, as a result of downstream consequences of replacing peroxidized phospholipids. These responses appear to be under mTOR (mechanistic target of rapamycin) control ([Head et al., 2021](#)).

### Vitamin E bioavailability

#### Absorption and plasma transport

Intestinal absorption of vitamin E is dependent upon normal processes of fat absorption. Specifically, both biliary and pancreatic secretions are necessary for solubilization of vitamin E in mixed micelles containing bile acids, fatty acids and monoglycerides. α-Tocopheryl acetates (or other esters) from vitamin E supplements, are hydrolyzed by pancreatic esterases to release α-tocopherol prior to absorption. Various cholesterol transporters [scavenger receptor class B type I (SR-BI), CD36 molecule (CD36), NPC1-like transporter 1 (NPC1L1), and ATP-binding cassettes A1 and G1 (ABCA1 and ABCG1)] are involved in vitamin E uptake from micelles into enterocytes ([Reboul, 2019](#)). Following uptake, vitamin E is largely retained within the intestinal cells until the next meal ([Traber et al., 2019b](#)). During fat consumption, lipid droplets are rapidly formed inside enterocytes ([Soayfane et al., 2016](#)), and retained rather than being immediately secreted in chylomicrons ([Khalifeh-Soltani et al., 2016](#)). The next meal stimulates chylomicron secretion from enterocytes that have retained vitamin E and other lipid soluble compounds. Importantly, the various vitamin E forms accumulate in enterocyte lipid droplets, then these droplets coalesce with nascent chylomicrons to enrich their contents with vitamin E, and in the process vitamin E absorption is facilitated. Similar processes occur during absorption of cholesterol ([Beaumier-Gallon et al., 2001](#)).

Once in the circulation, chylomicron triglycerides are hydrolyzed by lipoprotein lipase. During chylomicron catabolism in the circulation, free fatty acids are released, and vitamin E is non-specifically transferred both to tissues and to other circulating lipoproteins. It is not until the vitamin E-containing chylomicrons reach the liver that discrimination between the various dietary

**Fig. 3** Impact of lipid peroxidation on other systems. During vitamin E deficiency insufficient antioxidant protection increases lipid hydroperoxides (e.g., LOOH-phosphatidyl choline). Glutathione peroxidase-4 uses glutathione (GSH) to reduce the LOOH. But the regeneration of the oxidized glutathione (GSSG) is through either (A) NADPH-mediated enzymatic reduction, or (B) via de novo GSH synthesis from cysteine. Studies using vitamin E-deficient zebrafish embryos have shown that they experience increased lipid peroxidation, depletion of phosphatidyl choline with docosahexaenoic acid (DHA-PC) and dysregulated phospholipid metabolism (McDougall et al., 2016, 2017). Choline and its oxidation product betaine became dysregulated, leading to impacts on the methionine cycle, S-adenosyl methionine (SAM) and methylation, as well as impacts on cysteine status. The increased need for GSH increases the requirement for cysteine for GSH synthesis. Thus, inadequate vitamin E also impacts the methionine cycle as well as the system Xc-, which exchanges glutamate for extracellular cystine. Adapted from Zhang et al. (2021).

vitamin E forms occurs (Fig. 4). The hepatic  $\alpha$ -TTP preferentially facilitates secretion of  $\alpha$ -tocopherol, specifically 2R- $\alpha$ -tocopherols, not other tocopherols or tocotrienols, from the liver into the plasma in very low-density lipoproteins (VLDLs). In the circulation, VLDLs are catabolized to low-density lipoproteins (LDL are also known as the “bad cholesterol” because high LDL levels are associated with increased heart disease).

During lipolysis of both chylomicrons and VLDL there is transfer of vitamin E to HDL. Estimates using a vitamin E-enriched lipid emulsion showed that the half-life of  $\alpha$ -tocopherol transfer to HDL during lipolysis in humans was 3 min (Traber et al., 2019b). Although all vitamin E forms are transferred during chylomicron lipolysis, during VLDL lipolysis because they are  $\alpha$ -tocopherol enriched, all of the circulating lipoproteins become enriched with  $\alpha$ -tocopherol.

### Plasma $\alpha$ -tocopherol concentrations and tissue delivery

Plasma  $\alpha$ -tocopherol concentrations in normal adult humans range from 11 to 37  $\mu\text{mol/L}$  (Ford et al., 2006). When plasma lipids are taken into account the lower limits of normal are 1.6  $\mu\text{mol}$   $\alpha$ -tocopherol/mmol lipid or 2.5  $\mu\text{mol}$   $\alpha$ -tocopherol/mmol cholesterol. If lipid concentrations are extraordinarily high or low, then correction for lipid levels are helpful to determine adequacy of vitamin E status because  $\alpha$ -tocopherol is transported in plasma lipoproteins. Additionally,  $\alpha$ -tocopherol concentrations in erythrocytes, adipose tissue or even peripheral nerve have been used to assess vitamin E status.

Vitamin E is delivered to tissues by three mechanisms: transfer from triglyceride-rich lipoproteins during lipolysis, as a result of tissue lipoprotein uptake by various receptors that mediate lipoprotein uptake, and as a result of vitamin E exchange between lipoproteins or tissues. The regulation of tissue vitamin E is not well understood, but  $\alpha$ -tocopherol is the predominant form in tissues as a result of its dominance in plasma. All evidence shows that no vitamin E specific-carrier protein is needed for plasma vitamin E transport, but rather vitamin E is non-specifically transported in lipoproteins. An advantage of vitamin E transport in lipoproteins is that easily oxidizable lipids are protected by the simultaneous transport of this lipid-soluble antioxidant. Thus, as peroxidizable lipids are taken up by tissue, the tissues simultaneously acquire a lipid soluble antioxidant.

**Fig. 4** Vitamin E absorption and trafficking. Intestinal absorption of dietary vitamin E is dependent upon normal processes of fat absorption including biliary and pancreatic secretion. Following vitamin E uptake by enterocytes, nascent chylomicrons (CM) enriched with vitamin E are secreted into the lymphatics, then into the circulation. During chylomicron catabolism by lipoprotein lipase in the circulation, free fatty acids are released, and vitamin E is non-specifically transferred both to tissues and to other circulating lipoproteins. The CM-remnants are taken up by hepatocyte receptor mediated processes. In the liver the hepatic  $\alpha$ -TTP preferentially facilitates secretion of  $\alpha$ -tocopherol, specifically *2R*- $\alpha$ -tocopherols, into the plasma in very low-density lipoproteins (VLDLs). In the circulation, VLDLs are catabolized to low-density lipoproteins (LDL). During lipolysis of both chylomicrons and VLDL there is transfer of vitamin E to HDL. During VLDL lipolysis, all of the circulating lipoproteins become enriched with  $\alpha$ -tocopherol. Hepatic  $\alpha$ -tocopherol ( $\alpha$ -T) has several possible fates: (A)  $\alpha$ -TTP can facilitate its transfer to VLDL; (B) it can be excreted in bile; (C) it can be catabolized to  $\alpha$ -CEHC, which can be secreted into plasma, transported to the kidney and excreted in urine; (D) it can be oxidized by a peroxy radical to  $\alpha$ -T $\bullet$ , but is likely rapidly reduced by other antioxidants, or (v) it may remain in the liver in lipid (triglyceride, TG) droplets. Adapted from [Traber et al. \(2019a\)](#).

### Plasma vitamin E kinetics

Vitamin E absorption gives an estimate of how much of consumed vitamin E is available to the body. The dual isotope method to measure fractional  $\alpha$ -tocopherol absorption is based on the ratio of the plasma concentrations of the administered oral  $\alpha$ -tocopherol to IV (equals 100%). Using this technique, fractional  $\alpha$ -tocopherol absorption in healthy women is  $55\% \pm 3\%$  (mean  $\pm$  SEM;  $n = 10$ ) ([Traber et al., 2019b](#)). Higher fractional absorption ( $\sim 80\%$ ) has been estimated using radioactive tocopherol with the balance method (oral minus excreted) ([Novotny et al., 2012](#)). Dietary fat (40% vs. 0% fat in the meal) had no effect on  $\alpha$ -tocopherol absorption. However, when labeled  $\alpha$ -tocopheryl acetate was used as the test dose, fat was necessary for absorption ([Bruno et al., 2006](#)). These data suggest that vitamin E esters in food or supplements should be consumed with a fat-containing meal for optimal absorption.

Half-life gives an estimate of how long half of a dose of labeled vitamin E remains in the plasma. The apparent half-life of *RRR*- $\alpha$ -tocopherol in plasma of normal subjects is approximately 48 h, while that of *SRR*- $\alpha$ -tocopherol or  $\gamma$ -tocopherol are only 15 h and the tocotrienols are less than 4 h. More recent estimates suggest that the *RRR*- $\alpha$ -tocopherol half-life is  $\sim 30$ – $34$  h ([Mah et al., 2015](#); [Traber et al., 2019b](#)).  $\alpha$ -Tocopherol half-life is slowed in persons with hyperlipidemia, likely because lipoprotein catabolism is slowed. Additionally, bioavailability is less in persons with metabolic syndrome or with fatty liver disease, which may exacerbate oxidative stress associated with the increased inflammation in these disorders.

### Vitamin E catabolism

$\alpha$ -TTP is the body's key to maintaining plasma  $\alpha$ -tocopherol concentrations, but the xenobiotic catabolism of non- $\alpha$ -tocopherol vitamin E forms and "excess"  $\alpha$ -tocopherol serves to increase their excretion and thus decrease their concentrations. Cytochrome P450 4F2 (CYP4F2) initiates vitamin E catabolism by omega-hydroxylation of the sidechain to form the long chain, 13'-hydroxy (13'-OH) catabolite ([Sontag and Parker, 2002, 2007](#)). The 13'-OH catabolite undergoes  $\omega$ -oxidation to form the 13'-carboxy (13'-COOH) catabolite, which then undergoes several rounds of  $\beta$ -oxidation to form carboxyethyl hydroxychromanol (CEHC) ([Sontag and Parker, 2007](#)).  $\alpha$ - and  $\gamma$ -tocopherols, as well as  $\alpha$ - and  $\gamma$ -tocotrienols, are metabolized to  $\alpha$ - and  $\gamma$ -CEHCs (2,5,7,8-tetramethyl- and 2,7,8-trimethyl-2-(2'-carboxyethyl)-6-hydroxychromanols), respectively. About 1% of a dose of  $\alpha$ -tocopherol or tocotrienol, or 5% of a dose of  $\gamma$ -tocopherol or tocotrienol is excreted in the urine as CEHC. Vitamin E catabolism is a key pathway for the regulation vitamin E status and essential for depleting the body of non- $\alpha$ -tocopherol forms.

Tissues involved in vitamin E catabolism based on their CYP4F2 expression include the liver and kidney (Hirani et al., 2008), and intestine (Wang et al., 2007; Uehara et al., 2015).  $\alpha$ -Tocopherol catabolism was quantitated using a dual isotope technique. An intravenous, deuterium-labeled  $\alpha$ -tocopherol that was administered as an oil:water emulsion to mimic chylomicrons and a differently deuterium-labeled  $\alpha$ -tocopherol was consumed (Traber et al., 2019b). Remarkably, more than 90% of the catabolism to urinary  $\alpha$ -CEHC took place in the liver when the experimental conditions mimicked normal meal eating. However, when the participants fasted for 12 h following the “test” breakfast, both the intestine and liver played equal roles in  $\alpha$ -tocopherol catabolism. These data suggest that delay in intestinal secretion of chylomicrons can markedly increase vitamin E catabolism and thus decrease bioavailability.

## Human vitamin E deficiency

The frequency of human vitamin E deficiency is very rare. There have been reports of vitamin E deficiency symptoms in persons with protein-calorie malnutrition. Dietary changes such as decreasing fat intakes, substituting fat-free foods for fat-containing ones and increased reliance of meals away from the home, have resulted in decreased consumption of  $\alpha$ -tocopherol-containing foods.

Erythrocyte fragility, hemolysis and anemia were described as vitamin E deficiency symptoms in various animals fed diets devoid of vitamin E. Additionally, studies in experimental animals have shown that a deficiency of both selenium (a required component of glutathione peroxidases) and vitamin E causes a more rapid and severe onset of debilitating deficiency symptom. Deficiency of both vitamins E and C should also cause more severe antioxidant deficiency symptoms, but most animals make their own vitamin C, so this interaction has been difficult to demonstrate in animals. However, when guinea pigs were fed a vitamin E deficient diet and then made vitamin C deficient, the results were catastrophic, resulting in the animals' death within weeks of feeding the vitamin C deficient diet.

In contrast to experimental vitamin E deficiency in rodents, in humans the major vitamin E deficiency symptom is a peripheral neuropathy characterized by the degeneration of the large caliber axons in the sensory neurons. Anemia has also been described.

Vitamin E deficiency was first described in children with fat malabsorption syndromes, principally abetalipoproteinemia, cystic fibrosis and cholestatic liver disease. Subsequently, humans with severe vitamin E deficiency with no known defect in lipid or lipoprotein metabolism were described to have a defect in the  $\alpha$ -TTP gene. This syndrome is called “Ataxia with Vitamin E Deficiency” or AVED. The neurologic defects in hypobetalipoproteinemia or chylomicron retention disease are also attributed to vitamin E deficiency.

The neurologic abnormalities can be halted and, in some cases, reversed by vitamin E supplements. Enormous daily supplemental  $\alpha$ -T amounts (>100 mg/kg body weight) given long-term can overcome the lack of apoB-lipoproteins in abetalipoproteinemia (Zamel et al., 2008) and prevent oxidative damage (Granot and Kohen, 2004). Reportedly, vitamin E supplementation even allows for normal pregnancy despite apparently low circulating  $\alpha$ -T concentrations (Ferreira et al., 2014). It is likely that high density lipoproteins (HDL) can fulfill this gap in apoB-containing lipoproteins (Anwar et al., 2007).

Similarly, supplemental  $\alpha$ -T (1000 mg/day) can prevent progression of neurologic defects in AVED (Di Donato et al., 2010); one patient has been reported to be stable for over 30 y (Kohlschütter et al., 2020).

Patients with fat malabsorption due to impaired biliary secretion generally do not absorb orally administered vitamin E. These patients are treated with special forms of vitamin E, such as  $\alpha$ -tocopheryl polyethylene glycol succinate that spontaneously form micelles, obviating the need for bile acids.

## Recommended intake levels

In 2000, the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences published the dietary reference intakes (DRIs) for Vitamin C, Vitamin E, Selenium and the Carotenoids. Their recommendations for vitamin E appear in Table 1.

The requirements for vitamin E intakes are based primarily on long-term (5–7 years) depletion and repletion studies in humans. Serum  $\alpha$ -tocopherol concentrations and corresponding hydrogen peroxide-induced erythrocyte hemolysis were determined at various intervals. Serum  $\alpha$ -tocopherol concentrations necessary to prevent in vitro erythrocyte hemolysis in response known levels of  $\alpha$ -tocopherol intake in subjects who had undergone experimentally-induced vitamin E deficiency were used to determine estimated average requirements (EARs). The recommended dietary allowances (RDAs) are levels that represent the daily  $\alpha$ -tocopherol intakes required to ensure adequate nutrition in 95%–97.5% of the population and are an overestimation of the level needed for most people in any given group.

## Dietary vitamin E

Vitamin E can be readily obtained from food. Generally, the richest sources are vegetable oils. Wheat germ oil, safflower oil, and sunflower oil contain predominantly  $\alpha$ -tocopherol, while soy and corn oils contain predominantly  $\gamma$ -tocopherol. All of these oils are polyunsaturated. Monounsaturated oils, such as olive or canola oils, also contain predominantly  $\alpha$ -tocopherol. Whole grains and nuts are also excellent sources of vitamin E. Most fruits and vegetables, although rich in water-soluble antioxidants, are *not* excellent sources of vitamin E. The FDA defines an excellent source as a usual serving having 20% of the reference daily intake

(RDI) (Code of Federal Regulations (eCFR), 2017a). The RDI for vitamin E is 15 mg  $\alpha$ -tocopherol, where 1 mg  $\alpha$ -tocopherol = 1 mg *RRR*- $\alpha$ -tocopherol = 2 mg *all rac*- $\alpha$ -tocopherol (Code of Federal Regulations (eCFR), 2017b).

### Vitamin E supplements

Most vitamin E supplements and food fortificants contain *all rac*- $\alpha$ -tocopherol, but can contain mixtures of tocopherols or tocotrienols. Supplements often are sold as esters, which protect  $\alpha$ -tocopherol from oxidation. These esters can be acetates, succinates or nicotinates of  $\alpha$ -tocopherol. Either the natural stereoisomer (*RRR*- $\alpha$ -tocopherol) or the synthetic (*all rac*- $\alpha$ -tocopherol) can be sold as an ester, e.g., *d*- or *dl*- $\alpha$ -tocopheryl acetate, respectively.

### Other vitamin E forms

It is often assumed that  $\gamma$ -tocopherol can substitute for  $\alpha$ -tocopherol with an efficiency of 10%. However, functionally  $\gamma$ -tocopherol, as well as other non- $\alpha$ -tocopherol forms, are not equivalent to  $\alpha$ -tocopherol, cannot be converted by the body to  $\alpha$ -tocopherol, and are rapidly excreted from the body.

### Precautions and adverse reactions

A number of meta-analyses of outcomes from vitamin E supplementation trials have been reported. Some of these report increased calculated risk of mortality with vitamin E supplementation, while others do not, despite using a similar assortment of clinical trial data. To date, there are no mechanistic studies demonstrating how vitamin E supplements cause to increased mortality. The US Preventive Services Task Force (Fortmann et al., 2013) concluded "trials of vitamin E supplementation showed mixed results and altogether had no overall effect on cancer, CVD, or all-cause mortality". The documented assortment of various adverse consequences from  $\alpha$ -tocopherol supplement intervention trials include increased bleeding (Lee et al., 2005), heart failure (Lonn et al., 2005), hemorrhagic stroke (Sesso et al., 2008; Schurks et al., 2010) and increased risk of prostate cancer (Klein et al., 2011).

### Over-dosage

The 2000 Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences recommended 1000 mg as an upper limit (UL) of all forms of  $\alpha$ -tocopherol in supplements taken by adults 19 years and older, including pregnant and lactating women. UL were set for children and adolescents by adjusting the adult limit on the basis of relative body weight. Table 3 gives the  $\alpha$ -tocopherol UL by age group. No UL was set for infants due to lack of adequate data. The 2000 Food and Nutrition Board did recommend that food be the only source of vitamin E for infants. However, a UL of 21 mg/day was suggested for premature infants with birth weights of 1.5 kg, based on the adult UL.

The vitamin E UL was set for supplements because it is almost impossible to consume enough  $\alpha$ -tocopherol-containing foods to achieve a daily 1000 mg intake for prolonged periods of time. The UL was defined for all forms of  $\alpha$ -tocopherol, not just the *2R*-forms, because all of the forms in *all rac*- $\alpha$ -tocopherol are absorbed and delivered to the liver. The appropriate conversion factors are different from those shown in Table 2, and necessary to estimate the UL for supplements containing either *RRR*- or *all rac*- $\alpha$ -tocopherol supplements. The UL amounts given in IU are shown in Table 4. The UL for *RRR*- $\alpha$ -tocopherol is apparently higher because each capsule of *RRR*- $\alpha$ -tocopherol contains less  $\alpha$ -tocopherol than does one containing *all rac*- $\alpha$ -tocopherol.

### Increased tendency to bleed

High vitamin E intakes are associated with an increased tendency to bleed and this was the symptom that the Food and Nutrition Board used to set the UL. It is not known if increased bleeding is a result of decreased platelet aggregation caused by an inhibition of protein kinase C by  $\alpha$ -tocopherol, some other platelet related mechanism, or decreased clotting due to a vitamin K and E interaction causing abnormal blood clotting. Notably, the Women's Health Study reported that nosebleeds were an adverse effect of

**Table 3** Upper limits (UL) for  $\alpha$ -tocopherol intakes.

Age (years)	UL (mg/day)
1–3	200
4–8	300
9–13	600
14–18	800
>19	1000

Adapted from Food and Nutrition Board and Institute of Medicine (2000).

**Table 4** Upper limits (UL) reported in IU for  $\alpha$ -tocopherol-containing supplements.

	Number of IU that equal 1000 mg
<b><i>all rac</i>-<math>\alpha</math>-tocopherol and esters</b>	
<i>dl</i> - $\alpha$ -tocopheryl acetate	1100
<i>dl</i> - $\alpha$ -tocopheryl succinate	1100
<i>dl</i> - $\alpha$ -tocopherol	1100
<b><i>RRR</i>-<math>\alpha</math>-tocopherol and esters</b>	
<i>d</i> - $\alpha$ -tocopheryl acetate	1500
<i>d</i> - $\alpha$ -tocopheryl succinate	1500
<i>d</i> - $\alpha$ -tocopherol	1500

Adapted from Food and Nutrition Board and Institute of Medicine (2000).

vitamin E supplements (39,876 women  $\geq$  45 years of age, 600 IU *RRR*- $\alpha$ -tocopherol or placebo on alternate days for 10 y) (Glynn et al., 2007). Additionally, they found that vitamin E supplements decrease the risk of venous thromboembolism (blood clots). Individuals who are deficient in vitamin K or who are on anticoagulant therapy are at increased risk of uncontrolled bleeding. Patients on anticoagulant therapy should be monitored when taking vitamin E supplements to insure adequate vitamin K intakes.

### Adverse effects of pharmaceutical drugs on vitamin E status

Drugs intended to promote weight loss by impairing fat absorption, such as Orlistat or sucrose polyester, can also impair vitamin E and other fat-soluble vitamin absorption. Therefore, multivitamin supplementation is recommended when taking these drugs. Vitamin supplements should be taken with meals at times other than when these drugs are taken to allow adequate absorption of the fat-soluble vitamins.

### Chronic disease prevention

Importantly, vitamin E's potential role in preventing or ameliorating chronic diseases associated with oxidative stress leads us to ask whether vitamin E supplements might be beneficial. For many vitamins, when "excess" amounts are consumed, they are excreted and provide no added benefits. Antioxidant nutrients may, however, be different. Heart disease and stroke, cancer, chronic inflammation, impaired immune function, Alzheimer's disease—a case can be made for the role of oxygen free radicals in the etiology of all of these disorders, and even in aging itself. Do antioxidant nutrients counteract the effects of free radicals and thereby ameliorate these disorders? And if so, do large antioxidant supplements have beneficial effects beyond "required" amounts? The 2000 DRI report on Vitamin C, Vitamin E, Selenium and Carotenoids stated that there was insufficient proof to warrant advocating supplementation with antioxidants. But they also stated that the hypothesis that antioxidant supplements might have beneficial effects was promising. Even 20 years later, this remains a very controversial area in vitamin E research.

One approach that has been successful in demonstrating vitamin E effectiveness in mitigating chronic disease risk is the identification of patients with increased levels of oxidative stress. One such strategy, called pharmacogenomics by its proponents, identified that diabetic patients with the haptoglobin 2-2 genotype is associated with increased risk of cardiovascular disease (CVD). These patients were found to have benefit from vitamin E supplementation.

Another approach is to evaluate large populations, then follow their chronic disease progression. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention trial had 29,092 male participants. Men with higher serum  $\alpha$ -tocopherol at baseline had significantly lower all-cause mortality and significantly decreased mortality from cardiovascular disease, heart disease, stroke, cancer, respiratory disease, and other causes, with risk reductions from 17% to 47% for the highest versus lowest quintile (Huang et al., 2019). Conversely, low  $\alpha$ -tocopherol intakes increase serum  $\gamma$ -tocopherol concentrations. It is interesting that serum  $\gamma$ -tocopherol concentrations in a subset of 3904 men and 4461 women from the Multiethnic Cohort Study, were associated with increased mortality.

Specific interventions where vitamin E supplements have had a benefit include slowing the progression of macular degeneration (Age-Related Eye Disease Study Research, 2001; Evans and Lawrenson, 2017), slowing the decline of Alzheimer disease (Farina et al., 2017) and in the treatment of fatty liver disease (NAFLD, NASH) in both adults (Sanyal et al., 2010; Sato et al., 2015) and children (Lavine et al., 2010). Interestingly, all of these disorders occur in tissues that express  $\alpha$ -TTP, suggesting that these tissues may be more susceptible to damage by lipid peroxidation. This concept may be true for the liver where excess lipid droplets may prevent normal  $\alpha$ -tocopherol trafficking by  $\alpha$ -TTP (Podszun et al., 2020; Violet et al., 2020).

## Conclusion

Vitamin E is a nutrient that is necessary to be obtained from the diet and better quality diets have higher vitamin E contents and are associated with better health (Gicevic et al., 2021). Nonetheless, in the enthusiasm for vitamin E supplements to prevent, or perhaps treat chronic diseases, the role of vitamin E as a required nutrient is frequently overlooked. In this regard, recent studies in zebrafish embryos highlight the necessity of  $\alpha$ -tocopherol to protect the nervous system in the developing embryonic, vertebrate animal. This model system also highlights the need for  $\alpha$ -TTP for trafficking  $\alpha$ -tocopherol even before a liver has developed. In this regard, it is also interesting that plants synthesize a variety of molecules with vitamin E antioxidant activity, but animals have developed not only a preference for  $\alpha$ -tocopherol, but a strong xenobiotic system to rapidly catabolize non- $\alpha$ -tocopherols.

## Key points

- Only one of the eight natural vitamin E analogs ( $\alpha$ -tocopherol,  $\alpha$ T) is essential for humans
- The other seven vitamin E analogs reach low micromolar concentrations only in the postprandial state, after which they are metabolized and eliminated
- Vitamin E is the most active lipid-soluble chemical antioxidant protecting poly/mono-unsaturated fatty acids and cholesterol against damage induced by free radicals
- Vitamin E analog specific interactions with membranes, signaling enzymes, transcription factors, transport and structural proteins lead to genome-wide changes of gene expression
- Polymorphisms in genes related to vitamin E transport and action may help to identify sub-populations of individuals at risk for low vitamin E status susceptible to a personalized approach of disease prevention

## Introduction

This year nears 100 years since Herbert McLean Evans and Katherine Julia Bishop discovered a fat-soluble dietary constituent essential for reproduction in rats later named vitamin E ( $\alpha$ -tocopherol ( $\alpha$ T)). Initial studies mainly focused on the chemical structure of vitamin E, its synthesis, its antioxidant properties, and its requirements as an essential dietary component in studies with rodents. In the last 20–30 years, with the advance of modern molecular biology, genetics and biochemistry, the mechanisms of vitamin E uptake into the body, its metabolism and more recently its regulatory roles in cells have been elucidated. In animals, these studies firmly established the essential role of vitamin E in preventing reproductive failure and symptoms of neuro/muscular degeneration; in humans, clear evidence for its essential function came after the seminal discovery of a rare genetic disease with very low plasma levels of vitamin E, ataxia with vitamin E deficiency (AVED), with similar symptoms as observed in vitamin E deficient animals.

AVED is caused by mutations in a single gene, the alpha-tocopherol transfer protein ( $\alpha$ TTP), that is essential for enriching vitamin E in plasma to a level required for normal development and health. Whereas sufficient vitamin E is present in an equilibrated diet to sustain its essential functions, certain diseases and conditions impair the absorption of vitamin E from foods and supplementation is indicated. Health effects with vitamin E supplementation beyond the essential have extensively been investigated in animal studies, with however often equivocal results in human studies. These findings highlight the complexity of vitamin E action in humans, that depends on many factors that are difficult to control including interactions with other dietary components, individual-specific uptake and metabolism and the presence of genetic polymorphisms. Recent developments on the regulatory effects of natural and synthetic vitamin E analogs on genome wide gene expression and metabolomics emphasize the importance of maintaining life-long adequate levels of vitamin E for development and disease prevention.

## Chemistry of the eight natural vitamin E analogs

In photosynthetic organisms including higher plants, cyclization and differential methylation of precursors is leading to eight vitamin E analogs (the  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -tocopherols ( $\alpha$ T,  $\beta$ T,  $\gamma$ T,  $\delta$ T) and  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -tocotrienols ( $\alpha$ TT,  $\beta$ TT,  $\gamma$ TT,  $\delta$ TT)) (Fig. 1) (Mene-Saffrane, 2017).

The different chemical structure and the consequent differential interaction with membranes, organelles, and proteins (enzymes, transcription factors, transporters, structural proteins) are thought to be responsible for the vitamin E analog specific uptake, distribution and cellular effects.

Chemically, the eight vitamin E analogs act as free radical chain breaking molecules via the chromanol hydroxy group mostly when embedded in cellular membranes, lipid vesicles and lipoproteins and protect the membrane components (unsaturated lipids, cholesterol) from oxidation. The chemical antioxidant activity of the eight natural vitamin E analogs is similar, albeit at the molecular level some differences in the chemical, physical and biological effects can be distinguished that depend on the assay used as well as on the solvent, microenvironment and presence in membrane, micelles or lipoproteins (Miyazawa et al., 2019; Wagner et al., 2004). *In vitro*, the efficiency of inhibition of lipid peroxidation by tocopherols has been determined to be within the same range with  $\alpha > \gamma \approx \beta > \delta$ .

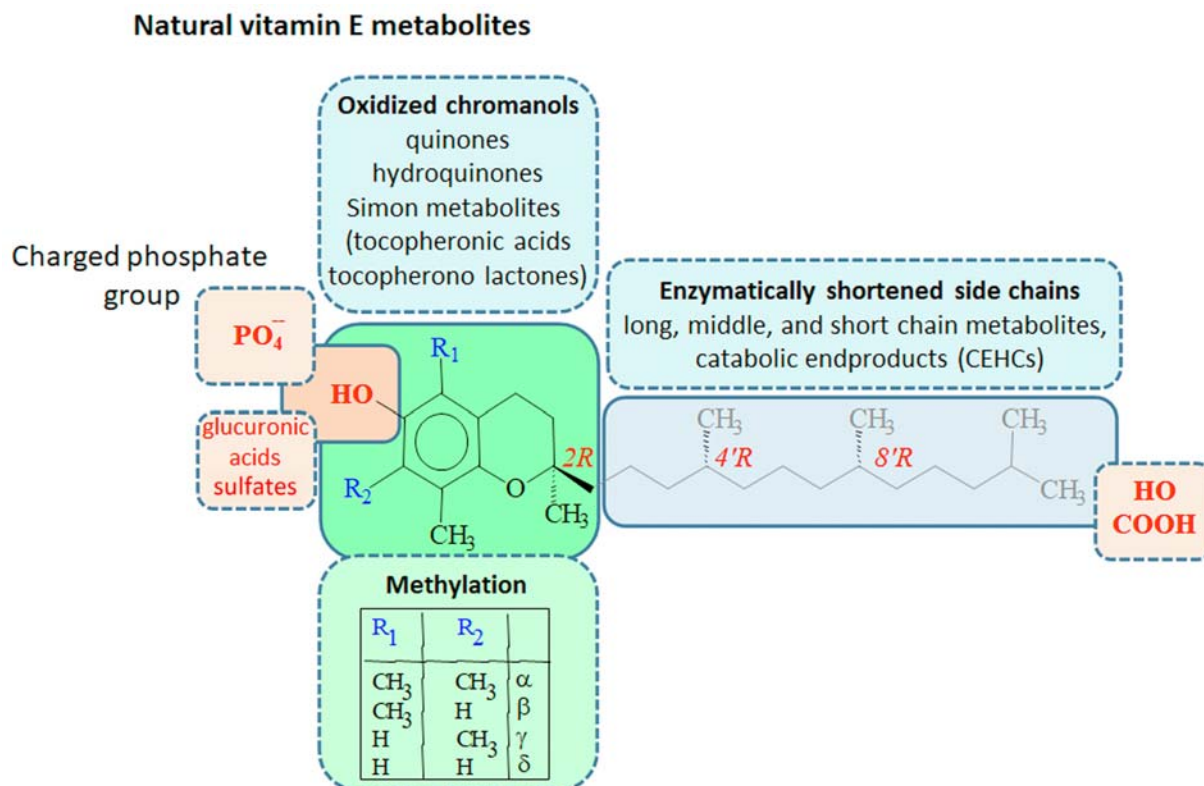

The chromane ring is methylated at various locations and differences in methylation not only defines the four tocopherol and tocotrienol analogs ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ) but also leads to different affinity to  $\alpha$ TTP resulting in preferential enrichment and retention of fully methylated  $RRR$ - $\alpha$ T (Fig. 1). Moreover, differential methylation of each vitamin E analog affects the interaction with enzymes, structural proteins, transporters, transcription factors and membrane lipids believed to be the main reason for the differential regulatory effects on signaling and gene expression that can occur by mechanisms independent of acting as a chemical antioxidant. Chemically,  $\alpha$ T is more stable than the other analogs since the reactive hydroxy group is located between two methyl groups so that the unpaired electron can delocalize over the fully substituted chromanol ring after reacting with a lipid peroxide thus slowing its chemical reactivity, until it is reduced and regenerated by vitamin C (L-ascorbic acid) and glutathione or fully oxidized to alpha-tocopheryl quinone ( $\alpha$ TQ). In  $\gamma$ T (and also  $\beta$ T and  $\delta$ T) the aromatic ring can react at the unmethylated sites with peroxynitrite forming 5- $\text{NO}_2$ - $\gamma$ T and the corresponding metabolite, 5- $\text{NO}_2$ - $\gamma$ -CEHC (Wagner et al., 2004), but unlike the  $\alpha$ T phenoxyl radical, 5- $\text{NO}_2$ - $\gamma$ T is not regenerated. Peroxynitrite is formed by macrophages during inflammation and scavenging by  $\gamma$ T suggests that it may act as a better anti-inflammatory agent – in particular in skin where the levels of  $\gamma$ T are generally high, but possibly even at the lower concentrations reached in plasma. Accordingly, neointima formation induced by vascular injury is reduced by  $\gamma$ T by reducing nitrosative stress in insulin resistant rats, whereas the effects seen with  $\alpha$ T are weaker.

The hydrophobic side chain present in all vitamin E analogs (for tocopherols, saturated derived from phytyl pyrophosphate; for tocotrienols, unsaturated derived from geranylgeranyl pyrophosphate) is responsible for its preferential location in the lipid phase (lipoprotein, membranes, vesicles, hydrophobic pockets of proteins). The tocotrienols (TT) have a more pronounced antioxidant effects since they are more homogeneously distributed in membranes facilitating recycling of the chromanoxyl radical. In

### Natural vitamin E analogues

**Fig. 1** Chemical structures of natural vitamin E. Natural vitamin E is a composite of three structural and functional entities: (1) the hydrophobic side chain that anchors vitamin E in the plasma membrane, vesicles and hydrophobic pockets of proteins (for tocopherols, a saturated phytyl side chain natural in the  $RRR$ -configuration; for tocotrienols and marine derived tocopherols, an unsaturated isoprenoid side chain); (2) the chromane group modified by differential methylation ( $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -tocopherols and tocotrienols), and (3) the hydroxy group responsible for the antioxidant activity.

**Fig. 2** Natural vitamin E metabolites. Vitamin E metabolites are generated from natural vitamin E either enzymatically or oxidatively. Enzymatically generated vitamin E metabolites become first hydroxylated at the hydrophobic side chain and then are progressively shortened to produce long-, intermediate- and short-chain metabolites until the metabolic end products (CEHCs) are formed. These enzymatic modifications of vitamin E lead to increasingly more water-soluble metabolites but still maintaining the antioxidant activity of the chromanol group known for the intact molecules. Thus, metabolism of vitamin E may liberate activities associated with the chromanol moiety (antioxidant, signaling molecule) and facilitate their movement into different cellular compartments as well their secretion by the kidney. In contrast, intracellular distribution of intact vitamin E is facilitated by several lipid transporters and lipid exchange reactions (by  $\alpha$ TTP, TAP1/2/2 or SEC14L2/3/4, respectively, NPCL1, NPC1, NPC2), or possibly can occur after enzymatic modification with polar residues (e.g., hydroxy, phosphate, sulfate, glucuronide). Oxidative metabolites contain oxidized chromanols (quinones, hydroquinones), and the so-called Simon metabolites (tocopheronic acids, tocopheronolactones). For better elimination by the kidney, the metabolites become modified by glucuronidation or sulfation.

membranes the vitamin E analogs are the main molecules that act as chain breaking antioxidants able to scavenge reactive oxygen (ROS) and reactive nitrogen species (RNS) with consequent reduction of the random formation and accumulation of damaged molecules such as membrane lipids, proteins and nucleic acids and consequent cellular dysfunction and death. Accordingly, the level of vitamin E may affect the generation of oxidized lipids in membranes and thus indirectly modulate their signaling function as active lipid mediators.

The hydrophobic side chains of the vitamin E analogs become hydroxylated and progressively shortened upon enzymatic metabolism, increasing the solubility of the metabolites but still maintaining the antioxidant activity of the chromanol group known for the intact molecules (Fig. 2).

Thus, metabolism of vitamin E may "liberate" activities associated with the chromanol moiety (antioxidant, signaling molecule) and facilitate their movement into different cellular compartments. In contrast, mobilization of intact vitamin E from membranes and lipid droplets and intracellular distribution requires lipid exchange reactions mediated by lipid transport proteins (e.g.,  $\alpha$ TTP, TAP1/2/3 also named SEC14L2/3/4, respectively, NPCL1, NPC1, NPC2), or possibly is facilitated after enzymatic modification with polar residues (e.g., with hydroxy, phosphate, sulfate, glucuronide).

### Only one of the eight vitamin E analogs, *RRR*- $\alpha$ T, is essential

Selective recognition by  $\alpha$ TTP in the liver and enrichment of plasma and tissue with one analog, *RRR*- $\alpha$ T, is believed to be the main reason for its much higher biological potency ( $\alpha \gg \gamma > \delta > \beta$ ) (Azzi, 2018), and since it fulfills all essential functions, it has been recognized as the analog that acts as vitamin E (Food and Nutrition Board, 2000). This is best demonstrated by comparing  $\alpha$ T to  $\alpha$ TT that both have the same chromanol head group but only  $\alpha$ T is enriched in plasma and considered to be essential, whereas  $\alpha$ TT not

despite having *in vitro* a comparable or more pronounced antioxidant and cellular activity. Upon supplementation and after a post-prandial peak at about 4–8 h, excess  $\alpha$ T and all the other tocopherols and tocotrienols become metabolized by the liver and eliminated, whereas  $\alpha$ T remains elevated even in the fasted state, with an average steady-state plasma concentration of  $\sim 23 \mu\text{M}$  ( $t_{1/2}$ –29 h). It is unknown whether the not-retained tocopherol analogs and their metabolites have some essential cellular function at their nanomolar to low micromolar concentrations reached in plasma, beyond a possible “E” function in support to  $\alpha$ T.

Preferential retention of *RRR*- $\alpha$ T may also be the result of evolutionary selection of the fully methylated vitamin E analog forming a more stable tocopheroxyl radical that upon full oxidation to alpha-tocopherol quinone/hydroquinone ( $\alpha\text{TQ}/\alpha\text{THQ}$ ) has non-aryllating electrophilic properties, whereas oxidation of  $\beta$ T,  $\gamma$ T and  $\delta$ T leads to the aryllating desmethyl analogs ( $\beta\text{TQ}$ ,  $\gamma\text{TQ}$ ,  $\delta\text{TQ}$ ) with mutagenic, cytotoxic and apoptotic properties. Moreover,  $\alpha\text{THQ}$  may be the vitamin E analog with higher activity to prevent ferroptosis and neurodegenerative dysfunction that occurs in the brain during vitamin E deficiency, by reducing the non-heme iron of 15-lipoxygenase from its active  $\text{Fe}^{3+}$  to an inactive  $\text{Fe}^{2+}$  state.

Whereas intake of vitamin E is generally regarded as safe (RDA for humans is 15 mg/day, supplements are usually between 200 and 400 mg/day, and the upper tolerable limit is 1000 mg/day), adverse effects have been reported to occur above 400 mg/day (Hathcock et al., 2005). Increased lipids in liver have been reported as one of the symptoms of hypervitaminosis E in rats and mice. Similarly, long-term intake of a 2% tocotrienol mixture showed some highly proliferative liver lesions and a reduction of the survival rate in rats. More insight into the biological reasons for selecting only  $\alpha$ T to become enriched in the body during evolution of higher organisms may come from an engineered  $\alpha\text{TTP}$ , that instead of  $\alpha$ T preferentially recognizes  $\gamma$ T ( $\gamma\text{TTP}$ ).

It should be emphasized at this point, that albeit natural *RRR*- $\alpha$ T harbors all the essential vitamin E functions, numerous experiments *in vitro* and *in vivo* have shown vitamin E associated regulatory effects and cellular responses with all natural vitamin E analogs and their contribution to disease prevention is under investigation. *In vivo* a vitamin E analog specific response has been mostly attributed to their different bioavailability and rate of metabolism. Intriguingly, rapid conversion of all the non-*RRR*- $\alpha$ T analogs into metabolites may increase their concentration in plasma to a level required for their action (Birringer and Lorkowski, 2019). However, even when used at equal concentration in cultured cells the eight vitamin E analogs and their metabolites often show differences suggesting additional regulatory mechanisms that go beyond that of scavenging free radicals.

## Natural and synthetic analogs of vitamin E ( $\alpha$ T)

Albeit eight different vitamin E analogs are present in nature, only *RRR*- $\alpha$ T is being considered as “the vitamin E” since it is enriched in the human body and carries all the to date known essential functions (Azzi, 2018). The natural tocopherols contain a phytyl side chain with three chiral centers which naturally occur in the *RRR* configuration, whereas the tocotrienols have an unsaturated isoprenoid side chain (Fig. 1). In commercially available products, natural vitamin E is present either as *RRR*- $\alpha$ T (formerly called *d*- $\alpha$ T), or as a mixture of naturally occurring tocopherols and tocotrienols (all as *RRR*-stereoisomers). In synthetic vitamin E products, as result of chemical synthesis, the side chain consists of all possible combinations of *R* and *S* side-chain stereoisomers occurring at equal amounts (e.g., synthetic racemic vitamin E or *all-rac*- $\alpha$ T, formerly called *dl*- $\alpha$ T) (Fig. 3).

For use in supplements and cosmetics stabilized vitamin E derivatives that are esterified at the chromanol hydroxy group and thus are not susceptible to oxidation have been synthesized (e.g.,  $\alpha$ -tocopheryl acetate ( $\alpha\text{TA}$ ),  $\alpha$ -tocopheryl succinate ( $\alpha\text{TS}$ ),  $\alpha$ -tocopheryl phosphate ( $\alpha\text{TP}$ )) having advantages for processing, storage and absorption. Depending on the application, these stabilized vitamin E analogs may have different solubility, transport and metabolism. Stabilized esters of  $\alpha$ T are mostly converted to the natural forms by pancreatic, intestinal or epidermal esterases and can be considered to be pro-vitamins since they ultimately perform the same function in the body as the natural vitamin E.

The activity of the natural and synthetic vitamin E analogs has been tested and compared using an assay preventing reproductive failure in rats, that was developed based on the original description of vitamin E as an essential nutrient for reproduction. The natural-source *RRR*- $\alpha$ T vitamin E has a 1.36-fold greater biological potency compared to synthetic *all-rac*- $\alpha$ T assumed to be mainly the result of the better retention of *RRR*- $\alpha$ T by  $\alpha\text{TTP}$  in the liver. Based on the rat fetal resorption assay, the units definition (United States Pharmacopoeia (USP)) of the different vitamin E analogs has been (1 USP of vitamin E = 1 mg of *all-rac*- $\alpha\text{TA}$ , or 0.67 mg *RRR*- $\alpha$ T, or 0.74 mg *RRR*- $\alpha\text{TA}$ ) (Food and Nutrition Board, 2000). One mg of the most commonly used synthetic form of vitamin E, *all rac*- $\alpha\text{TA}$ , is regarded as 1 international unit (IU), and the potency of natural form of  $\alpha$ T is set to be equal to 1.49 IU. Compared to that, the biological activity of  $\gamma$ T is about 1/10th of that of  $\alpha$ T.

In situations where ester hydrolysis is inefficient, the stabilized  $\alpha$ T derivatives may perform different cellular functions that are based on their different chemical and physical properties. Some of these derivatives, such as  $\alpha\text{TS}$ , may exert a dual function, first as anticancer pro-vitamin E in the non-hydrolyzed form, and second as vitamin E, in the hydrolyzed form (Neuzil, 2002). Within mesenchymal stem and progenitor cells, intact  $\alpha\text{TA}$  is thought to maintain primitive cells and attenuate mitochondrial oxygen consumption by mimicking hypoxia. Recent findings indicate that conversion of  $\alpha\text{TA}$  to  $\alpha$ T may less occur in lungs upon inhaling vapors from e-cigarettes containing  $\alpha\text{TA}$  that was present as vape-cartridge additive (DiPasquale et al., 2020). Increased levels of intact  $\alpha\text{TA}$  are reportedly detected in electronic-cigarette or vaping product use-associated lung injury (EVALI). Although the mechanisms by which intact  $\alpha\text{TA}$  may affect lungs in cases of EVALI are still unclear it may act as linactant and disrupt the pulmonary surfactant and/or contribute to the formation of macrophages foam cells detected in bronchoalveolar lavages and lungs after inhaling e-cigarette vapors from products containing  $\Delta^9$ -tetrahydrocannabinol (THC) and  $\alpha\text{TA}$ .

**Fig. 3** Natural and synthetic analogs of vitamin E ( $\alpha$ T). As result of chemical synthesis, synthetic vitamin E products consist of all possible combinations of *R* and *S* side-chain stereoisomers occurring at equal amounts (e.g., synthetic racemic vitamin E or *all-rac*- $\alpha$ T, formerly called dl- $\alpha$ T). In the liver,  $\alpha$ TTP recognizes preferentially *RRR*- $\alpha$ T and less also *RSR*, *RRS* and *RSS*-side chain isomers (the so-called *2*R**- $\alpha$ T-stereoisomers) for enrichment in very low-density lipoproteins (VLDL), whereas the so-called *2*S**- $\alpha$ T-stereoisomers are metabolized and excreted.

Intact  $\alpha$ TP can affect signaling and gene expression and modulates cellular events ranging from proliferation, survival/apoptosis, lipid uptake and metabolism, phagocytosis, long term potentiation, cell migration, telomere maintenance and angiogenesis. The bioavailability as an intact molecule is generally low, in skin, only about 3.1%–4.8% of  $\alpha$ TP were reported to be converted to  $\alpha$ T within 24 h, albeit other studies in other cell types suggested more rapid conversion. Similarly, conversion of  $\alpha$ TA to  $\alpha$ T was not observed on the surface or in the horny layers of human skin, while up to 50% was converted in the underlying skin.  $\alpha$ TP show improved penetration into epidermis and can form nanocarriers for delivery of molecules across the skin, such as drugs (e.g., caffeine, oxycodone), vitamins (vitamins, including  $\alpha$ T and  $\alpha$ TP itself, vitamin D3), fatty acids (omega-3 fatty acid docosahexaenoic acid (DHA)) and other molecules such as carnosine, insulin and coenzyme Q10.

## Vitamin E metabolites

Broadly, two different types of vitamin E metabolites can be distinguished reflecting the mechanism by which they are generated in the body (enzymatically and oxidatively) (Fig. 2). Enzymatically generated vitamin E metabolites are produced when their level exceeds the capacity of  $\alpha$ TTP to export them from the liver. For  $\alpha$ T, which is selectively recognized by  $\alpha$ TTP and specifically sorted for incorporation into very low-density lipoproteins (VLDL), much higher micromolar concentrations need to be reached for metabolism to occur when compared to the other seven tocopherols and tocotrienols that become metabolized and excreted already at nanomolar to low micromolar plasma concentrations (reviewed in (Zingg and Azzi, 2004)). However, even in  $\alpha$ TTP knockout mice non- $\alpha$ T analogs are preferentially metabolized suggesting increased recognition by metabolic enzymes as mechanism for their more efficient elimination.

The proposed pathway of enzymatic metabolism of the vitamin E analogs proceeds first via  $\omega$ -oxidation of the side-chains catalyzed by the cytochrome P<sub>450</sub> enzymes CYP3A and CYP4F2 in the endoplasmic reticulum leading to 13'-hydroxychromanols (13'-OHs), and then  $\beta$ -oxidation in peroxisomes and mitochondria leading to long chain metabolites (LCM), e.g., 13'-carboxychromanols (13'-COOHs), that are further  $\beta$ -oxidized to intermediate- and short-chain metabolites, e.g., the carboxymethylbutyl hydroxychromans (CMBHCs), and finally to the metabolic end products, the carboxyethyl hydroxychromans (CEHC) (Birringer and Lorkowski, 2019).

With increasing intake and after a threshold of plasma  $\alpha$ T has been exceeded,  $\alpha$ -CEHC excretion in urine is augmented and the intact chromane structure suggests that it is enzymatically generated and not derived from  $\alpha$ T that has reacted as antioxidant. Metabolism of  $\delta$ T leads to  $\delta$ -CEHC, and that of  $\gamma$ T to  $\gamma$ -CEHC, which has been identified in human urine and proposed to act as a natriuretic factor. For better excretion, these increasingly more water-soluble metabolites become further conjugated with glucuronide or sulfate.

Mechanistically, metabolism and elimination occur by induction of cytochrome P<sub>450</sub> enzymes via activation of the pregnane X receptor (PXR) (reviewed in (Traber, 2004)). The extent by which the chromanol hydroxy group is exposed may determine the strength of activation of PXR, with  $\alpha$ T being the weakest, whereas  $\beta$ T,  $\gamma$ T,  $\delta$ T and the tocotrienols being stronger. Interestingly, the tocopherol metabolic products do not activate PXR by themselves suggesting that vitamin E transport proteins may be required to facilitate transport of intact vitamin E analogs to PXR in the nucleus and/or to cytochromes P<sub>450</sub> enzymes in the endoplasmic reticulum and in mitochondria. Similar requirements for intracellular transport of other hydrophobic molecules have been described, such as for squalene (by supernatant protein factor (SPF), also known as TAP1/SEC14L2), vitamin A/retinoids (by intracellular retinoid-binding proteins such as cellular retinol-binding protein (CRBP), cellular retinoic acid-binding protein (CRABP) and cellular retinal-binding protein (CRALBP)), for fatty acids (by several fatty acid binding proteins (FABP)), phospholipids (phospholipid transfer protein (PLTP)), or cholesterol and cholesteryl esters (triacylglycerols or cholesteryl ester transfer protein (CETP), oxysterol-homology binding protein 4 (OSH4p)) (Kono and Arai, 2015). Since activation of PXR mediates metabolism of many drugs by inducing cytochromes P<sub>450</sub> enzymes (e.g., CYP3A) and ATP-binding cassette (ABC) transporters, the vitamin E metabolism may be influenced by other drugs and nutrients including the different vitamin E analogs themselves. In fact, some inhibitors of the CYP3A family, like sesamin and ketoconazole, inhibit the formation of  $\gamma$ -CEHC, explaining the increased serum  $\gamma$ T levels in humans after dietary intervention with sesame oils. On the other hand, activators of CYP3A such as rifampicin can lead to higher formation of  $\alpha$ -CEHC in HepG2 cells.

Oxidatively generated vitamin E metabolites are generated upon scavenging free radicals by vitamin E. The so-called "Simon metabolites" (tocopheronic acid and tocopheronolactone) are excreted in the urine as glucuronides or sulfates. These metabolites have a shortened side chain and an opened, oxidized, chromane structure that is often quoted to demonstrate their antioxidant function *in vivo*. A marked increase of these metabolites is observed in the urine of healthy volunteers after daily intake of 2–3 g *all rac*- $\alpha$ T. Likewise, in children with type 1 diabetes, the presence of conjugated  $\alpha$ -tocopheronolactone (sulfate and glucuronide) in urine has been suggested as a biomarker for oxidative stress.

The nitrated metabolite of  $\gamma$ T, NO<sub>2</sub>- $\gamma$ -CEHC, can be generated from  $\gamma$ T after nitration to 5-NO<sub>2</sub>- $\gamma$ T and subsequent metabolism. However, since 5-NO<sub>2</sub>- $\gamma$ T is apparently inefficiently incorporated into liver cells, it is not detected in urine while  $\gamma$ -CEHC is abundant and it is to date unknown whether it exerts any cellular activity at higher concentrations. In smokers,  $\alpha$ T supplementation reduces circulating  $\gamma$ T in part by increasing its metabolism and competition with uptake with consequent lower 5-NO<sub>2</sub>- $\gamma$ T formation by scavenging of RNS.

As recently critically reviewed, some of the metabolites act as bioactive molecules that modulate the activity of transcription factors, membrane channels and enzymes even at the low nanomolar concentrations reached in plasma and in the intestine (low micromolar concentrations can be reached after supplementation) (Birringer and Lorkowski, 2019). Among the activities of metabolites (LCM, CEHC) are: natriuretic activity of  $\gamma$ -CEHC, anti-inflammatory and antioxidative activities by inhibiting several enzymes (e.g., cyclooxygenase-1 and 2 (COX-1/2), prostaglandin E2 (PGE2) synthase, 5-, and 12-lipoxygenases (5-, 12-LOX), inducible nitric oxide synthetase (iNOS), leukotriene synthase). Furthermore, gene regulatory activities relevant for lipid homeostasis including upregulation of CD36 scavenger receptor/fatty acids transporter (CD36/FAT) and the lipid droplet-associated protein perilipin 2 (PLIN2) have been observed. At higher micromolar concentrations, some metabolites can induce apoptosis in cancer cell lines. In prostate cancer cells, inhibition of cyclin D1 expression by  $\gamma$ -CEHC leads to inhibition of cell proliferation, and since the inhibitory effect of  $\gamma$ -CEHC is competed for by  $\alpha$ -CEHC non-antioxidant mechanism have been suggested.

## Dietary sources

The eight natural vitamin E analogs are exclusively synthesized in photosynthetic organisms including higher plants. Significant amounts are present in all green tissues and also in seeds, where the eight vitamin E analogs are present in different relative amounts (reviewed in (Mene-Saffrane, 2017; Zingg and Azzi, 2004)). The major source of vitamin E in the human diet are olive and vegetable seed oils (corn, soybean, safflower, palm) that contain different relative amounts of each vitamin E analog (Wagner et al., 2004; Jiang, 2014). Sunflower seed oil and corn oil are excellent sources of  $\alpha$ T, whereas corn and soybean oil contain the highest amounts of  $\gamma$ T (Jiang, 2014). Olive, sunflower, canola oil and corn oil are classified as a good food source of tocopherols, whereas animal products are generally a relatively poor source of vitamin E. Tocotrienols are mainly present in oils from palm, wheat germ, barely, and rice bran. Grape seed oils contain  $\alpha$ TT and  $\gamma$ TT and annatto/achiote seeds contain predominantly  $\delta$ TT. Palm oil also contains  $\alpha$ -tococomonoenol, and some marine organisms contain marine derived tocopherol (MDT) having a single unsaturated bond at the end of the phytol side chain as a possible adaption to maintain membrane fluidity in cold water. Other sources of tocopherols are nuts, seeds, whole grain and wheat germ (200–1000 mg/kg), and to a lesser extend fruits (with the exception olives (a stone fruit)) and vegetables. Preferential intake of corn oil leads to higher intake of  $\gamma$ T and in the US, high intake of soybean oil leads to more intake of  $\gamma$ T and  $\delta$ T in Asia, whereas preferential intake of olive and sunflower oils in Europe leads to higher intake of  $\alpha$ T (Wagner et al., 2004; Zingg and Azzi, 2004). Adherence to certain diets and cooking habits (e.g., Mediterranean, Asian) are thought to influence the relative intake of vitamin E analogs with possible consequence for human health.

## Interaction of vitamin E with MUFA and PUFA

As the main lipid-soluble antioxidant, vitamin E stabilizes membranes by itself as a structural lipid and protects other unsaturated lipids such as polyunsaturated and monosaturated fatty acids (PUFA and MUFA, respectively) by scavenging lipid peroxyl radicals and acting as a chain-breaking antioxidant that can be regenerated by vitamin C and glutathione. With a typical dietary PUFA intake, the vitamin E requirements have been estimated to range between 12 and 20 mg (Raederstorff et al., 2015), an amount that is as determined by the Institute of Medicine within the range of the recommended dietary allowance (RDA) of 15 mg vitamin E (Food and Nutrition Board, 2000). The relative level of vitamin E and PUFA appears to be particularly important when PUFA are increased in the diet by supplementation (Raederstorff et al., 2015; Zingg and Meydani, 2019). It is to date unknown whether scavenging of peroxynitrite by  $\gamma$ T could reduce the formation of nitro-fatty acids from PUFA, such as conjugated linoleic acid (CLA) that have emerged as important regulators of vascular and inflammatory functions.

The n-3 and n-6 polyunsaturated fatty acids (omega-3 or omega-6 PUFA, respectively) are nutritionally essential since they cannot be synthesized *de novo* from 2-carbon fragments. As a result of their unsaturated double bonds, PUFA are susceptible to chemical reactions with ROS and RNS. PUFA in phospholipids not only influence membrane fluidity, curvature and the properties of membrane microdomains, but increase also the risk for chain reactions of lipid peroxidation with consequent membrane destabilization and cellular dysfunction. Supplementation with vitamin E decreases the urinary level of F2-isoprostane (a biomarker for oxidized arachidonic acid, an n-6 PUFA) in *ApoE*<sup>−/−</sup> atherosclerotic mice that have elevated levels in urine, plasma, and vascular tissue. However, in humans very high doses of vitamin E over a prolonged time were required to reduce F2-isoprostane in plasma. Thus, vitamin E and PUFA interact with each other as a pair in which vitamin E protects PUFA and excess PUFA “consume” vitamin E, and a high PUFA/vitamin E ratio is generally considered as disadvantageous (Raederstorff et al., 2015; Zingg and Meydani, 2019).

In cells, both vitamin E and PUFA have redox-independent regulatory functions, mostly after being metabolized to active lipid mediators via binding to specific enzymes and receptors involved in modulating signal transduction and gene expression relevant for immune, inflammatory, developmental and metabolic pathways (Zingg and Meydani, 2019). In recent studies that investigate the role of PUFA and vitamin E in the brain, gene regulatory effects of vitamin E and PUFA have been analyzed using genome-wide gene expression analysis and metabolomics (Traber, 2020). In 1 year old zebrafish (*Danio rerio*) with vitamin E deficiency and limiting dietary long-chain PUFA, a protective antioxidant effect of vitamin E on PUFA in brain has been demonstrated. However, of the 155 lipids surveyed in brain extracts by lipidomics, only four phospholipids (PL) were significantly different suggesting additional regulatory mechanisms.

Interestingly, as revealed by metabolomics vitamin E supplementation (400 mg/d RRR- $\alpha$ TA, for 4 wks) increased the levels of a number of lysophosphatidylcholine (LPC) species (16:0, 18:0, 18:1, 18:2, 20:3, 22:6) in human plasma. Some LPC species are selectively transported across the blood brain barrier (BBB) by Mfsd2a, a member of the major facilitator superfamily of proteins, and furthermore converted into the n-3 fatty acid docosahexaenoic acid (DHA), suggesting that their increased plasma presence in response to vitamin E may indirectly lead to changes in DHA-mediated signaling and gene expression in the brain. The importance of adequate uptake of LPC-DHA by Mfsd2a for brain growth and function was demonstrated both in zebrafish and in humans in which mutations in Mfsd2a were associated with a microcephaly syndrome.

In the retina of vitamin E deficient  $\alpha$ TTP-knockout mice, an age-related decrease of n-3 PUFA was detected that was more pronounced when compared to controls, suggesting enhanced PUFA peroxidation and accelerated retinal degenerative damage. Alternatively, vitamin E may act indirectly by increasing LPC-DHA levels in plasma with consequent increased transport of LPC-DHA in the eye relevant for the development of photoreceptor discs.

Taken together, the efficiency of uptake, transport and metabolism of vitamin E and PUFA, their interaction and their consequent relative levels in cells and tissues may act as important determinants for both physiological and patho-physiological cellular functions and therefore influence the risk for a number of diseases such as atherosclerosis, inflammation, chronic heart failure, rheumatoid arthritis, retinal degeneration, allergies and neurodegenerative disorders.

### Molecular mechanisms of vitamin E absorption, metabolism and excretion

Differential transport, retention and metabolism of natural  $\alpha$ T over the other 7 vitamin E analogs is believed to be the main reason for the essential role of only  $\alpha$ T (Fig. 4) (Kono and Arai, 2015).

The absorption of the vitamin E analogs in the intestine is affected by several dietary factors (food matrix, fat, micronutrients) that facilitate emulsification and mixed micelles formation, and in the case of stabilized  $\alpha$ TA is dependent on hydrolysis by intestinal and pancreatic esterases. Passage across the intestinal epithelium follows a similar route as fatty acids, and recent research has highlighted the involvement of scavenger receptors such as CD36 and SR-BI, as well as intracellular lipid transporters such as Niemann-Pick -C1 like 1 (NPC1L1), fatty acids binding proteins (FABPs) and tocopherol associated proteins (TAP1/2/3) (Reboul, 2018). The eight natural vitamin E analogs and also synthetic *all-rac*- $\alpha$ T are taken up across the intestinal epithelium with similar efficiency ranging from 10 to 80%. Distribution to peripheral cells of these vitamin E analogs coming from the intestine is mediated by chylomicrons (and in part also from high density lipoproteins (HDL)), and chylomicron remnants bring the remainder to the liver. In the liver,  $\alpha$ T (preferentially *RRR*, but less also *RSR*, *RRS* and *RSS*-side chain isomers, the so-called 2*R*- $\alpha$ T-stereoisomers (Fig. 3)) are recognized by  $\alpha$ TTP, retained and incorporated into VLDL, leading to an up to 50 fold enrichment of  $\alpha$ T in plasma.

**Fig. 4** Uptake, distribution, metabolism and secretion of different natural and synthetic vitamin E analogs and the most important genes involved. The eight natural vitamin E analogs ( $\alpha$ T,  $\beta$ T,  $\gamma$ T,  $\delta$ T and  $\alpha$ TT,  $\beta$ TT,  $\gamma$ TT,  $\delta$ TT) are present in the diet in different quantities, and upon formation of mixed micelles are absorbed by the intestine with similar efficiency. Intestinal and pancreatic esterases convert the stabilized vitamin E form ( $\alpha$ TA) present as precursor in many supplements into  $\alpha$ T before it can be taken up by the intestine. Transport of the eight vitamin E analogs across the intestinal epithelium is mediated by transport proteins (MTTP, NPC1L1, ABCA1/G1, SR-BI, CD36), after which they are secreted within chylomicrons to the blood stream. Lipoprotein lipase (LPL) releases the vitamin E analogs from chylomicrons to the cells in peripheral tissues. Several proteins (SR-BI, CD36, LDLR, afamin, albumin) facilitate uptake of the vitamin E analogs into cells in which they are transported by  $\alpha$ TTP, TAP1/2/3 or SEC14L2/3/4, respectively, and secreted by ABCA1/G1. The liver takes up vitamin E from chylomicron remnants and LDL/HDL via LDLR, SR-BI and CD36. In the liver,  $\alpha$ T (preferentially *RRR*- $\alpha$ T, but also all the 2*R*- $\alpha$ T stereoisomers) is selectively recognized by  $\alpha$ TTP, enriched (~50x) and incorporated into very low-density lipoproteins (VLDL), whereas the other vitamin E analogs ( $\beta$ T,  $\gamma$ T,  $\delta$ T, excess *RRR*- $\alpha$ T, the 2*S*- $\alpha$ T stereoisomers, and the four tocotrienols) are metabolized by CYP3A/CYP4F2 and secreted in urine and bile involving MDR2. Uptake and transport is most efficient for the natural *RRR*- $\alpha$ T stereoisomer, less for the 2*R*- $\alpha$ T stereoisomers and the other seven vitamin E analogs, whereas the synthetic 2*S*- $\alpha$ T stereoisomers are inefficiently recognized by  $\alpha$ TTP and become metabolized in the liver. The 2*R*- $\alpha$ T stereoisomers are preferentially transported to the brain (blood brain barrier), to the embryo/fetus (endometrial glands, placenta) and to the newborn (mammary glands). In tissues, the vitamin E analogs differently affect several signal transduction pathways leading to changes in the activity of several transcription factors (TF). Polymorphisms within these genes involved in uptake, transport, distribution and metabolism can play a role in vitamin E bioavailability and bioactivity and thus can also influence signaling and gene expression.

After a postprandial peak, the other seven vitamin E analogs, excess  $\alpha$ T and the so-called 2S- $\alpha$ T-stereoisomers (Fig. 3) are metabolized and excreted, explaining their differential efficiency of cellular uptake, transport, intracellular distribution, and conversion to different metabolites. Metabolism of  $\gamma$ T in  $\alpha$ TTP knockout mice is still higher than that of  $\alpha$ T suggesting increased recognition by metabolic enzymes and not differential transport as reason for metabolic discrimination of non- $\alpha$ T analogs, albeit binding to  $\alpha$ TTP protected to some degree  $\gamma$ T from being metabolized *in vitro*.

Some non- $\alpha$ T analogs, such as  $\gamma$ T occur in relatively high amounts in adipose tissue, muscle and skin, suggesting passive partition into lipid-rich environments after post-prandial increase of these analogs in plasma or possibly to some extent also selective transport. In these tissues,  $\gamma$ T may have regulatory effects, for example on inflammatory processes as it inhibits cyclooxygenase-2 (COX2) activity, leading to decreased prostaglandin E2 (PGE2) production. Likewise, in a mouse model for Parkinson's disease,  $\gamma$ T prevented damage to dopaminergic neurons by treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) better when compared to  $\alpha$ T. When vascular and lymphatic endothelial cells were exposed to physiological levels of  $\alpha$ T,  $\gamma$ T, or  $\delta$ T (0–40  $\mu$ M), no toxicity was observed but  $\delta$ T was more potent to limit cell behaviors related to inflammation/angiogenesis.

Intestinal epithelial cells may be more exposed to the different vitamin E analogs present in the diet. In adult and fetal-derived intestinal epithelial cell lines, the peroxy radical-induced membrane oxidation and inflammatory response were prevented by the vitamin E analogs in the order  $\delta$ T >  $\gamma$ T >  $\alpha$ T. Interestingly, at concentrations of 50–100  $\mu$ M apoptosis-induced cytotoxicity was increased by  $\delta$ T and  $\gamma$ T, whereas  $\alpha$ T was not cytotoxic. These results point out an important role of the non-essential dietary vitamin E analogs during their absorption by the intestine, at least until they become metabolized and eliminated by the liver.

Vitamin E transport to the brain involves recognition of HDL by SR-BI expressed in the microvascular endothelial cells of the BBB (Fig. 4) (Lee and Ulatowski, 2019). Vitamin E is incorporated into HDL either by exchange from LDL by the phospholipid-transport protein and cholesterol-ester transport proteins (PL-TP, CE-TP, respectively), or to a lower degree by transport from cells via ABC transporters A1 and G1 (ABCA1/G1). It is likely that the preference of the BBB for HDL limits the access of the non- $\alpha$ T analogs and non-natural stereoisomers to the brain, as found in infant rhesus macaques, rats as well as humans. Accordingly, during mouse neurodevelopment, the brain preferentially acquires the 2R- $\alpha$ T over 2S- $\alpha$ T stereoisomers (Traber, 2020).

Vitamin E secretion by endometrial glands and transplacental transport are important for proper development of the embryo and fetus and may involve selective recognition of RRR- $\alpha$ T by  $\alpha$ TTP and TAP1/SEC14L2 that are expressed at the placental interface. By comparing vitamin E levels in maternal and umbilical cord plasma, preferential transport of natural RRR- $\alpha$ T over synthetic S- $\alpha$ T was observed, albeit measurable levels of S- $\alpha$ T were also detected.

In human milk, RRR- $\alpha$ T is the predominant stereoisomer suggesting selective transport and secretion by epithelial cells of the mammary glands. In fact, several vitamin E transport and metabolic genes ( $\alpha$ TTP, TAP1/SEC14L2, CYP4F2) are expressed in bovine as well as human mammary gland tissues and are possibly involved in selective transport to milk to provide vitamin E to the newborn. Whether a similar selective transport occurs in other glands (e.g., sebaceous, salivary or lacrimal glands) needs to be determined.

## Vitamin E deficiency

Mutations in a number of genes involved in vitamin E uptake and distribution leading to defective transport of  $\alpha$ T are responsible for primary and secondary vitamin E deficiency disorders in humans. Vitamin E plasma levels below  $\sim$ 12  $\mu$ M are regarded as deficient, with an average normal level of about 23  $\mu$ M. In humans severe vitamin E deficiency with plasma  $\alpha$ T concentrations below  $\sim$ 2  $\mu$ M and full neurological symptoms is a rare familial disease usually resulting from mutations of the  $\alpha$ -tocopherol transfer gene ( $\alpha$ TTP) leading to ataxia with vitamin E deficiency (AVED). The symptoms in these patients include ataxia, peripheral neuropathy, dysarthria, vibratory and proprioceptive sensory loss, loss of neurons, retinal atrophy, massive accumulation of lipofuscin in neurons and retinitis pigmentosa. Supplementation with high doses of vitamin E (up to 2000 mg/day) can prevent the symptoms of AVED.

More frequent than severe vitamin E deficiency is vitamin E insufficiency as result of suboptimal dietary vitamin E supply and inefficient uptake and distribution of vitamin E. A low efficiency of vitamin E uptake can occur with certain diseases, like cystic fibrosis, abetalipoproteinemia, chronic cholestatic liver disease, short-bowel syndrome, chronic pancreatitis, progressive systemic sclerosis, or several other lipid malabsorption syndromes as well as patients with total parenteral nutrition. In these cases, the symptoms can be prevented/reversed by supplemental vitamin E.

The human plasma average  $\alpha$ T concentrations (22–28  $\mu$ M) are about 10–100 times higher than that of the not-retained analogs ( $\gamma$ T ( $\sim$ 2.5  $\mu$ M),  $\delta$ T ( $\sim$ 0.3  $\mu$ M), tocotrienols ( $\sim$ 1–5  $\mu$ M)). It can be assumed that at these nanomolar and low micromolar concentrations the “non-essential” vitamin E analogs either support the function of  $\alpha$ T or exert regulatory effects on their own. Vitamin E levels in plasma may not be the only relevant measure for vitamin E adequacy, since the main biological function is thought to occur in tissues (Traber, 2014). The tissues with the highest  $\alpha$ T contents are adipose tissue (150  $\mu$ g/g tissue) and the adrenal glands (132  $\mu$ g/g tissue), other organs (e.g., brain, kidney, heart or liver) contain between 7 and 40  $\mu$ g/g tissues, whereas erythrocytes contain only 2  $\mu$ g/g tissue. RRR- $\alpha$ T is usually the analog with the highest concentration in tissues, with some exceptions such as skin, adipose tissue and muscle where  $\gamma$ T can also be high (reviewed in (Zingg and Azzi, 2004)). It remains to be elucidated whether these differences in the relative amounts of the different tocopherols are the result of tissue specific mechanisms for enrichment and/or storage and are involved in a tissue-specific regulatory functions.

## Molecular mechanisms of vitamin E action

Over the last decades, both, the essential function of vitamin E ( $\alpha$ T) as well as non-essential, associated functions of the other vitamin E analogs has been extensively studied. However, most studies addressing the molecular mechanisms of action have been done in cell culture models and it remains to be resolved whether they represent physiological events occurring also *in vivo* and to what degree they are responsible for the essentiality of vitamin E. In cultured cells and at equal concentration, not all of the regulatory effects can be explained by an antioxidant action of the eight vitamin E analogs and alternative, non-antioxidant roles have been proposed (reviewed in (Zingg and Azzi, 2004)). Differential regulatory effect of each vitamin E analog on signaling and gene expression are believed to be the consequence of specific binding of each vitamin E analog with different strenght to enzymes, transport and structural proteins, and transcription factors and/or result from vitamin E induced alterations of physical and structural properties of membrane lipid domains in which it is embedded (reviewed (Zingg, 2019)). Activity differences between natural vitamin E analogs observed in animal and human studies indicate that their regulatory effects on signaling and gene expression observed in cells also play a role *in vivo*.

The activity of several signal transduction enzymes is affected in a vitamin E analog specific manner leading to modulation of gene expression and cellular behavior, including proliferation, apoptosis, ferroptosis, auto-phagocytosis, survival, secretion, adhesion, migration, inflammation, immunity, senescence, tumorigenesis, metastasis and differentiation. In part as a consequence of modulating signaling enzymes, the activity of a number of transcription factors is modulated in a vitamin E analog specific manner (reviewed by (Rimbach et al., 2010)). Entire regulatory networks are affected by vitamin E suggesting that in many cases the observed regulatory effects may only represent secondary events, and a primary site for vitamin E signaling still needs to be identified. A selection of molecular mechanisms and targets by which the vitamin E analogs may affect signal transduction and gene expression is summarized in Table 1 (reviewed in (Galli et al., 2016; Rimbach et al., 2010; Mocchegiani et al., 2014; Jiang, 2017; Zingg, 2019)).

## Gene expression arrays, proteomics, metabolomics and lipidomics

With the advancement of novel techniques such as genome-wide gene expression arrays, RNAseq, proteomics, metabolomics and lipidomics new insights into the regulatory effects of vitamin E and its analogs have been achieved. Whereas initially it was thought that natural *RRR*- $\alpha$ T and synthetic *all-rac*- $\alpha$ T essentially share an identical transcriptional activity, e.g., when assessed in cultured HepG2 cells, a number of recent studies indicate that some differences can be detected *in vivo* in particular when genome-wide regulatory effects are assessed (reviewed in (Kim and Han, 2019)). Differential expression of a number of genes was observed in mouse T-cells supplemented with *RRR*- $\alpha$ TA and synthetic *all-rac*- $\alpha$ TA as well as *RRR*- $\alpha$ TA and *RRR*- $\gamma$ TA.

**Table 1** Molecular mechanisms by which vitamin E modulates signal transduction and gene expression.

Chemically scavenging reactive oxygen and nitrogen species (ROS and RNS, respectively), and prevention of peroxidation of lipids (PUFA, MUFA) in membranes and of their active lipid mediators
Redox regulation of signal transduction enzymes (e.g., protein kinase C (PKC) isoforms, protein phosphatase 2A (PP2A), protein tyrosine phosphatase 1B (PTP1B)), and transcription factors (e.g., nuclear factor erythroid-derived 2-like 2 (NRF2), nuclear factor kappa B (NF $\kappa$ B))
Changing plasma membrane properties, such as membrane stability, curvature, fluidity, permeability, composition, membrane microdomains (lipid rafts/non-rafts), modulation of Ca <sup>2+</sup> influx and Ca <sup>2+</sup> -mediated signaling, membrane repair
Direct binding to and modulation of enzymes involved in signal transduction and in production of active lipid mediators (e.g., protein kinase C alpha (PKC $\alpha$ ), phospholipase A2 (PLA2), 5-, 12-, 15-lipoxygenase (5-, 12-, 15-LOX), cyclooxygenase 1 and 2 (COX-1, COX-2))
Direct binding to transport proteins involved in signal transduction (e.g., CD36/FAT scavenger receptor/fatty acids transporter, tocopherol associated proteins 1, 2 and 3 (TAP1/SPF/SEC14L2, TAP2/SEC14L3, TAP3/SEC14L4, respectively), $\alpha$ -tocopherol transfer protein ( $\alpha$ TTP))
Modulation of membrane-protein interaction and protein translocation to the plasma membrane (e.g., protein kinase C alpha (PKC $\alpha$ ), pleckstrin homology domain leucine-rich repeat protein phosphatase, isoform 1 (PHLPP1), diacylglycerol kinase alpha (DAGK $\alpha$ ), phosphatidylinositol-3-kinases alpha and gamma (PI3K $\alpha$ , PI3K $\gamma$ ), protein kinase B (PKB/Akt), phospholipase A2 (PLA2), phospholipase C (PLC))
Modulation of expression and cell surface exposition and function of membrane receptors such as CD36 and SR-BI scavenger receptor expression
Modulation of transport and conversion of lipids to signaling mediators (DHA), competition with uptake of hydrophobic vitamins A, D, and K and modulation of their regulatory function, modulation of mitochondrial fatty acids desaturases
Modulation of the activity of a number of transcription factors by various mechanisms (e.g., peroxisome proliferator-activated receptor gamma (PPAR $\gamma$ ), nuclear factor erythroid-derived 2-like 2 (NRF2), nuclear factor kappa B (NF $\kappa$ B), signal transducer and activator of transcription factor 3 (STAT3), RAR-related orphan receptor alpha (ROR $\alpha$ ), hypoxia-inducible factor 1 alpha (Hif1 $\alpha$ ), estrogen receptor beta (ER $\beta$ ), pregnane X receptor (PXR))
Conversion of vitamin E to active metabolites and lipid mediators (e.g., carboxyethylhydroxychromans (CEHC) and long-chain CEHC precursors (LC-CEHC), $\alpha$ -tocopherol quinone ( $\alpha$ TQ), $\alpha$ -tocopherol hydroquinone ( $\alpha$ THQ), 5-NO <sub>2</sub> - $\gamma$ T), $\alpha$ -tocopheryl phosphate ( $\alpha$ TP)
Modulation of cell proliferation, inflammation and apoptosis in cancer cells by modulating the activity of the MAPK and PI3K/Akt signaling pathways and of cyclooxygenase 1 and 2 (COX-1, COX-2) and of 5-lipoxygenase (5-LOX)
Modulation of <i>de novo</i> cholesterol synthesis by inhibition of $\beta$ -hydroxy- $\beta$ -methylglutaryl coenzyme A (HMG-CoA) reductase by different vitamin E analogs (tocotrienols > tocopherols)
Conversion of cytochrome c into a peroxidase by $\alpha$ -tocopheryl phosphate, induction of free radicals production and modulation of signaling

These genome-wide regulatory effects of different vitamin E analogs on gene expression may also lead to changes in the production of metabolites as detected by metabolomics and lipidomics, although direct interaction of vitamin E with metabolic enzymes may also contribute. Using non-targeted metabolomics, transcription factors involved in energy metabolism (PGC1 $\alpha$ , PPAR $\alpha$ , PPAR $\gamma$ ) were lower and CD36/FAT was higher in liver of vitamin E deficient rats, possibly leading to the observed decrease of glucose and increase in creatine, phosphocholine, and betaine. Similarly, in vitamin E deficient zebrafish (*Danio rerio*), energy metabolism and cognitive functions were dysregulated with increased oxidative stress resulting in elevated PUFA oxidation (especially DHA), altered brain phospholipids and lysophospholipids composition, mitochondrial dysfunction, depleted choline/methyl-donor and glucose levels and altered thiols and amino acids, and lipidomics suggested protective antioxidant effects of vitamin E. In humans, metabolomic profiling revealed increased levels of a number of LPC species in human plasma after vitamin E supplementation (400 mg/d RRR- $\alpha$ TA, for 4 wks) (Traber, 2020).

Transcriptomic profiling (RNAseq) identified over 1000 differentially expressed genes in SR-BI deficient mice with and without failure to close the neural tube during embryonic development. SR-BI plays a role in transport of vitamin E across the BBB and across the maternal-fetal interface, and mouse embryos lacking SR-BI fail to close the neural tube and show cephalic neural tube defects that can be prevented by vitamin E supplementation. In this study, using gene regulatory network analysis, the androgen receptor was identified as a candidate transcription factor regulating genes associated with the expression of several genes involved in neural development and lipid metabolism. Similarly, single-cell RNA-seq revealed changes in signaling in mechanosensitive dorsal root ganglion neurons with vitamin E deficiency involving phospholipase C (PLC), protein kinase C (PKC), diacylglycerol kinase (DAGK), inositol-3-phosphate (IP3), diacylglycerol, and Ca<sup>2+</sup> that may explain the symptoms of sensory neuropathy.

### Vitamin E and disease prevention

In addition to acting as an essential molecule for the prevention of diseases caused with vitamin E deficiency, animal models as well as humans studies have assessed the possible preventive effects of supplementation with vitamin E and its analogs against several diseases including atherosclerosis, non-alcoholic steatohepatitis (NASH), certain types of cancer, inflammation, respiratory infections (influenza, pneumonia), asthma, allergy, fibrotic diseases, diseases of the eye and neurodegenerative diseases such as Alzheimer's or Parkinson's disease (reviewed in (Hathcock et al., 2005; Jiang, 2017)). These studies are based on the observation that intake of vitamin E is generally below the RDA (Traber, 2014) and that vitamin E levels can be increased by extra dietary supplementation with no adverse effects (up to a certain level, e.g., 200–400 mg/day). However, whereas the beneficial effect of vitamin E have been mostly confirmed in animal studies, in humans the situation is less clear. Epidemiological studies indicating preventive effects of vitamin E against cardiovascular events, neurodegenerative disease, macular degeneration, and cancer were in general not confirmed by larger clinical intervention studies, with to date best evidence for a lower risk for diseases such as NASH, CVD, inflammation and immune-modulation in the elderly and prevention of infection, but with a higher risk for prostate cancer (reviewed in (Borel and Desmarchelier, 2016; Mocchegiani et al., 2014; Sozen et al., 2019; Nagashimada and Ota, 2019; Lewis et al., 2019)). In some meta-analyses of clinical studies, increased all-cause mortality was observed with higher doses of vitamin E supplementation, although this was not confirmed in later studies. Several factors may explain the often mixed outcome of these vitamin E supplementation studies, including the high levels of vitamin E already present at baseline, the various doses and duration of supplementation, the diet composition and presence of phytochemicals, micronutrients and other vitamin E analogs, environmental and patho-physiological circumstances that affect the level and action of vitamin E to various degree such as inflammation, infection, smoking or UV irradiation, and most importantly the presence of specific vitamin E related polymorphisms in the analyzed population.

Vitamin analogs that do not reach high concentrations in plasma may reach over time sufficient amounts in peripheral tissues or they may be converted to metabolites able to reduce the risk for diseases. In particular, these analogs may reach higher levels in the gastrointestinal tract and prevent intestinal inflammatory, autoimmune and allergic events or colon cancer. Moreover, these vitamin E analogs could modulate cells in the proximity of tissues that interface with the external environment (the epithelial surface of the skin, the gastrointestinal mucosa, the eye, and the respiratory system). As an example, the tocotrienols (TT) decreased scratching behavior, dermal thickening, and the serum histamine in a mouse model of atopic dermatitis. In IgE-sensitized and dinitrophenyl-BSA (DNP-BSA) stimulated rat RBL-2H3 mast cells,  $\gamma$ TT and  $\delta$ TT suppressed degranulation via inhibition of protein kinase C (PKC). In a model for canine atopic dermatitis with mastoparan-stimulated canine mastocytoma cells (C2), vitamin E (RRR- $\alpha$ T, 100  $\mu$ M) inhibited histamine, prostaglandin D2 (PGD2), and chymase release but the signaling pathways involved have not been resolved in detail.

### Polymorphisms relevant for vitamin E action

Polymorphisms in genes involved in uptake and distribution, oxidation, metabolism and action may contribute to the variability of individuals to respond to vitamin E and explain the often mixed outcomes of supplementation studies (Fig. 4) (Zingg et al., 2008; Mocchegiani et al., 2014; Borel and Desmarchelier, 2016). Among the genes relevant for vitamin E uptake and distribution, polymorphisms in  $\alpha$ TTP, TAP, CD36/FAT, SR-BI and ABCA1/G1 have been identified that influence the plasma and possibly tissue levels of vitamin E. Polymorphisms in apolipoprotein E (apoE) that are well known to influence the plasma lipid profile and inflammatory cytokine expression have been associated with higher levels of vitamin E in plasma but lower levels in tissues. Vitamin E

metabolic genes, such as LPL, MRP2, PXR, CYP3A4 and CYP4F2 are highly polymorphic (100 bp/coding SNP) and likely to influence inter-individual variation of vitamin E levels.

Some of these polymorphic genes (e.g., TAP1/2/3, CD36, PXR, PPAR $\gamma$ , SREBP2) play also a role in modulating signal transduction and gene expression and thus may affect the cellular responsiveness to vitamin E. The differential responsiveness to the anti-inflammatory effects of vitamin E has been associated with polymorphisms detected in cytokines genes. However, only few polymorphisms have been directly associated with regulatory effects of vitamin E and it remains to be further elucidated to what degree the presence of these polymorphisms translate into altered risks for diseases such as atherosclerosis, cancer and metabolic syndrome.

The elevated risk for prostate cancer observed in the SELECT study upon vitamin E supplementation has been associated with polymorphisms in  $\alpha$ TTP or TAP1, most likely as result of regulatory effects of these genes on vitamin E levels as well as on signaling and gene expression in the prostate. Alternatively, the elevated risk in response to vitamin E can be explained by modulating the biosynthesis of cholesterol/steroids by supernatant protein factor (SPF, also named TAP1) able to regulate squalene epoxidase or HMG-CoA reductase activity. Increased oxidative damage as result of activation of phase I activating cytochrome P<sub>450</sub> (CYP) enzymes involved in metabolism of polycyclic aromatic hydrocarbons (PAH) such as benzo[a]pyrene by high doses of vitamin E (*all-rac*- $\alpha$ TA) may also contribute to an elevated risk in the prostate.

The best studied polymorphism relevant for the bioavailability and bioactivity of vitamin E has been identified in the haptoglobin (Hp) gene (Somer and Levy, 2020). There are two Hp alleles, the Hp1 and Hp2, leading to 3 genotypes in the population, Hp1-1, Hp1-2, and Hp2-2 (estimated occurrence 15–18%, 46% and 38%, respectively). Haptoglobin is an important plasma protein relevant for the binding and clearing of free hemoglobin (Hb), a toxic oxidant molecule released during intravascular destruction of erythrocytes. Diabetic patients with the Hp2-2 allele have an up to five times higher risk for cardiovascular disease (CVD) since clearance of the Hp2-2/Hb complex by CD163 receptor on monocytes/macrophages is impaired resulting in increased oxidative stress and reduced plasma vitamin E and C levels. In fact, as revealed by retrospective analysis of the HOPE and WHS studies as well as of the prospective ICARE study, vitamin E-supplemented diabetic subjects with Hp2-2 may have a reduced risk for CVD complications (Somer and Levy, 2020). Thus, albeit the number of patients analyzed in these studies is relatively small, at least in diabetic patients the Hp2-2 polymorphism may be an important determinant for the preventive effects of vitamin E against CVD complications. Interestingly, reduction of oxidative stress may not be the only explanation for the preventive effects since the combination of vitamin E ( $\alpha$ T) with vitamin C (L-ascorbic acid) did not increase or even mitigated the protective effect of  $\alpha$ T on HDL oxidation.

The importance of certain SNPs on vitamin E status has been revealed in several candidate gene association studies (CGAS) and genome-wide association studies (GWAS) (reviewed in (Borel and Desmarchelier, 2016)). However, the readouts from these studies may be limited and only the most relevant gene variants may be detected, since often more than one SNP may be responsible and other regulatory mechanisms can have an influence (e.g., epigenetics, copy number variants, insertions/deletions, diet composition). Nevertheless, such studies may identify sub-populations of individuals at risk for low vitamin E uptake and molecular action that can be corrected using a personalized approach of vitamin E supplementation as a strategy to increase the benefits of vitamin E, as exemplified with diabetic subjects and the Hp2-2 allototype.

## Summary and conclusion

The diet contains eight natural vitamin E analogs but only one of them ( $\alpha$ T) has been selected during evolution of higher organisms to become essential. After a transient post-prandial peak, the other seven vitamin E analogs are metabolized and eliminated, but numerous *in vitro* and *in vivo* studies indicate that they can perform important vitamin E associated regulatory functions. Adequate levels of vitamin E in the body are maintained by first allowing access to all eight analogs by the intestinal epithelium and then by selective retention of mainly *RRR*- $\alpha$ T by the liver, and by specific metabolism of all the other tocopherols, tocotrienols, and of excess  $\alpha$ T. At a molecular level, natural and synthetic vitamin E analogs differently interact with membranes, enzymes and structural proteins and differently affect signaling and gene expression. Vitamin E analog specific cellular responses may also be the consequence of different efficiency of their cellular uptake and transport, intracellular distribution by tocopherol binding proteins, metabolism and secretion. Preferential transport across cellular barriers of *RRR*- $\alpha$ T is particularly relevant in the placenta, mammary glands and the brain. In that respect the brain represents a special organ, as it is separated by microvascular cells of the BBB with preferential transport of natural vitamin E. In the brain as well as in other organs, the balance between vitamin E with PUFA and their interactions are important during development and for the prevention of diseases associated with low vitamin E levels. Polymorphisms in genes related to vitamin E transport and action have been identified and may help to identify sub-populations of individuals at risk for low vitamin E status that can be corrected using a personalized approach of vitamin E supplementation.

## Key points

- Vitamin K is a term that includes phyloquinone and 10 menaquinone forms.
- Whereas phyloquinone is well characterized in the food supply, menaquinones have not been systematically analyzed, which limits their use in dietary assessment.
- Phyloquinone absorption is lipid-driven whereas less is known about absorption of menaquinones.
- All vitamin K forms serve as an enzyme cofactor and support gamma-carboxylation of vitamin K-dependent coagulation proteins. Multiple vitamin K-dependent extra-hepatic proteins exist but less is known about their role in human health.
- Non-enzymatic roles for vitamin K are emerging but the research is still in its infancy.
- Initial associations between vitamin K status and chronic diseases such as osteoporosis and cardiovascular disease have not been substantiated in randomized clinical trials.
- Because there are major gaps in knowledge regarding the relative intake and metabolism of the multiple dietary vitamin K forms, current dietary recommendations are approximations. It is unlikely that gut-derived menaquinones substantially contribute to the dietary requirement.

## Introduction

Vitamin K is a family of fat-soluble vitamins that share a common chemical structure and a common function. The discovery of vitamin K dates back to 1929, when Danish biochemist Henrik Dam observed hemorrhaging in chicks that were fed a diet free of fat and cholesterol. Dam deduced that removing lipid from the diet also removed an essential fat-soluble compound, which he termed “vitamin K” for koagulation (as spelled in German and Scandinavian languages). The structure of vitamin K was confirmed nearly a decade later by American biochemist, Edward Doisy, and in 1943, Dam and Doisy shared the Nobel Prize in Physiology or Medicine for their work in vitamin K (Suttie, 2009).

Of all the fat-soluble vitamins, vitamin K is the least studied in terms of its role in human nutrition. In part, this is driven by the assumption that vitamin K's role is to support normal coagulation, and among the general adult population, vitamin K-related coagulation disorders are rare. Until recently, many assumed that the human requirement for vitamin K was partially met by production of vitamin K by gut bacteria, hence was not considered a shortfall nutrient. There is no single validated biomarker for measuring overall vitamin K status, which has given rise to considerable confusion in the scientific literature regarding the interpretation of observational studies examining the associations between vitamin K status and health outcomes beyond that of normal coagulation. The purpose of this review is to provide an overview of vitamin K based on current scientific knowledge, its sources, biological functions, and role in human health and disease.

## Forms

The term vitamin K refers to 11 known forms. Each of the 11 naturally occurring forms of vitamin K have a common 2-methyl-1,4-naphthoquinone ring with a prenylated side chain. It is the length and saturation of the side chain that differs among the forms. Phylloquinone (historically referred to as vitamin K1) has a side chain containing four isoprenoid units, three of which are saturated. Menaquinones, of which there are at least 10 naturally occurring forms, have side chains with four to thirteen isoprenoid units, which are mostly unsaturated. The number of isoprenoid units in the side chain differentiates the menaquinone forms. For example, menaquinone-7 (MK7) has a side chain containing 7 isoprenoid units, whereas the side chain of menaquinone-4 (MK4) has 4 units (Fig. 1). Menaquinones are collectively referred to as vitamin K2, which has fostered some confusion in the literature because not all menaquinones are the same in terms of origin and function. Therefore, for the purpose of this review, we will only refer to the individual menaquinones to avoid further confusion. Menadione (historically known as vitamin K3) is a synthetic vitamin K precursor comprised of the naphthoquinone ring without a prenylated side chain.

## Sources

Phylloquinone is found in all photosynthetic plants, serving as an electron acceptor during photosynthesis. Its concentration is highly correlated with chlorophyll, which confers the green color of leaves. Hence, primary dietary sources of phylloquinone are green leafy vegetables and vegetable oils. Mixed dishes that are made with certain vegetable oils, such as soybean, canola or rapeseed, and olive, also contain appreciable amounts of phylloquinone (Tables 1 and 2) (Harshman et al., 2017). Most menaquinones are produced by bacteria, and in the food supply, MKs are found primarily in fermented foods. Because different bacteria can produce different MKs, the MK contents of fermented foods depend on the bacteria used in the fermentation process. For example, natto, a fermented soy food commonly consumed in some regions of Japan, is high in MK7 because the bacteria *natto bacillus* produces MK7. However not all bacteria produce menaquinones so it cannot be assumed that all fermented foods are rich in menaquinone content. MKs are found in some dairy foods and meats, in highly variable amounts that are also dependent on the fermentation process. MK contents of dairy foods are influenced by fat content of the food, with low fat dairy containing lower amounts of MKs. Being bacterially synthesized, MKs are also abundant in the gut microbiome, albeit in highly variable amounts. MK4 is unique among the MKs. Although it is produced in trace amounts by bacteria, it is found mainly in poultry and pork because it is synthesized from menadione, which is abundant in animal feed in certain geographical regions.

The USDA Food Data Central provides the phylloquinone contents of >40,000 foods in the US food supply. The database also provides the MK4 content of ~1200 foods, with more being incorporated. Food composition databases in Australia and the Netherlands include phylloquinone and menaquinones. Some databases, such as the Swedish and Finnish food composition databases,

Fig. 1 Forms of vitamin K.

**Table 1** Vitamin K contents of foods.

<i>Vitamin K form</i>	<i>Food</i>	<i>Amount per serving</i>
Phylloquinone	Collard greens, raw	157 µg/cup
	Spinach, raw	145 µg/cup
	Romaine lettuce	48 µg/cup
	Green peas, raw	36 µg/cup
	Soybean oil	26 µg/teaspoon
	Mayonnaise	23 µg/teaspoon
	Lasagna, cheese	21 µg/cup
	Olive oil	8.4 µg/teaspoon
	Stir fried rice, meatless	4.7 µg/cup
	Safflower oil	1 µg/teaspoon
Menaquinone-4	Corn oil	0.3 µg/teaspoon
	Pepperoni	35.4 µg/3 oz
	Hot dog, 5 inch	17.1 µg/hot dog
	Beef, cooked	0.17 µg/3 oz
	Chicken, cooked	35 µg/3 oz
	Cheddar cheese	11 µg/cup
Menaquinone-7	Cream cheese	1.3 µg/teaspoon
	Natto	360 µg/40 g

list vitamin K values without specification as to the individual vitamin K forms being measured. However, caution must be taken when comparing the phylloquinone and menaquinone contents of foods across databases because different analytical methods and sampling plans have been used for quantification. Moreover, since the MK content of the food supply is not yet well characterized, and food composition databases that differentiate the contents of individual MKs (other than MK4) are lacking, studies reporting intakes of specific MKs should be interpreted carefully.

## Absorption and metabolism

Phylloquinone is the major circulating form of vitamin K and has large inter- and intra-individual variances in response to intake. The factors contributing to this variance in circulating phylloquinone are still not well-characterized, although recent advances indicate that multiple lipid-related factors influence this large variability. Phylloquinone is absorbed from the diet following pathways of most dietary lipids, involving bile acids, pancreatic juices, mixed micelle formation, and uptake into enterocytes (Shearer and Newman, 2008). Whereas it was historically assumed that phylloquinone had passive absorption, current evidence suggests the Niemann-Pick C1-like 1 (NPC1L1), scavenger receptor class B type I (SR-BI), and a cluster of differentiation 36 (CD36) proteins all could be involved in the active transport of phylloquinone into the enterocyte. In the enterocyte, phylloquinone is then packaged into triglyceride-rich lipoproteins (TRLs) with other lipids and is exported from the enterocyte to the lymph for entry into circulation at the thoracic duct (Shearer and Newman, 2008).

**Table 2** Characterized vitamin K dependent proteins.

<i>Protein</i>	<i>Primary action</i>	<i>Tissue location</i>
Prothrombin (factor II)	Pro-coagulant liver	Liver
Factor VII	Pro-coagulant liver	Liver
Factor IX	Pro-coagulant liver	Liver
Factor X	Pro-coagulant liver	Liver
Protein C	Anti-coagulant liver	Liver
Protein S	Anti-coagulant liver	Liver
Protein Z	Anti-coagulant liver	Liver
Osteocalcin	Bone mineralization	Bone
Matrix gla protein	Calcification inhibitor	Bone, cartilage, other soft tissues
Gla-rich proteins	Calcification regulator	Universal
Gas 6	Ligand for tyrosine kinase Axl	Universal

Phylloquinone is predominantly transported with TRLs in circulation (Ellis et al., 2019), and its absorption seems to be a predominantly lipid-driven effect and not dependent on existing vitamin K status or non-dietary factors, such as age, sex, BMI, or percent body fat (Ellis et al., 2019). Through use of stable isotope tracers, it has been shown that phylloquinone absorption from food varies, in part, according to the meal composition or food matrix. Consistent with absorption of other fat-soluble vitamins, there is higher absorption of phylloquinone when consumed with fats. However, unlike other fat-soluble vitamins that are stored in the body, vitamin K is rapidly excreted. Vitamin K is catabolized to 5-carbon and 7-carbon aglycones, which can be measured in urine.

Less is known about the absorption and transport of MKs. In contrast to phylloquinone, menaquinones are not typically detected in circulation. Absorption of intestinally-synthesized MKs is questionable because the colon, where gut bacteria produce MKs, lacks the bile salts needed for fat-soluble nutrient absorption. Dietary MKs are presumed to be absorbed following pathways of other lipid-soluble nutrients (Shearer and Newman, 2008) so this relative absence of MKs in circulation erroneously led the vitamin K field to assume that phylloquinone was the predominant form in the diet. However, with new mass spectrometry techniques that have enabled more sensitive quantification of MKs in foods, it is now evident that menaquinones are as, if not more, abundant than phylloquinone in the human diet. This presents a conundrum in our understanding of vitamin K metabolism that has given rise to multiple competing theories regarding similarities and differences in the absorption and metabolism of the different vitamin K forms.

Reliance on the measurement of the parent form of vitamin K in circulation may result in an oversimplification in our understanding of vitamin K metabolism. There is also a lack of systematic terminology used in the literature so circulating measures of the parent vitamin form can be referred to as measures of absorption, transport, bioaccessibility and/or bioavailability, which further contributes to the confusion about the interpretation of the data. For example, based on the results of one study which compared post-prandial concentrations of phylloquinone and MK7 in blood of 15 healthy volunteers after ingestion of 1 mg of each vitamin dissolved in corn oil, in which MK7 had higher circulating concentrations compared to phylloquinone (Schurgers et al., 2007), some have claimed superior bioavailability of MK7. An alternative interpretation is that uptake of MK7 by tissues is relatively lower compared to phylloquinone. Unfortunately, no study has compared multiple forms of vitamin K in equimolar doses in humans, which limits the ability to interpret the relative absorption and bioavailability of individual vitamin K. Furthermore, stable isotope tracer studies have not yet been conducted in humans with menaquinones.

This concept of differences in absorption and transport and relative bioavailability among individual vitamin K forms has recently been challenged by the results of an animal experiment. Vitamin K tissue concentrations were measured in mice after they were fed a diet containing equimolar doses of isotopically labeled phylloquinone, MK4, MK7, or MK9 for one week. Surprisingly, this study found no differences in the absorption or transport of the different vitamin K forms studied. Furthermore, MK4 was the primary form of vitamin K in most tissues. As demonstrated through stable isotope technology, all the dietary forms of vitamin K were similarly converted to MK4, and the naphthoquinone ring of the MK4 originated from the dietary phylloquinone or menaquinone form. Except for the liver and intestine, in which the parent vitamin K form was predominant, MK4 was the only form of vitamin K detected in extra-hepatic tissues (Ellis et al., 2022). The conversion to MK4 involves side-chain cleavage, which liberates menadiene, followed by transfer a geranylgeranyl group, via the prenyltransferase UBIAD1 in target tissues (Nakagawa et al., 2010). That labeled MK4 was detected in the intestine of mice fed all the forms of labeled vitamin K, including MK4, indicates MK4 biosynthesis begins in the intestine and side chain cleavage is not specific to any particular form of vitamin K. However, the exact mechanism underlying side chain cleavage remains to be identified. Until such studies are complete, our knowledge of menaquinone absorption and transport remains speculative.

## Functions

### Enzymatic

Vitamin K's main function is as an enzymatic co-factor for the post-translational carboxylation of certain  $\gamma$ -carboxyglutamic acid (gla)-containing proteins, commonly referred to as vitamin K dependent (VKD) proteins. A vitamin K cycle is responsible for VKD protein carboxylation (Fig. 2). Dietary vitamin K (the quinone form) is reduced by the vitamin K epoxide reductase (VKOR), which then recycles the oxidized 2,3-epoxide vitamin K, for the cycle to continue. The reduced form of vitamin K is required for the post-translational glutamate carboxylase (ggcx) (Fig. 2). The glutamate carboxylase is responsible for the addition of a second carboxyl group to the glutamate amino acid residues, resulting in protein functionality (Suttie, 2009).

Vitamin K antagonists (i.e., warfarin) target the VKOR enzyme, thus inhibiting vitamin K recycling, which reduces the amount of vitamin K available for carboxylation of coagulation factors II, VII, IX, X and protein C and S (Suttie, 2009). A second gene, VKORC1L1, has been found to support the activity of VKOR, respond to vitamin K antagonists, and is present in extra-hepatic tissues. However, VKORC1L1 is unique in that it appears to be 50-fold more resistant to the antagonists, which may explain the low susceptibility of extra-hepatic tissues to vitamin K antagonism and a concomitant lack of effects on vitamin K-dependent proteins.

While the most studied VKD proteins are clotting factors synthesized in the liver, vitamin K and VKD proteins are also present in extrahepatic tissues, including bone, cartilage, and vascular tissue. Osteocalcin, which is produced by osteoblasts during bone formation, is the predominate non-collagenous protein in bone and is vitamin K dependent. Once carboxylated, osteocalcin has a strong affinity for binding calcium in the bone matrix. However, the precise function of carboxylated osteocalcin in bone is

**Fig. 2** Carboxylation of Vitamin K-dependent Proteins. The vitamin K hydroquinone is reduced to the vitamin K quinol, which serves as a cofactor to the  $\gamma$ -glutamyl carboxylase enzyme that carboxylates vitamin K-dependent proteins. As a result, the quinol is oxidized to vitamin K epoxide, which is reduced back to the quinone form (Shea and Booth, 2019).

unclear. Matrix gla protein (MGP) and Gla rich protein (GRP, also known as unique cartilage matrix-associated protein (UCMA)) are VKD proteins present in vascular tissue and cartilage, where they are involved in inhibiting mineralization. Additional VKD proteins have been identified in multiple extra-hepatic tissues (Suttie, 2009). However, little is known about the relevance of their carboxylation status because antibodies that differentiate the carboxylated from undercarboxylated forms of these proteins have not been developed.

Phylloquinone and menaquinones are capable of functioning as an enzyme co-factor, but the relative efficacy of the different vitamin K forms in carboxylation is not well understood (Shea et al., 2021). Some have proposed differentiating phylloquinone and menaquinone-dependent proteins. This proposition is based on phylloquinone being present in higher amounts in the liver, where clotting proteins are synthesized, while MK4 being more abundant in extra-hepatic tissues. However, menaquinones are also present in the liver (Suttie, 2009), and recent evidence indicates conversion of phylloquinone and different menaquinone forms to MK4 in the liver and extrahepatic tissues (Ellis et al., 2022). Therefore, the proposition that some VKD proteins require phylloquinone and others require menaquinones is not supported by current data.

### Non-enzymatic

Vitamin K is reported to have anti-inflammatory properties via pathways independent of carboxylation. In cell-culture, pretreatment of macrophages with phylloquinone, MK4, and MK7 suppressed the LPS induced production of IL6. In a follow-up experiment that only tested MK4, this effect was found to be through the NF $\kappa$ B signaling pathway. In osteoblast and osteoclast precursor cells, MK7 treatment suppressed the production of pro-inflammatory cytokines, also via the NF $\kappa$ B signaling pathway. In microglia-derived cells, MK4 suppressed the LPS-induced production of IL6, TNF $\alpha$ , IL1B and Cox2 and NF $\kappa$ B nuclear translocation. Microglia are involved in neuroinflammation and MK4 is the main form of vitamin K found in the brain.

MK4 is a ligand for the steroid and xenobiotic nuclear receptor (SXR) (also known as pregnane X receptor, PXR) and can regulate gene expression. In culture experiments using bone-derived cells, genes involved in bone formation and collagen accumulation (Ichikawa et al., 2006) were regulated by MK4 via SXR activation. In animal models, PXR deletion resulted in a phenotype consistent with osteopenia. In this experiment, the PXR, which is highly expressed in the liver and intestine where it functions in xenobiotic metabolism, was deleted systemically, so it is possible systemic effects were involved. Together these observations suggest vitamin K

is involved in cell-signaling and gene expression, but whether this function of vitamin K is relevant to human health or disease remains to be determined.

## Vitamin K dietary requirements

The current Adequate Intakes (AI) for vitamin K in North America are set at 90 µg/d and 120 µg/d for women and men respectively, 19 years and older. The European Food Safety Administration (EFSA) recommends 70 µg/d for all adults  $\geq 18$  years old. These recommendations are based on phyloquinone. In the US, current phyloquinone intakes approximate the AI, but the actual range of intake is wide and varies across age groups, geographic regions, and racial/ethnic groups (Harshman et al., 2017). On average, 43% of adult men and 63% of adult women consume the recommended AI for vitamin K, but the percentage of individuals meeting or exceeding the AI declines with age (Harshman et al., 2017). There are currently no dietary requirements specific to menaquinone intakes.

## Vitamin K status, health & disease

### Vitamin K status biomarkers

Nutritional status is commonly estimated using objectively measured biomarkers. In contrast to other micronutrients, there is not a single measure that is considered a gold-standard biomarker of vitamin K status. Instead, multiple measures are recommended to capture overall status, as reviewed in detail elsewhere (Shea and Booth, 2016). Phyloquinone, the main circulating form of vitamin K, changes in response to intake and serum/plasma phyloquinone has been used to rank individual's vitamin K status in population- and clinic-based studies globally (Shea and Booth, 2016). External quality assurance programs are available to standardize circulating phyloquinone assays and monitor inter-laboratory variation (Card et al., 2009), and indeed any laboratory measuring circulating phyloquinone should actively participate in this program to ensure accuracy of the reported measures. Menaquinones are not typically detected in circulation so have not been measured in many population-based studies. Pilot KEQAS schemes for MK4 and MK7 are available, which laboratories seeking to measure circulating MKs should participate in. Similar quality assurance programs for other MKs are not available, hence accuracy of these measures is uncertain.

The undercarboxylated fractions of three VKDPs are measurable in circulation. PIVKA (undercarboxylated prothrombin, or protein induced in vitamin K absence—factor II) increases in response to dietary vitamin K depletion or warfarin treatment. However, PIVKA does not generally reflect variation in vitamin K intakes in generally healthy individuals, which limits its utility as an indicator of vitamin K status in population-based studies. Serum undercarboxylated osteocalcin (ucOC) is considered a functional indicator of vitamin K status in bone and plasma dephospho-undercarboxylated MGP ((dp)ucMGP), a functional indicator of vitamin K status in vascular tissue or other tissues that use MGP. Both ucOC and (dp)ucMGP decrease in response to vitamin K supplementation and inversely correlate with circulating phyloquinone (Shea and Booth, 2016). In addition to vitamin K availability for carboxylation, the amount of undercarboxylated OC and MGP in circulation depends on synthesis of the protein. To reflect vitamin K status more accurately, ucOC and (dp)ucMGP should be corrected for the total amount of protein in circulation, which itself can vary based on factors independent of vitamin K. Validated assays are available to quantify total OC in circulation and ucOC is typically expressed as a ratio or percent of total OC (i.e., %ucOC). However, validated assays that quantify total circulating MGP are not commercially available, thereby limiting the use of (dp)ucMGP as a sole biomarker of vitamin K status (Shea and Booth, 2016).

### Vitamin K status in the newborn

Infants have low vitamin K stores due to poor placental transfer of vitamin K, low concentrations of vitamin K in breastmilk, and possibly insufficient vitamin K from gut microbiota. This renders newborns, particularly those born premature, at risk for vitamin K deficiency bleeding (VKDB) (Shearer, 2009). There is a two-pronged approach to address this potential deficiency: (1) prophylactic administration of vitamin K; and (2) phyloquinone fortification of infant formula. Prophylaxis, the dose and mode of which varies by country, confers effective protection for the first week of life (Sankar et al., 2016), after which feeding, and potentially vitamin K produced by the infant gut microbiota, contribute to the vitamin K status of the infant. Countries that do not offer vitamin K prophylaxis at birth have persistently higher rates of VKDB, although the data are incomplete in areas without a public health infrastructure. In the United States, there has been an episodic decline in parental approval for the vitamin K prophylactic shot at birth, in part due to persisting misinformation regarding its safety, and has resulted in an increase in VKDB cases. The daily intake of exclusively breastfed infants averages 1–2 µg/day phyloquinone, whereas formula-fed infants have an average intake of around 50 µg/day phyloquinone (Shearer, 2009). In preterm infants who received both vitamin K prophylaxis and phyloquinone supplementation through parenteral nutrition feeds, the presence of metabolites in serum and excretion of a less-metabolized vitamin K catabolite in urine were suggestive of a possible overload of both vitamin K recycling and metabolic pathways. These data were recently confirmed in a recent study of infant-mother dyads, in which high concentrations of unmetabolized phyloquinone were measured in feces of formula-fed infants. These observations raise the question that in the context of prophylaxis, what are the nutritional vitamin K requirements of the infant?

## Vitamin K status and chronic disease

While evidence is accumulating that vitamin K-dependent mechanisms underlie several chronic diseases, currently osteoporosis and cardiovascular disease are the most-studied.

The carboxylation of osteocalcin in bone provides a mechanistic link between vitamin K and skeletal health. A 2006 meta-analysis identified 13 vitamin K supplementation randomized clinical trials (RCTs) that evaluated BMD and 7 RCTs that evaluated fracture as outcomes (Cockayne et al., 2006). The summarized results suggested benefit of vitamin K supplementation with respect to bone mineral density. It was later determined that the results of several of the early RCTs were compromised by allegations of research misconduct and indeed these trials have been retracted in the literature. In 2019, the meta-analysis was updated to exclude the discredited trials and add new trials completed since 2006. The updated results did not support a beneficial effect of vitamin K supplementation with respect to bone mineral density (Mott et al., 2019). There was some indication of a potential protective effect with respect to clinical fracture, but data were too sparse to draw definitive conclusions. Most trials provided 45 mg of MK4, which is used pharmaceutically as an anti-osteoporotic medication in some Asian countries, such as Japan. This dose is not attainable by diet alone, no matter what form of vitamin K is consumed. Nutrient supplementation is most likely to benefit individuals with lower nutrient status at baseline, yet none of the available vitamin K supplementation RCTs screened individuals for low baseline vitamin K status. It is also possible that certain segments of the population may derive more benefit from vitamin K supplementation than others. However, it is unlikely that vitamin K supplementation will have a meaningful effect on bone health in individuals with replete calcium and vitamin D status. Characteristics related to bone quality, such as bone material properties or microarchitecture, effect fracture risk independent of bone mineral density. It is possible vitamin K and osteocalcin are involved in fracture through mechanisms not reflected by BMD. However, corroborative research is needed in this area.

Coronary artery calcification (CAC) is a subclinical manifestation of atherosclerotic CVD and higher CAC is associated with a higher risk for clinical CVD events, such as myocardial infarction. MGP and GRP can inhibit arterial calcification when carboxylated, which requires vitamin K. Several observational studies have associated higher circulating (dp)ucMGP and/or lower circulating phylloquinone (both reflective of lower vitamin K status) with less CAC and a lower risk for CVD. However, as reviewed in detail elsewhere (Shea et al., 2021), not all studies agree. Some have suggested MK7 has unique cardioprotective properties based mainly on observational studies which reported higher MK intakes were associated with less CAC and a lower CVD risk. A recently completed systematic review and meta-analysis identified nine RCTs that tested the effect of vitamin K supplementation on subclinical CVD, the majority of which evaluated vascular or valvular calcification and also reported changes in (dp)ucMGP (Vlasschaert et al., 2020). Six trials provided MK7 and three provided phylloquinone supplements, with follow-up ranging from 6 months to 3 years. Both MK7 and phylloquinone supplementation consistently reduced plasma (dp)ucMGP, although the magnitude of the reduction varied considerably (Shea et al., 2021). However, reductions in plasma (dp)ucMGP were not accompanied by reductions in arterial calcification, thereby challenging the clinical importance of lowering plasma (dp)ucMGP, at least with respect to CVD. Individuals with chronic kidney disease (CKD) frequently develop arterial calcification and are reported to have lower vitamin K status and so were thought to particularly benefit from vitamin K supplementation. However, the results of RCTs that evaluated the effect of vitamin K supplementation on vascular calcification in patients with CKD have been mainly null. The available evidence when considered altogether does not support a benefit of vitamin K with respect to CVD, even among high-risk patient populations.

## Vitamin K and the gut microbiome

Bacteria residing in the human gut produce menaquinones, but the relevance of gut-derived menaquinones to the vitamin K function and health of the human host is still speculative. Within the gut microbiota, menaquinones play critical roles in bacterial energy metabolism as electron carriers in microbial respiration, yet some bacterial taxa have lost key genes in menaquinone. Menaquinones secreted by some human gut bacterial species act as a growth factor for neighboring bacteria with incomplete menaquinone synthesis pathways, suggesting menaquinones may be an important commensal factor in the human gut microbiota, so gut-derived menaquinones may also influence human health indirectly through modulation of the gut microbial composition.

In female mice, dietary vitamin K deficiency altered the intestinal menaquinone profile, but dietary supplementation with phylloquinone, MK4 or MK9 did not. Similar trends were observed in males, but statistical significance was not reached (Ellis et al., 2021). These findings suggest the amount, rather than the form, of vitamin K in the diet influences intestinal microbial composition. In humans, there appear to be two dominant menaquinone profiles in the gut microbiome, such that individuals tend to either have greater abundance of *Prevotella* spp. and be rich in MK5 and MK11-13, or have greater abundance of *Bacteroides* spp. and be rich in MK9-10. These menaquinone profiles do not appear to change in response to dietary interventions not designed to alter vitamin K intake nor is it known what the implications are for these groupings with respect to overall vitamin K status. More research is needed to elucidate the role, if any, of gut-derived menaquinones in human health.

## Conclusion

Vitamin K remains one of the few essential nutrients for which there are insufficient data from which to generate a dietary requirement. Whereas its biochemical role as an enzyme cofactor is well characterized with respect to supporting normal coagulation, and

among the general adult population, vitamin K-related coagulation disorders are rare. Vitamin K prophylaxis is also widely and successfully used to prevent vitamin K deficiency bleeding among newborns who are vitamin K deficient. Unfortunately, there is no single validated biomarker for measuring overall vitamin K status, which has led to an abundance of conflicting theories regarding the relative contribution of the multiple dietary vitamin K forms to health outcomes beyond that of normal coagulation. The production of vitamin K by gut bacteria does not appear to be a major contributor to vitamin K status of the host but may have other roles critical to gut health. There is indeed growing evidence that vitamin K has biochemical and physiological roles beyond that of an enzyme cofactor. However, there are still many gaps in knowledge that need be addressed prior to establishing dietary requirements for vitamin K.

## Glossary

**Bioavailability** The proportion of the nutrient content of a food or meal that is absorbed and retained.

**Phytate : zinc molar ratio** The molar ratio between phytate (molecular weight 660 g mol<sup>-1</sup>) and zinc (molecular weight 65.4 g mol<sup>-1</sup>) and is used to estimate the bioavailability of zinc in food and mixed diets.

**Phytic acid** Myo-inositol hexaphosphate, the principal storage form of phosphorus in many plants and the major inhibitor of zinc absorption (also described as phytate).

**Zinc** A trace element essential for the human body as it required for the activity of >100 enzymes involved in most major metabolic pathways.

**Zinc deficiency** Lack of sufficient zinc to meet the physiological requirement.

## Causes of Zinc Deficiency

As with other micronutrient deficiencies, four main factors are responsible for the development of zinc deficiency in lower-income countries: inadequate dietary zinc intake; poor zinc absorption from high-phytate, plant-based diets; disease states that either induce excessive losses or impair utilization of zinc; and physiological states that increase zinc requirements, such as the periods of rapid growth during childhood and pregnancy.

Adequate zinc nutrition is essential for human health because of zinc's critical structural and functional roles in multiple enzyme systems that are involved in gene expression, cell division and growth, and immunologic and reproductive functions.

### Inadequate Dietary Zinc Intake

Inadequate dietary intake of absorbable zinc is one of the major causes of zinc deficiency. Animal-source foods, in particular shellfish, small whole fish, beef, and organ meats such as liver and kidney, are rich sources of zinc. Plant-source foods, such as most fruits and vegetables including green leaves, and starchy roots and tubers, have relatively low zinc content. Although whole grains, nuts, and legumes have moderate to high zinc content, these foods also contain large quantities of phytate (phytic acid or myo-inositol hexaphosphate), the most potent identified dietary inhibitor of zinc absorption.

Plants synthesize phytate, which occurs in highest concentrations in seeds and to a lesser extent in vegetative plant parts. Phytate forms chelates with zinc and other minerals, making these minerals less available for absorption. The inhibitory effect of phytate on zinc absorption appears to follow a dose-dependent response, and the phytate : zinc molar ratio can be used to estimate the proportion of absorbable zinc. The phytate : zinc molar ratio of foods or diets is calculated as follows, where 660 equals the molecular weight of phytate and 65.4 the molecular weight of zinc:

$$\frac{\text{mg phytate}/660}{\text{mg zinc}/65.4}$$

The zinc and phytate content, and the phytate : zinc molar ratio in some foods are shown in **Table 1**. If information on the phytate content of the diet cannot be calculated, then diets can be categorized as having low or average zinc bioavailability based on certain dietary characteristics. For example, unrefined cereal and/or legume-based diets generally have phytate : zinc ratios >18, which is associated with relatively low zinc bioavailability. In contrast, mixed diets containing higher amounts of animal-source foods and less plant-source foods, or refined plant-based diets generally have phytate : zinc ratios between 4 and 18, which are associated with higher zinc bioavailability.

### Other Causes of Zinc Deficiency

Under normal physiological conditions, zinc is secreted into the intestine in large quantities together with digestive juices, but is largely reabsorbed. Diarrhea may not only lead to a reduced absorption of dietary zinc during the episode due to decreased intestinal transit time, but may also cause an increase in the loss of endogenous zinc. Given the important role of the intestine in

**Table 1** The average content of zinc and phytate, and the phytate : zinc molar ratio in uncooked foods

<i>Food</i>	<i>Zinc (mg per 100 g)</i>	<i>Phytate (mg per 100 g)</i>	<i>Phytate : zinc molar ratio</i>

Milk	0.4	0	—
Pork	1.9	0	—

regulating dietary zinc absorption, and the secretion and reabsorption of endogenous zinc during digestion, conditions that affect the health or integrity of the intestine, such as tropical enteropathy, could interfere with the adequate maintenance of zinc balance. The contribution of these conditions to zinc deficiency in lower-income countries requires investigation.

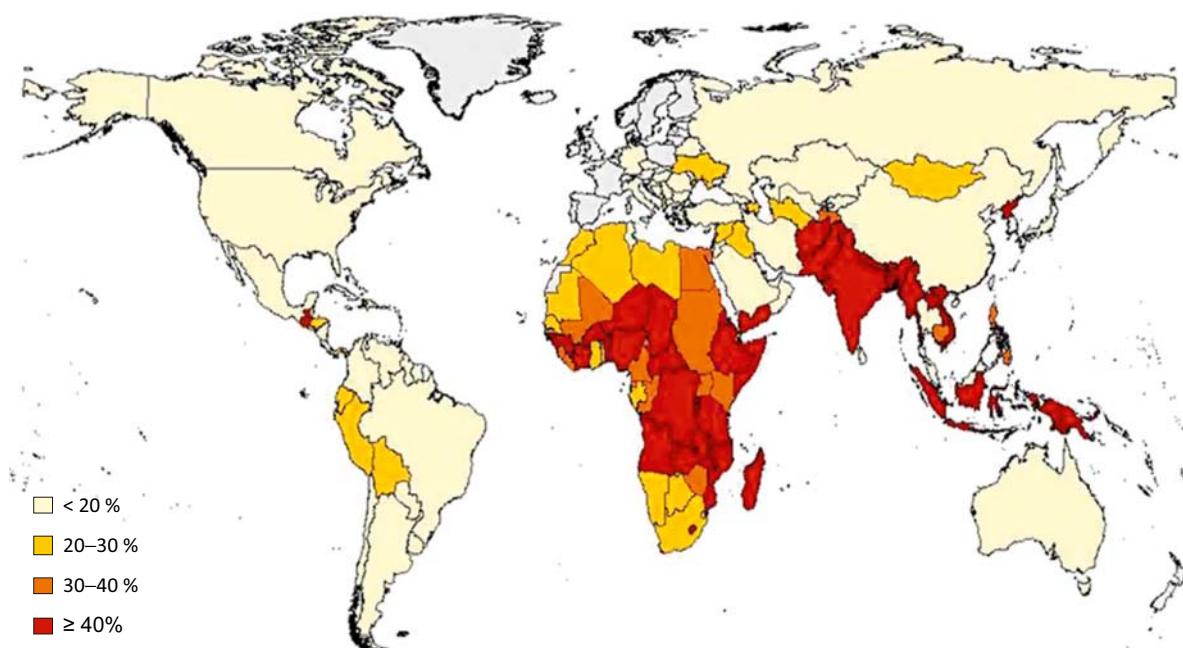

### High Physiological Requirements

In accordance with age and physiological status, some population groups have increased daily physiological requirements for absorbed zinc. During growth and pregnancy, the incorporation of zinc into newly synthesized tissue requires relatively larger amounts of zinc daily. Similarly, the amount of zinc transferred from mother to infant in breastmilk must be added to the lactating women's physiological requirement for absorbed zinc. These increased needs for zinc add to the challenge of acquiring sufficient amounts of absorbable zinc from the food supply. Those groups with higher zinc requirements and who are thus at elevated risk of zinc deficiency include: infants (particularly those born prematurely), young children, children recovering from severe malnutrition or diarrhea, adolescents, and pregnant and lactating women. Some evidence exists for the occurrence of zinc deficiency among each of these groups in lower-income country settings.

The elderly may also be at elevated risk of zinc deficiency, due to a decline in zinc intakes and possibly a reduction in the absorption of dietary zinc. However, evidence for zinc deficiency among the elderly has thus far only been reported from industrialized countries; studies are needed among elderly populations in lower-income countries.

### Prevalence of Zinc Deficiency in Developing Countries

Guidelines on the assessment of population zinc status were recently published following a consensus conference convened by the World Health Organization (WHO), the United Nations Children's Fund (UNICEF), the International Atomic Energy Agency (IAEA), and the International Zinc Nutrition Consultative Group (IZiNCG). The three main types of zinc status assessment that were considered included biochemical, dietary, and functional methods. Because so little information is available from nationally representative surveys on the prevalence of low serum zinc concentration or inadequate dietary zinc intake, current estimates of the extent of risk of zinc deficiency must rely on the prevalence of stunting among children less than 5 years of age. Approximately 30% of children less than 5 years of age worldwide are stunted (height-for-age Z-score  $< -2$  SD with respect to the distribution of the reference population data). WHO recommends a prevalence of stunting greater than 20% of the population to indicate a public health concern. The highest prevalence rates of stunting ( $>30\%$ ) are observed in countries in sub-Saharan Africa, South Asia, Southeast Asia, and Central America. Intermediate prevalence rates (20–30%) are found in the Andean countries, some Central American countries, Southern Africa, and some countries in North Asia. As zinc deficiency is not the only factor affecting children's growth, assessment of dietary zinc intake and serum zinc levels should be used to confirm the risk of zinc deficiency in these countries. (Figure 1)

**Figure 1** Prevalence of nutritional stunting in children under 5 years of age. Data derived from WHO or most recent Demographic Health Surveys. <http://www.izincg.org/stunning>

## **Consequences of Zinc Deficiency in Developing Countries: Evidence Derived from Zinc Supplementation Trials**

In the context of developing country settings, present knowledge on the health consequences of zinc deficiency has been almost entirely derived from community-based trials of zinc supplementation among populations at possible risk of zinc deficiency. In these trials, individuals in the study population are randomly allocated to receive either a zinc supplement, usually in the form of tablets or syrups, or the same supplement format without zinc (i.e., placebo). The condition under study is then monitored for a given period (typically for 2 months to 1 year), and the occurrence of or change in the condition is compared between the zinc-supplemented group and the corresponding control group. Given that several other nutritional and environmental factors can influence the health conditions hypothesized to occur with zinc deficiency, such studies have been essential in demonstrating unequivocally the causal role of zinc deficiency in these conditions among human populations. The following section provides an overview of the population groups at elevated risk of zinc deficiency, and the health consequences associated with zinc deficiency, as concluded from these studies.

### **Child Growth**

Zinc plays an important role in child growth. Several mechanisms may be involved, including the role of zinc in the transcription and translation of genetic material and perhaps more importantly, the regulatory role of zinc in the endocrine system, which controls growth (i.e., the growth hormone–somatomedin axis). Specifically, zinc status is associated with the concentration of circulating insulin-like growth factor-1, the principal growth factor that controls early childhood growth. Among populations where growth restriction occurs, both height and weight gain have improved following supplemental zinc. Stimulation of linear growth appears to be the primary response, while the increase in body weight likely reflects the synthesis of lean tissue, such as bone, cartilage, and muscle, associated with linear growth. This is evident because, in general, weight does not increase independently of improved height in response to zinc supplementation.

According to a recent meta-analysis including 37 studies in infants, preschool, and older prepubertal children, zinc supplementation produces a small, but significant increase in linear growth and weight gain. Zinc deficiency has been demonstrated to be an important limiting factor to the growth of children across a wide range of geographical settings in developing regions. However, it should be noted that not all the studies have demonstrated a significant, positive effect of zinc on growth. Possible explanations for this include: the prevalence or severity of growth stunting in the study communities was low, zinc status was adequate, or deficiencies of other growth-limiting nutrients coexisted thus preventing a positive effect of zinc on growth. The latter situation may also explain the observation in some studies of a transient effect of zinc on growth.

Low-birth-weight infants (<2.5 kg) may have additional needs for zinc, presumably to facilitate their rapid postnatal catch-up growth. Some benefits of supplemental zinc to growth have been observed among low-birth-weight infants in the first 6 months of life.

Severely malnourished infants and children have exhibited improved rates of weight gain, height gain, or synthesis of lean tissue when supplemental zinc has been included in their usual rehabilitation treatment regimen. In these recovering children, zinc has been shown to augment the deposition of lean tissue by increasing protein synthesis. Thus, the inclusion of zinc among other micro-nutrients is recommended by WHO in the treatment of severely acute malnourished children.

### **Morbidity and Mortality**

Zinc is involved in many aspects of the immune system, contributing both to specific and nonspecific immune functions. Zinc has an important role in both the prevention and treatment of diarrhea, which may be mediated both through functions in immune competence and maintenance of the integrity of the intestine. Preventive zinc supplementation reduces the incidence of diarrhea by approximately 20% among children in lower-income countries, although the current evidence indicates that this beneficial effect of zinc may be limited to children greater than 12 months of age. Zinc also has therapeutic benefits for recovery from diarrheal infections. Overall, supplemental zinc provided to children during either acute or persistent diarrhea leads to a reduction in the duration and possibly the severity of the episode. It has been recommended that zinc should be used in the management of acute diarrhea, in conjunction with oral rehydration salt solution. Zinc deficiency appears to also be associated with an increased incidence of pneumonia. Present evidence from studies that diagnosed acute lower respiratory tract infections (ALRI) based on counting respiratory rate or a physician's examination indicates that preventive zinc supplementation reduces the incidence of pneumonia and ALRI in children by about 21%. Some studies also suggest that zinc supplementation reduces the incidence of malaria, although this remains uncertain because of the limited amount of evidence that is currently available. Based on recent reviews on the impact of zinc on mortality, zinc supplementation reduces the overall mortality rate in children by 6–9%. Similarly to the impact of zinc on diarrhea incidence, the benefits seem to be limited to children above 12 months of age in which the mortality reduction is approximately 18%.

### **Pregnancy**

Zinc requirements during pregnancy have been estimated from the zinc content of accrued tissues during pregnancy. In addition to the zinc transferred to the fetus, zinc is deposited in the placenta, amniotic fluid and uterine, and mammary tissue. The estimated

total additional zinc needed for pregnancy is approximately 100 mg. Few firm conclusions can be made as to the consequences of zinc deficiency during pregnancy on maternal, fetal, and infant health. Observational studies in human populations suggest that maternal zinc deficiency during pregnancy may cause adverse pregnancy outcomes for the mother and the fetus. However, results from zinc supplementation trials have been inconsistent and therefore difficult to interpret. This may be partly attributed to an inadequate study design or failure to consider the zinc status of the women studied. Nevertheless, a recent meta-analysis of supplementation trials indicates a 14% reduction in premature delivery among zinc-supplemented women.

## Zinc Intervention Strategies

There are numerous zinc intervention strategies available and all have their strengths and weaknesses. While some approaches are considered short-term solutions, others may require a longer period until successful and effective implementation is achieved. In some cases, a combination of these intervention strategies may be needed to ensure the prevention of zinc deficiency in the most vulnerable population groups.

### Preventive Zinc Supplementation

As described above, most of the evidences on the beneficial effects of zinc are derived from randomized controlled trials of preventive zinc supplementation and benefits include improved growth, reduced incidence of diarrhea, ALRI, and reduced all-cause mortality. Evidence to date shows no significant adverse effects on indicators of iron and copper status. It has been stated previously that zinc needs to be provided on a daily basis for an extended period of time, although weekly supplementation may also be beneficial. IZiNCG recommends a daily dose of 5 mg zinc for young children. Zinc supplementation is a short-term strategy that relies heavily on the availability of zinc supplements and individual compliance. The challenges for scaling up zinc supplementation programs are similar to those faced by other programs that attempt to procure and distribute nutritional supplements or medicines in lower-income countries. Several existing delivery platforms have been identified, which could be used for delivering preventive zinc supplements with or without other micronutrients. As these programs are being developed, monitoring and evaluation should be included to allow the required assessment of the program's effectiveness.

### Therapeutic Zinc Supplementation in the Treatment of Diarrhea

WHO and UNICEF recommend that zinc supplementation should be included as a component in the treatment of all cases of diarrhea. It is recommended to provide children with 20 mg per day of supplemental zinc for 10–14 days (10 mg per day for infants under six months old) along with oral rehydration salt solution and continued feeding. The aim is that the recommendations become routine practice both in the home and health-care facility and that caretakers will act quickly at the first sign of diarrhea. Efforts are underway to reinforce national diarrhea programs and scale up the inclusion of therapeutic zinc supplementation in many countries.

A recent analysis confirmed that there is strong evidence that therapeutic zinc supplementation during diarrhea decreases the duration of diarrheal episodes by ~0.5 day. To what extent the dose of supplemental zinc provided during diarrhea episodes can prevent zinc deficiency is uncertain. Although it is believed that therapeutic zinc supplementation has the potential to prevent future diarrhea episodes following diarrhea treatment, present evidence is weak.

### Food Fortification with Zinc

Food fortification is increasingly recognized as an effective approach to improve population's micronutrient status. Available absorption studies clearly show that zinc fortification can increase dietary zinc intake and total daily zinc absorption. Most studies also indicate that adding zinc to food does not adversely affect the sensory properties of the food or the absorption of other micronutrients, such as iron. However, despite the positive effect of zinc fortification on total zinc absorption, the impact as a public health intervention remains unknown.

There are different types of food fortification: foods fortified that are widely consumed by the general population (mass fortification), foods fortified for specific population subgroups, such as complementary foods for young children or rations for displaced populations (targeted fortification), and foods fortified voluntarily by the manufacturers and available in the market place (market-driven fortification).

#### Mass Fortification of Staple Foods

As described above, mass fortification is the addition of one or more micronutrients to foods commonly consumed by the general public, such as cereals, condiments and milk. Zinc fortification of cereal food staples (wheat flour, maize flour, or rice) is not yet widely practiced, but many new flour fortification programs are beginning to include zinc. Currently, in four countries—Indonesia, Mexico, Jordan, and South Africa—fortification of wheat flour with zinc is mandatory. Thirteen countries include zinc in voluntary wheat flour fortification programs, and five countries have recently proposed new programs that would include zinc. WHO recently adopted guidelines for fortification of wheat flour with zinc. The recommended levels range from 30 to 100 parts per million (ppm)

depending on the extraction of the wheat flour and the estimated per capita flour consumption, and the amount of zinc and phytate in the rest of the diet. Although several fortification compounds are generally recognized as safe (GRAS) by the US Food and Drug Administration, zinc oxide is most widely used in food fortification due to its low cost.

### **Targeted Fortification**

Infants from 6 to 24 months of age in lower-income countries are especially vulnerable to deficiencies of zinc and iron because: (1) rapid rate of growth during this period imposes relatively high requirements of these nutrients, (2) breastmilk intakes decrease with age, and the zinc and iron contents of human milk decline to low levels in the second semester post-partum, and (3) most home-available complementary foods are limited in the amounts and bioavailability of these nutrients. Reviews of the theoretical nutrient requirements during the period of complementary feeding indicate that it is very difficult for infants in lower-income countries to meet their requirements for zinc and iron from home-available preparations. One approach is to fortify complementary foods to help meet the physiological needs of young children. However, recent analyses of commercially available fortified complementary foods revealed that the zinc content is in many cases insufficient. Various strategies for 'home' fortification, or point-of-use fortification (POUF), have been developed to ensure adequate micronutrient intakes by infants and young children. These types of products include micronutrient powders, crushable tablets, and lipid-based nutrient supplements, which are added to the complementary food at the time of consumption. To date, there is only inconsistent evidence that zinc fortified complementary foods or POUF can improve zinc status, as measured by biochemical or functional indicators. Whether this is due to the low bioavailability of zinc from cereal-based complementary foods (due to the high phytic acid concentration) or due to other reasons is uncertain.

### **Dietary Diversification and Modification**

The most desirable approach to eliminate zinc deficiency will be to ensure access to diets with adequate zinc content and bioavailability. Dietary diversification and modification have the potential to prevent deficiencies of zinc and other micronutrients. The best strategy for enhancing the zinc content of household diets is to promote the consumption of meat, poultry and fish, all good sources of readily-available zinc. This is because beef, pork, lamb, and liver have a higher content of readily absorbed zinc (3.0 to 6.8 mg of zinc/100 g) than poultry (~1.1 to 2.7 mg of zinc/100 g), eggs (~1.0 to 1.3 mg of zinc/100 g), dairy products (~0.3 to 1.0 mg of zinc/100 g), or finfish (~0.3 to 0.7 mg of zinc/100 g for flesh only; ~3.2 mg of zinc/100 g for whole, soft-boned fish with bones).

Several household food preparation and processing methods can be used to reduce the phytate content of diets based on cereals and legumes. These methods are based on the enzymatic hydrolysis of phytic acid to lower inositol phosphates that occurs during germination and fermentation. A combination of dietary strategies involving increased consumption of animal-source foods and phytate reduction is the preferred method to enhance both the content and bioavailability of zinc in the diets in rural areas of lower-income countries. To be effective, such strategies must be integrated with ongoing national agriculture, food, nutrition, and health education programs and implemented using a participatory approach to ensure their acceptability, adoption, and sustainability.

Promotion and support of appropriate breastfeeding practices should also be considered among the recommended dietary strategies to enhance the zinc status of infants and young children, for two reasons: breastmilk is an important source of bioavailable zinc, and breastfeeding protects against diarrhea, which causes excessive zinc losses. Public health programs targeting young children should consider the promotion of the three key recommendations: (1) early initiation of breastfeeding, (2) exclusive breastfeeding to 6 months, and (3) continued breastfeeding to 24 months.

### **Biofortification**

Biofortification is an agricultural strategy that aims to increase the content of selected micronutrients, including zinc, in staple foods such as rice, wheat, maize, pearl millet, and others. Biofortification of staple foods can be achieved through the following processes: conventional breeding, by selecting for genotypes with the highest micronutrient content observed for that crop; use of genetic modifications, such as gene insertions or induced mutations; and use of agronomic practices, such as applications of zinc-containing fertilizers. When consumed, biofortified staple foods would lead to improved adequacy of zinc intakes and hence a reduced risk of dietary zinc deficiency, among those who currently have high rates of inadequate intakes. Although the feasibility and efficacy of biofortification to prevent zinc deficiency still needs to be evaluated through efficacy trials, theoretical analyses indicate that it has a potential to improve zinc intakes in adults and children.

### Glossary

**Acrodermatitis enteropathica** A genetic disorder leading to zinc deficiency, associated with mutations in the ZIP4 transporter and impaired zinc absorption.

**Metallothionein** A small, cysteine-rich zinc binding protein that modulates intracellular zinc homeostasis and acts as an antioxidant.

**MTF-1** A zinc-regulated transcription factor.

**ZIP transporters** A family of zinc transporters responsible for moving zinc into the cytoplasm. Also known as SLC39.

**ZnT transporters** A family of zinc transporters responsible for moving zinc out of the cytoplasm. Also known as SLC30.

### Introduction

Zinc is moderately abundant in nature, ranking 23rd of the elements. Of the trace elements in the body, it is second only to iron, but unlike iron, it has only a single redox state. Together with its size and charge characteristics, this has led to its widespread use within proteins of the body. The number of zinc proteins is unknown but growing, including several hundred enzymes and many more nuclear proteins that regulate gene expression. Additional proteins are responsible for zinc homeostasis. Binding sites and functions of zinc within some of these proteins are well understood, but for others this is less clear. In particular, the links between these biochemical roles of zinc within proteins and its physiological functions are often obscure. The range of physiological functions of zinc is broad and can be observed in all tissues of the body. In general, zinc is required for DNA synthesis, cell division and

growth, for protein synthesis and macronutrient metabolism, and for the development and function of most body systems. Lack of an appropriate assessment tool makes it difficult to estimate deficiency prevalence, but undiagnosed marginal zinc deficiency may be a concern.

## History of Zinc as a Nutrient

The essentiality of zinc for bacterial growth has been known for almost 150 years. Later, it was shown to be required by plants and then in 1934 for the rat. Because of its broad distribution in the food supply, human zinc deficiency was initially thought to be unlikely. However, in the early 1960s Prasad and others in Iran described a syndrome of dwarfism and lack of sexual development in teenage boys and young adults. The Iranian young men consumed a diet based on unleavened bread with very little animal protein and also ate large amounts of clay (geophagia). They were anemic and responded to treatment with ferrous sulfate, coupled with a more balanced diet including animal protein. The other symptoms also resolved but it seemed unlikely that lack of iron itself was responsible. Prasad then moved to Egypt, where he encountered a similar syndrome. These patients were not geophagic, but ate mostly bread and beans and also were infested with schistomiasis and hookworm. Zinc deficiency was documented in these individuals and treatment with zinc was shown to be more effective at increasing growth rates than either iron or a diet with animal protein. Thus dietary zinc deficiency was demonstrated, presumably due to impaired absorption because of the high fiber and phytate contents of the diet.

## Chemistry of Zinc

The conjunction of chemical properties of zinc underlies its biological significance. It is a relatively small ion (atomic number=30) and carries a positive charge of two. It attracts electrons as a strong Lewis acid and this property can be important in its catalytic functions. It has relatively flexible coordination geometry and while binding its ligands with high affinity, exhibits rapid rates of exchange that can facilitate chemical reactions and biological processes. Its single redox state, in contrast to iron or copper, eliminates danger of oxidative damage. Although other trace elements share some of these properties, none share them all. This is what makes zinc so valuable for protein structure and function.

## Zinc in Foods

Zinc is associated with proteins in the body and is found associated with proteins in food. Protein rich foods tend to be good sources (Table 1). However, there is great variability, ranging from egg whites, which have almost no zinc, up to oysters at 400 mg kg<sup>-1</sup>. Legumes and grains have moderate zinc content, though refinement results in large losses, whereas fruits and vegetables are poor sources. Zinc bioavailability is quite variable, due to other food components eaten at the same time. A principal concern is phytate, which renders zinc unavailable. On the other hand, animal proteins appear to enhance zinc absorption, perhaps because amino acids derived from them keep zinc in a soluble form. Enriched breakfast cereals can make significant contributions to zinc intake.

## Control of Zinc Homeostasis

The size and charge characteristics of zinc mandate the use of carriers to traverse biological membranes. Two families of transporters have been described and partially characterized. The ZIP family (also called Solute Carrier 39; SLC39), functions to move zinc into the cytoplasm, either from outside of the cell or from subcellular compartments. The second group of transporters, the ZnT family (SLC30), is responsible for zinc egress from the cytoplasm. Fourteen transporters belonging to the ZIP and 10 belonging to the ZnT family have been identified. Cellular zinc homeostasis is tightly regulated by these transporters in normal and pathological states. For example, the normally zinc-rich prostate exhibits zinc loss with malignancy that is associated with the down regulation of ZIP transporters. ZnT-1 is localized to plasma membranes and functions as a cellular efflux protein. ZnT-2 transports zinc into storage vesicles under conditions of high cellular zinc. Collectively, the ZIP and ZnT proteins are likely to underlie the homeostatic control of zinc distribution around the body.

## Zinc Absorption

The absorption, distribution, and excretion of zinc are shown in Figure 1. Overall, approximately 20–40% of consumed zinc is absorbed, depending on bioavailability within the particular food source. Zinc is absorbed by both saturable and nonsaturable processes, with the greatest rates of absorption occurring in the jejunum. Absorption is adjusted to meet needs, being proportionately increased in deficiency states and reduced when intake is high. Zinc status is reflected by the intestinal concentration of the zinc binding protein, metallothionein (MT). MT may trap zinc within the epithelial cells, causing it to be lost to feces as the cells are

**Table 1** Dietary sources of zinc

<i>Food</i>	<i>Zinc content mg kg<sup>-1</sup> raw weight</i>
Oysters	400
Beef, lean	50

Polished	12
Breakfast cereals, fortified	100–500
Kidney beans	27
Lentils	36
Potatoes	3
Broccoli	4
Apples	0.4

sloughed off. This may be part of the explanation of how zinc absorption is adjusted to meet needs. Acrodermatitis enteropathica is an autosomal recessive condition of zinc malabsorption, which can lead to severe deficiency. Gene mutations that lead to this condition have been identified in *ZIP4*, which encodes one of the zinc transporters. This protein has been localized to the apical membrane of intestinal epithelial cells and, given the severity of symptoms associated with its inactivation, appears to be necessary for normal zinc absorption. The zinc efflux protein ZnT-1 is found at the basolateral membrane and so likely promotes passage of zinc out of the intestine. Acrodermatitis enteropathica can be treated with large doses of zinc, supporting the existence of paracellular transport at high intake levels. A large amount of zinc is secreted into the gut from the pancreas and intestine (**Figure 1**). Malabsorption syndromes can lead to a failure to reabsorb these endogenous secretions and a rapid loss of body zinc.

### Transport and Distribution

The zinc plasma pool is relatively small, representing only approximately 0.1% of total body zinc. It circulates bound to albumin and  $\alpha$ -2-macroglobulin, with approximately 3% complexed with amino acids. Approximately five-fold greater amounts of zinc are found in whole blood, with erythrocytes accounting for approximately 75% of the total. However, approximately 85% of erythrocyte zinc is complexed within carbonic anhydrase and therefore does not exchange easily. Egress of zinc from the circulation across endothelial cells and into tissues of the body is not well understood. Uptake in association with albumin has been suggested but members of the ZIP family of transporters are likely to play a role here. The tissue distribution of zinc is relatively uniform. All cells require the mineral and no cell stores it. The concentration of zinc in the adult human is approximately  $0.5 \mu\text{mol g}^{-1}$ , giving a total body content of approximately 2 g. More than half is found in skeletal muscle and approximately 30% in bone. The bone pool appears to be more labile than the muscle pool and this has been used as an index of zinc status in experimental animals. Liver represents another labile pool. It receives dietary zinc from the portal circulation and contains approximately 5% of body zinc. At the cellular level, approximately 30–40% zinc is present in the nucleus whereas, 50% of zinc is distributed among the cytoplasm, organelles, and specialized vesicles. The remaining zinc is associated with membranes.

**Figure 1** Whole body zinc homeostasis. Zinc in the intestine comes from the diet and endogenous secretions. A portion is absorbed, but much is lost in the feces, which constitute the major site of excretion. Absorbed zinc passes through the liver and then to the general circulation. Zinc is distributed throughout the body with muscle and bone constituting the largest pools. A minor but controlled amount of zinc is lost in the urine.

### Excretion

Zinc is lost from the body primarily through the feces (**Figure 1**). Feces contain unabsorbed dietary zinc, zinc contained within intestinal epithelial cells, which have been sloughed off, and endogenous secretions into the gut from the pancreas, the gall bladder, and the cells lining the gastro-intestinal tract. The endogenous secretions and the extent to which they are reabsorbed can be controlled and represent an important homeostatic mechanism for regulating zinc status. Zinc losses in urine are relatively minor, but do respond to extremes of intake to help maintain homeostasis. Shed skin cells, sweat, hair, menstrual blood, and semen represent additional routes of loss.

### Zinc Biochemistry

Zinc homeostasis and action involves an intimate association of the mineral with proteins. These include membrane transporters responsible for the absorption of zinc in the gut and its passage into and out of cells and subcellular organelles, transport and delivery proteins, both in the circulation and within cells, sensing proteins that adjust homeostasis and function according to zinc availability and then a large range of proteins to which zinc is ultimately delivered. Two major classes of these latter proteins are the enzymes and transcription factors.

### Homeostasis

The interaction of zinc with its transporters has not been well characterized, though transmembrane domains have been identified thought to be responsible for the transport function. Free concentrations of zinc within the cell appear to be extremely low and may not constitute a sufficient pool for the supply of zinc to its protein ligands. This implies the existence of delivery proteins, a role suggested for MT, which has been shown to transfer zinc to apoenzymes *in vitro*. MT is a small protein that is unusually cysteine-rich and can bind seven atoms of zinc. It may influence the subcellular distribution and availability of zinc, because its own distribution varies. For example, the nuclear content of MT varies with the cell cycle. MT expression is regulated by zinc and also by a range of other signals including glucocorticoids, interleukins, and cAMP. In addition, its zinc binding activity is influenced by the cellular redox state. For example, an increase in the glutathione disulfide/glutathione ratio results in release of zinc from MT and thus its availability for other proteins.

Investigation of the mechanism whereby zinc regulates the expression of MT led to the discovery of the single protein known to act as a zinc sensor within mammalian cells, MTF-1 (metal response element (MRE)-binding transcription factor-1). MTF-1 binds to MREs in the promoter region of MT and other genes and regulates their expression. The ability of MTF-1 to localize to the nucleus and bind to its target genes is dependent on its zinc content. Thus, an increase in cellular zinc concentrations results in greater MTF-1 activity and elevated expression of its target genes. In addition to MT, which will bind more zinc, these include ZnT-1, which will transport zinc out of the cell. Both actions serve to buffer the increase in cytosolic zinc (**Figure 2**).

## Zinc Enzymes

The three-dimensional structures of more than 200 zinc-containing enzymes have now been characterized, and many more have been identified. All six International Union of Biochemistry classes are represented. In some cases (e.g., carbonic anhydrase), zinc is a direct participant in the catalytic function of the enzyme. The zinc atom is coordinated by three amino acids from the enzyme and a molecule of water at the active site. Other enzymes (e.g., protein kinase C) have structural zinc sites, where the metal binds four amino acids within the protein and ensures appropriate folding for bioactivity. For nitric oxide synthase, zinc has been found to serve a bridging function between two separate polypeptides, stabilizing a biologically active larger complex. A selection of zinc enzymes is listed in [Table 2](#) and help to illustrate the wide variety of metabolic functions requiring zinc.

## Zinc Transcription Factors

There are many zinc enzymes but even more transcription factors utilize zinc. Variable numbers of zinc atoms are each coordinated by four cysteine or histidine residues to stabilize a DNA binding structure. A search of the human genome has revealed over 1000 genes (approximately 3% of those identified) containing these characteristic zinc finger domains. An important class of zinc finger transcription factors is the steroid/thyroid receptor superfamily, responsible for mediating the biological response to a wide range of hormonal and metabolic signals, including retinoic acid and vitamin D. These all have nine conserved cysteine residues in the DNA binding region, eight of which are coordinated by two atoms of zinc. Loss of zinc from these sites would interrupt biological function but it is not clear that this ever happens in a physiological context. Gene expression profiling has been used to assess the genome-wide response to changing zinc availability in different tissues, including intestine, liver, and cells of the immune system. The gene products identified as zinc-sensitive by these approaches amount to approximately 5% of the expressed genes within a tissue. MTF-1 is likely to mediate some but not all of these changes and other transcription factors whose activity is dependent on zinc may soon be found.

## Zinc Physiology

The enormous range of biochemical roles for zinc predicts broad effects on physiological function. The physiological roles of zinc may be further extended by secondary effects mediated by altered food intake and effects on the function of other nutrients. Although the physiological roles for zinc are well described, it is important to note that the connections between the biochemistry and physiology of zinc remain unclear. Thus the specific zinc-sensitive biochemical step leading to altered physiology is often unknown. The broad spread of zinc through the body at the organ, cellular and even protein levels suggests that the function of most systems is dependent on zinc. Its physiological roles become manifest under the circumstance of deficiency and that framework will be used to discuss principal functions here.

**Figure 2** Cellular zinc homeostasis. Zinc is delivered to the cytoplasm from either the extracellular space or vesicles within the cell by members of the ZIP family of transporters. A rise in cellular zinc results in activation and nuclear translocation of MTF-1. In the nucleus, MTF-1 regulates transcription of a set of target genes including MT and ZnT-1. MT will bind zinc and ZnT-1 transports zinc out across the plasma membrane. MT may govern delivery of zinc to other proteins within the cell. Other members of the ZnT family transport zinc into vesicles.

**Table 2** Examples of mammalian zinc-dependent enzymes

<i>Enzyme</i>	<i>Function</i>
RNA polymerase	Transcription, synthesis of mRNA
Carboxypeptidase A	Protein digestion in intestine
Protein kinase C	Signal transduction
Carbonic anhydrase	Respiration/buffering/hydration of CO <sub>2</sub>
Cytochrome <i>c</i> oxidase	Respiration/electron transport chain
Alcohol dehydrogenase	Ethanol metabolism
Superoxide dismutase	Inactivation of free radicals
Nitric oxide synthase	Signaling, vasodilation
Angiotensin converting enzyme	Blood pressure regulation/activation of angiotensinogen

### Growth

The requirement of zinc for growth of numerous organisms ranging from bacteria to humans is well established. Growth failure is an early consequence of zinc deficiency in experimental animals. Numerous processes seem to contribute to the growth failure. Experiments with animals have shown that zinc deficiency leads to a drop in food intake, though the use of pair-fed controls demonstrates clear effects of zinc deficiency beyond feeding behavior. Multiple effects of zinc deficiency on the somatotrophic axis have been demonstrated, notably a reduction in circulating concentrations of insulin-like growth factor-1 (IGF-1). Again, this is only part of the story because administering exogenous IGF-1 does not restore the growth failure of zinc deficiency. Growth of cultured cells is dependent on media zinc. DNA synthesis is interrupted and production of thymidine kinase mRNA is diminished by removal of zinc, but again this is only a partial explanation. The IGF-1 signaling pathway within cells also seems to be affected. Zinc is also required for wound healing, presumably due to related processes.

### Immune Function

The immune system is particularly sensitive to zinc deficiency. Lymphopenia and thymic atrophy are observed and both cell-mediated and antibody-mediated responses are reduced. As with growth, multiple mechanisms appear to be at play. In addition to generalized effects on DNA synthesis, zinc deficiency appears to induce apoptosis, resulting in a loss of B and T cell precursors within the bone marrow. Thymulin, a zinc-dependent enzyme that stimulates the development of T cells within the thymus, may be involved. Production of cytokines by mononuclear cells is also reduced by zinc deficiency. These effects can be of clinical significance. Infections occur more frequently in individuals with acrodermatitis enteropathica and reduced immune function is accompanied by zinc deficiency in several other conditions, including sickle cell anemia and various gastro-intestinal disorders.

Zinc has been used therapeutically in individuals with immune-compromised diseases. In the United States, zinc lozenges have become popular as a treatment for the common cold. Zinc supplementation has also been used as a supporting therapy for patients with HIV and AIDS, herpes simplex viruses, and hepatitis C infections. A shortening of cold duration, improved phagocytosis and increase in the number of Th cells, and a reduced frequency of opportunistic infections was observed in patients with HIV infection. However, results from controlled trials of zinc treatment with these diseases have been variable. Treatment effectiveness may depend on initial zinc status, with greater success being seen in individuals with marginal, undetected zinc deficiency.

### Reproduction

The original description of zinc deficiency in humans included lack of pubertal development. Spermatogenesis is a zinc-dependent process. Seminal fluid is particularly rich in zinc and the sperm appears to accumulate zinc from this source before ejaculation. Zinc is also crucial for normal fetal development and deficiency leads to abnormalities in humans and animals. Maternal zinc deficiency has also been linked with pregnancy-associated morbidity, including preterm delivery.

### Nervous System

The brain is one of the sites shown to be particularly sensitive to zinc deficiency during fetal development, with neural tube defects and other disorders being found. Although this work was performed with animals, a similar relationship appears likely with humans. Zinc is distributed throughout the brain, but greater concentrations are found within the hippocampus. Here a brain-specific transporter, ZnT-3, concentrates zinc in vesicles within glutamatergic neurons. It is co-secreted with the neurotransmitter and appears to serve as a modulator of neurotransmission. Very high concentrations of zinc (>100  $\mu$ M) are found within the synaptic cleft during this process. In addition, brain injury, resulting from ischemia or trauma causes the release of massive amounts of zinc, which is thought to be responsible for the resultant cell death.

### Antioxidant Defense System

Although not an antioxidant itself, there are several ways in which zinc participates in the antioxidant defense system of the body, with important implications for health. It can bind to thiol groups in proteins, making them less susceptible to oxidation. By displacing redox-reactive metals such as iron and copper from both proteins and lipids it can reduce metal-induced hydroxyl radical formation and thus protect the macromolecules. Copper/zinc superoxide dismutase is an important antioxidant enzyme, which contains zinc and whose activity is impaired in the deficient state. Zinc depletion affects the activity of reactive oxygen species (ROS) and reactive nitrogen species (RNS) scavengers such as glutathione, ascorbic acid, uric acid, and  $\alpha$ -tocopherol. The role of zinc in inducing MT has already been mentioned and this protein scavenges hydroxyl radicals. Increased oxidative stress results in the release of zinc from MT, presumably making it more available for other proteins. However, although zinc deficiency has been linked to greater oxidative stress, excess zinc can also lead to the same condition. So although MTs possess intrinsic antioxidant properties, there is evidence that in some circumstances, MTs may also serve as a source of injurious zinc release. Recent findings also suggest that nitrosative stress can act as a critical trigger for zinc mobilization. Nitric oxide (NO) or peroxy nitrite ( $-\text{ONOO}$ ) interact with MT and promote zinc release both *in vitro* and *in vivo*.

The likelihood of increased oxidative stress under conditions of zinc deficiency suggests a potential anticarcinogenic role for this mineral. Indeed, zinc deficiency has been shown to result in DNA damage. The tumor suppressor gene, p53, which is frequently mutated in human cancers, is a zinc-containing transcription factor whose expression is also dependent on zinc. Dysregulation of cellular zinc homeostasis is linked not only to oxidative stress but also mitochondrial dysfunction and activation of apoptotic pathways.

### Macronutrient Metabolism

Many of the enzymes of intermediary metabolism contain zinc and deficiency affects all macronutrients. Protein synthesis, as well as DNA and RNA synthesis requires zinc. Insulin is secreted from the pancreas and circulates in association with zinc. This secretion is diminished under conditions of deficiency, leading to impaired glucose metabolism. Lipid metabolism is also affected, with zinc deficiency associated with reductions in circulating high-density lipoprotein.

### Human Zinc Deficiency

In addition to dietary inadequacy, there are several other routes that lead to zinc deficiency. Acrodermatitis enteropathica, the genetic disorder of zinc malabsorption has already been mentioned. Other, more generalized malabsorption syndromes (e.g., celiac disease) can also lead to zinc deficiency. Deficiency has also resulted from inappropriate intravenous feeding and use of chelation therapy. Children are likely to be particularly at risk for zinc deficiency, because of its involvement in growth.

#### Mild

Given the difficulty of assessing marginal impairments in zinc status, effects of deficiency can often only be verified by a response to treatment. Growth provides a good example of this. Children in Denver, Colorado who were of low height for their age showed increased growth rates in response to zinc supplementation, whereas zinc had no effect in children of normal height. In addition to growth, improvements in immune function, taste and smell acuity, and reproductive function have been noted with zinc supplementation.

#### Severe

Severe human zinc deficiency has been well characterized by the original descriptions in the Middle East and in patients with acrodermatitis enteropathica. The symptoms of mild deficiency are continued and exaggerated. Thus stunting can be extreme and is accompanied by delayed sexual maturation and impotence. Characteristic skin lesions are found, originating around the mouth and nose but becoming widespread as deficiency develops. Diarrhea is also present. Deficits in taste and smell are accompanied by anorexia and other behavioral changes, including increased irritability and impaired cognitive function. Eye pathologies similar to those seen with vitamin A deficiency are observed.

### Zinc Toxicity

Toxicity of zinc from food sources has not been reported and seems unlikely because absorption is homeostatically regulated. Acute gastro-intestinal symptoms and headaches from ingestion of amounts approximately 10–20-fold higher than the recommended intakes have been described. Chronic ingestion of these large amounts has been shown to impair immune response and lipoprotein metabolism. However, the key danger from excessive zinc intake is reduced copper status. This is likely due to a zinc-induced blockage of copper absorption and in fact is clinically useful in individuals with Wilson's disease, a condition of copper toxicity. In the United States, an Upper Limit of 40 mg day<sup>-1</sup> has been set for adults, based on the threat to copper status. The popularity

**Table 3** Recommended intakes for zinc

Age group			FAO/WHO reference nutrient intake		
			Bioavailability		
			High	Moderate	Low
Children (1–3 years)		3	2.4	4.1	8.3
Adolescents (14–18 years)	Female	9	4.3	7.2	14.4
	Male	11	5.1	8.6	17.1
Adults (>19 years)	Female	8	3.0	4.9	9.8
	Male	11	4.2	7.0	14.0
Pregnant women	3rd trimester	11	6.0	10.0	20.0
Lactating women	0–3 months	12	5.8	9.5	19.0

of zinc lozenges for treatment of the common cold could lead to circumstances where this intake could be exceeded. Thus use of these treatments should be limited in duration.

## Assessment

The prevalence of marginal zinc deficiency in human populations is unknown because of the lack of a good means for assessing zinc status. Measurement of plasma zinc is straightforward, but it does not serve as a reliable indicator of status. Plasma zinc is a quantitatively minor pool that can be easily influenced by minor shifts in tissue zinc. Plasma concentrations do not fall with dietary intake, except at very low intakes. Plasma zinc can also be affected by other factors unrelated to zinc status (e.g., time of day, stress, infection). Cellular components of blood can be assayed, but erythrocyte concentrations of zinc are maintained in deficient states and variable results have been found with leukocytes. Hair zinc concentrations may reflect available zinc but will also be dependent on rate of hair growth.

Several different zinc-dependent enzymes have been investigated as potential markers of zinc status but none has proved reliable. MT in blood cells has been suggested as a useful indicator of zinc status, either assayed at the protein or mRNA levels. MT expression is likely to be regulated by factors other than zinc and therefore may lack the specificity required of a good indicator. The gene array approaches that have recently been used to determine the global effects of zinc deficiency within a tissue would appear to offer hope for the identification of an appropriate functional marker of zinc status.

## Recommended Intakes

In the absence of a reliable index of zinc status, both the US Food and Nutrition Board and the Food and Agriculture Organization/World Health Organization (FAO/WHO) expert committee used the factorial method to estimate human zinc requirements. Under this approach, routes of zinc loss from the body are estimated and summed. The requirement is then set as the amount of dietary zinc required to make up for these losses, making appropriate assumptions about bioavailability. For children, an additional amount is added to account for the zinc requirements for growth.

As shown in [Table 3](#), the FAO/WHO give three sets of recommendations, depending on the zinc bioavailability of the diet. The US figures fall between those given for moderate and low availability diets. Both groups also set Upper Limits for intake, based largely on the risk of impairing copper status. These values are similar (40 mg US, 45 mg FAO/WHO, for adults).

Mycotoxins: Toxicity, occurrence, risk assessment and prevention <i>L Manyes and G Font</i>	492
Nutraceuticals: Health effects and clinical applications <i>Oliver Chen and Eunice Mah</i>	501
Nuts and seeds <i>J Salas-Salvadó and M Pascual-Compte</i>	513
Organic foods <i>Léon Guéguen and Gérard Pascal</i>	523
Phytochemicals: Classification and occurrence <i>A Cassidy and C Kay</i>	530
Phytochemicals: Health effects of proanthocyanidins and related compounds <i>Yi Lin, Ningping Zhan, and Dejian Huang</i>	539
Probiotics and prebiotics <i>Jose M Saavedra</i>	545

Protein quality and sources <i>Daniel Tomé</i>	559
Protein: Requirements and role in diet <i>DJ Millward</i>	568
Salt, hypertension and cardiovascular outcomes <i>Tilman B Drüeke and Paolo M Suter</i>	579
Sucrose: Dietary sucrose and disease <i>Philipp A Gerber</i>	596
Supplementation: Dietary supplements <i>SS Percival</i>	606
Sustainable diets: Their definition, measurement and promotion <i>Shauna M Downs, Alexandra Payne, and Wiktoria Staromiejska</i>	612
Sweeteners: Sensory properties, digestion, consumption trends, and health effects <i>Richard D Mattes, Sze-Yen Tan, and Robin M Tucker</i>	624
Traditional and indigenous foods for food security and sovereignty <i>Emily V Merchant and James E Simon</i>	639
Trans-fatty acids: Health effects, recommendations, and regulations <i>SK Gebauer and DJ Baer</i>	648
Ultra-processed foods <i>Paula dos Santos Leffa</i>	653
Vegetarian diets <i>J Dwyer and J Harvey</i>	663
Whole grains and chronic disease risk <i>Caleigh M Sawicki, Nicola M McKeown, Shatabdi Goon, and Shilpa N Bhupathiraju</i>	675

## CONTRIBUTORS TO VOLUME 2

---

Concepción M Aguilera

*Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology "José Mataix", Center of Biomedical Research, University of Granada, Armilla, Spain; Instituto de Investigación Biosanitaria ibs.GRANADA, Granada, Spain; and CIBEROBN (Physiopathology of Obesity and Nutrition Network CB12/03/30038), Institute of Health Carlos III (ISCIII), Madrid, Spain*

Augusto Anguita-Ruiz

*Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology "José Mataix", Center of Biomedical Research, University of Granada, Armilla, Spain; Instituto de Investigación Biosanitaria ibs.GRANADA, Granada, Spain; CIBEROBN (Physiopathology of Obesity and Nutrition Network CB12/03/30038), Institute of Health Carlos III (ISCIII), Madrid, Spain; and Barcelona Institute for Global Health, ISGlobal, Barcelona, Spain*

DJ Baer

*US Department of Agriculture, Beltsville, MD, United States*

K Beaulieu

*School of Psychology, University of Leeds, Leeds, United Kingdom*

Shilpa N Bhupathiraju

*Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States; and Department of Nutrition, Harvard T.H. Chan School of Public Health, Boston, MA, United States*

JE Blundell

## EDITOR BIOGRAPHIES

---

### Editor in Chief

#### Professor Benjamin Caballero

*Emeritus Professor, Bloomberg School of Public Health and School of Medicine, Johns Hopkins University, Baltimore, MD, United States.*

Dr. Caballero is Professor Emeritus at the Department of International Health, Bloomberg School of Public Health, with joint appointment at the Department of Pediatrics, School of Medicine, Johns Hopkins University. He obtained his MD from the University of Buenos Aires, Argentina, and his PhD (in neuroendocrine regulation) from MIT, in Cambridge, Massachusetts. He started his academic career at Boston Children's Hospital, Harvard Medical School, and subsequently became the Founding Director of the Center for Human Nutrition at Johns Hopkins University.

Dr. Caballero has focused his research on child nutrition and health in developing countries. In particular, he has explored the combination of undernutrition and overweight that has become increasingly prevalent in low- and middle-income countries.

He is currently a member of the Council of the International Union of Nutritional Sciences. He has served on the Food and Nutrition Board of the US National Academy of Medicine and on a number of expert panels, including the Dietary Reference Intakes Committee, the Expert Panel on Macronutrient Requirements, and the Childhood Obesity Task Force. He was also a member of the U.S. Dietary Guidelines for Americans Advisory Committee, of the Scientific Advisory Board of the Food and Drug Administration, and of advisory committees of the National Institutes of

Health and the Department of Agriculture. He is a Fellow of the American Society for Nutrition and of the Royal Society of Medicine (UK), and a member of the Spanish Academy of Nutritional Sciences.

He is the Editor-in-Chief of the *Encyclopedia of Food Sciences and Nutrition*, a 10-volume work on food production, consumption, and biological effects. He is also Editor-in-Chief of the *Encyclopedia of Human Nutrition*, which received the Book of the Year Award from the British Medical Association. His *Guide to Dietary Supplements* summarizes the current scientific basis for the use of mineral and vitamin supplements. He also co-edited a widely used textbook on human nutrition, *Modern Nutrition in Health and Disease*.

## Section Editors

### Section 1: *The Foundations of Human Nutrition*

#### Professor Angel Gil

Honorary President of the Iberoamerican Nutrition Foundation (FINUT), Emeritus Professor, Department of Biochemistry and Molecular Biology II, Institute of Nutrition and Food Technology, Centre of Biomedical Research, University of Granada, Campus de la Salud, Avda. del Conocimiento, 18100 Armilla, Granada, Spain.

**Angel Gil** is an Emeritus Professor at the University of Granada and a Full Professor in the Department of Biochemistry and Molecular Biology. He is Doctor Honoris Causa at the Autonomous University of Nuevo León, Monterrey, México, and a visitant Professor of the University of Chile, Santiago de Chile, and University of San Miguel de Tucumán, Argentina. He got a major degree in Biology (1973) and PhD in Biochemistry and Molecular Biology (1978).

Prof. Gil is an internationally recognized authority in Food and Nutrition: His expertise extends from the study of human milk composition to the molecular effects of food bioactive compounds and probiotics and the design and development of novel products for infant and clinical nutrition. He conducted pioneering and innovative research, leading 7 international, 27 national, and more than 50 projects and 120 contracts; he has taught since 1981, supervising more than 50 PhD students.

Prof. Gil has several areas of interest that include evaluating the role of dietary nucleotides in early life and the development of infant nutrition products. Besides, the isolation, identification, and description of the mechanism of action of probiotics and the metabolic, molecular, and genetic factors involved in obesity and the early onset of metabolic syndrome (MS) in childhood; and the design, development, and evaluation of enteral clinical nutrition products. What describes Prof. Gil best is the variety of fields

and problems he has faced during his professional carrier and his significant ability to combine his knowledge and expertise in Food Science and Human Biochemistry. This has allowed him to design, develop, innovate, and evaluate exclusive products for Human Nutrition, which are demonstrated in his published articles and his patents' impact.

The multi- and interdisciplinary nature of his work is reflected in the variety of international journals in which he has published 546 articles. Also, he has published 28 books and about 180 book chapters. His five volumes *Treatise of Nutrition*, 3rd Edition, Ed. Medica Panamericana, 2017, with more than 3500 pages, is the "bedside" book for the study of Nutritional Sciences in Spain and all Latin American countries.

He has also been the Chairman of the International Union of Nutritional Sciences (IUNS) 21st International Congress of Nutrition (2013) and the Executive Director of the 23rd International Congress of Nutrition (2017) and has been engaged in the organization of other renowned international congresses. He is a member of prestigious international and national nutrition societies and Honorary President of the Iberoamerican Nutrition Foundation (FINUT), a nonprofit organization promoted by the IUNS, in which the main goal is to contribute to the formation of young scientists in Food and Nutrition in the setting of Iberoamerica. He has received 42 National and International Awards for his contribution to Nutrition and Food Science, among them, the Class Fellow 2022 of the American Society of Nutrition; the Sir David Cuthbertson Lecture Award of the European Society of Clinical Nutrition and Metabolism for scientific achievement in clinical nutrition on 2021; the Award "Granada, City of Science and Innovation" 2021 to the Scientific Career; the Gregorio Marañón Award 2018 to the best Spanish Scientist in the field of Food Science and Nutrition; the Institute Danone Spain Award 2017; the Award of the Spanish Federation of Dairy Industries, 2015; the Nutra Excellence Award 2014, Nutra India Summit; the UIB Honorary Award of 2013; and the NAOS Strategy Prize 2012, Special recognition for his extensive professional experience in the field of nutrition and obesity, Spanish Ministry of Health, Social Services and Equality (AESAN).

### Section 2: *Molecular Mechanisms for the Interaction of Nutrients and Health*

#### Dr. Noel W. Solomons

Center for the Studies of Sensory Impairment, Aging, and Metabolism (CeSSIAM), Guatemala City, Guatemala, Guatemala

**Noel W. Solomons** was Assistant and Associate Professor from 1977 to 1984 in the former Department of Nutrition and Food Science of MIT. A resident of Guatemala since 1975, he cofounded the Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM) in 1985, where he has been Scientific Director ever since. He is an Adjunct Professor at Tufts University in both the Friedman School of Nutrition Science and Policy and the Department of Public Health and Community Medicine.

Dr. Solomons received his MD degree from Harvard Medical School and subsequently undertook clinical and research training in infectious diseases and in gastroenterology and clinical nutrition at the Universities of Pennsylvania and University of Chicago, respectively. He was Editor-in-Chief of the *Food and Nutrition Bulletin* from 2016–2020. He has 364 publications indexed on PUBMED. In addition, he has edited 2 books and contributed over 100 articles, reviews, editorials, and commentaries in nonindexed venues and over 50 book chapters. These are dedicated to the scientific and academic interests of his career including: clinical nutrition; human growth and body composition; lactose maldigestion; dietary intake, nutritional status, intestinal absorption, and food fortification related to various micronutrients (vitamins, trace elements, and essential fatty acids); complementary feeding; nutrition in aging and chronic disease; and the interaction of malnutrition and infection. Also, he has supervised doctoral dissertations for 12 PhD candidates from the USA, Canada, Germany, Spain, the UK and the Netherlands through CeSSIAM.

## Section 3: Diet Composition

**Professor Anura Kurpad**

Department of Physiology, St John's Medical College, Bengaluru, India

**Anura Kurpad** works at St. John's Medical College, Bengaluru. He received his MBBS and MD from St. John's, and his PhD from Bangalore University in 1992. He was a Postdoctoral Fellow at the Rowett Research Institute and at Cambridge University, UK, and a visiting Scientist at MIT, Cambridge, United States. He is an elected Fellow of the Royal College of Physicians (London), Fellow of the Indian National Academy of Medical Sciences, Indian Academy of Sciences, and International Union of Nutritional Sciences. His interests are in human, clinical, and public health aspects of nutrition, applied throughout the life cycle. His research focuses on the physiology and clinical aspects of human energy and protein requirements and metabolism, with more recent interests in micronutrient status and metabolism. He is an Associate Editor of *The American Journal of Clinical Nutrition*. He was the President of the Nutrition Society of India from 2012 to 2016 and is the current President of the Asia Pacific Clinical Nutrition Society. He has been, and is, on many national and international advisory bodies, including being the Chair of the Indian Nutrient Requirements Committee.

## Section 4: Disorders Directly Related to Inadequate Nutrient Intake

**Dr. Katherine L. Tucker**

Department of Biomedical and Nutritional Sciences, Center for Population Health, University of Massachusetts Lowell, Lowell, MA, United States

**Katherine L. Tucker**, PhD, is University Distinguished Professor of Nutritional Epidemiology in the Department of Biomedical and Nutritional Sciences, and Director of the Center for Population Health, at the University of Massachusetts Lowell. She holds an adjunct appointment at the University of Massachusetts Medical School. She received her PhD from Cornell University and her undergraduate degree from the University of Connecticut, both in nutritional sciences. Between these degrees, she spent 2 years as a Peace Corps volunteer in the Philippines. Before joining UMass Lowell, she was at the USDA Human Nutrition Research Center on Aging at Tufts University, and McGill University. Dr. Tucker has contributed to more than 450 articles in scientific journals. Her research focuses on dietary intake and risk of chronic disease, including osteoporosis, cognitive decline, obesity, metabolic syndrome, and heart disease, with an emphasis on health disparities. She is the PI of the Boston Puerto Rican Health Study, an ongoing cohort study, to examine the roles of diet, health behaviors, stress, and genetic predisposition in relation to chronic conditions, including heart disease, cognitive decline, and bone health; and is actively involved as a scientific advisor for the NHLBI Jackson Heart Study. She served two terms on the Food and Nutrition Board of the National Academies of Science and Engineering. She is a Fellow of the American Society for Nutrition (ASN), the Gerontological Society of America, and the American Society for Bone Mineral Research and is

currently the Editor-in-Chief of *Advances in Nutrition*, the international review journal of the ASN, and Senior Editor of the forthcoming 12th edition of the textbook, *Modern Nutrition in Health and Disease*.

## Section 5: Nutrition in Disease States

**Dr. Paolo M. Suter**

Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital, Zurich, Switzerland.

**Paolo M. Suter**, MD, MS, is a Professor of Medicine presently affiliated with the Department of Endocrinology, Diabetology and Clinical Nutrition at the University Hospital Zurich (Switzerland). He received his MD at the University of Zurich and an MS in Nutrition at Tufts University (Boston, USA). He specialized in Internal Medicine and was a Faculty Member at the Medical Polyclinic of the University Hospital Zurich, where he was directing the well-known Hypertension and Obesity Outpatient Consultation. His research activities focused on vitamin nutriture in the elderly, alcohol metabolism and obesity, blood pressure and hypertension, as well as nutrition and lifestyle in non-communicable disease prevention. During his clinical work he focused on the ideal combination of pharmacological therapy with nonpharmacological strategies and on the therapy and prevention of diseases especially hypertension and obesity. Besides many research publications and review articles he authored a widely used textbook entitled *Checkliste Ernährung (Checklist Nutrition)*. He served on different national and international boards in the area of his expertise.

**Section 6: Nutrition in the Life Cycle****Professor Lawrence J. Cheskin**

*Department of Nutrition and Food Studies, George Mason University, Fairfax, VA, United States*

*And*

*Department of Medicine, Johns Hopkins School of Medicine, Baltimore, MD, United States*

**Lawrence J. Cheskin, MD, FACP, FTOS**, is Professor and Chair of the Department of Nutrition and Food Studies at George Mason University in Fairfax, VA, and an Adjunct Faculty Member of the Department of Medicine at the Johns Hopkins School of Medicine in Baltimore, MD, United States. He received his medical degree from Dartmouth and was a Postdoctoral Fellow in gastroenterology and liver diseases at Yale University-New Haven Hospital. Dr. Cheskin's work is at the intersection of public health nutrition and clinical medicine and has dedicated his career to research, education, and program building in the service of combating obesity, through both treatment and prevention. He founded the Johns Hopkins Weight Management Center, a multidisciplinary clinical research and treatment program. He was also Director of Clinical Research of the Global Obesity Prevention Center at Johns Hopkins and directed its Pilot Studies Core, which evaluated systems-focused proposals worldwide to study such areas as school policies and the built environment in preventing childhood obesity. He is co-PI of the Mason Cohort Study of entering college freshmen and has authored over 240 peer-reviewed journal articles and 8 books. He is committed to mentoring the next generation of public health and clinical scholars dedicated to nutrition and obesity.

**Section 7: Nutrition Epidemiology****Dr. Manuel Franco**

*Associate Professor at the Department of Surgery, Medical and Social Sciences, University of Alcalá, Madrid, Spain, and adjunct faculty at the Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States.*

**Manuel Franco, MD, PhD**, Epidemiologist, is an Associate Faculty at the University of Alcalá and an Adjunct Faculty at the Johns Hopkins Bloomberg School of Public Health.

He is the Principal Investigator of the European Research Council Starting Grant Heart Healthy Hoods (<http://www.hhhproject.es>) studying urban characteristics in relation to eating patterns, physical activity levels, smoking, and alcohol consumption. He is also the PI of the Participatory Project on food in the cities: Photovoice Villaverde (<https://youtu.be/VliFggKzVas>).

Manuel Franco trained in Medicine both in Madrid and Berlin. As a Fulbright Scholar he joined the Johns Hopkins Bloomberg School of Public Health Department of Epidemiology to obtain his PhD and Postdoctoral Fellowship in the fields of social epidemiology and urban health.

His work focuses on the prevention of chronic diseases and their major risk factors as nutrition. He has published 94 international peer-reviewed articles and has led 15 studies as PI raising over 2.9 million € in competitive international research bids. His methodological interests include the measurement of urban characteristics related to chronic diseases and nutrition, the use of mixed methods, and the conduction of participatory action research methods.

**Section 8: Global aspects of Human Nutrition****Professor Daniel J. Hoffman**

*Department of Nutritional Sciences and director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States*

**Daniel J. Hoffman, PhD**, is a Professor in the Department of Nutritional Sciences and Director of the Program in International Nutrition at Rutgers University, New Brunswick, NJ, United States. He graduated from St. John's University, Collegeville, MN, United States, and received his PhD in Human Nutrition from the Tufts University Friedman School of Nutrition Science and Policy, Boston, MA, United States. For his doctoral training, Dr. Hoffman studied the metabolism of children living in the shantytowns of São Paulo, Brazil. He then completed a Postdoctoral Fellowship at Columbia University, New York, NY, United States, before joining the faculty at Rutgers University.

Dr. Hoffman's research focuses on the long-term impact of undernutrition early in life on body composition and metabolism later in life. This work is complemented by research on sustainable methods to improve diet and growth in lower- and middle-income countries, including Brazil, Mexico, Kenya, South Sudan, and Vietnam. He also directs the Center for Childhood Nutrition Research at the New Jersey Institute for Food, Nutrition, and Health where members conduct interdisciplinary research on childhood growth and development. Dr. Hoffman is an Associate Editor of the *Food and Nutrition Bulletin* and a Section Editor for the *Annals of Human Biology*. His other responsibilities include serving on the editorial board of the *Journal of Nutrition*, serving in leadership positions for the American Society for Nutrition, and advising international and national agencies on matters related to childhood nutrition. Aside from his

academic life, Dr. Hoffman is a published documentary photographer whose portfolio includes work on the life of Roma in Europe, urban landscape of São Paulo, Brazil, gentrification of Times Square in New York City, and punk music as the "American Mosaic."

## PREFACE

---

By the middle of last century, the science of nutrition had identified most of the essential nutrients and had provided evidence to propose specific dietary intake recommendations for many diet constituents, with the practical aim of preventing nutrient deficiencies. As chronic, noncommunicable diseases such as cardiovascular disease, cancer, etc., began to emerge as an important causal factor for disability and early death, scientists turned their attention to the potential effects of nutrients and diet patterns on chronic disease risk. Pioneering studies by Burkitt, Keys, Breslow, and others were followed by a large number of studies on the role of dietary patterns and constituents on certain chronic diseases. Many important studies were completed over the second part of the century, providing the evidence to support specific dietary recommendations to reduce disease risk.

The 21st century ushered the next transition in nutrition science, this time centered on the interrelationships between nutrients, dietary patterns, and the human genome. Over the past few decades, advances in our understanding of the human genome and on the molecular tools to explore it have permitted to probe those interactions in increasing detail. In turn, findings from nutrient–gene interaction studies have informed population-wide and clinical and metabolic studies, further advancing our understanding of the effects of diets on human health at the molecular level. This understanding of the links between genotype, phenotype, and nutrient/dietary intake became a key contributor to the emerging area of personalized nutrition/precision medicine.

All those phases of research emphasis, to different degree, continue to exist today and result in a vast, multidisciplinary, ever-expanding amount of information reaching the peer-reviewed literature. This massive amount of information needs to be organized and summarized in a way that makes it accessible to experts, teachers, and, as much as possible, the general public. This has been and continues to be the goal of the *Encyclopedia of Human Nutrition* since its first edition, over 20 years ago.

Such an ambitious task can only be achieved by the collective work of many people. We all have experienced the challenge of writing an article that combines focus and relevance with conciseness, so we are very appreciative of the work of our contributors. Their effort was backed up by an excellent editorial board, which reviewed and provided feedback on every manuscript. Finally, we must acknowledge the outstanding support of the Major Reference Works division at Elsevier. A publication like this *Encyclopedia* has a lot of moving parts, and it is a great privilege to be able to concentrate on the content, knowing that the other parts of the process are in the hands of excellent professionals.

We hope that this book will help satisfy the need for accurate and concise information to the many students and professionals who are committed to use nutrition science as a tool to improve people's quality of life.

## Key points

- Review the nature of human eating behavior and appetite control
- Discuss the role of learning in acquired eating behavior traits.
- Consider methodological issues relevant to the measurement of appetite control and energy balance.
- Discuss the role of environmental factors (meal patterns, social and situational influences) on human appetite control.
- Summarize the role of diet composition in appetite control and weight management.

## Glossary

**Appetite** The subjective expression of willingness or motivation associated with qualitative selection and quantitative *ingestion* of specific foods during an ingestive event. Appetites are specific to certain foods. Appetite is not necessarily solely related to situations of nutritional depletion and can be influenced by a number of physiological and non-physiological factors.

Appetites are often learned and frequently sensory specific

**Hunger** The subjective sensation and associated processes that can be described as a general motivation to eat. An increase in subjective hunger usually predicts meal initiation in *ad libitum* feeding subjects. It does not necessarily predict type or amount of food eaten

**Food hedonics** Liking (an experience of pleasure) and wanting (anticipatory motivation), are distinct hedonic processes with dissociable neural pathways that are thought to serve as a basis for animals (including humans) to acquire through learning, eating behaviors that lead to the acquisition of energy and nutrients. They may be influenced by the food, the *physiological state* of the organism, and the environment in which food and subject interact

**Liking** The sensory pleasure elicited by contact with food contributing to the hedonic motivation to consume (wanting)

**Wanting** The motivation to consume a specific food, manifesting explicitly (craving/desire) or implicitly (food cue responsiveness)

**Satiation** Processes during a meal that generate the negative feedback leading to its termination (within-meal inhibition) (strengthened by meal volume and weakened by palatability)

**Satiety** The motivational process of not wanting to eat and often expressed as degree of satisfaction and/or fullness. This bears some reciprocal relationship to hunger. Some authors (Le Magnen, Blundell) argue that satiation and satiety are mechanistically distinct, the former determines meal size; the latter meal frequency

## Introduction

Human eating behavior is complex and influenced by physiological, environmental, genetic factors and learned experience. Eating behavior studies commonly focus on assessment of food intake and its physiological, psychological and environmental determinants (Blundell and Stubbs, 2003). Often, these studies are very short-term and have limited capacity to explain mechanisms affecting longer-term energy balance. Because overnutrition is increasingly prevalent and undernutrition is still a significant problem, it is important to consider how appetite control relates to energy balance. It is also necessary to consider some important methodological issues in appetite research and environmental factors (including the composition of the diet) that influence energy intake and longer-term energy balance (Stubbs and Finlayson, 2018).

## The nature of feeding behavior and appetite control

Mammalian feeding occurs regularly and intermittently and despite a general lack of conscious nutritional knowledge on the part of the animal, usually appears to match *energy intake* (EI) and nutrient intakes with requirements. How is this achieved? The common explanation is that appetite, EI or feeding behavior are regulated to ensure that physiological requirements are met. However, there is a lack of direct evidence for this regulation. Neither feeding behavior, nor appetite are regulated in a strictly physiological sense because (1) they are not held constant within certain narrow limits and (2) feeding responses are not an inevitable response to an altered physiological signal or need. Feeding behavior is responsive to a number of induced states such as pregnancy, cold exposure, *growth and development*, emotions, and *weight loss*. These responses have often been cited as an evidence of a system that is regulated through homeostatic, symmetrical negative feedback loops. It is probable that some aspects of body size and composition are regulated and changes in feeding behavior are functionally coupled to those regulatory processes. Evidence suggests that the regulation of human energy balance is largely asymmetric. Human eating behavior has evolved in resource-limiting environments to defend against energy deficits (weight loss) rather than excess energy intake (weight gain) (Stubbs and Turicchi, 2021).

Hunger and satiety often have a large learned, anticipatory component rather than solely being the direct consequences of unconditioned physiological signals *per se*, such as reduced *gastrointestinal content*. Such physiological events can act as important cues for feeding but they do not necessarily directly determine that behavior.

The mechanism by which feeding behavior is coupled to physiological events (and other events) is the process of learning. To understand feeding behavior, hunger, and satiety processes, the mechanism by which learning links feeding behavior to physiological, sensory, nutritional, situational, and other learning cues, must be appreciated. This mechanism is termed as associative conditioning of preferences, appetites, and satieties (Blundell and Stubbs, 2003; Mela and Rogers, 2013).

## Learned appetites, satieties, and feeding behavior

Animals and humans learn (or become conditioned) to associate a given food with the physiological consequences of having ingested it. They associate certain proximal stimuli such as the smell, color, taste, or texture of a food (the conditioning stimulus), with a set of sensations that are directly felt (sensory afferent inputs), in relation to the external stimulus and to the endogenous changes such as physiological and neuroendocrine responses to food. The physiological changes that occur as a result of ingesting the food are termed as the unconditioned stimulus. The individual forms a learned or conditioned association between the conditioning stimulus and the unconditioned stimulus (the detectable consequence of eating), which informs them of the sensory and physiological consequences of ingesting that food (Blundell and Stubbs, 2003; Mela and Rogers, 2013). This process is summarized in Fig. 1. Conditioned or learned associations are most efficiently established if the food is sensorially distinct, if there is a significant detectable postingestive consequence of ingesting the food, or if a training or learning schedule is encountered (e.g., by repeated exposure to the food under similar conditions). Learning is facilitated by social interaction.

As regards with the notion of *appetite regulation*, a problem arises when foods are constructed to look and taste like foods with a different composition. For sometime, after the initial exposure to the food, subjects will respond to it in a manner that is determined not by immediate exposure to the food but by what they have learned during the previous period of exposure to the similar foods upon which the learning was originally based. Only if the food produces a very large unconditioned stimulus will this

**Fig. 1** The process by which the subject learns to associate the postingestive consequences of eating with the food eaten and the environment in which it was eaten. Environmental influences can vary in strength from negligible effect to influences so strong that they can constitute the major factor determining a subject's subsequent response to that food.

previously learned response be instantly over-ridden. This raises the possibility that the use of food mimetics (e.g., high intensity sweeteners) may disrupt stable patterns of learned feeding behavior in consumers at large.

The above view of the nature of feeding behavior has implications for the way the appetite system functions in relation to the development of obesity. Physiological models of body weight (energy balance) regulation suggest that feeding behavior is geared to the regulation of a stable body weight through homeostatic negative feedback. Obesity has therefore been seen as a consequence of defects in the regulation of physiology and behaviors related to energy balance. The evidence from behavioral studies suggests the following: (1) feeding behavior is inherently more responsive to decreases rather than increases in body weight; (2) current secular trends in body weight suggest that, over time, it is very easy to increase body weight, which infers body weight is not tightly regulated, at least with reference to weight gain (for instance, in the National Health and Nutrition Examination Survey (NHANES) *dietary surveys* of American adults, average weight increases by 0.2–2.0 kg per year), and (3) there is very limited evidence of clear lean/obese differences in feeding behavior of a type that suggest defects in a regulatory system. For example, evidence suggests that people living with obesity tend to select a diet that is higher fat, energy dense and containing more highly processed foods, which itself facilitates over-consumption. However, the tendency to select fat cannot be viewed as a defect in *physiological regulation*, but rather a difference in food preferences that subsequently impact body weight (Blundell and Stubbs, 2003; Mela and Rogers, 2013; Stubbs and Turicchi, 2021). There are interesting individual differences in response to food-based reward stimuli according to body weight status. Individuals with obesity are more reactive to food cues i.e., their attention is more easily grabbed and held by these cues. In a hungry state, these “attention grabbing” effects become more pronounced in participants with overweight/obesity compared to lean. High BMI also correlates with cravings while dieting and subjective cravings in individuals with overweight is associated with food cue reactivity. Similarly, increased BMI has been associated with more frequent craving, and craving specifically for high fat foods along with increased intake of them. It may be far more profitable to attempt to understand how feeding responds to environmental and endogenous stimuli and which of these responses are functional and adaptive, and which are not (Finlayson et al., 2007). In this context it is important to remember that evolution has selected us to optimize resources in uncertain environments, bank surplus energy, and compensate for energy deficits. Under conditions of environmental uncertainty there is little need

to evolve regulatory systems that protect from weight gain. Furthermore, accumulating body fat provides the ecological advantage of maintaining functional integrity and survival under conditions of food shortage. As a species, humans may have never had the time nor circumstance to evolve patterns of feeding behavior that are protective against weight gain because such evolved behaviors would have little functional or evolutionary advantage. Throughout the development of civilization humans have increasingly manipulated their food production and consumption environment to suit these biological design specifications. This promotes weight gain. Supermarket society is *Optimal Foraging Theory* taken to its logical conclusion. We do not tightly regulate energy balance. Human eating behavior is designed by evolution to feast in times of plenty as protection from famine. Modern industrial marketing strategies play on the constraints our species has evolved with, as an opportunistic *forager*. These considerations influence the methodological approaches that attempt to investigate how feeding behavior responds to endogenous and environmental influences (Stubbs and Tolkamp, 2006; Stubbs and Turicchi, 2021).

## Methodological issues

### Measuring hunger

Hunger is a subjectively expressed construct that people use to express a motivation to eat. The most appropriate measure of hunger is its subjective expression at a given time. This is achieved by asking subjects to mark a *visual analog scale*, which takes the form of a straight line with two extreme representations of hunger anchored at either end. It is most useful to track changes in subjective hunger over time and in relation to feeding events, diet composition, or physiological parameters. Hunger itself exhibits a large learned component (see the Section on **Learned appetites, satieties, and feeding behavior**, above) as reflected by the fact that most of the variation in a person's subjectively expressed hunger is accounted for by time. If hunger is plotted against time in Western subjects feeding *ad libitum* then it generally exhibits 3 peaks and troughs, which broadly correspond to the 3 main meal times of a Western feeding schedule (Fig. 2). Although subjective hunger is a relatively poor proxy for the amount eaten it is a reasonably good predictor of when eating will occur. It is important to recognize that hunger can be influenced by a large number of factors and so a search for a specific unitary hunger signal is likely to prove fruitless. Thus a large survey of over 600 men, women, boys, and girls could find no clear constellation of traits, sensations, or characteristics that typified hunger. A variety of hormones and drugs, the sight and smell of food, its perceived palatability, timing and social situation can all influence hunger (Blundell et al., 2010).

### Measuring food intake

Appetite is specific to foods, exhibits wide inter-subject variability, and tends to decline for a specific food as that food is eaten, leading to selection of other foods. Appetite is therefore, said by Le Magnen to be sensory specific (Magnen, 2012). The sensory specificity of appetite has been shown to relate *inter alia* to the postingestive consequences (satiation and satiety) of having ingested a food. The most objective measure of appetite for a given food in a specific experimental situation is therefore the amount of that food that a subject chooses to eat. Appetite is not rigidly determined by physiological signals *per se* although they may greatly influence it. Both the palatability of a food and the appetite for it tend to co-vary and are often increased subsequent to a period of negative energy balance. Two examples are dieting and illness, both of which lead to lowered intake and a subsequent rebound in appetite. As discussed above, the appetite for a food will be learned on the basis of the consequences of having ingested that food on previous eating occasions. Because of this it is possible to use covertly manipulated foods to deceive subjects into behaving in a manner largely determined by prior learned experience. If this were not so, such deception would be impossible because the

**Fig. 2** Subjective hunger tracked during waking hours in six subjects feeding on isoenergetically dense high-protein, high-fat, and *high-carbohydrate* diets. Subjects exhibit the three peaks and troughs of hunger that typify the Western feeding schedule.

physiological signals produced by the sensorially similar, yet nutritionally different food, would immediately translate (through physiological signals) into behavioral compensation. This fact has implications for consumers because food technology can now dissociate the sensory and nutritional properties of foods, which may undermine the learned basis of food intake control in some people.

### Measuring feeding behavior

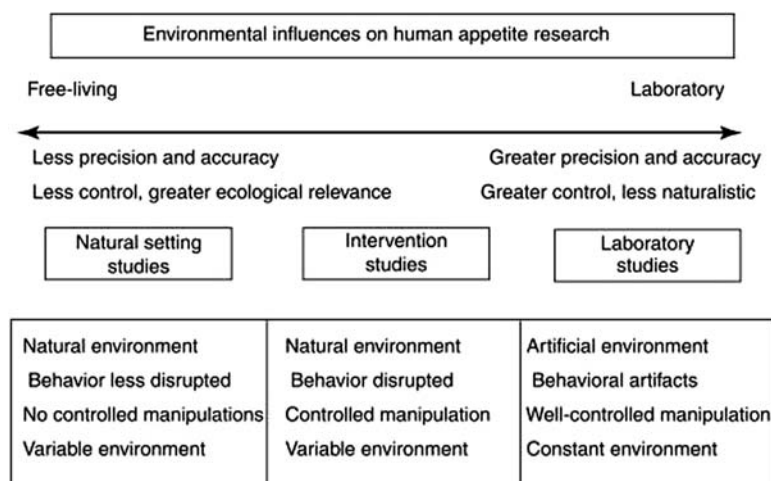

There are many different techniques that can be used to measure feeding behavior in a number of different environmental situations. These techniques are used in naturalistic and/or laboratory studies of feeding. Generally in the laboratory, specific aspects of the appetite and energy balance system are manipulated at the cognitive, sensory, gastrointestinal, or even the metabolic level, for example, by deceiving subjects about the energy content of foods, altering the sensory variety of the diet, changing energy expenditure through systematic alterations in physical activity, administering *nasogastric infusions* or *parenteral infusions*, respectively. A number of other manipulations can be achieved. Because the environment can have such a large influence on feeding behavior, it is important to consider a particular influence on feeding in several environmental contexts. For instance, the effects of fat on *energy intake* have been considered in several laboratory and real life contexts. Under most sets of circumstances increasing the energy density of foods using *dietary fat* appears to be a risk for excess intake. The relationship between the experimental context and how it influences the investigations made is depicted in Fig. 3 (Blundell et al., 2010; Blundell and Stubbs, 2003; Stubbs et al., 1998).

### Sensory stimulation and food hedonics

Food “liking” and “wanting” are emerging constructs in a conceptual approach to appetite where psychological processes of affect and motivation can be viewed as major influences on food intake. Liking and wanting achieve importance in light of the recognition of the contrast between homeostatic and hedonic processes that control eating.

The liking and wanting constructs stem from research exploring the neural basis of palatability and addictive behavior. With principle focus on distinct dopamine and opioid pathways in the brain, the research suggests that processes of liking and wanting can be separately manipulated to produce patterns of behavior that are either exclusively affective or motivational in conjunction with a food stimulus. Liking and wanting are thought to reflect processes that can operate without conscious awareness. This means that they have implicit components (Finlayson et al., 2007). However, their explicit counterparts express themselves subjectively in the form of hedonic feelings from the ingestion of a specific food (i.e., explicit liking) and the intent or desire to consume a specific food (i.e., explicit wanting). Under normal circumstances, explicit liking (“I like this”) is closely associated with explicit wanting (“I want this”). However, there is also evidence to suggest that wanting can be “irrational”; i.e., when implicit wanting for a food is greater than explicit wanting, and not proportional to experienced or expected liking (Finlayson et al., 2007).

Liking and wanting appear to have separate and disproportionate roles in promoting overconsumption. In terms of liking, some individuals at risk of weight gain may experience an exaggerated hedonic response to palatable foods, so that foods are enjoyed

**Fig. 3** The constraints and limitations that the experimental environment places on studies of human feeding. In general the environment ranges from totally free living, which is realistic but very difficult to make measurements into the laboratory where measurements are easy but may be contaminated by artifacts due to the artificiality of the laboratory surroundings.

more and therefore eaten in greater amounts for longer periods of time. Conversely, susceptible individuals may have a diminished ability to experience pleasure from food and therefore consumption of palatable food is driven up to satisfy an optimum level of stimulation. Processes of wanting may also bring about vulnerability to weight gain through increased reactivity toward cues signaling the availability of food. Moreover, a reduced ability to resist the motivation to eat when satiated may promote non-homeostatic overconsumption. A widely held notion is that wanting rather than liking may be the crucial process in maintaining an obese state. Moreover, food liking is often a rather stable characteristic within an individual and appears relatively uninfluenced by increasing weight status. The implication is that liking may be important in establishing the motivational properties of food, but once these are retained it is the upregulation of wanting in an obesogenic environment “insensitivity to homeostatic signals but over-reactivity to external cues” that promotes overconsumption by influencing what and possibly how much is eaten from moment to moment (Finlayson et al., 2007).

### **Sensory stimuli and body weight**

It was originally proposed that obese subjects are more susceptible to external stimuli such as sensory stimuli than lean subjects who were more reliant upon internal physiological cues. This predicted that in a Western context the numerous external food stimuli would promote excess EI in susceptible individuals. As can be appreciated from much of this text, the interplay between “external” and “internal” signal is much more complex and interactive than was initially supposed. Nevertheless, given the multiplicity of afferent inputs that can influence feeding it is possible that some subjects have learned to base feeding predominantly on some cues rather than others. However, dividing these cues into simply internal and external sources is perhaps oversimplified. Current questionnaires which attempt to characterize subject’s responsiveness to food attempt to dissociate “externality,” “restraint,” and “emotionality.” It is becoming increasingly clear that emotional and reward-based responses to food are critically important in facilitating over-consumption. A theoretical framework that integrates these eating behavior traits into coherent domains that have methodological and predictive validity is still needed (Mela and Rogers, 2013).

Systematic differences have been found in sensory preference profiles, but not perceptions of intensity of various tastes between lean and obese subjects. Work has suggested that subjects with a history of *weight fluctuation* have an enhanced sensory preference for high-fat stimuli that are sweet. It has also been shown that sensory preference for fats is associated with degree of overweight in adults and children. This may be important. Although there is little evidence that sensory stimuli alone promote positive energy balances, there is evidence that people select foods they prefer. Preferential selection of energy-dense foods can lead to excess EI without any apparent change in the amount of food eaten. Thus sensory factors are likely to play a role in the selection of foods, which are conducive to weight gain (Blundell and Stubbs, 2003; Mela and Rogers, 2013).

### **Sensory versus nutritional determinants of intake**

The major problems with the concept of sensory preference or liking as determinants of *hyperphagia* and obesity in humans are that (1) there is little direct evidence for this effect *per se* (because the appropriate experiments are very difficult to do) and (2) both animals and humans appear to acquire sensory preferences for foods dense in readily available energy. Dissociation of the sensory characteristics and postingestive consequences of ingesting a food becomes difficult and perhaps artificial. It seems that at the present time the data from animal studies tends to suggest that maximal sensory preference for a food or diet is achieved when the sensory stimulus is reinforced by the metabolic consequences that form part of the satiety sequence. Indeed, there is controversial evidence that ingestion of one sensory stimulus (sweetness) without the associated nutrient (carbohydrate) promotes ingestion of energy shortly afterward. The contribution of sensory and nutritional determinants of feeding is still poorly understood in humans (Blundell and Stubbs, 2003; Mela and Rogers, 2013).

### **Emotional stimuli and over-consumption**

As an intensely gregarious species we are bound together by numerous relationships ranging from mother–offspring bonds developed at birth, through kin relations to culturally defined positions in any given social structure. Positioning in social structures is also common among the primates and is inextricably intertwined with access to resources, safety (e.g., predatory avoidance), and food. This is critically important to the survival of groups of animals under ecological conditions. Humans have not lost the neuro-anatomical bases of our emotions and behavior with which we evolved. Hence, food is as, if not more emotionally important today as it has always been during our evolutionary heritage. However, the social and emotional meanings of food have changed. Food is still important for sharing social emotions and creating social bonds through ceremonies, rituals, and traditions. Food is a major source of reward for achievements or simply as treats. Interestingly, in children, there is evidence that more energy-dense foods are more preferred. More energy-dense foods are also generally cheaper than less energy-dense but nutritionally balanced foods, making the *fast food* outlet phenomenon self-perpetuating. Food is a major source of soothing for emotional distress in others, for example, when parents comfort children. In the context of this discussion it is notable that food is also a major source of reward, soothing, and comfort in binge eaters, and is a common theme that emerges, in people struggling to control their weight. Thus, the emotional drives and social facilitators of excess energy intake are powerful, if not more powerful than ever in modern Western society (De Castro, 1997; Finlayson et al., 2007; Mela and Rogers, 2013).

## Meal patterns, appetite, and energy balance

The effect of meal patterns on appetite and energy balance is also an unresolved issue. It has been noted that snacking and commercially available *snack* food are often believed to elevate EI. However, there is considerably less evidence that meal or snack patterns contribute to the development of obesity. It is important to note at this point that the relationship between a meal and a snack relates to timing and size of ingestive events in meal feeding animals. In nonhuman species (and indeed humans) that engage in numerous small feeding bouts throughout their diurnal cycle there is little if any distinction between a meal and a snack. Meal-feeding animals are conditioned to ingest the majority of their EI in a few large ingestive events in their diurnal cycle, at approximately the same time points. Under these conditions, a snack can be defined as an energetically small, intermeal ingestive event. To avoid confusion with a common use of the word to describe a certain type of “commercially available food,” we use the phrase “commercially available snack foods” to describe those specific foods. Commercially available snack foods tend to differ from the rest of the diet as they are more energy dense, high in fat and carbohydrate and low in protein and usually contain a large fraction of their edible mass as dry matter. They are by no means the only food eaten as a small inter-meal ingestive event by many people at large.

The evidence in relation to meal patterns, appetite, EI, and body weight is indirect and fragmentary. On aggregate, *cross-sectional studies* tend to support no, or a negative, relationship between meal frequency and BMI. However it has been convincingly argued that examinations of the relationship between snacking and energy balance in free-living subjects are extensively flawed by misreporting, misclassification of meals and snacks, and potentially by reverse causality. Under these conditions it is difficult to draw clear conclusions about the effects of snacking in cross-sectional studies. It is therefore important to conduct controlled laboratory interventions over a number of days in humans. These studies suggest that in the short-to-medium term adding mandatory snacks to the diet leads to over-consumption. This effect is most pronounced in those who do not habitually snack and least pronounced in those who do. It is also of note that rats tend to be “snackers” and Western humans tend to be meal feeders. The rat tends to adjust EI by varying meal frequency; the human by varying meal size. However, if rats are *meal fed*, they learn to adjust EI by varying meal size. Humans placed in time isolation begin to adjust intake by varying meal frequency. These comparisons illustrate the fact that adjustment of intake to energy or nutrient requirements occurs within a conditioned time framework, which itself is variable depending on the conditioning environment. Despite large changes in the pattern of feeding, EI can still be adjusted to satisfy requirements.

## Social and situational influences on feeding behavior

There are a number of social and situational influences on food intake in humans. In general, the shorter the time period of measurement, the greater the effect of situational and social influences. Thus there are a large number of factors that can influence single meal size in humans. These factors are summarized in Fig. 4.

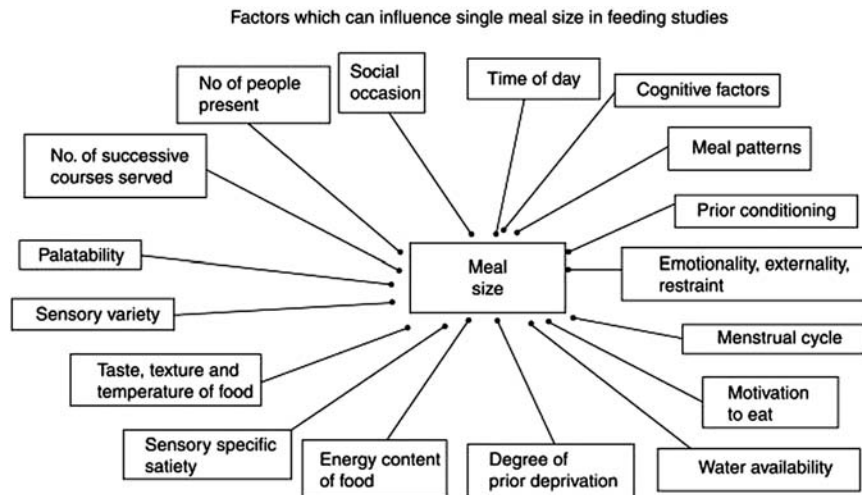

Time of day appears to influence meal size in that the amount eaten and the EI increases on going from breakfast, to lunch, to the evening meal. Meal size also increases across the feeding period in rats. It has been suggested that this occurs in learned anticipation of the energy requirements in the fasting period (night for humans, day for rats). Meal size and EI tend to be greater at weekends than on weekdays, in Western adults. Meal size also varies as a power function of the number of people present at a meal. DeCastro has termed this effect “social facilitation” of feeding. Social facilitation and daily routine account for much of this effect.

Seasonality can influence feeding. A number of studies also suggest that EI, meal size, and eating rate are all elevated in the autumn. In one particular study hunger was associated with meal size in winter and spring, but not so clearly in the autumn (Mela and Rogers, 2013; Stubbs, 2014).

## Cognitive and social cues

Throughout the 1960s and 1970s a large number of behavioral studies examined the effect of cognitive and social cues (perceived energy content of foods, salience of cues, eating behavior of others present) on feeding in relation to the externality hypothesis. Although a large number of studies found that so called external cues do relate to short-term feeding behavior, a large number of others did not. However, the presence of external cues alone does not reliably predict how much food people will eat. Neither does the presence of external cues always relate to lean/obese differences in feeding patterns. Some of these differences in relation to cognitive and social cues are better explained in relation to dietary restraint. Restraint is a term used to describe people who are attempting to limit or reduce their body weight by means of cognitive energy restriction (dieting). In doing so it is proposed that they are placing their motivation in relation to feeding at odds with physiological feeding stimuli. Placing cognition at odds with physiological drives can result in pathologies of eating since the normal “regulatory” processes are cognitively undermined. Furthermore it is argued that restraint will increase the probability that a person will break a diet. It has been shown that an intervention (usually a preload) that breaks the rules of restraint, almost paradoxically induces a greater intake. This phenomenon has been termed counter-regulation. This effect is cognitive, because it can be induced by deceiving a restrained eater into believing that a *preload* was high in *calories* (Mela and Rogers, 2013). Because the concept of restraint has predictable behavioral outcomes it is a useful tool in characterizing different people with respect to their feeding behavior. However, it is now generally

**Fig. 4** Major factors known to affect single meal size in humans. In general, the shorter the time interval of measurement, the greater the influence these factors have on the observed feeding behavior.

accepted that restraint is not a unitary construct and people who attempt to lose weight and who show flexible restraint are more successful than those who are rigid in their patterns of cognitive restraint.

It is useful to consider the role of dual process models of behavior in the context of energy balance (weight change). Models of behavior and behavior change have focused historically on social cognition (e.g., beliefs, intentions, attitudes and decisions), emphasizing pathways of reasoned action in which pre-decisional motivation leads to the formation of intentions and the implementation of those intentions as volitional action. Automatic processes (emotions, desires, habits resulting from associative learning and physiological states) may also impact eating behavior and behavior change. These processes tend to be relatively rapid, impulsive (less conscious) and habitual in comparison to the slow, deliberative processes of motivation and cognitive self-regulation. Furthermore, in the context of appetite and energy balance behaviors, the development of self-regulatory behavior change is effortful, particularly in the face of physiological responses to weight loss, while unconscious or automatic components of EB behaviors are rapid and effortless. Physiological mediators of homeostatic and hedonic appetitive drives, and changes in physical activity that are triggered by weight loss may feed into such automatic process of behavior change to undermine self-regulation of eating behavior.

## Diet composition and appetite

Food and nutrient *ingestion* influence human appetite through multiple feedbacks at several levels, which can be traced through the processes of food location, ingestion, digestion, absorption, and metabolism. Satiety is therefore maintained by a functional sequence or cascade of sequential physiological events that reinforce each other. Removing parts of a food or nutrient's effects on this sequence will therefore diminish its impact on satiety.

## How do macronutrients and energy density affect satiety?

Because the control of food intake in humans is imprecise, alterations in the energy density of the diet can lead to changes in *energy intake*, even over quite prolonged periods. Macronutrients are not all equal when it comes to how satisfied one feels after eating them. Protein has the greatest effect on satiety, followed by carbohydrate, followed by fat. Studies using smaller *preloads* (typically of 250 kcal or less) do not always find this effect. Although fat is the most energy-dense macronutrient it is also the least satisfying. The effect macronutrients have on satiety is illustrated in **Fig. 5**. Foods that are high in protein include lean meat, fish, beans, peas, lentils, *mycoprotein*, *tofu*, and eggs. Foods rich in carbohydrates and fiber include wild rice, potatoes, cereals and *oats*, *bread*, beans, peas, lentils, and couscous. Fat-rich foods include *savory snacks*, pies, biscuits, cakes, cream, and most cheese (Stubbs et al., 2010).

## Diet composition and satiety to prevent weight gain

Any *weight reduction* strategy that focuses on one simple aspect of diet alone will have limited effects on *weight control*. Dietary *monotherapies* are very limited in what they will achieve. Several aspects of diet composition can be used simultaneously to influence

**Fig. 5** Effect of increasing energy content of macronutrient loads on satiety Index subjectively expressed over 3.25 h.

satiety and help people navigate to a healthy body weight. In other words, we should be taking a package definition of what constitutes a reasonable dietary approach to weight management and that should be integrated with evidence-based behavior change approaches. Dietary factors that help with self-management of eating behavior include a low fat content, tolerably low energy density of  $\sim 1.1\text{--}1.3 \text{ kcal g}^{-1}$ , a high water content; avoiding where possible, caloric beverages, fiber content should be tolerably high (which parenthetically is not much more than 20–30 g per day). Fiber holds water in foods, which lowers energy density, and decreases the rates at which those foods are digested. To enhance satiety, protein content of the diet can be relatively, tolerably, and reasonably high (probably not exceeding 25–30% of an energy-reduced diet, for example, a diet that is followed to induce a negative energy balance. This translates into less than 20–25% of energy requirements from protein). *Protein intake* from red and processed meats should be limited. The carbohydrate content depends very much on type. There is a good deal in the literature that suggests sweet, short-chain carbohydrates can elevate *energy intake*, especially when combined with fat. This combination is most common in commercial processed and *snack foods*. The orosensory properties of foods need to be maintained to encourage people to select those foods, so that they become a practical option for the development of healthy eating habits (Stubbs et al., 2010).

## Conclusion

Human appetite is influenced by both physiological and psychological cues which themselves are shaped by the environment. Appetite control and energy balance regulation are geared to defend against weight loss and less tightly geared to defend against weight gain. Many of the environmental eating-related cues that are part of modern society also act as stimuli that promote higher levels of food and energy intake, reinforced by an interaction of the sensory properties of foods with liking and wanting circuits. Because many aspects of eating behavior are learned through associative conditioning they are often habitual and not under immediate, direct conscious control. These factors facilitate weight gain in modern environments, but may also provide some potential opportunities for obesity prevention and long-term management of body weight. Gaining weight and excess adipose tissue across the adult lifespan requires little conscious effort. Losing weight and preventing weight regain requires considerable effort and weight loss attempts are often subject to subsequent weight regain. Because most of energy intake and less than half of energy expenditure is behavior, appetite control and self-management of eating behaviors are major targets for many weight management interventions. The effects of behavior change interventions on weight management are still relatively modest and our understanding of the factors that disrupt and undermine self-management of eating behaviors is limited. These factors include physiological resistance to weight loss, gradual compensatory changes in eating and physical activity and reactive processes related to stress, emotions, rewards and desires that influence eating to meet psychological needs. In the future it is likely that more interdisciplinary research between the areas of appetite control, energy balance and behavior change research, together with methodological developments in these areas

will lead to more effective interventions to improve weight and health outcomes in the general population. Better matching evidence-based intervention content to the needs of individuals and better objective tracking of appetite and energy balance behaviors may improve outcomes in the future.

### Glossary

**Arachidonic acid** AA, is the trivial name for cis-5,8,11,14-eicosatetraenoic acid (20:4n-6). This polyunsaturated fatty acid can be biosynthesised from the omega-6 essential fatty acid, linoleic acid, and is abundant in the phospholipid membranes of several tissues, including the brain. It is a precursor of several important signaling molecules such as eicosanoids.

**Attention Deficit Hyperactivity Disorder** ADHD is a behavioral disorder, mainly of children, that includes a group of symptoms such as short attention span, easily distracted, restlessness, constant fidgeting, and impulsiveness. ADHD is estimated to affect 3–9% of children and about 2% of adults: it is normally diagnosed between the ages of 3 and 7 years. There is no cure, but the disorder can be managed by a combination of behavior therapy and drug therapy, in particular the use of psychostimulant drugs that enhance activity of the neurotransmitters, noradrenaline (norepinephrine) and dopamine. These may induce more focussed attention while lessening impulsivity and limiting behavioral repertoires. However, the perceived overprescription of such drugs to children remains a controversial topic.

**Docosahexaenoic acid** DHA, 22:6n-3, cervonic acid. This polyunsaturated fatty acid is abundant in fish oils (e.g., tuna oil) and is a significant component of the membrane phospholipids of most tissues, especially the brain, sperm, and the retina of the eye. It can be biosynthesised from the omega-3 essential fatty acid,  $\alpha$ -linolenic acid, but the rate of conversion is very low.

**Eicosanoids** Metabolites of 20-carbon polyunsaturated fatty acids, such as arachidonic acid (AA), and eicosapentaenoic acid (EPA). They possess both autocrine and paracrine signaling roles, and have actions in many biological processes such as, inflammation, fever, regulation of blood pressure, immune system modulation, and control of reproductive processes.

**Eicosapentaenoic acid:** EPA, 20:5n-3, timnodonic acid. This polyunsaturated fatty acid is present in most fish oils, and is found at low levels in tissue membrane phospholipids. It is a precursor of some eicosanoids, which tend to antagonise the actions of arachidonic acid derived eicosanoids.

**Essential fatty acids** Polyunsaturated acids of the omega-6 and omega-3 families, which are essential for life and good health. The only true essential fatty acids are the omega-6 and omega-3 fatty acids, linoleic acid and  $\alpha$ -linolenic acid, respectively. The other omega-6 and omega-3 fatty acids can be derived from these respective precursors, albeit at low levels.

**Hypothalamic–pituitary–adrenal axis** The HPA axis is a representation of a cascade of hormonal signaling known to be sensitive both to stress and nutritional state. Such events alter activity of selective nerve cells in the hypothalamus (a collection of nuclei in the base of the brain), which release corticotrophin releasing hormone (CRH). This in turn activates cells in the adjacent anterior pituitary gland to release adrenocorticotrophic hormone (ACTH) into the blood circulation. ACTH is carried to the adrenal glands, near the kidneys, where cells are stimulated to release cortisol, a glucocorticoid steroid hormone, into the circulation. Cortisol has anti-inflammatory and glucose counter-regulatory activity.

**Neurotransmitters** Chemical messengers that transfer neuronal activity signals across the synapse (microscopic gap) between one nerve cell and another. Electrical activity in the presynaptic nerve cell causes release of pockets (vesicles) of neurotransmitter into the synapse from where they reach receptors on the postsynaptic cell, whose activation may either excite or inhibit activity in the postsynaptic nerve cell. Neurotransmitters discussed here include the monoamine group, serotonin (5-hydroxytryptamine, 5-HT), adrenaline (epinephrine), noradrenaline (norepinephrine) and dopamine. This group is synthesized from essential amino acids (i.e., that must be obtained from the diet): tryptophan for serotonin, and tyrosine for the others. This is of particular interest here because rate of synthesis of these neurotransmitters is sensitive to availability of their precursor amino acids, and thus to the latter's availability from the diet. Another transmitter group discussed is opioid peptides, derived from larger precursor proteins, but synthesis of these is not sensitive to diet.

**Omega-3 polyunsaturated fatty acid** Also called  $\omega$ -3, or n-3 fatty acids. These are named after their shared structural motif of having their terminal double bond three carbons from the methyl (or omega) end of the carbon chain. They are derived from  $\alpha$ -linolenic acid, by carbon chain-elongation and desaturation and include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).

**Omega-6 polyunsaturated fatty acid** Also called  $\omega$ -6 (omega-6) acids. These are named after their shared structural motif of having their terminal double bond six carbons from the methyl (or omega) end of the carbon chain. They are derived from linoleic acid, by carbon chain-elongation and desaturation, and include arachidonic acid (AA).

## Introduction

Effects of diet on behavior have long been topics of folklore superstition and popular mythology, and more recently the subject of rigorous, and not so rigorous, scientific study. Most research into dietary effects on human behavior has assessed changes in mood or mental function after eating (or drinking), or after fasting. Typical measures of mental function include tests of reaction time, attention, memory, problem solving ability and intelligence (intelligence quotient; IQ). In addition, research has addressed effects of diet on disturbed behavior, including Attention Deficit Hyperactivity Disorder (ADHD) in children, antisocial behavior and aggression, mental illness such as depression, and dementia (see [Table 1](#)).

Clearly, chronic malnutrition can seriously affect behavior by impairing brain development, and acutely by denying sufficient nutrients for optimal cognitive function. However, this article concentrates on dietary effects on behavior that are not the result of chronic malnutrition, nor of pharmacologically active ingredients of the diet such as alcohol or caffeine. Rather, they arise from more subtle effects of variation in nutrient intake within the normally nourished population.

## Effects of Meals

The commonest way in which food can affect behavior is the change in mood and arousal that occurs from before to after eating a meal. This might sound trite, but it is not trivial: this general meal effect is probably the most reliable example of an effect of diet on behavior. Many animals, including human beings, tend to be aroused, alert, and even irritable when hungry. This encourages their search for food. However, their mental efforts become distracted by this task, to the detriment of other behaviors. After eating a satiating meal, we and other animals become calm, lethargic, and may even sleep.

Nevertheless, even this seemingly straightforward phenomenon can be distorted, and can vary across individuals and situations. The impact of a food or drink will depend on the person's initial state. For example, thirsty people improved their vigilance when allowed to drink water, whereas when people were asked to drink when not thirsty, their performance deteriorated. Numerous experiments have shown that manipulation of the structure of meals results in variation in postprandial changes in mood and mental function. One obvious facet of meals that has been investigated is what is eaten, i.e., nutrient composition; the other two main aspects of meal structure that have been studied are meal timing and meal size. Of course, the effect of a meal on appetite also represents a behavioral effect, but this aspect is covered elsewhere in this encyclopedia.

Besides any nutritional effects, two other influences on behavior are also known to interact with attempts to measure dietary effects on behavior. First, most people are very habitual in their choice of food, and size and timing of meals. As a result, they

**Table 1** Examples of nutritional variables known or suspected to affect behavior, mood, and cognition

<i>Category</i>	<i>Variable description</i>
Food restriction	Early life undernutrition Chronic semistarvation Dieting to lose weight Short-term fasting (e.g., missing a meal)
Meal effects	Pre to postmeal changes Meal timing (e.g., morning, afternoon, night) Meal size Macronutrient composition (acute and chronic effects) Breast milk
Amino acids	Neurotransmitter precursors (e.g., tryptophan, tyrosine, phenylalanine) Phenylketonuria
Sugars	Sucrose (dietary intake) Glucose (supplement; tolerance)
Lipids	Essential fatty acids: Arachidonic acid (omega-6 PUFA) Eicosapentaenoic acid (omega-3 PUFA) Docosahexaenoic acid (omega-3 PUFA)
Micronutrients	Iodine Iron Selenium B-vitamins: B1, B6, B12, Folate Vitamin C Vitamin E Zinc
Diabetes	Acute effects of hypoglycemia Chronic effects
Pharmacological	Caffeine Alcohol Nutraceuticals (e.g., plant compounds)

have learned a set of beliefs and expectations about the impact of their habitual dietary regime. Therefore, particularly in short-term tests, these expectations may over-ride or mitigate physiological changes. Dietary experiences that differ from a person's habitual eating could lead their behavior to change through cognitive rather than (or as well as) physiological influences.

Secondly, there are circadian rhythms and sleep–wake cycles in arousal and performance, which complicate interpretation of meal effects, as we discuss in the next section on meal timing.

### Meal Timing

Does the timing of a meal in the day make a difference to any effects on behavior? In other words, do any behavioral effects differ between breakfast, midday, and evening meals, or mid-morning and afternoon snacks?

#### Breakfast

The potential effects of breakfast on performance and well-being continue to attract much interest, not least from industry, especially concerning performance of schoolchildren. Pollitt and colleagues have argued that children are likely to be more susceptible to the effects of fasting than adults, due to greater brain metabolic demands relative to glycogenic and gluconeogenic capacity. The numerous studies in this area have produced inconsistent results, which is partly attributable to variation in populations studied, their nutritional status, and designs used. There is a consensus that breakfast is more likely than not to benefit schoolchildren's performance, particularly if the children are already nutritionally vulnerable and have mental abilities with room for improvement. Moreover, breakfasts achieving slower release of glucose into the blood may be more effective in sustaining performance over the morning than those allowing rapidly absorbed glucose.

In all of us, there is a tendency for levels of arousal and alertness to rise during the morning, reaching a peak near midday. Some evidence suggests that breakfast may help to control this arousal, so that attention can be successfully focused on the task in hand. Conversely, omitting breakfast may increase autonomic reactivity, leading to less focused attention. This effect could explain one finding that children without breakfast showed better recall of objects to which they had not been asked to attend: such attention to irrelevant stimuli is also known to occur with increased anxiety. Furthermore, increasing hunger is likely to be distracting.

Less attention has been paid to effects of breakfast in adults. However, there are several studies of effects of giving breakfast to students that show a benefit on spatial and verbal recall tasks 1–2 h later, compared to missing breakfast. Interestingly, attention-based and reaction-time tasks were not improved by breakfast, and a logical reasoning task was even slightly impaired. Perhaps those tests benefit more from mild arousal, which could be acutely reduced by some breakfasts. These studies did not determine whether performance later in the morning would be affected by breakfast. Differential effects of breakfast content and size will be discussed below.

### **Midday Meal**

Several studies have demonstrated a drop in performance after the midday meal, particularly for vigilance tasks requiring sustained attention. However, this 'postlunch dip' may not simply be an effect of eating, because vigilance has also been found to decline from later morning to early afternoon in subjects not eating lunch. That is, there is an underlying circadian rhythm in performance that is confounded with the effect of a midday meal. In fact, using noise stress to arouse subjects during a midday meal prevented any decline in performance due to the meal. It has also been shown that the more anxious one is feeling before lunch, the less one will experience any postlunch dip in performance. In support of this, another study found that subjects scoring highly on a personality measure of extraversion and low on neuroticism were more likely to be affected by postlunch dip. These are examples of the importance of individual differences and context on meal effects.

### **Evening Meal**

There are few studies of effects of eating later in the day, although there has been some interest in effects of meals during nightshifts. Accuracy of performance declines with eating during a nightshift, but unlike lunch, premeal anxiety levels had no effect. One study in students of effects of eating a large freely chosen evening meal found little evidence for consistent changes in performance relative to missing the meal. Despite this, the students who omitted the meal reported feeling more feeble and incompetent and less outgoing than those who had eaten.

### **Snacks**

One study specifically addressed whether an afternoon snack (approximately 1–1.2 MJ, 240–290 kcal, of yoghurt, or confectionery) eaten 3 h after lunch (or no lunch) would affect task performance. A beneficial effect of the snack was found on memory, arithmetic reasoning and reaction time 15–60 min later. The comparison was with performance after a 'placebo' zero-energy drink (participants were unaware of energy content). This rather different placebo does not preclude effects due to differences in sensory experience and expectations. Moreover, whether or not lunch had been eaten beforehand had little effect on the outcomes, suggesting that any nutritional effects must be due to acute impact of the snack, irrespective of prior nutritional state. It is known that snacks of this size eaten after a meal have only a small effect on blood glucose, although insulin rises sufficiently to inhibit lipolysis and suppress the release of plasma free fatty acids later in the postprandial period.

The authors reported that these performance benefits from an afternoon snack were not found with a snack taken late morning. The most likely reason is that the beneficial effect depends on the decline in alertness normally occurring during the afternoon.

Other studies have found differential effects of macronutrient content of snacks; these are discussed below.

### **Meal Size**

This topic has been little studied regarding behavioral effects, perhaps because there are a number of methodological difficulties and an absence of theory. For example, what counts as a large or small meal? Should the difference be in terms of absorbed energy, or weight or volume eaten, or even consumption time? If the former, then behavioral outcomes would need to be measured with sufficient delay for differences in energy absorption to be discriminable. Moreover, the influence of expectations and habit might confound experimental nutritional differences.

Two studies in adults found that large lunches (at least 4 MJ, 1000 kcal) impaired vigilance relative to eating small or medium-sized lunches. There was also evidence that this effect depended on the meal size being different from that habitually consumed. In adolescents, a larger breakfast (2.6 MJ, 634 kcal on average) resulted in poorer vigilance but better short-term memory 3 h later, compared to after a smaller breakfast (1.6 MJ, 389 kcal on average). Thus, there is some evidence that vigilance is adversely affected by a large meal.

### **Meal Composition**

#### **Carbohydrate Versus Protein**

The effects of varying the nutrient composition of meals have been studied extensively, and rather more for mood than performance. This is largely because of evidence that plasma and brain levels of precursor amino acids for synthesis of monoamine

neurotransmitters (chemicals responsible for signaling between nerve cells), strongly implicated that mood disorders, can depend on carbohydrate:protein ratios in the diet. Synthesis of the neurotransmitter serotonin (or 5-hydroxytryptamine; 5-HT) depends on dietary availability of the precursor essential amino acid, tryptophan (TRP), due to a lack of saturation of the rate-limiting enzyme, tryptophan hydroxylase, which converts TRP to 5-hydroxytryptophan (see **Figure 1**). An important complication is that TRP competes with several other amino acids, the large neutral, primarily branched-chain, amino acids (LNAA), for the same transport system from blood to brain. If the protein content of a meal is sufficiently low, such as 5% (or less) total energy as protein, then relatively few amino acids will be absorbed from the food in the gut. At the same time, insulin will stimulate tissue uptake of competing amino acids from the circulation, and the plasma ratio of TRP to those of amino acids (TRP/LNAA) will rise, favoring more TRP entry to the brain. Conversely, a high-protein meal, which would be less insulinogenic, results in absorption of large amounts of competing amino acids into the blood, especially the branched-chain amino acids, leucine, isoleucine, and valine. On the other hand, TRP is scarce in most protein sources, and is readily metabolized on passage through the liver: thus, the plasma ratio of TRP to competing amino acids falls after a protein-rich meal. Indeed, the protein-induced reduction in plasma TRP ratio often seems to be more marked than any carbohydrate-induced rise. Such effects also depend on the interval since, and nutrient content of the last meal.

This evidence is particularly relevant to dietary effects on mood and arousal, because 5-HT has long been implicated in sleep, as well as affective disorders such as depression and anxiety. However, cognitive performance might also be affected, given the known role of 5-HT in responsiveness to environmental stimuli and stressors, impulsivity, and information processing. Importantly, there is evidence that dietary availability of TRP can influence brain function in humans: for instance, feeding a TRP-free diet, which considerably reduced plasma TRP (and so could be expected to impair 5-HT function) induced depression in previously recovered depressives or in people with a genetic predisposition to depression. Furthermore, a TRP-free drink has been shown to impair performance on tests of visuospatial and visual discrimination learning, as well as memory. In addition, TRP depletion enhances accuracy of predicting events associated with negative consequences, and reduces accuracy of emotional face recognition, supporting the theory that 5-HT normally biases attention in favor of positive events. Typically, manipulations that should increase 5-HT synthesis and release, such as consuming TRP-rich proteins, produce opposite behavioral effects.

There is evidence that people feel calmer and more sleepy after snacks or meals rich in carbohydrate but virtually free of protein (an unusual situation) than after protein-rich meals with little carbohydrate. This is compatible with changes in 5-HT function, but these studies did not determine whether this is due to an increase in 5-HT after the carbohydrate-rich meal, or a decrease after the protein meal, which could prevent the postprandial sleepiness. Furthermore, adding more than 5 or 6% protein (of total energy) to the carbohydrate meal has been shown to prevent the increased synthesis of central 5-HT, relative to fasted levels, in both rats and people (see **Figure 2**). Also, even pure carbohydrate does not appear to induce sleepiness in everyone.

Another difficulty in comparing effects of carbohydrate and protein intake is that relative changes in mood and performance might be due to protein-induced raised plasma tyrosine (TYR), the precursor amino acid for synthesis of the catecholamine neurotransmitters (adrenaline, noradrenaline, dopamine), which also competes with LNAA for entry into the brain. In catecholamine systems where the neurones are firing rapidly, acute physiological increases in brain TYR, for example, by feeding a high-protein diet, can raise TYR hydroxylation rate and catecholamine turnover. Such systems include dopaminergic neurones involved in

**Figure 1** Diagram representing pathways to the synthesis of the neurotransmitter 5-hydroxytryptamine (5-HT, serotonin) from the precursor essential amino acid, tryptophan (TRP). TRP is taken up by neurones from blood, but its passage across the blood brain barrier (BBB) is in competition with another group of essential amino acids known as the large neutral amino acids (LNAA). Thus, the ratio of TRP to total LNAA (TRP:LNAA) determines how much TRP enters the brain. Most TRP is normally bound to albumin in plasma, so not available for uptake into the brain. However, after a carbohydrate-rich low-protein meal, increased release of insulin raises levels of free fatty acids (FFA) in plasma, and these displace TRP from albumin. In addition, insulin promotes tissue uptake of the LNAA from plasma. Hence, the TRP:LNAA ratio increases and more TRP enters the brain. Increased availability of TRP in neurones drives greater synthesis of 5-HT because the rate-limiting enzyme, TRP hydroxylase, which converts TRP to the intermediate 5-hydroxytryptophan (5-HTP), is not fully saturated.

arousal, attention, and motivation. Nevertheless, high-protein meals in human beings do not always raise the plasma TRP/LNAA ratio, depending on nutritional status or time of day.

Differential effects on performance have been seen with less extreme variations in protein and carbohydrate intake. For example, a lunch of 55% energy as protein and 15% as carbohydrate produced faster responses to peripheral stimuli, but greater susceptibility to distraction, compared to eating the reverse proportions of protein and carbohydrate. Sleepiness was not affected by macronutrient composition in that study. However, with these protein:carbohydrate ratios, the plasma TRP/LNAA ratio could still be lowered by the protein-rich meal relative to the carbohydrate-rich one, even if TRP/LNAA does not rise from premeal levels after a carbohydrate-rich meal with much more than 5% protein (Figure 2).

A delay of at least 2 h after eating may be necessary to allow neurotransmitter precursor changes to influence behavior. Earlier effects may be related to changes in glucose availability, and levels of insulin and counter regulatory hormones such as adrenaline, glucagon, and cortisol. These changes could underlie recent results with breakfasts of 20:80, 50:50, and 80:20% protein:carbohydrate ratios (1.67 MJ, 400 kcal). A measure of central attention improved initially after the carbohydrate-rich breakfast, but then later improved after the protein-rich ones; the opposite was found for peripheral attention. This study also found that the 80% protein breakfast produced the best short-term memory performance approximately 1–2 h after eating, but not at 3.5 h.

### Effects of Dietary Fat

Most studies of effects of fat have varied its level with that of carbohydrate, while keeping protein constant and so allowing equicaloric meals. Comparisons have been made for low-fat (e.g., 11–29% of energy as fat), medium-fat (e.g., 45%), and high-fat (e.g., 56–74%) breakfasts, midmorning, and midday meals, as well as intraduodenal infusions of lipid or saline. On balance, high-fat meals appear likely to increase subsequent fatigue and reduce alertness and attention, relative to high-carbohydrate/low-fat meals. However, there are inconsistencies relating to changes in specific moods and effects of meal timing: for instance, feelings of drowsiness, confusion, and uncertainty were found to increase after both low- and high-fat lunches but not after a medium-fat lunch. One possibility is that mood may be adversely affected by meals that differ substantially in macronutrient composition from habitual ones. An alternative is that similar mood effects could be induced (albeit by different mechanisms) by high carbohydrate in one meal, and high fat in the other: for example, 1.67 MJ (400 kcal) drinks of pure fat or carbohydrate taken in the morning both increased an objective measure of fatigue relative to a mixed-macronutrient drink, although the two single-nutrient drinks had opposite effects on plasma TRP/LNAA ratios; this is of course an unusual situation and may not generalize to normal mixed-nutrient meals.

In many of these studies, the meals were designed to disguise variation in fat level from participants. It is therefore possible that effects on mood may have resulted from discrepancies between subjects' expectations of certain postingestive effects, and the actual effects that resulted from neurohormonal responses to detection of specific nutrients in the duodenum and liver. A case in point may be the increase in tension, 90 min postlunch, with increasing fat intake, reported by predominately female subjects: this might reflect an aversive reaction to (unexpected) fat-related postingestive sensations.

**Figure 2** The data show the effect in rats of no meal, a carbohydrate meal with no protein, and one with increasing amounts of protein, on (a) the plasma ratio of tryptophan to the large neutral amino acids (TRP:LNAA) with which TRP competes for entry across the blood brain barrier (crosshatched bars) (b) levels of TRP ( $\mu\text{mol g}^{-1}$ ) measured in the hypothalamus of rat brain (hatched bars) (c) the levels of 5-hydroxytryptophan ( $\mu\text{g g}^{-1} 10^{-1}$ ), an intermediate precursor of serotonin synthesis, in the hypothalamus. The rise in TRP entering the brain after a carbohydrate meal drives increased serotonin synthesis, but this effect is progressively inhibited by increasing protein content. The figure is based on data obtained from Fernstrom MH and Fernstrom JD (1995) Brain tryptophan concentrations and serotonin synthesis remain responsive to food consumption after the ingestion of sequential meals. *American Journal of Clinical Nutrition* 61: 312–319, with permission from American Society for Nutrition.

Postprandial declines in arousal can be quite noticeable 2.5–3 h after high-fat meals, but fat in midmorning meals seems more sedating than at lunchtime, which might relate to expectations. By comparison, when lipid was infused directly into the duodenum, a decline in alertness was apparent much sooner, by 30–90 min after the meal. These effects of fat may result from increased release of the gastric regulatory hormone, cholecystokinin. However, in a study comparing ingestion of pure fat, carbohydrate, and protein (1.67 MJ, 400 kcal, at breakfast), measures of memory, attention, and reaction time deteriorated more after carbohydrate and protein than after fat. This beneficial effect of fat was attributed to the demonstrated relative absence of glycemic and hormonal (insulin, glucagon, and cortisol) perturbations in the 3 h following fat ingestion.

## Carbohydrates, Stress, Mood, and Mental Function

### Susceptibility to Mood Enhancement by Diet

The possibility that a carbohydrate-rich low-protein meal could raise 5-HT function gave rise to the proposal that some depressed people may self-medicate by eating carbohydrate, so leading to increased 5-HT release in a manner reminiscent of effects of anti-depressant drugs, which enhance aspects of 5-HT function by inhibiting removal of 5-HT from the synaptic cleft between nerve cells. For the most part, however, early behavioral and pharmacological evidence for such a phenomenon was not very convincing.

Nevertheless, recent research provides some further support for beneficial effects of carbohydrate-rich/protein-poor meals on mood and emotion in some people. When participants were divided into high or low stress-prone groups, as defined by a questionnaire, carbohydrate-rich/protein-poor meals before a stressful task were found to block task-induced depressive feelings and release of the glucocorticoid stress hormone, cortisol, but only in the high stress-prone group. This finding was replicated using high- versus low-TRP containing proteins (alpha-lactalbumin and casein, respectively). It was argued that, because stress increases 5-HT activity, the poor stress-coping of this sensitive group might indicate a deficit in 5-HT synthesis that is improved by this dietary intervention.

There is another link between macronutrient intake, stress, and mood. Chronic dysfunction of the stress-sensitive hormone, cortisol, and its controlling hypothalamic pituitary adrenal (HPA) axis, is associated with depression and anxiety, as well as abdominal obesity. Moreover, protein-rich meals that prevent a meal-induced fall in arousal also stimulate release of cortisol in unstressed people, and the size of this effect is correlated positively with poor psychological wellbeing. Chronically, a carbohydrate-rich diet is associated with better overall mood state and lower average plasma cortisol than a high-protein diet. Acutely, a carbohydrate pre-load, but not protein or fat load, enhances cortisol release during stress. This may be related to findings from both human and animal research suggesting that eating carbohydrate-rich and perhaps high-fat foods can help restore normal HPA axis function and glucocorticoid stress responses. Raised levels of cortisol in stressed people contribute to insulin resistance, which in turn promotes abdominal obesity. However, insulin resistance may increase the likelihood that high-carbohydrate/low-protein foods would raise brain TRP and 5-HT levels, because of increased levels of plasma fatty acids, which result in more unbound TRP in plasma. Conversely, it has also been found that high baseline cortisol predicts induction of depression by dietary depletion of TRP. This might underlie recent findings that insulin resistant people are less prone to suicide and depression, both of which are believed to be increased by low 5-HT function. Similarly, patients with Seasonal Affective Disorder show increased insulin resistance in the winter, together with a greater predilection for sugar-rich foods. Unfortunately, despite this protective effect, insulin resistance is a substantial risk to health by promotion of cardiovascular disease.

### Sugars and Opioids

Endogenous opioids are released during stress, and are known to be important for adaptive effects such as resistance to pain. They are also involved in motivational and reward processes in eating behavior, such as stimulation of appetite by palatable foods. Perhaps the best evidence for opioid involvement in an interaction between stress and eating is the finding that, in animals and human infants, the ingestion of sweet and fatty foods, including milk, alleviates crying and other behavioral signs of stress. Recently, this effect was shown to depend on sweet taste rather than calories, as non-nutritive sweeteners also reduce crying. This stress-reducing effect can be blocked by opioid antagonists. The conclusion that adults select sweet fatty foods for opioid-mediated relief of stress is tempting, but remains speculative. Also, such behavior would need to be explained in the context of stress itself enhancing endogenous opioid release.

## Glucose, Mood, and Mental Function

The possibility that ingesting glucose could alter mood and improve mental function has generated considerable research interest. However, there is only space here to summarize and interpret the key findings and controversies. The interest in glucose arises from two observations: (1) that the primary source of energy for brain function is glucose, and (2) that mental function and mood deteriorate when blood glucose concentration falls below basal physiological levels, i.e., hypoglycemia ( $<3.6 \text{ mmol l}^{-1}$ ).

The first observation must be qualified by a recent evidence that (1) in times of metabolic demand, the brain can also use lactate very effectively as an energy source, and (2) the brain contains significant stores of glycogen in specialized cells called astrocytes, which can be metabolized for energy by neighboring neurones. Nevertheless, in rats, extracellular glucose levels in a specific region

of the brain critical for memory, the hippocampus, decline to a greater extent during more demanding memory tasks, and this decline is prevented by a systemic glucose load.

As for hypoglycemia, this is rarely induced by normal food, although large amounts of sugar-rich drinks on an empty stomach might do so in some people. Yet, many studies of effects of glucose use a method similar to the Oral Glucose Tolerance Test (OGTT), in which fasted patients drink aqueous solutions containing 50–75 g of some form of glucose. This is not meant to be a normal nutritional manipulation, but a test of glucoregulation. Associations have been reported between rapid and substantial declines in blood glucose after OGTTs and aggressive thoughts and behavior: however, this might be mediated by greater counter-regulatory hormone release.

In studies comparing sugar-rich drinks with zero-energy sweet placebos, many find no effect on mood, but some report a rise in subjective energy within an hour, followed by increased calmness. In children, controlled studies failed to support the popular myth that sugar is excitatory: again, it had either no effect or was calming. However, it is worth noting that some adults, and probably children, are especially sensitive to rapid drops in blood glucose, showing counter-regulatory hormone release and ‘hypoglycemic symptoms’ even though actual hypoglycemic levels of glucose are not reached.

It may be that beneficial effects of glucose ingestion only become consistently apparent when demands are placed on mental function or when there is a compromised nutritional state such as food deprivation or a metabolic disorder. The findings on glucose and cognitive performance can be summarized as follows:

- The majority of studies that administered a glucose drink found subsequent improvements in some performance compared to placebo, particularly on tests of short-term memory or vigilance tasks that require a large component of ‘working memory’.
- Improvements in performance can be associated with rising or falling blood glucose, even independently of consuming a glucose load.
- Young healthy subjects require more demanding tasks than the elderly to detect a beneficial effect of glucose load.
- Associations between performance and glucose may be mediated by individual glucoregulatory efficiency.
- Both glucoregulation and performance are influenced by hormones sensitive to stressful or arousing cognitive tasks, such as adrenaline and cortisol. Emotion-dependent learning resists improvement by glucose.
- Personality, stress-sensitivity, and task involvement can influence glucose uptake and disposal, and also the effects of glucose on cognition.

However, one important pattern does emerge that memory performance is worse in poorer than better glucoregulators (see [Figure 3](#)). This is true not just for elderly patients but among a healthy student population too, especially if the task is sufficiently demanding. Peak blood glucose predicts poor memory performance in elderly patients, whether or not a glucose load has been given before testing. This relationship between raised glucose levels and poor memory performance could underlie a recent finding that a snack with a high glycemic index (greater plasma glucose rise) resulted in poorer memory performance 2–3 h later, relative to a low glycemic index snack. Even so, it seems that a moderate glucose load can lessen the memory deficit present in young and old poor glucoregulators (with little consistency or no effect in good glucoregulators).

One reason why poor glucoregulation predicts poor memory performance may be that glucose intolerance is associated with higher basal and stress-induced cortisol secretion. Raised cortisol is known to impair memory, probably by an action on hippocampal neurons, including inhibition of glucose uptake. However, the substantial rise in insulin induced by a glucose load in poor glucoregulators may overcome the negative impact of cortisol in some cases: hyperinsulinemia induced independently of hyperglycemia has been shown to ameliorate memory deficits in patients with Alzheimer-type dementia.

Two other mechanisms might explain the ability of a glucose load to improve performance in subsequent challenging tasks. One is an increase in sympathetic activation by the glucose load: adrenaline is known to enhance memory. The other is increased synthesis and release of the neurotransmitter acetylcholine during challenging tasks: acetylcholine is also known to be critically involved in learning and memory, and is synthesized from dietary choline and acetyl CoA, which is a by-product of glucose metabolism. These complex interactions between glucose ingestion and brain function are illustrated in [Figure 4](#).

Docosahexaenoic acid (DHA), a long-chain polyunsaturated fatty acid (PUFA) of the omega-3 series may also be an important regulator of brain energy metabolism and glucose uptake. For example, feeding rats an omega-3 PUFA deficient diet decreased brain DHA levels and reduced brain glucose uptake by 30–40% and cytochrome-c oxidase activity by 20–40% in the fronto-parietal cortex, hippocampus, and suprachiasmatic nucleus, compared to animals on the control diet. The level of expression of the GLUT-1 glucose transporters were also decreased in endothelial cells, although GLUT-3 levels were unaffected in neurons. Impairment in brain (especially hippocampal) glucose uptake is a common feature of age-related cognitive decline, and treatment with DHA may provide a potential therapeutic approach to support the maintenance of brain energy metabolism.

### Hyperactivity and Antisocial Behavior

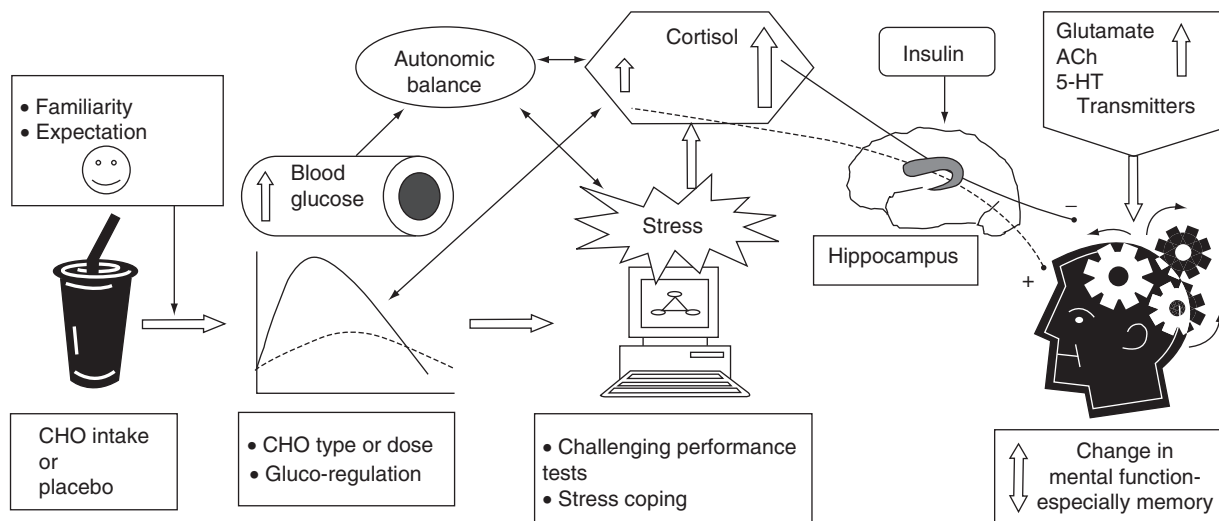

In children, there is an increasing frequency of diagnosis of ADHD, a condition characterized by inattention, impulsive, and disruptive behavior, learning difficulties, and increased levels of gross motor activity and fidgeting. Also, prevalence of food allergies and intolerance has been increasing. Perhaps it is not surprising that dietary explanations and treatments for ADHD have been sought regularly for several decades, given theories of allergic reactions or intolerance to food additives, ingredients in chocolate, and even refined sugar (often grouped as the ‘Feingold Theory’, after an early instigator of unproven dietary intervention). There has also been a longstanding interest in the possibility that antisocial behavior in children and adults might in part result from poor nutrition,

**Figure 3** The graph represents a model of changes in blood glucose levels after a glucose load in people who are either good regulators (solid line) or poor regulators (broken line) of blood glucose. The increased peak and delayed recovery of blood glucose in worse regulators suggests glucose intolerance and insulin resistance. In such people, there may be a brief period of mild hypoglycemia before return to baseline levels. This type of difference in glucoregulation has been demonstrated in both young and elderly people without diabetes. Poor glucoregulation predicts poor cognitive performance in challenging tests, especially those involving memory.

although early studies were poorly designed. A behavioral effect of sugar and of many additives has by and large not been supported by controlled studies: however, determining unequivocally whether behavior of young children is affected by specific dietary components is difficult to achieve. ADHD may be associated with disrupted eating behavior and poor nutrition, so that removal of a number of nutrient deficiencies might improve behavior. In addition, parents or unqualified health professionals may devise unsuitable dietary regimes that can raise the risk of undernutrition. As a result, there is little consensus as to what in the diet may or may not provoke disturbed behavior in children, other than that only a small minority of children are likely to be affected. Nevertheless, a recent British study, in which children were given a collection of food colorings and preservatives, or placebo in drinks, found deterioration in behavior reported by parents for both hyperactive and normal children given the additives, which seemed unrelated to allergic history. This effect was not detectable in a clinical setting. Clearly, a definitive answer awaits more research.

Specific deficiencies or imbalances in blood levels of essential fatty acids, particularly omega-3 polyunsaturated fatty acids (PUFAs), have consistently been shown in developmental disorders such as ADHD, dyslexia, dyspraxia, and autistic spectrum disorders. Indeed the severity of ADHD correlates with the level of DHA deficiency in plasma, although the nature of this relationship is

**Figure 4** A summary diagram of putative pathways linking carbohydrates and mental function, with various modulatory influences. One explanation for variability in findings is that some individuals, especially if poor glucoregulators, may be much more susceptible to manipulations of mood and mental function by glucose availability, particularly when brain function is increased by a stressful challenge. However, associations between glucoregulatory ability and mental performance may be more directly mediated by differential release of cortisol than by changes in glucose availability. It is suggested that this neuroendocrine consequence of glucose absorption and stressful tasks might help explain the narrow dose-response function, and why slower glucose delivery, for example, by low-GI foods, has been reported to benefit cognition compared to faster glucose delivery. Identifying sensitive individuals, and the relevant nutritional, physiological, and psychological parameters, remains a potentially fruitful topic of research in this area. Reproduced with permission from Gibson EL (2007) Carbohydrates and mental function: Feeding or impeding the brain? *Nutrition Bulletin* (Supplement 32), 71–83.

unclear. There is a strong rationale for investigating the effects of essential fatty acid supplementation in children with ADHD; however, so far few randomized controlled trials have been undertaken, and results have been inconclusive. For example, two double-blind trials showed no benefits following DHA treatment, whereas another, which provided a mixed omega-3 and omega-6 PUFA supplement found significant improvements in symptoms. Given the safety and tolerability of essential fatty acids, these compounds offer an intriguing prospect as a potentially new therapeutic approach and the evidence so far strongly supports the case for further research.

Other effects of essential fatty acids on cognition are discussed below.

### Micronutrients and Mental Function

There has been, over the years, an increasing body of evidence suggesting that vitamin and mineral status is significantly related to both brain development in childhood and the degree of cognitive decline experienced as we age. Indeed, it is certainly the case that deficiencies of some vitamins are associated with negative neurological symptoms such as neural tube defects. The work examining vitamin and mineral supplementation comprises both cohort studies and nutritional interventions and has generated much confusing and contradictory data. To a large degree, this confusion and contradiction is dependent on a number of factors such as the methodological rigor of each study, the measures of cognitive function used and the precise nutrient being studied.

Early work in this area concentrated on the notion that supplementing the diet of schoolchildren with multi-vitamin supplements would improve both their IQ scores and academic achievement. This work was controversial and marked by a number of deficiencies, such as any clear indication as to whether participants were actually nutritionally compromised before treatment, difficulties in determining, which if any, of the vitamins in the cocktail were producing effects, and the lack of any clear hypotheses regarding mechanisms responsible. The consensus now is that supplementation will have a benefit on cognitive development and IQ (especially non-verbal) in a minority of children who are not otherwise adequately nourished. In Britain and the USA at least, there is particular concern that a significant proportion of adolescents, especially girls, are deficient in iron. There is good evidence that iron deficiency contributes to poor cognitive ability, perhaps in association with low vitamin C status, which has also been linked to reduced cognitive function. Iron is known to be essential for synthesis and function of neurotransmitters, such as dopamine, noradrenaline, and serotonin (5-HT). Selenium is another mineral, which may be important for brain function, and low levels of which have been associated with cognitive decline and depressed mood in the European population. There is also evidence that zinc deficiency is associated with problematic cognitive development in children and that dietary supplementation with zinc leads to cognitive improvements, relative to nonsupplemented controls.

Much recent work, however, has concentrated on the use of vitamins in the treatment of age-related cognitive decline and dementia and, to varying degrees, is more scientifically rigorous than the earlier work. The overwhelming majority of the experimental work has targeted the action of two groups of micronutrients; anti-oxidant and B-complex vitamins. The work concerning the effects of antioxidant vitamins, although showing some promise with correlational studies in that levels of these vitamins (vitamin E most consistently) are associated with function in a range of cognitive domains, is more contradictory when one considers the clinical intervention trials. The work on B-complex vitamins is, however, more consistent and supported by a strong hypothetical basis. This relies on the role of vitamins B<sub>12</sub> and folate in methylation of membrane phospholipids and neurotransmitters, and in breaking down the toxic sulfur-amino acid homocysteine. High levels of homocysteine are now considered by some to be a far greater risk factor for the development of coronary and vascular problems than high levels of cholesterol. Elevated levels of homocysteine may be a cause of minor ischemic events, which cumulatively, lead to a degradation of cognitive function due either to sub-clinical deficiencies of, or problems with the absorption of, B-complex vitamins. Indeed, a large number of studies has consistently demonstrated relationships between homocysteine levels, B-complex vitamin levels and neuropsychological task performance. The number of direct intervention trials, which have supplemented the diet of the elderly with B-complex vitamins is, however, small. Although some studies have shown no net benefit of supplementation on the cognitive function of the elderly, a larger number of studies have shown a stabilization of cognitive function and reduction of homocysteine levels to result from B-complex vitamin supplementation. As with the antioxidant vitamins, however, these studies must be interpreted with a degree of caution because they use differing dosages, periods of supplementation, and measures of neuropsychological function.

### Lipids

Lipids are another nutrient category, which has attracted a good deal of research interest in terms of their possible effects on psychological function. The main nutrients studied fall into three groups; these being cholesterol, omega-3 and omega-6 essential fatty acids, and phospholipids. In general, the theoretical basis underpinning the effects (or lack of) these nutrients on psychological function relates to how their relative concentrations affect cell membrane fluidity. The rigidity of lipid bilayers of cell membranes is thought to be essential for neurotransmitter function by maintaining maximum exposure of receptors at the synaptic cleft between neurons.

### Cholesterol

The interest in cholesterol as a substance that is related to psychological well-being stems back to the 1980s. During this period, a number of epidemiological studies found that individuals with low cholesterol levels were more prone to aggressive behavior,

risk of suicide, and violent death. In addition, it was also found that nonhuman primates increased their incidence of aggressive behavior when kept on a low cholesterol diet. In terms of neuropsychological function, a number of studies have found associations between cholesterol levels and choice reaction time or memory function. Two of these studies to date have sought actively to reduce cholesterol levels by means of pharmacological or dietary means, both finding that lowering cholesterol produced small but statistically significant impairments in memory and attention. Conversely, however, a number of studies have also demonstrated that high cholesterol levels are also a significant risk factor for the development of Alzheimer Dementia. One mechanism for these negative effects of cholesterol lowering may be loss of rigidity in neural cell walls, thereby decreasing the relative exposure of serotonin (5-HT) membrane receptors at the synaptic cleft and impeding 5-HT signal transmission. Interestingly, omega-3 PUFA have been shown to reduce the cholesterol content of neuronal membranes.

### Essential Fatty Acids

The central nervous system is highly enriched in long-chain polyunsaturated fatty acid (PUFA) of the omega-6 and omega-3 series, specifically arachidonic acid and docosahexaenoic acid (DHA), respectively. The presence of these fatty acids as structural components of neuronal membranes influences cellular function both directly, through effects on membrane properties, and also by acting as a precursor pool for lipid-derived messengers. For example, DHA alters membrane properties and thereby influences membrane proteins, such as receptors, ion channels, and enzymes. It alters dopaminergic, serotonergic, and cholinergic neurotransmission, regulates signal transduction pathways, production of eicosanoids and other lipid-derived messengers, regulates transcription factors and gene expression, and stimulates hippocampal neurogenesis and neurite outgrowth. A summary of some of the potential mechanisms of action of omega-3 PUFA is shown in [Figure 5](#).

An adequate intake of omega-3 PUFA is essential for optimal visual function and neural development. Fetal development has a high requirement for essential fatty acids, especially DHA. Maternal DHA levels influence infant levels, such that higher maternal levels produce higher levels in the neonate. Higher level of maternal plasma DHA during pregnancy correlates with more mature neonatal sleep-state patterns, which is a measure of maturity in the central nervous system. Such effects probably underlie evidence that higher intake of seafood during pregnancy is associated with improved social and cognitive function in the offspring, and may contribute to the advantage to cognitive development seen for breast versus formula-fed infants.

There is increasing evidence that an increased intake of the long-chain omega-3 PUFA, eicosapentaenoic acid (EPA), and DHA, may confer benefits in a variety of psychiatric and neurological disorders, and in particular neurodegenerative conditions. For example, patients suffering from depression typically exhibit reduced DHA levels in plasma, and several cross-sectional studies show associations between seafood consumption and rates of both depression and bipolar disorder, suggesting that low omega-3 PUFA levels may be a factor in the etiology of these disorders. Furthermore, a recent meta-analysis of trials involving patients with major depressive disorder and bipolar disorder has provided evidence that omega-3 PUFA supplementation reduces symptoms of depression.

It is beyond the scope of this article to discuss all of the evidence however, a number of lines of research suggest that an elevated intake of EPA and DHA may confer benefits in depression, schizophrenia, Alzheimer's disease, and Parkinson's disease. However, the mechanisms underlying these beneficial effects are still poorly understood. It is very likely that EPA and DHA operate through a number of different, potentially overlapping mechanisms, involving various cellular targets. These PUFA can act as endogenous agonists for transcription factors such as the retinoid receptors, and the peroxisome-proliferator activated receptors. Neuronal excitability can be modulated by PUFA through their effects on sodium and calcium channels or the activation of the TREK potassium channels, which are two-pore potassium channels abundantly expressed in the brain. Furthermore, it cannot be ruled out that their effects may also involve specific fatty acid receptors, such as the recently identified GPR40 receptor, which has a widespread expression in the central nervous system. Because many neurological conditions share common features, such as excitotoxicity, oxidative stress, and inflammation, which appear to be modified by omega-3 PUFA, this may explain the therapeutic potential of EPA and DHA across disease boundaries. However, the relative importance of certain mechanisms and targets may vary depending on the condition considered.

Membrane-bound DHA is also a positive modulator of biosynthesis of the membrane phospholipid phosphatidylserine in neuronal tissues. It has been suggested that the observed anti-apoptotic (i.e., cell protective) effect of DHA is due at least in part to the DHA-induced phosphatidylserine accumulation. A further potential benefit of DHA-induced phosphatidylserine accumulation may be to prevent the age-related decline in cognitive ability, because phosphatidylserine supplementation has been shown to improve age-related decline in cognitive ability and memory. Certainly, epidemiological evidence links diets higher in PUFA to saturated fat ratio to improved cognitive function in the elderly.

### Food Deprivation

There is evidence to suggest psychological effects of undernutrition. In severe cases such as anorexia nervosa, neuropsychological function is impaired primarily as a result of structural changes in brain anatomy resulting from starvation. Evidence that undernutrition is associated with psychological problems in those not suffering eating disorders was first hinted in the Minnesota Study of Semi-Starvation in the 1950s. Volunteers who were kept on a half-calorie intake diet for a period of months reported mood swings, increased irritability, poorer memory, and an inability to concentrate. Although these self-reported effects were not supported by objective testing, the lack of a nondeprived control group means that this lack of effect could have been masked by a practice effect.

**Figure 5** EPA and DHA potentially operate through a variety of overlapping mechanisms of action. These are related to direct actions on plasma membranes, altered inflammatory response and control of gene expression. The effects on membrane bound proteins such as ion channels, G-protein coupled receptors (GPCR), and the Na<sup>+</sup>, K<sup>+</sup> ATPase appear to relate to alterations to the biophysical properties of the cell membrane. Alterations in inflammatory response are mediated through competition between AA and EPA for eicosanoid biosynthetic enzymes, with a high EPA content favouring the production of EPA derived anti-inflammatory mediators, such as series 3 prostaglandins, prostacyclins and thromboxanes, and series 5 leukotrienes. Nonesterified EPA and DHA are also the precursors of anti-inflammatory resolvins, such as RvE1 and NPD1, respectively. Nonesterified EPA and DHA may also regulate gene expression *via* transcription factors, such as retinoid and peroxisomal proliferator signaling pathways. Solid arrows indicate positive effects, flat arrow-heads inhibition, dotted arrows competition, and open arrows phospholipase A<sub>2</sub>-induced release from the cell membrane. Abbreviations: 2-pore K<sup>+</sup>, 2-pore potassium channel; Ca<sup>2+</sup>, L-type calcium channel; cPLA<sub>2</sub>, cytosolic PLA<sub>2</sub>; iPLA<sub>2</sub>, Ca<sup>2+</sup>-independent PLA<sub>2</sub>; GPCR, G-coupled protein receptor; K<sup>+</sup>, K<sub>v</sub>, and K<sub>ir</sub> channels; LT, leukotriene; Na<sup>+</sup>, voltage-gated sodium channel; PG, prostaglandin; PGI, prostacyclin; PPAR, peroxisomal proliferator-activated receptor; RXR, retinoid X receptor and TXA, thromboxane.

Dieting to lose weight is one of the most common food choice related behaviors in the Developed World and it has been consistently associated with negative psychological consequences such as preoccupation with body shape and depression. In addition, a number of investigators have also found that dieting to lose weight is associated with impairments in cognitive function, with dieters performing more poorly than nondieters on measures of reaction time, immediate memory, and the ability to sustain attention. This is unlikely to be due to pre-existing differences between individuals who happen to be dieting or not dieting at the time of testing because, within the same individuals, performance is poorer when dieting than when not dieting. It is unlikely that these effects are due to the gross physical effects of food deprivation because experimentally induced food deprivation of varying lengths fails to produce a comparable impairment in task performance, in addition to the poorer task performance being found amongst dieters who claim not to have actually lost any weight over the course of the diet.

Rather than being a function of food deprivation per se, the poorer task performance amongst current dieters appears to be a function of the preoccupying concerns with hunger and body shape, which are characteristic of dieters. Indeed, the impairments in task performance amongst dieters appear to be comparable in both structure and magnitude found to result from the preoccupying concerns of the characteristic of clinical depression and anxiety disorders. Specifically, the primary deficit appears to be a reduction in the amount of available working memory capacity, working memory being the primary cognitive system which serves to allocate processing capacity to ongoing cognitive operations. A threshold hypothesis has been formulated to account for this phenomenon. Nondieting, highly restrained eaters are characterized by an enduring, trait concern with body shape, which consumes a certain amount of working memory capacity (explaining why nondieting restrained eaters perform at a level intermediate to that of current dieters and unrestrained eaters). When they decide to diet, they then experience preoccupations with food and an increased desire to eat, this extra drain on working memory capacity reaches a point where sufficient capacity is unavailable to maintain task performance. Support for this hypothesis can be seen in a study in which highly restrained nondieters were instructed to imagine eating their favorite food or their favorite holiday while performing a reaction time task. When imagining their favorite food, but not their favorite holiday, restrained nondieters performed as poorly as current dieters on the reaction time task.

Although evidence seems to be mounting that the poor cognitive function of current dieters is due to psychological and not biological factors, work still continues to examine some of the more subtle possible biological mechanisms which, may underlie the effects. One possible mechanism is that a low dietary intake of the amino acid TRP (the precursor for 5-HT) leads dieters to have impaired serotonergic function. However, analysis of the urine of dieters for the 5-HT metabolite, 5-hydroxyindoleacetic acid (5-HIAA), found no evidence for this. Another possibility (not yet investigated) is that, by avoiding eating red meat, dieters

experience mild iron deficiency, with deleterious consequences for hemoglobin status, brain oxygen supply, and neurotransmitter function.

The types of dieter studied so far are those who attempt to lose weight in an unsupported, unsupervised manner. Comparisons between this type of dieter and those who attempt to lose weight in the context of an organized weight loss group reveal dramatic differences. Those who diet as part of a group do not show the impairments in task performance typical of unsupported dieters. In addition, unsupervised dieters display an elevated stress response after one week of attempted weight loss (as measured by salivary cortisol levels) whereas supported dieters do not. It would appear, therefore, that the poor performance characteristic of unsupervised dieting is a result of the stress associated with this type of weight loss attempt and that the psychological manifestation of this stress is the preoccupying thoughts outlined above. The motivational processes underlying weight loss also appear to be mediating factors in any cognitive processing deficits observed, because it has been found that individuals dieting for esthetic reasons display impaired cognitive function, whereas those dieting for other, health related, reasons do not.

### Functional and Pharmacological Components of Foods and Drinks

There is growing interest, particularly in the food and beverage industry, in developing foods and drinks with functional properties (nutraceuticals) attractive to the consumer. These include effects on behavior, such as improvements in cognitive function, mood, and physical performance. Components of interest include caffeine, herbal extracts such as ginkgo biloba and panax ginseng, micro-nutrients, essential fatty acids, amino acids, and carbohydrates. In the context of caffeine and glucose, however, there is some evidence to support the view that any beneficial effects of these substances on psychological function is, at least in part, due to an expectancy regarding their potential effects. There is some support for beneficial effects of these components, but they are not reviewed further here.

### Conclusion

The scientific understanding of dietary effects on behavior has begun to move in from the fringes of respectability, indeed sufficiently to attract substantial commercial interest. Advances in nutritional and neuropsychological knowledge, experimental design, and sensitivity of measures of behavior and brain function have produced replicable findings in some areas to mollify earlier skepticism. New understanding of the impact of nutrition on brain function, and predictors of individual susceptibility, has also allowed reinterpretation of old data. Promising areas with encouraging developments in understanding include the interactions between macronutrients, stress, and mood disorders, and the effects of vitamins, minerals, and lipids on cognition, dementia, and psychiatric disorders. Some findings, including recent awareness of poorly nourished sectors of the population, suggest useful interventions. Nevertheless, research in this field is at an early stage, and the coming years should bring further revelations on the link between diet and behavior. With industrial backing, few may escape the consequences.

## Key points

- To know the physiology of brown adipose tissue
- To know the metabolic significance of brown adipose tissue
- To know ways to measure brown adipose tissue activity in humans
- To understand mechanisms by which brown adipose tissue may exert metabolic effects
- To understand the potential of brown adipose tissue as a therapeutic target to treat obesity

**Glossary**

**Batokines** Specific molecules secreted by brown adipose tissue into the bloodstream which signal to metabolically active organs such as skeletal muscle, liver and brain

**Brite** Brown-in-white adipocytes, also known as beige adipocytes. Brite cells have a multilocular morphology, are enriched in mitochondria, and also express UCP1. They are peculiar in that they share characteristics with white and brown adipocytes

**Brown adipose tissue (BAT)** It is a lipid-containing tissue, which produces heat in response to cold exposure via a procedure known as thermogenesis

**Capsaicinoids** Capsaicinoids are alkaloids found in chili peppers that are thought to enhance energy expenditure when ingested

**Glucagon-like peptide-1 receptor (GLP-1R)** It is a receptor protein found on beta cells of the pancreas and neurons of the brain. It is involved in the control of blood sugar levels by enhancing insulin secretion. Stimulation of the GLP-1R receptor was found to enhance BAT thermogenesis in mice.

**NIRS** Near-infrared spatial resolved spectroscopy is a simple, non-expensive, and non-invasive method to measure tissue oxygenation in vivo. It measures different optical properties of the tissue based on oxygen-dependent absorption changes, and it allows the calculation of the tissue saturation index and the concentrations of total hemoglobin, oxyhemoglobin, and deoxyhemoglobin

**Positron emission tomography (PET)** It is a nuclear medicine procedure based on the measurement of positron emission from radiolabeled tracer molecules

**UCP-1:Uncoupling protein 1 (UCP1)** The UCP1 is a member of a superfamily of homologous proteins formed by the mitochondrial metabolite transporters. It is devoted to adaptive thermogenesis, a specialized function performed by brown adipocytes. Whereas the family of mitochondrial metabolite carriers comprises ~40 members, UCP1 is the only member able to translocate protons through the inner membrane of brown adipocyte mitochondria. By this process, UCP1 uncouples respiration from ATP synthesis and therefore provokes energy dissipation in the form of heat while, also stimulating high levels of fatty acid oxidation

**<sup>18</sup>F-fluorodeoxyglucose (<sup>18</sup>F-FDG)** It is a radiolabeled sugar (glucose) molecule. Chemically, it is 2-deoxy-2-[<sup>18</sup>F]fluoro-D-glucose, a glucose analog, with the positron-emitting radionuclide fluorine-18 substituted for the normal hydroxyl group at the C-2 position in the glucose molecule. The uptake of <sup>18</sup>F-FDG by tissues is a marker for the tissue uptake of glucose, which in turn is closely correlated with certain types of tissue metabolism. Imaging with <sup>18</sup>F-FDG PET is used to determine sites of abnormal glucose

**Introduction****Obesity is a global problem**

The global prevalence of obesity has doubled over the past three decades, affecting over 600 million adults worldwide in 2015. Obesity is characterized by the accumulation of excess body fat and is defined as a body mass index (BMI) equal to or over 30 kg/m<sup>2</sup>. It increases the risk of diseases such as type 2 diabetes mellitus, hypertension, stroke, dementia and several cancers, and contributes to a decline in quality of life and life expectancy. The fundamental cause of obesity is a chronic positive energy balance caused by overnutrition. The imbalance between calories consumed and calories spent then leads to the deposition of excess energy as triglycerides in white adipose tissue (WAT). The main three elements influencing the energy balance are diet, activity and metabolism.

Weight-loss interventions commonly target the first two elements, diet and activity, through dietary caloric restriction and exercise. However, these weight-loss interventions are frequently not successful in the long term. The development of drugs to treat obesity has also been mainly focused on weight loss, but many of the drugs have had limited success and some have been withdrawn due to harmful side effects. The third element influencing the energy balance, metabolism, is heavily influenced by heritable factors. Less effort has been spent in involving this element in weight-loss interventions. However, the relatively recent re-discovery of brown adipose tissue (BAT) in humans has ignited an interest in increasing metabolic energy expenditure to combat obesity (Nedergaard et al., 2007).

**Brown adipose tissue as a target to combat obesity**

BAT is a lipid-containing tissue, which produces heat in response to cold exposure via a procedure known as thermogenesis. Brown adipocytes are essential to thermogenesis due to their unique expression of uncoupling protein (UCP)-1, which uncouples the movement of protons across the inner mitochondrial membrane from the synthesis of adenosine triphosphate (ATP). As a result of the uncoupling, all energy produced by the mitochondria is released as heat. For this reason, thermogenesis represents one

mechanism through which energy can be expended without exercise, and the stimulation of BAT thermogenesis represents a possible approach to increase energy expenditure in humans.

Hence, strategies able to activate BAT are of great interest to the scientific community. As such, this article aimed is to provide a framework of knowledge to support the development of new strategies by reviewing the historical and current knowledge of BAT and its implications for human health. Therefore, we will first describe the discovery of active BAT in humans, followed by the current knowledge of the physiology of human BAT. Subsequently, the metabolic activity of BAT in humans will be considered, and possible alternative functions of BAT in humans beyond its metabolic activity will be highlighted. Several existing pharmacological approaches to the activation of BAT for the treatment of obesity will also be described. Finally, we will discuss future perspectives on the stimulation of BAT, which have the potential to lead to new strategies for the treatment of obesity.

## The discovery of brown adipose tissue

### Brown adipose tissue discovered in rodents

BAT was first discovered in small mammals as early as 1551 by the Swiss physician Konrad Gesner, who found BAT in hibernating marmots (Fig. 1). He distinguished brown adipocytes from white by their characteristic brown color, which we now know originates from the high density of iron-containing mitochondria in the cells. The second main histological characteristic of brown adipocytes is their multilocular appearance. This appearance is in contrast to white adipocytes, which contain only a single lipid droplet.

The role of the tissue remained unclear until the second half of the twentieth century. Thermogenic activity was found in rodent interscapular fat during *in vitro* experiments in 1961. The role of BAT in thermoregulatory heat production was directly demonstrated three years later in experiments with rodents by recording the temperature increase in the interscapular fat in response to cold stimulus.

### Early investigations of human brown adipose tissue

The discovery of its function renewed interest in the tissue, and in 1966 the functioning of BAT in humans was investigated by studying tissue samples collected during necropsies. BAT was found to be widely distributed through the body in infants. It was found in adipose deposits including the interscapular area, under the clavicles, around the neck, near the pancreas and kidneys and in para-aortic deposits. In tissue samples of newborn human infants, the brown adipocytes were observed to decrease in fat content in the hours directly after birth, suggesting the burning of fat in thermogenic activity similar to that observed in rodents.

Contrary to finding in rodents, the presence of the tissue in humans was found to gradually disappear during adolescence, particularly from more peripherally situated areas, while persisting in more deeply situated areas until as late as the eighth decade. It was inferred that the collective function of the tissue was to form a thermogenic jacket, particularly during the first years of life when other heat regulation mechanisms have not yet matured sufficiently to protect against cold. It was assumed that BAT gradually disappeared in later stages of life as the thermogenic capacity of the jacket was no longer required.

However, an investigation of cadaver tissue of winter outdoor workers in 1981 found evidence of greater BAT presence in adult humans adapted to cold. BAT was found in the neck and the pericardium of outdoor workers, compared to indoor workers who had none. The amount of BAT was greater in outdoor workers who were exposed to cold recently, as the outdoor worker who perished in February had more multilocular adipose tissue than the worker who died in August. Similarly, retired farmers also showed a decrease in BAT after their return to warmer conditions. These findings suggest that humans can retain BAT during the later stages of life if

2009: Re-discovery of BAT in humans

**Fig. 1** The Discovery of brown adipose tissue in humans.

sufficiently exposed to cold, but that BAT gradually disappears in warm environments. It also implied that BAT activity can be enhanced by recent cold exposure.

The role of thermogenesis in human metabolism remained controversial. Until its discovery in live adult humans in the 21st century, the general belief was that adult humans only possess vestigial amounts of BAT and that its metabolic effects in humans are negligible. However, the physiology of BAT continued to be studied in rodents. Thermogenesis was found to be defective in several animal models of obesity, and it was theorized that BAT plays an important role in rodents in maintaining leanness through promoting energy expenditure.

### **The re-discovery of active brown adipose tissue in live humans**

Evidence of BAT in living humans was finally discovered in 2002. The tissue was detected on fluorine-18 fluorodeoxyglucose (FDG) positron emission tomography (PET) scans, which had been introduced mainly for oncological imaging.  $^{18}\text{F}$ -FDG uptake represents glucose uptake and is normally present in the brain, the kidneys and the urinary collecting system, in various malignancies including carcinomas, lymphomas and melanomas, as well as in inflammatory sites and exercised muscle. A specific symmetrical pattern of  $^{18}\text{F}$ -FDG uptake in the shoulder, neck and thoracic spine region appearing on the PET scans of several cancer patients was reported in 1996. The presence of the pattern was unusual; however, the resolution of PET scans was insufficient to pinpoint the exact origin of the signal, and at first it was attributed to muscular uptake. In 2002, it was investigated the pattern by means of co-registered  $^{18}\text{F}$ -FDG PET and computed tomography (CT), which can visualize the density of tissues with a higher spatial resolution. The combination of functional imaging by PET with the images from CT allowed exact anatomical localization of the  $^{18}\text{F}$ -FDG uptake pattern, and it became clear that the pattern originated not from muscles, but from adipose tissue. Due to its anatomical location, it became briefly known as Uptake in the Supraclavicular Area (USA) - fat, although it was hypothesized that it represented active BAT.

After that, questions arose why it had taken so long to recognize BAT in the  $^{18}\text{F}$ -FDG uptake pattern, as there was ample evidence of BAT in humans. However, at the start of the 21st century, it was still the general belief that adult humans only possess vestigial amounts of BAT. Evidence for BAT in adult humans had been largely ignored, until the discovery that the tissue is metabolically active and can be visualized by  $^{18}\text{F}$ -FDG PET/CT scan, which challenged the accepted dogma.

In 2007, Nedergaard et al. published an authoritative review on the previous  $^{18}\text{F}$ -FDG PET/CT findings. The observations of metabolically active fat on  $^{18}\text{F}$ -FDG PET scans were published in nuclear medicine journals since the uptake of  $^{18}\text{F}$ -FDG by BAT was considered a disturbing complication during the diagnosis of tumors. However, with the review by Nedergaard et al. the findings were viewed in a positive light, and BAT was hypothesized to be of metabolic significance. Although further investigation of BAT in live humans would require dedicated studies, the evidence gathered from PET/CT so far demonstrated that the knowledge of the physiology of BAT in animal models could also be relevant to humans.

### **The physiology of brown adipose tissue**

The discovery of active BAT in living humans led to the hypothesis that BAT was of metabolic significance. A concerted effort was made to investigate the physiology of human BAT.

#### **Adaptive thermogenesis by brown adipose tissue**

Mammals generate heat and increase their energy expenditure in response to cold exposure in a process known as adaptive thermogenesis. The two main tissues known to be responsible for adaptive thermogenesis are skeletal muscles, which contribute to adaptive thermogenesis by shivering in response to cold exposure, and BAT, which contributes by non-shivering thermogenesis (NST). However, the contribution of BAT to NST remains unclear. A substantial difference between rodents and human adaptive thermogenesis is the ratio of energy expenditure between shivering and non-shivering thermogenesis, as the contribution of skeletal muscle is much greater in humans compared to rodents (Blondin et al., 2015a,b).

#### **Adaptive thermogenesis in response to cold exposure**

Cold exposure is detected by the brain, leading to the activation of the sympathetic nervous system which innervates both BAT and skeletal muscle. NST in BAT is activated in response to adrenaline and noradrenaline, which are the main effectors of the sympathetic nervous system. Evidence of this interaction was gathered from mice lacking adrenaline and noradrenaline as a consequence of knocking out the gene that encodes dopamine beta-hydroxylase. The mice were found to be intolerant to cold, as they were unable to activate thermogenesis in BAT. Similar intolerance to cold was observed in mice lacking the  $\beta_1$ ,  $\beta_2$  and  $\beta_3$ -adrenergic receptors. The observations obtained from animal models were validated by the results of PET/CT scans in humans. Cold exposure also increases  $^{18}\text{F}$ -FDG uptake by BAT, which could be fully suppressed by keeping the subject warm during the procedure. The activation of human BAT is similarly sympathetically stimulated, as demonstrated by early observations when patients scheduled for PET scans were administered the  $\beta$ -blocker diazepam as a treatment for nervousness. In response,  $^{18}\text{F}$ -FDG uptake by BAT was inhibited.

In response to the sympathetic signal, adaptive thermogenesis is achieved by increasing mitochondrial respiration. During respiration, mitochondria catabolize nutrients and synthesize adenosine triphosphate (ATP) from adenosine diphosphate (ADP), producing heat as a byproduct. As mitochondrial respiration continues, cellular ADP stores deplete, and ATP will need to be consumed to resume heat production. Several mechanisms are known through which cells can use the synthesized ATP to generate additional heat. One mechanism is the activation of a futile cycle, where two metabolic pathways run simultaneously in opposite directions. An example of a futile cycle is the simultaneous activity of the glycolysis and gluconeogenesis metabolic pathways: when the futile cycle is complete there is no overall effect other than the dissipation of energy as heat. A second mechanism for using ATP is employed by skeletal muscle cells. ATP is converted to ADP by myosin when it releases actin during muscle relaxation. During shivering, muscle contraction and relaxation result in the consumption of ATP and the generation of heat.

An alternative method of heat production is present in brown adipocytes. Instead of producing and using ATP during mitochondrial respiration, the production of ATP is bypassed altogether. In normal mitochondria, the production of ATP is invariably linked to respiration, as ATP is produced in a sequence of coupled reactions. This signifies that the catabolism of a nutrient always results in the generation of a fixed amount of NADH and FADH<sub>2</sub>, which in turn results in a fixed number of protons moving across the inner mitochondrial membrane and the production of a fixed number of ATP units by ATP synthase. In brown adipocytes, the production of ATP is uncoupled from mitochondrial metabolism, so that nutrients can be catabolized and directly converted to heat without requiring the activation of other metabolic pathways.

### Mitochondrial metabolism is uncoupled in brown adipocytes

Brown adipocytes possess specific proteins to uncouple the production of ATP from mitochondrial respiration. The uncoupling is the result of a proton leak in the mitochondria of brown adipocytes, which is catalyzed by uncoupling protein (UCP)-1. In normal mitochondria, nutrient catabolism eventually results in a proton gradient across the inner mitochondrial membrane. Protons can only move across the membrane through channels in ATP synthase, resulting in the synthesis of ATP. However, the presence of UCP-1 in the mitochondria of brown adipocytes allows protons to leak through the membrane and bypass ATP synthase, which allows the energy of the proton movement to be directly converted to heat. Current evidence indicates that BAT thermogenesis is fully dependent on mitochondrial uncoupling by UCP-1. Two homologs of UCP-1 have been identified: UCP-2 and UCP-3. However, no indication of uncoupled brown adipocyte mitochondria was found in UCP-1-ablated mice, even though UCP-2 and UCP-3 expression was unchanged, and the absence of UCP-1 in mice led to low cold tolerance.

The activity of UCP-1 in brown adipocytes is regulated by  $\beta$ -adrenergic receptor stimulation by the sympathetic nervous system. Activation of the  $\beta$ -adrenergic receptor results in an increase in cellular cAMP, which activates lipolysis through protein kinase A. The increase in free fatty acids generated by lipolysis acutely stimulates UCP-1 activity and increases thermogenesis.

### Brite adipocytes can be recruited in response to cold exposure

Rodents can recruit additional UCP-1 expressing adipocytes as part of the long-term adaptation to cold. Although cold-induced adipocytes express UCP-1 and other functional thermogenic genes, they were found to lack transcription factors associated with classic brown adipocytes. The newly discovered adipocytes were named recruitable or inducible BAT, or beige or “brite” (brown-in-white) adipocytes, as they are located in WAT but were capable of expressing brown adipocyte markers such as UCP-1 during cold acclimation. These cells are thought to originate from white adipocytes, which transdifferentiate into beige adipocytes after stimulation of the  $\beta$ 3-adrenergic receptor in a process known as the “browning” of fat. The transdifferentiation of white adipocytes has been found to occur in major WAT depots in mice, including the anterior subcutaneous and abdominopelvic depots. Mice were also found to be capable of recruiting brown adipocytes from precursor cells in the intrascapular BAT depot; however, this process is ontogenically different from fat browning.

Cells with an expression profile similar to murine beige adipocytes were also found in humans, which indicates that fat browning occurs in humans as well. Histological analysis of the BAT deposits detected in <sup>18</sup>F-FDG PET/CT scans showed that human BAT consists partially or even completely of beige adipocytes, which suggests that fat browning may play an important role in cold adaptation in humans.

### Brown adipose tissue activity in humans

After the physiology of BAT was elucidated, it was hypothesized that BAT activation could potentially prevent obesity. The next step was to investigate the presence of BAT in humans and its activity during cold exposure.

### Retrospective analysis of brown adipose tissue activity

Since <sup>18</sup>F-FDG PET/CT was the only available noninvasive technique to measure BAT activity in humans, it became the most widespread method and remains so currently. As the method had previously been in use in oncology, a large number of <sup>18</sup>F-FDG PET/CT scans were available to be retrospectively analyzed. Several retrospective studies reported a prevalence of BAT in humans of around 5–10% (36–38), which suggested that BAT has a limited role in metabolism. However, a review by Lee et al. reevaluated PET scans

from several studies and concluded that the prevalence of BAT is higher than the previous publications indicated (Lee et al., 2010). The detection of BAT was found to be particularly hard to reproduce; among patients with detectable BAT, a second PET/CT scan was only positive in 13.3% of cases.

### **Brown adipose tissue detection by cold exposed $^{18}\text{F}$ -FDG PET/CT scan**

The retrospective studies also identified a significant correlation between the probability of BAT detection and outdoors temperature at the time of the scan. Since BAT activity was known to depend on the environmental temperature in animal models,  $^{18}\text{F}$ -FDG PET/CT was used to investigate BAT activity during cold exposure in humans. BAT was found to be detectable in 23 out of 24 subjects during cold exposure, but not under thermoneutral conditions. BAT could also be detected in obese subjects during cold exposure, which suggests that BAT is present in the obese and activation of BAT can be induced. Increased BAT activity in response to cold exposure was subsequently reported in several studies (Chen et al., 2016). The successful detection of BAT proved to be partially dependent on the environmental temperature and the exact method of cold exposure prior to the scan (Chen et al., 2016). Measurement of BAT activity was found to be most successful when using a personalized protocol aimed at maximizing non-shivering thermogenesis by water cooling.

### **Dysfunction of brown adipose tissue in obese individuals**

BAT glucose uptake is lower in obese compared to lean individuals. It was assumed that BAT thermogenesis was impaired in obese individuals because BAT glucose uptake had earlier been found to correlate with BAT activity in healthy individuals.

The  $^{18}\text{F}$ -FDG PET/CT method visualizes glucose uptake, which is generally understood to imply metabolic activity. However, it can be hypothesized that glucose uptake by BAT does not reflect an increase in metabolic rate in the tissue. This hypothesis is supported by evidence from cultured rodent brown adipocytes, where glucose uptake is directly adrenergically stimulated, even in the absence of UCP-1. However, conflicting evidence from live mice indicates the opposite, as BAT was unable to take up glucose following noradrenaline administration if UCP-1 was knocked out. As additional support for the hypothesis that glucose uptake and BAT activity are disconnected, BAT glucose was found to be predominantly utilized for liponeogenesis in rats, and BAT is known to predominantly utilize fatty acids, not glucose, as a fuel source.

### **Brown adipose tissue glucose uptake may be independent of thermogenic capacity**

Older age, higher BMI and type 2 diabetes were all previously associated with defective BAT due to lower glucose uptake by BAT. In 2015, Blondin et al. investigated whether BAT thermogenesis is truly impaired in individuals with type 2 diabetes, compared to both age-matched controls and young healthy control subjects (Blondin et al., 2015a,b). They used  $^{18}\text{F}$ -FDG PET/CT to monitor BAT glucose uptake during cold stimulation in subjects with type-2 diabetes.  $^{18}\text{F}$ -FDG was supplemented with two other radiotracers:  $^{18}\text{F}$ -fluoro-thiaheptadecanoic acid (FTHA), a non-esterified fatty acid (NEFA) tracer and  $^{11}\text{C}$ -acetate, a measure for oxidative activity. As expected, the observed volume of  $^{18}\text{F}$ -FDG-positive BAT, as well as glucose uptake per BAT volume, were significantly lower in both the subjects with type-2 diabetes and the obese age-matched controls compared to the healthy control subjects. However, after cold exposure, the three subject groups showed similar increases in oxidative activity and NEFA uptake per BAT volume. BAT effectively metabolized fatty acids in response to cold exposure, despite a reduction in  $^{18}\text{F}$ -FDG-positive BAT volume and glucose uptake in individuals with type 2 diabetes. These results imply that BAT oxidative metabolism is not blunted by obesity or type-2 diabetes as previously thought, but that the reduced uptake of  $^{18}\text{F}$ -FDG by BAT is a consequence of insulin resistance.

### **Alternative PET tracers to quantify brown adipose tissue activity in humans**

These findings also demonstrate that  $^{18}\text{F}$ -FDG PET/CT may not be an adequate measure of BAT activity in obese individuals, as it could underestimate BAT activity. Uptake of FTHA may theoretically be a better marker for BAT activity, but the fatty acid tracker is of limited use on its own as it offers little contrast between active BAT and WAT. During cold exposure and in lean individuals, uptake of fatty acids such as FTHA by BAT is also rather slow compared to  $^{18}\text{F}$ -FDG. This makes fatty acid tracers a suboptimal choice for the imaging of BAT activity. The third tracer used in the investigation by Blondin,  $^{11}\text{C}$ -acetate, as well as  $^{15}\text{O}$ -labelled  $\text{O}_2$  allow for the estimation of tissue oxidative metabolism. However, both isotopes are cyclotron-produced and have a very short half-life, so their use is restricted to research institutes with access to an in-house cyclotron.

### **The metabolic significance of brown adipose tissue**

After the presence of active BAT in humans was demonstrated, its metabolic significance was assessed. Studies with animal models have shown that the presence and activation of BAT provides significant health benefits for rodents. The absence of BAT activity quickly results in obesity in animal models. The benefits of active BAT were subsequently investigated in humans.

### Brown adipose tissue is metabolically significant

Alike in animal models, the presence of BAT was found to have health benefits in humans. Individuals with detectable  $^{18}\text{F}$ -FDG uptake by BAT had significantly lower glucose levels and body weight compared to individuals without detectable BAT. In agreement with these findings, [Becher et al. \(2021\)](#) found similar correlations after reviewing 134,529  $^{18}\text{F}$ -FDG PET/CT scans of 52,487 patients. Individuals with detectable BAT showed a significantly lower prevalence of type 2 diabetes, dyslipidemia, cardiovascular disease, coronary artery disease, cerebrovascular disease, congestive heart failure and hypertension. Additionally, while obesity was negatively correlated with detectable BAT, obese individuals who retained detectable BAT appeared to be protected against cardiovascular disease. In a follow-up study of 19,019  $^{18}\text{F}$ -FDG PET/CT scans the presence of detectable BAT was found to correlate with an improved metabolic profile, as the presence of detectable BAT was associated with lower white blood cell count and blood triglycerides and higher high-density lipoprotein. This indicates that the positive effects can be partially explained by the healthier body fat distribution associated with BAT. These findings suggest that active BAT might be beneficial for obese individuals. It is possible that BAT can be reactivated by cold exposure, which in turn can protect against type 2 diabetes and cardiovascular disease.

### Contribution of human brown adipose tissue to cold-induced thermogenesis

Several studies aimed to investigate BAT energy expenditure in response to a cold stimulus. In one study, cold stimulation resulted in a 1.8 fold increase in whole-body energy expenditure, although the contribution of BAT was not assessed. However, other findings were less optimistic. In a study BAT energy expenditure was measured separately by  $^{15}\text{O}$ -labelled  $\text{O}_2$  PET imaging. The increase in BAT energy expenditure in response to a cold stimulus was found to be relatively low at less than 20 kcal/day. In a similar study by U Din et al., seven healthy subjects were scanned by PET/CT for the uptake of  $^{15}\text{O}$ -labelled  $\text{O}_2$ ,  $^{15}\text{O}$ -labelled  $\text{H}_2\text{O}$  and FTHA at room temperature and during acute cold exposure. Whole-body energy expenditure was measured by performing indirect calorimetry simultaneously with PET scans. Cold exposure resulted in an increase of 2–47% in whole-body energy expenditure, and oxygen consumption was likewise increased. However, the change in BAT-specific energy expenditure in response to cold exposure was estimated to be  $4 \pm 3$  kcal/day, which accounted for only 1% of the total change in whole-body energy expenditure. Meanwhile, the increase in energy expenditure by skeletal muscle in the field of view of the PET scanner correlated with the increase in whole-body energy expenditure. These results suggest that skeletal muscle in the vicinity of BAT, rather than BAT itself, is the main contributor to the increase in energy expenditure in response to cold exposure. These findings are in line with an earlier investigation, where glucose uptake in response to cold exposure was found to be more than one order of magnitude greater in skeletal muscle compared to BAT.

### Brown adipose tissue as an endocrine organ

As previously shown, BAT activity is thought to play a role in lipid metabolism. However, combustion of fatty acids by BAT likely plays only a minor role, as energy expenditure of activated BAT was found to be relatively low compared to whole-body energy expenditure. Recent evidence suggests that BAT may instead indirectly affect lipid metabolism through its endocrine function. This hypothesis is based on the observation that the transplantation of BAT could improve glucose tolerance, increase insulin resistance and reduce body weight in high-fat diet-induced obese insulin-resistant mice. These results surpass what could be expected from the thermogenic activity of the transplanted tissue. Instead, BAT likely influences systemic signaling through the secretion of brown adipokines, so called batokines ([Fig. 2](#)). The genes encoding proteins secreted by BAT have been identified as part of the pattern of genes expressed by BAT in response to cold stimulation.

Fibroblast growth factor 21 (FGF21) was among the first batokines discovered to be secreted by BAT in mice. FGF21 has been suggested to have an autocrine role in stimulating the browning of adipose tissue, as it has been shown to increase expression of UCP-1 and other thermogenic genes in murine WAT, and FGF21-deficient mice are impaired in their ability to adapt to chronic cold exposure. Experiments with human adipocytes *in vitro* support this theory, as treatment with FGF21 was able to induce UCP-1 expression, respiratory uncoupling and heat production in white adipocytes. FGF21 secretion seems to be induced by cold exposure along with the myokine irisin, which suggests that these autocrine agents play a role in the long-term adaptation to cold by the stimulation of fat browning.

Secretion of FGF21 by BAT may also influence cardiac health. FGF21 was found to be expressed by the liver and the heart in rodents, and expression is elevated in the heart of animal models of induced cardiac hypertrophy and myocardial infarction. Secretion of FGF21 by the heart was shown to protect against cardiac hypertrophy in mice, suggesting FGF21 to be a cardioprotective molecule secreted by the heart in response to stress. BAT secretion of FGF21 was also found to provide cardiac protection during hypertension in mice. A similar interaction could be expected in humans, considering the previously reported beneficial effects of BAT activity on human cardiovascular health. FGF21 expression levels are increased in the failing human heart, and FGF21 was found to act as an antioxidant factor in the heart by inducing the expression of several enzymes involved in the removal of reactive oxygen species in cardiomyocytes. These findings suggest a cardioprotective role for FGF21 secreted by the heart, which may also apply to FGF21 secreted by BAT, as BAT has been shown to contribute significantly to systemic FGF21 levels, particularly during cold exposure.

**Fig. 2** Endocrine factors released by brown and beige adipocytes might signal to distinct organs, such as bone, white adipose tissue, brain, liver, pancreas heart or skeletal muscle. BMP8b: bone morphogenetic protein 8b; FGF21: Fibroblast growth factor 21; IL6: Interleukin 6; Slit 2-C: Slit Guidance Ligand 2; NRG4: Neuregulin 4; 12,13-diHOME: 12,13-dihydroxy-9Z-octadecenoic acid; 12-HEPE: 12-Hydroxyeicosapentaenoic acid.

A second batokine implicated in cold adaptation during long-term cold exposure is Interleukin-6 (IL-6). IL-6, along with the cytokines interleukin-1 and tumor necrosis factor alpha, has previously been found to stimulate heat production and induce fever by acting on the brain during the systemic inflammatory response. However, it was also found to be important for cold-induced thermogenesis. In mice, IL-6 was shown to be required for the browning of WAT in response to long-term cold exposure, as IL-6 knockout mice were found to have a blunted induction of UCP-1 protein expression in WAT after cold exposure. In humans, blocking IL-6 signaling as a treatment for rheumatoid arthritis results in weight gain, which suggests a reduction in energy expenditure through blunted adaptive thermogenesis similar to the observations in rodents. IL-6 was also shown to be directly involved in fat browning in humans. Secretion of IL-6 was observed in *ex vivo* differentiating beige adipocytes, but not in classical brown adipocytes. Blocking of the IL-6 receptor by specific antibody resulted in the downregulation of UCP-1 and other brown adipocyte marker genes in the differentiating cells, and led to morphological changes that are characteristic of white adipocytes. Based on these observations, IL-6 secretion by beige adipocytes may be part of autocrine positive feedback that stimulates the differentiation of adipocytes toward a beige phenotype to increase the capacity for thermogenesis.

Another identified batokine is myostatin, which is also known to be secreted by skeletal muscle. The main function of myostatin was found to be the inhibition of muscle growth. In mice, myostatin loss of function leads to muscle hypertrophy and the suppression of body fat accumulation, as well as WAT browning. In humans, increased secretion and expression of myostatin are associated with obesity. The effect of myostatin was found to be inhibited by follistatin, which can be secreted by skeletal muscle, the liver and BAT. Follistatin is a promotor of skeletal muscle growth that was also found to directly stimulate murine WAT browning *in vitro*. Myostatin and follistatin expression are both known to be influenced by exercise. In humans, the concentration of circulating follistatin acutely increases during exercise. Furthermore, eight weeks of concurrent training resulted in a significant decrease in myostatin serum concentration, while serum follistatin was increased. The same study also observed significant improvements in weight, muscle mass and body composition. From these results, it can be hypothesized that the secretion of myostatin and follistatin facilitates crosstalk between skeletal muscle and BAT, resulting in muscle growth and fat browning after exercise. In mice, myostatin secretion by BAT was found to significantly impact exercise capacity. If the same holds true for humans, BAT activity can potentially influence human energy metabolism by controlling skeletal muscle function.

### Potential novel batokines have been recently identified

Possible novel batokines have been discovered by performing high-sensitivity mass-spectrometry-based proteomics on the cell media of brown and white adipocytes. A total of 101 proteins were exclusively discovered in the secretome of brown adipocytes; the method was validated by the discovery of vascular endothelial growth factor A (VEGF-A) among them, which has been previously reported as being secreted by developing BAT. Certain growth factors, granulins and hepatoma-derived growth factor (HDGF), were found to be more abundant in brown compared to white adipocyte cell media, and are possible novel batokines. These growth factors have not been associated with BAT before, though granulins have been associated with the mediation of systemic insulin resistance in mice and humans. Among the proteins secreted by BAT was also mammalian ependymin-related protein 1 (EPDR1), which has been suggested to act as a lipid transporter. After further investigation, human EPDR1 knockout brown

adipocytes were found to display blunted thermogenic activity, and EPDR1 knockout mice had a deficiency in thermogenic capacity and a pronounced accumulation of body fat. These data suggests that EPDR1 plays a role in the development of brown adipocytes. However, injection of EPDR1 also resulted in an increase in energy metabolism in mice without an increase in BAT activity, though no long-term effects of EPDR1 injection on metabolism were observed. This suggests that EPDR1 is not only involved in the development of functional thermogenic adipocytes, but also acts in an endocrine fashion. The pathway through which EPDR1 acts remains to be explored.

### A subpopulation of acetate-secreting brown adipocytes may regulate thermogenesis

It has been reported a previously unknown population of adipocytes in mice that can regulate the activity of other adipocytes. A small subpopulation of both mature white and brown adipocytes was found to express a set of genes including the marker gene *Cyp2e1* and *Aldh1a1*. The cells were first thought to represent recruited brown adipocytes, but this was discredited by the observation that the population increased under thermoneutral conditions. Instead, the cells were found to inhibit thermogenesis in brown adipocytes through the secretion of acetate by acting on G-protein-coupled receptor 43 (GPR43) on the surface of brown adipocytes.

Acetate is related to insulin sensitivity before, but the findings were inconclusive. Supporting the findings of Sun et al., circulating acetate has been negatively associated with peripheral insulin sensitivity in obese individuals. However, a beneficial effect of orally ingested acetate on insulin sensitivity was reported in rodent studies, and colonically administered acetate was found to increase energy expenditure and fasting fat oxidation in obese humans. Maybe circular and colonic acetate may play different roles in the regulation of metabolism. It can also be proposed that acetate produced by the gut microbiome is not entirely cleared by the liver, and may enter the circulation to interfere in thermoregulation by endocrine brown adipocytes. However, current data remains inconclusive and elucidating the role of acetate in obesity will require further research.

### Brown adipose tissue as a therapeutic target

BAT activity may increase energy expenditure and could have cardiometabolic positive effects through the secretion of batokines (Fig. 2). Thus, pharmacological approaches to the activation of BAT are of interest.

#### Activation of brown adipose tissue to treat obesity

BAT is an attractive therapeutic target for the treatment of obesity. Activation of BAT increases energy expenditure, which could lead to a significant reduction in body weight if the effects are sustained. Activation of BAT through short-term cold exposure has also been shown to increase insulin sensitivity, and active BAT may have a beneficial effect on lipid metabolism and cardiovascular health, as described in the previous section. Although daily cold exposure is effective in increasing BAT activity, it may be challenging to adhere to a lifestyle involving acute cold exposure. Consequently, current research aims to develop pharmacological compounds that can activate BAT. Among the proposed pharmacological agents are  $\beta$ -adrenergic receptor ( $\beta$ -AR) agonists, which may be able to activate BAT through the adrenergic sympathetic pathway, and peroxisome proliferator-activated receptor- $\gamma$  (PPAR- $\gamma$ ) agonists, which may increase BAT thermogenic capacity.

#### Activation of brown adipose tissue by $\beta$ -adrenergic receptor agonists

The activation of BAT through the adrenergic sympathetic pathway was first studied in rodents. Three  $\beta$ -adrenergic receptors were identified:  $\beta$ 1-AR,  $\beta$ 2-AR and  $\beta$ 3-AR. Stimulation of  $\beta$ 3-AR was found to increase energy expenditure in mice (Berbée et al., 2015), although  $\beta$ 3-AR agonists failed to produce clinical effects on weight loss in humans. As these studies were performed before the development of  $^{18}\text{F}$ -FDG PET/CT imaging, it was unclear if  $\beta$ 3-AR agonists were capable of stimulating BAT in humans. Interest in  $\beta$ 3-AR agonists reignited in 2015, when the new  $\beta$ 3-AR agonist mirabegron was approved to treat overactive bladder. Stimulation with mirabegron was found to increase lipid oxidation, supraclavicular skin temperature and a decrease in BAT fat fraction and an increase in BAT activity as measured by  $^{18}\text{F}$ -FDG PET/CT. However, there were also reports of unwanted cardiovascular responses, which led to the suspicion that high doses of mirabegron were not selective to the  $\beta$ 3-AR, and that the responses were the result of general  $\beta$ -AR stimulation. This hypothesis was proven to be correct when a high dose of mirabegron was found to increase heart rate and WAT lipolysis, which are  $\beta$ 1- and  $\beta$ 2-AR-dependent responses. Furthermore, the activation of BAT was found to rely on stimulation of  $\beta$ 2-AR. *In vitro* stimulation of brown adipocytes with the highly selective  $\beta$ 2-AR agonist formoterol increased uncoupled respiration, while the  $\beta$ 3-AR agonist mirabegron had no such effect (Blondin et al., 2020). The previously reported clinical results of the administration of mirabegron were attributed to its activation of the  $\beta$ 2-AR at high doses. The effect of  $\beta$ 2-AR stimulation on BAT activity in humans has yet to be investigated.

#### Other pharmacological approaches to the activation of brown adipose tissue

Products that have been proposed to stimulate BAT activity through means other than the activation of the adrenergic sympathetic pathway include capsaicinoids, the glucagon-like peptide-1 receptor (GLP-1R) agonist exenatide, the dipeptidyl peptidase-4 (DPP4)

inhibitor sitagliptin and secretin. Capsaicinoids are alkaloid found in chili peppers that are thought to enhance energy expenditure when ingested. Capsaicinoid analogs, known as capsinoids, have been found to be able to activate BAT, and the combination of capsinoids with cold exposure has a synergistic effect on BAT development. This suggests the activation of BAT by cold exposure can be enhanced by the consumption of capsinoids.

Stimulation of the GLP-1R receptor was found to enhance BAT thermogenesis in mice. In humans, the GLP-1R agonist exenatide was found to have no effect on energy expenditure in obese individuals. However, exenatide has an anorexic effect that could lead to a decrease in energy expenditure in the short term, which could obfuscate potential increases in BAT thermogenesis. Following this hypothesis, the GLP-1R agonist liraglutide was found to increase energy expenditure when observed during a 1-year study period. Furthermore, administration of exenatide was recently shown to increase BAT glucose uptake during cold exposure as measured by  $^{18}\text{F}$ -FDG PET/CT scan, which is thought to represent an increase in BAT volume. The enhanced BAT activity in response to exenatide is thought to be mediated by an increase in sympathetic output to BAT; whether other GLP-1R agonists can similarly increase BAT activity remains to be investigated.

Sitagliptin is another promising agent that was found to stimulate BAT activity by increasing UCP-1 expression in adipose tissue in mice. However, administration of sitagliptin failed to increase  $^{18}\text{F}$ -FDG uptake by BAT in obese humans, although improvements in glucose tolerance and lipid metabolism were observed. It was hypothesized that insulin resistance obfuscated the effects of sitagliptin by affecting  $^{18}\text{F}$ -FDG uptake. As such, BAT stimulation by sitagliptin could be more accurately assessed in the future by using fatty acid PET/CT trackers.

The hormone secretin has also been found to activate BAT in mice and humans. Secretin is a peptide hormone secreted by the duodenum that is known to regulate food intake by acting on the hypothalamus. It was recently shown to be able to activate BAT and stimulate meal-associated thermogenesis in humans, independent of sympathetic innervation. It is hypothesized that the postprandial activation of meal-associated thermogenesis by secretin induces satiation and reduces feeding through a gut-BAT-brain axis. The potential of secretin in reducing food intake will have to be assessed in future clinical trials.

### **Adipose tissue browning by peroxisome proliferator-activated receptor- $\gamma$ agonists**

Thiazolidinediones are a class of PPAR- $\gamma$  agonists primarily used to increase insulin sensitivity for the treatment of type-2 diabetes. Thiazolidinediones primarily act on adipose tissue and have been shown to induce UCP-1 expression in human adipose-derived stem cells. The browning of adipose tissue in response to PPAR- $\gamma$  agonists was also observed in rodents. However, the PPAR- $\gamma$  agonist-induced increase in BAT mass was not associated with an elevation in thermogenesis; an increase in energy expenditure occurred only after subsequent pharmacological stimulation of the adrenergic sympathetic pathway by  $\beta$ -AR agonists. This observation led to the hypothesis that adipose tissue could be primed by treatment with PPAR- $\gamma$  agonists, followed by the activation of BAT by  $\beta$ -AR agonists. However, a later study found that PPAR- $\gamma$  activation impairs BAT activation, likely caused by the inhibition of  $\beta$ -AR expression by PPAR- $\gamma$  agonists, and the combined treatment did not yield significant results in humans. Furthermore, thiazolidinediones and other PPAR- $\gamma$  agonists are associated with an increased risk of cardiovascular events. It is currently unclear if the benefits of treatment with PPAR- $\gamma$  agonists can outweigh the risks.

### **Future perspectives**

Several new strategies for the detection and activation of BAT can be considered. In the future, these strategies may lead to the effective treatment of obesity and cardiovascular disease through the activation of BAT.

### **New methods for to assessment of brown adipocyte tissue mass and function**

The accurate quantification of BAT is a challenge, as no specific imaging biomarker has been reported. Although  $^{18}\text{F}$ -FDG PET/CT is the most commonly used method to measure BAT activity, its application has limits. As such, there has been a search for novel imaging probes that can consistently detect BAT. A potential strategy is the use of a BAT-specific PET/CT tracker, such as  $^{11}\text{C}$ -PBR28, which is a translocator-specific ligand that can be used to assess BAT mass under thermoneutral conditions. An alternative to PET/CT is near-infrared spectroscopy (NIRS), which can be used to non-invasively measure changes in light absorption in the tissue. NIRS can be employed to estimate BAT mass under thermoneutral conditions by measuring tissue oxygenation, and optically active probes can also allow for the imaging of metabolites such as fatty acids. NIRS could be a useful non-invasive strategy for the assessment of BAT activity, although further validation is necessary (Acosta et al., 2019).

### **Batokines as a therapeutic target**

The beneficial effects of BAT on lipid metabolism and cardiometabolic health can be partially attributed to its secretion of batokines. These endocrine factors could represent potential targets for the treatment of metabolic disorders. For example, the administration of FGF21 mimetic antibodies was able to reduce body weight and improvement in cardiometabolic parameters in obese humans. This suggests that the pharmacologic activation of pathways targeted by batokines can achieve positive effects associated with active BAT.

### Transplantation of brown adipocyte tissue

BAT transplantation has considerable beneficial effects in rodent models of obesity. Transplantation reverses obesity in genetically obese mice, and BAT-deficient mice experience increases in energy expenditure and insulin sensitivity when transplanted with BAT from healthy mice. A different approach does not rely on a healthy BAT donor mouse, but instead involves a tissue-grafting strategy where WAT is converted to BAT through *ex vivo* browning and reimplanted. This strategy could potentially be used to treat obesity in humans lacking active BAT.

### Conclusion

The activation of BAT represents a potential approach for the treatment of obesity and cardiovascular disease in humans. A possible strategy for the treatment of obesity is the sustained activation of BAT through pharmacological compounds such as  $\beta$ 2-AR agonists to achieve weight loss. Future strategies should also consider the endocrine function of BAT, through which it may protect against type 2 diabetes, cardiovascular disease and heart failure. Batokines represent potential targets for the treatment of metabolic disorders. The stimulation of BAT by means of pharmacological agents may lead to the effective treatment of obesity and cardiovascular disease, but further research is warranted.

### Key points

- Chronodisruption: a serious disturbance of the internal temporal order of the biochemical, physiological and behavioral circadian rhythms
- Epigenetics: science that studies the heritable regulation of gene expression without change in nucleotide sequence.
- Nutrigenetics: science that aims to study the effect of genetic variations on the interaction between diet and disease.
- Single-nucleotide polymorphism (SNP): genetic variations in a single nucleotide at a specific position in the genome. These variations are present in more than 1% of the general population.

## Introduction

What we eat plays an important role in our health, however, it is well established that when we eat might be crucial as well, regardless the number of calories (i.e., total energy intake). Our physiology changes during the day, and the optimal synchronization of behavioral and physiological events is an essential mechanism in humans and other species. The circadian system acts as a synchronizer and is affected by other external synchronizers such as the changes between light and darkness, eating and fasting, or activity and resting, and it influences sleep, body temperature, hormones, and appetite. Consequently, several hormones that are related to obesity (cortisol, leptin, adiponectin, insulin, among others) display circadian rhythmicity (Garaulet and Madrid, 2010).

When all this system is altered, we talk of chronodisruption (CD), which is related to several disturbances in many systems and organs of our body. The study of how nutrition relates to our circadian system has been recently called Chrononutrition, which involves energy intake distribution along the day, meal frequency and regularity, duration of the eating and the fasting periods, and the relative importance of these factors in metabolic health and the risk of chronic diseases. Evidence from both animal and human research reveals adverse metabolic consequences of circadian disruption. Conversely, aligning food intake to periods of the day when circadian rhythms in metabolic processes are optimized for nutrition may be effective for improving metabolic health. The importance of the “when” we eat is tied to our internal 24 h biological timing system, the circadian clock, regulating the metabolic processes across the body.

In our modern society, CD may be produced by external situations that are relatively common such as jet-lag, shift work, night light pollution or overnight recreational activities (social jet lag). Other factors are endogenous or internal, and may produce CD by alterations of the core machinery of the molecular circadian clock. BMAL1, PER2 and CLOCK, among others clock proteins, have a specific role in our physiology as well as in the circadian molecular clock. To date, several studies performed in mutant animals have demonstrated that several mutations in clock genes are related to obesity and metabolic disturbances. In humans, different association studies have been focused to elucidate the genetic variations in one SNP that underlie differences in the vulnerability to diseases. Furthermore, epigenetic changes such as DNA methylation at different CpG sites (i.e., regions of DNA where a cytosine nucleotide is followed by a guanine nucleotide) of *CLOCK* are associated with obesity and obesogenic behaviors, indicating that eating behaviors could help to modulate our destiny. Hence, nutrigenetics may help to change our eating habits in order to change our behavior and our adiposity. These association studies between clock genes and several behaviors will be explained in the following lines. In this article, we will describe how the circadian system works and how chronodisruption may aggravate body weight gain and increase adiposity. Besides, we describe how the timing of food intake is an external synchronizer of the biological clock and why eating at a “wrong” timing may have metabolic consequences. We will explain which are the organs and systems involved in chrononutrition, and describe different types of food timing interventions and which are their potential effects on obesity and metabolic dysfunction. Finally, we will describe the particular role of food timing in nutrigenetics and its contribution to the development of new strategies for personalized nutrition programs in overweight and obese people.

## Circadian system and chronodisruption

### How does the circadian system work?

The circadian rhythm is a natural, internal process that regulates the sleep–wake cycle, which is repeated on each rotation of the Earth, roughly every 24 h. This system allows the organism to anticipate and adapt to the predictable rhythmic changes in the environment (e.g., light/dark cycle). In mammals, endogenous circadian rhythms are produced by a multi-oscillator system composed of the central circadian pacemaker, located in the hypothalamic suprachiasmatic nucleus (SCN), as well as by peripheral clocks in virtually every organ, tissue, and cell (Fig. 1). The SCN is primarily entrained by light through direct photic inputs received from the retina that are transmitted to the SCN via the retinohypothalamic tract. It functions to synchronize peripheral clocks via

**Fig. 1** Schematic representation of how the endogenous circadian system works. Hypothalamic suprachiasmatic nucleus (SCN) is entrained by light through direct photic inputs from retina to the SCN via retinohypothalamic tract (RHT). It synchronizes through autonomic nervous system to peripheral tissues such as heart, vascular tissues, kidney, among others.

a combination of neuronal, behavioral, body temperature, and endocrine outputs (Garaulet et al., 2020). Light is the dominant “zeitgeber” (time giver) for the SCN oscillator, which in turn orchestrates rhythms in the peripheral organs/tissues at appropriate phases. At the epicenter of the molecular complex that constitutes the circadian clock are the core transcription factors CLOCK and BMAL1 that orchestrate the transcription of their own repressors, period (PER) and cytochrome (CRY), forming a self-regulated feedback loop. The internal timing system, or circadian clock, coordinates the rhythmic regulation of physiological and behavioral processes in mammals. Therefore, chronobiology comprises different aspects related to the internal clock and its genes and proteins such as the study of (a) the external synchronizers (i.e., light, food intake, or exercise); (b) several hormones and tissues highly related to the clock; and (c) physiological aspects such as nutrient processing, sleep/awakening, body temperature, hormone secretion, tissue repair and many others that when altered may be related to disease.

### What is chronodisruption?

CD is a relevant disturbance of the circadian organization of physiology, endocrinology, metabolism and behavior, which links light, biological rhythms and the development of several diseases, being melatonin a key biological intermediary. The terms “circadian disruption” or “disruption of circadian rhythms” refer to the fact that 24 h rhythms can become desynchronized and that this may have adverse effects on health. In the modern lifestyle, factors such as shift work, night eating syndrome and sleep disorders can disrupt the inner biological rhythm and impair synchronization between the internal clock and the metabolic rhythm. In humans, even 2 h of “social jetlag”, a disruption to the typical sleep wake cycle, is associated with adverse endocrine, behavioral and cardiovascular risk factors in apparently healthy individuals, further illustrating the significance of the circadian regulation on the biological and behavioral rhythms. Nowadays, it is widely demonstrated the existence of tight connections between circadian-related factors and obesity, diabetes, heart and metabolic diseases, psychosocial mental disorders such as depression and anxiety and certain types of cancer.

## Chronodisruption, obesity, and metabolic dysfunction

### Mutations in experimental animals related to obesity and metabolic dysfunction

Circadian rhythms are widely characterized at a molecular level and they are generated through the expression of several clock genes. Studies performed in experimental animals with specific mutations in different clock genes have demonstrated a relationship between these mutations, further failures in the circadian system, and metabolic alterations and diseases. Indeed, a genetic mutation in the homozygous mutant mice for *clock*, displayed obesity, adipocyte hypertrophy and metabolic syndrome. In addition to that, *Bmal1* (–/–) mice had reduced lifespan (mean lifespan of knockout animals was 37 weeks vs. 120 weeks for wild type animals) and displayed various symptoms of premature aging, including sarcopenia, alteration of the percentage of lymphocytes and impaired vision among others. Furthermore, *Bmal1* (–/–) mice have suppressed diurnal variations in glucose and triglycerides and abolished gluconeogenesis while. Together with these examples, many other mutations in clock genes have been related with metabolic diseases, such as those in *Per2* knockout mice, that have shown to display obesity when fed a high-fat diet (HFD); or those in *Cry1/2*–/– mice that display increased insulin secretion and lipid storage in adipose tissue and elevation of proinflammatory cytokines.

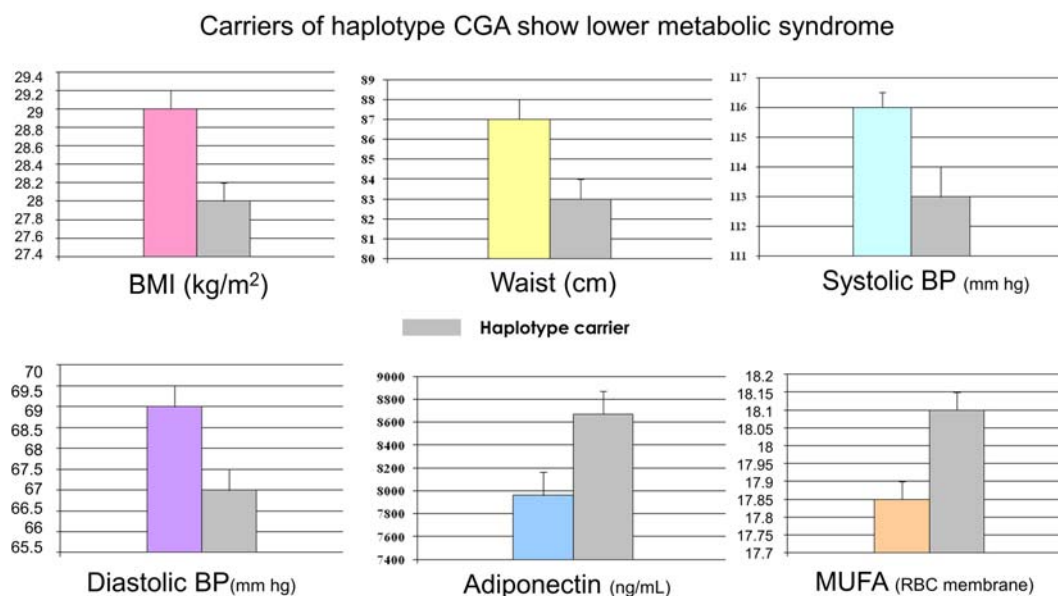

### Genetic variations of clock genes in human obesity and metabolic dysfunction

#### Genetic variations associated with obesity

Even though mutations are rare in humans, genetic variations are present in more than 1% of the population and are characterized by variations in one SNP at some specific position of the genome. As predicted by Turek et al. (2005) in the homozygous mutant mice for *clock*, in humans, genetic variants at *CLOCK* are associated with obesity, especially with abdominal adiposity, and this gene plays a relevant role in the development of metabolic syndrome, type 2 diabetes (T2D) and cardiovascular disease (CVD). Similarly, Garaulet and Madrid (2010) revealed several *CLOCK* SNPs (rs3749474, rs4580704, and rs1801260 (3111T > C)) associated with metabolic syndrome and body mass index (BMI), energy intake, and different variables related to obesity (Fig. 2). In fact, the individuals carrying the minor alleles ate more quantity (and energy), ate more fat, and were more obese. On the other hand, minor allele carriers (A) of *CLOCK* rs4580704 showed decreased risk of developing diabetes (31% lower) and hypertension (46% lower) than non-carriers. Besides, one genetic variation in *CLOCK* rs1801260 (3111T > C) was associated with increased obesity and with lower weight loss effectiveness during dietary treatments for obesity. Some of these associations are functionally explained by the presence of a polymorphism involving a change in the structure of the mRNA leading to a change in gene expression (Garaulet and Madrid, 2010).

As predicted by studies in knock-out *Per2*–/– mice which displayed obesity when fed a high fat diet, in humans several SNPs in *PER2* (rs2304672C > G and rs4663302C > T) have been associated with abdominal obesity and obesogenic behaviors. In particular, *PER2* rs2304672C > G minor allele carriers G (6% of the population) showed several obesogenic behaviors such as an

### Significant associations of *CLOCK* haplotype CGA (rs3749474/rs4580704/rs1801260) and metabolic syndrome

**Fig. 2** Significant associations of *CLOCK* haplotype CGA (rs3749474/rs4580704/rs1801260) and metabolic syndrome. BP, blood pressure; FA, fatty acid; MUFA, monounsaturated fatty acid; RBC, red blood cell.

increased attrition of the weight-loss treatment, increased frequency of snacking, stress while dieting, eating while bored and skipping breakfast, when compared with non-carriers C (Garaulet and Madrid, 2010). Other results from Garaulet and Gómez-Abellán (2014) group also showed that different genetic variants of the clock such as rs2314339 in *REV-ERB-α* were also associated with obesity and this association replicated in two independent populations: a Mediterranean population from Spain and a North American population. *REV-ERB-α* is the major regulator of rhythmic *BMAL1* transcription and it is considered to be the molecular link between the positive elements of the clock (*CLOCK* and *BMAL1*) and the negative (*PER* and *CRY*). The already mentioned genetic variant at *REV-ERB-α* (rs2314339) has been associated with obesity through a decrease in physical activity, differently to other clock genetic variants, which were associated with obesity through changes in dietary intake. These results were also predicted by studies in mutant mice for *Rev-erbα*<sup>-/-</sup>, which displayed reduced spontaneous locomotor activity.

#### Genetic variations interact with several behaviors for obesity

Clock genes may also interact with behaviors for obesity, some examples are those behaviors directly related to emotional eating. In this way, those emotional eating individuals who attended to a weight-loss program and who carried the risk allele C at *CLOCK* 3111T > C had difficulties to lose weight during the intervention. However, those carriers of the risk allele C that were not emotional eaters, together with those non-risk allele carriers T (independently to their emotional eating profile) had no difficulties in losing weight. These findings help to understand that we can reduce the deleterious effect of a genetic variant if we change the “how” we eat.

In addition to genetic variants at *CLOCK*, subjects carrying minor alleles at *SIRT1* and *CLOCK* loci displayed a higher resistance to weight loss and a lower weight loss rate as compared with homozygotes for both major alleles (Fig. 3). Besides, carrying the minor alleles for both variants associated with a lower intake of carbohydrates and monounsaturated fats, and a higher intake of saturated fats, suggesting a less adherence to Mediterranean diet patterns among carriers.

In order to achieve a better understanding of the relationship between circadian rhythms and obesity, Bandín et al. (2013) evaluated changes in circadian rhythmicity in C carriers of *CLOCK* 3111T > C SNP as compared to T carriers, by continuously recording body temperature (wrist temperature, WT), actimetry and position during one week. Interestingly, risk carriers (C) displayed a less marked circadian rhythm than TT carriers and a delayed acrophase that characterizes “evening-type” subjects (Bandín et al., 2013).

#### Clock genes and body weight loss during obesity treatments

One of the main problems in weight loss treatments is the dramatic inter-individual variability in response to the treatment. It is believed that an elucidation of the genetic component may help to predict weight loss effectiveness. Some studies carried out in monozygotic twins analyzed genetic factors for effectiveness of weight loss programs, other studies emphasized the familial aggregation in the ability to lose weight; and the role that parental obesity plays in this matter. In this context, Garaulet et al. (2011) detected in a Spanish overweight and obese population a significant interaction between the *PPARγ* Pro12Ala polymorphism and fat intake for total weight loss. When total fat intake was high, Ala12-carriers exhibited a significantly lower weight loss than major allele carriers indicating that *PPARG2* genotype could be used as a predictive gene to improve the weight loss effectiveness. Clock genes are also related to body weight loss. Indeed, *CLOCK* 3111T > C (rs1801260) associated with the effectiveness of a weight loss program, demonstrating that C carriers are more resistant to lose weight than TT homozygotes. These data suggest that *CLOCK* SNPs may predict weight loss in response to a low-energy diet.

#### Other pathologies

In addition to obesity and weight loss management, circadian rhythms regulate key biological processes influencing several metabolic pathways and therefore affecting the metabolic risk for T2D and CVD. For example, a significant association has been observed between the *CLOCK*-rs4580704 SNP and the incidence of T2D and CVD in 3671 non-T2D participants of PREDIMED study, with G allele carriers showing decreased incidence (dominant model) compared with CC homozygotes. Besides, the protection was higher in the Mediterranean diet intervention group compared to control, and only those T2D subjects carrying the *CLOCK*-rs4580704 SNP had higher risk of stroke, suggesting that core clock genes may significantly contribute to increased CVD risk in T2D.

#### Epigenetic mechanism of clock genes in obesity

Epigenetics is the study of heritable phenotype changes that do not involve alterations in the DNA sequence. In particular, DNA methylation is an epigenetic mechanism that modifies the function of genes and affects gene expression. Aberrant DNA methylation has been found to be associated with various complex human diseases, including obesity. With regards to the circadian system, DNA methylation at different CpG sites of *CLOCK* are more frequent in women with obesity and have been associated to several obesogenic behaviors such as an increased frequency of snacking, eating when bored or eating from great packages. Similarly, Milagro et al. (2012) demonstrated significant associations between the methylation levels of several CpGs located in *CLOCK* with the metabolic syndrome, with difficulties in weight loss and with obesity. In this study, performed in 60 women, it was demonstrated that the methylation degree in several CpG sites of *CLOCK*, such as CpG 1, 5, 6 and 8, increased with obesity. More importantly, the “how” we eat was related to methylation levels at *CLOCK*. The authors observed that those patients who tended to snack more frequently had 12 times higher methylation levels in *CLOCK* CpG1 than those who did not usually snack; whereas those individuals who tended to eat when bored or to eat from great packages had 9 to 19 times higher methylation levels, respectively (Table 1). These increases in methylation suggest a suppression of *CLOCK* expression, which has also been related to obesity. Furthermore,

**Fig. 3** Weight loss and Clock genes. Weight loss progression during 30 weeks of treatment in subjects of different SIRT1-CLOCK combined genotypes after adjusting for sex, age and study center. SIRT1 minor and CLOCK minor in evening types for subjects resistant in total weight loss (kg). SIRT1 major and CLOCK major in morning types for subject's protector. Differences between the groups ( $P < 0.050$ ).

**Table 1** Effect of different behaviors in methylation levels of *CLOCK* CpG1, which shows the importance of "how we eat".

<i>CLOCK</i> CPG1 (highly methylated)	Methylation levels	P-value
Snacking frequency	12x	0.026
Eat fast	9x	0.08
Eat when bored	3x	0.008
Eat from great packages	19x	0.004

research from the same group showed that a weight loss intervention based on a Mediterranean diet modifies the methylation pattern of *BMAL1*, *CLOCK*, and *NR1D1*, and changes in the methylation levels of *BMAL1*, because of the dietary treatment, associated with a reduction in metabolic risk parameters, i.e., serum lipids.

More recently, [Monti et al. \(2021\)](#) found a significant association between the exposure to airborne atmospheric pollutants and methylation at several clock genes in individuals with overweight and obesity. In particular, short-term exposure to airborne particulate matter induced higher methylation of *CLOCK*, *CRY1*, *CRY2*, and *PER3*, and lower of *PER2* in the blood of people with obesity. These findings indicate that BMI may be a variable that might influence the effect of air pollutants on clock genes methylation, clock genes expression, and therefore may affect circadian rhythms in obesity ([Monti et al., 2021](#)). Another study found different DNA methylation patterns at six circadian rhythm pathways genes (*RORA*, *PER3*, *BHLHE40*, *FBXL3*, *CREB1* and *PRKAG2*) correlated with BMI, metabolic profiles and dietary intakes, revealing potential associations of DNA methylation profiles at circadian genes with obesity.

A recent study showed a relationship between obesity, depression and epigenetic changes (more DNA methylation) in clock genes *CRY1* and *CRY2* in women affected by overweight or obesity, establishing an association between BMI and depressive symptoms through clock genes.

Since childhood obesity has dramatically increased in the last decades, a study identified several CpG sites in *PER3*, among other genes, that were differentially methylated between obese and non-obese children, suggesting a role for DNA methylation concerning development of childhood obesity. Overall, epigenetics changes in several clock genes such as DNA methylation are associated with obesity and obesogenic behaviors, indicating that chronobiology is related to obesity through epigenetics.

### Adipose tissue as a circadian organ in obesity

The discovery of peripheral clocks in different tissues such as the white adipose tissue, kidney or liver, links those tissues to chronobiology, playing a crucial role in the regulation of the whole body metabolism. These peripheral clocks seem to regulate the rhythmicity of at least 10% of the genes expressed within each tissue, and their discovery has revolutionized our understanding of the physiological processes in the body ([Froy and Garaulet, 2018](#)) ([Fig. 4](#)).

As already discussed in this article, animal studies have shown that a high fat diet may contribute to the development of obesity and insulin resistance via alterations in the circadian period of locomotor activity rhythms and changes in the oscillation of clock genes in adipose tissue. In this context, *CLOCK*, *BMAL1*, *PER1*, *PER2*, *CRY1* and *REV-ERB $\alpha$*  play a dual role in regulating the core clock mechanism, as well as adipose tissue metabolism, and link circadian rhythms with lipogenesis and lipolysis.

CD occurs when the synchronization between external environmental cues and internal physiological processes are lost. This can either result in a total loss of rhythmicity, in a reduction in rhythm amplitudes, or in phase differences between the SCN and peripheral clocks. As already discussed earlier in this article, experiments performed in clock gene mutants (*CLOCK*, *BMAL1*, *CRYs*, *PER2* and *REV-ERB $\alpha$* ) and knockouts have demonstrated the most compelling linkage between metabolic disorders and the circadian clock ([Froy and Garaulet, 2018](#)). For example, a combination of the *clock* (*delta19*) mutation with the leptin knockout (*ob/ob*) leads

**Fig. 4** Temporal expression of adipocytokines in rodents and humans. The peak expression of each adipokine is depicted. Representation of the acrophase or timing of the maximum levels of adipokine expression in human adipose tissue: comparison with human circulating levels and with rodent adipose tissue mRNA levels. Data are represented as the 5 h of active and resting phase in both humans and rodents, as this is the timing when most adipokines peak. IL-6, interleukin 6; PAI-1, plasminogen activator inhibitor 1; PPAR, peroxisome proliferator-activated receptor.

to obesity, reiterating the contribution of clock disruption to the obese phenotype. Similarly, *Per2* knockout mice under high fat diet feeding developed obesity compared with wild-type mice. Adipocyte-specific deletion of *Bmal1* results in obesity in mice and leads to changes in the expression of hypothalamic neuropeptides that regulates appetite, emphasizing the role of the adipocyte clock in the temporal organization of energy regulation.

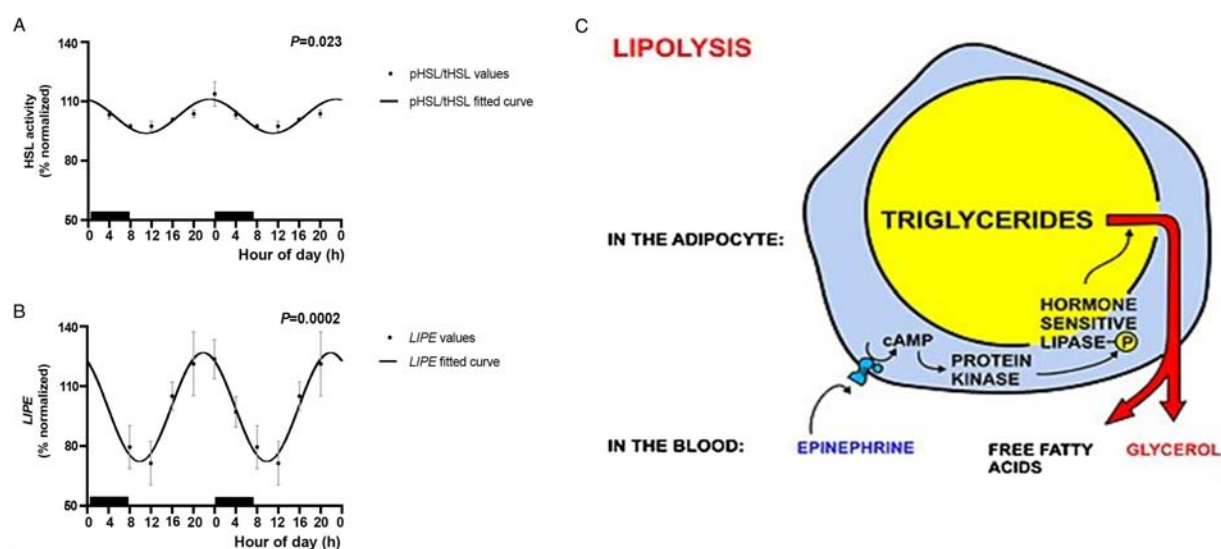

In humans, glucose tolerance varies with the time of the day and plasma glucose excursions in response to meals, oral glucose, and intravenous glucose are markedly higher in the evening and at night than in the morning. Garaulet et al. (2011) demonstrated that both the negative elements (*PER2* and *CRY1*) and the positive elements (*CLOCK* and *BMAL1*) of the clock showed circadian rhythmicity in *ex vivo* adipose tissue explants and oscillated independently of the SCN for at least two circadian cycles after surgery. Moreover, insulin sensitivity, which is related to body fat accumulation, also shows an endogenous circadian rhythm in subcutaneous adipose tissue, with maximum sensitivity at noon and minimum at midnight. Regarding fat mobilization in white adipose tissue, a recent study has shown circadian rhythms in the hormone-sensitive lipase (HSL) activity in human adipose tissue, which allows a better understanding of the intricate relationships between food timing, fasting duration and body fat regulation (Arredondo-Amador et al., 2020) (Fig. 5). Overall, great evidence supports the important role of adipose tissue as a circadian organ in obesity that regulates the whole-body metabolism.

## The circadian system and nutrition (chrononutrition)

### Timing of food intake as an external synchronizer of the biological clock

Food is one external synchronizer of our peripheral clocks. The primary role of the circadian clock is to entrain the organism to the environmental cues and changes in timing of food may lead to an uncoupling of peripheral oscillators from the central pacemaker. Therefore, unusual feeding time can induce a disruption of the circadian system, which might produce unhealthy consequences in humans. For example, changes in the timing of food intake may alter the circadian rhythmicity of many hormones involved in metabolism, such as insulin, glucagon, adiponectin, corticosterone, leptin, chemerin, lipocain and visfatin. A study reported that the times during which subjects were awake and eating during their biological night resulted in multiple metabolic alterations including increased concentration of both glucose and insulin. Moreover, night leptin values in plasma were decreased, which could influence energy balance. It is known that in humans, plasma leptin levels display circadian rhythms that results from the daily variations in food intake and the endogenous clock.

The time and number of meals fluctuate greatly from culture to culture and through time. Certainly, the timing of food intake is a modifiable behavior that may influence energy regulation and consequently the risk of obesity. The “three meals a day” pattern, which consists of one intake in the morning, another at noon, and another at night, helps to maintain the internal temporal order of the circadian system. However, the current 24 h society in which we live causes us to frequently abandon these patterns, not only for example, by the shift work and jet-lag, but also, and especially in young people, due to social jet-lag, the discrepancy in a person’s sleep pattern between the weekday and the weekend, which can cause a person to feel “jet lagged” or tired and fatigued. While social

**Fig. 5** HSL activity and LIPE expression in subcutaneous AT, circadian rhythms, and phase map. Timing is represented both in circadian time (CT, bottom x-axis) and relative local clock time (top x-axis). (A) presence of significant circadian rhythms in HSL activity (pHSL/tHSL) in the total population ( $n = 18$ ). HSL activity is represented in double plotted graphs of a 24 h sinusoidal curve. Data (% normalized) are reported as means  $\pm$  standard error of the mean SEM and represented by black dots. The solid line represents the 24 h sinusoidal curve of the total population; (B) Rhythmic expression of LIPE in adipose tissue explants. Data (% normalized) are reported as means  $\pm$  SEM and represented by black dots. The solid line represents the 24 h sinusoidal curve of the total population. (C) Schematic representation of fat mobilization in adipocyte by lipolysis.

jet lag can affect anyone, the problem is particularly common in teenagers due to the growing demand for study and even leisure and pleasure.

**Lunch timing:** The first study performed in humans about the timing of meals, was focused in the main meal of the day that is lunch in Spain. [Garaulet et al. \(2013\)](#) evaluated the role of food timing in weight-loss effectiveness in 420 individuals who followed a 20-week weight-loss treatment and they were grouped in early eaters and late eaters. In fact, late lunch eaters lost less weight and displayed a slower weight-loss rate during the treatment. Though energy intake, dietary composition, appetite hormones and sleep duration were similar between groups, the late eaters were more evening types, had less energetic breakfasts and skipped this meal-time more often.

**Midpoint of intake:** More recently, in a cohort of 3362 subjects (ONTIME clinical trial), [Dashti et al. \(2020\)](#) demonstrated that late eating is associated with cardiometabolic risk factors and reduced efficacy of a weight-loss intervention in a Spanish cohort. They observed that late eaters had higher BMI, higher concentrations of triglycerides, lower insulin sensitivity and higher concentrations of the satiety hormone leptin in the morning ([Dashti et al., 2020](#)). In this study, authors used the “Midpoint of intake”, as an indicator of food timing. Midpoint of meal intake was determined by calculating the midpoint between the weekly averages for breakfast and dinner times. The reason was that this variable was an endogenous marker of food intake.

**Eating at night:** [Wang et al. \(2014\)](#) demonstrated that while energy intake in the morning was not associated with obesity, those who consumed  $\geq 33\%$  of daily energy intake in the evening were two-fold more likely to be obese than morning eaters ([Fig. 6](#)). Thus, eating more of the day's total energy intake at midday is associated with a lower risk of being overweight/obese. Consequently, lighter changes in meal timing such as the distribution of caloric intake across the normal wake episode, appear to influence not only obesity, but also the success of weight loss therapy.

**Breakfast:** Indeed, it has been shown in a 12-week experimental study that subjects assigned to high caloric intake during breakfast lost significantly more body weight than those assigned to high caloric intake during the dinner. Furthermore, a study performed by measuring meal timing relative to sleep timing as a proxy marker of circadian time, showed that a higher percent of total daily energy intake consumed during the morning window was associated with lower odds of being overweight or obese. This association was stronger in people with an earlier chronotype. Authors also found that for the earlier chronotype a higher percent of sugar and fiber intake during the morning window was associated with a substantial decrease in the odds of being obese ([Xiao et al., 2019](#)). Therefore, it seems that breakfast intake may affect body weight and energy balance. In the last years, the proportion of adults who skip breakfast has increased from 14% to 25%, raising the question of whether there could be a causal relationship between breakfast skipping and obesity. The study demonstrated through Mendelian randomization (MR), the existence of causal links between genetically determined breakfast skipping and higher BMI.

Higher energy intake at night five times the probability of being obese (Evening type)

**Fig. 6** Associations between percent of total energy consumed during the night window and the odds of being overweight or obese in the overall study population and as divided according to sleep timing. Earlier chronotype was defined as a chronotype earlier than the median (3:04 a.m.), while the later chronotype was defined as a chronotype later than the median. The model was adjusted for age, sex, race/ethnicity, total time in bed, chronotype (in the overall population), total steps per day, duration of sedentary time, and total daily energy intake. All quintiles are based on the overall population. Abbreviations: CI confidence interval, OR odds ratio.

## Organs and systems involved in chrononutrition

Different organs and tissues related to food intake present a large number of genes that display oscillations in their expression and encode for important regulators of carbohydrates, lipids and proteins metabolism (Garaulet and Madrid, 2010). These organs are involved in digestive processes as motility, digestion and absorption of nutrients, or in the post absorptive process.

The digestive process begins in the mouth where food is chewed and mixed with saliva, which contains enzymes that begin the chemical process of digestion and, in fact, the salivary  $\alpha$ -amylase, which is involved in the chemistry degradation of polysaccharides (starch) to disaccharide such as maltose, is a circadian enzyme. A study has suggested that salivary  $\alpha$ -amylase levels may be associated with the individual chronotype being lower in the morning-type than in the evening-type subjects. Although digestion begins in the mouth, most of digestive processes are performed in the stomach and intestine with the help of the pancreas. Nowadays, it is well known that a large number of digestive and intestinal enzymes are expressed in a circadian manner and are synchronized by food.

*In stomach:* the most important processes related to digestion are those connected to the mechanical digestion. In this sense, it has been demonstrated that the rate of gastric emptying changes during the day, and it shows lower rates after evening meals than after morning meals. Eating late during the day or having a high caloric intake during dinner may be associated with an impaired digestion. Moreover, the stomach is highly related to the control of food intake though ghrelin, one orexigenic hormone secreted by stomach and popularly known as the "hunger hormone". Circulating levels of ghrelin increase before meals and decrease after food intake. Changes in the timing of food intake may modify ghrelin 24 h rhythmicity, and consequently may alter the physiological control of hunger, influencing total energy intake and as a result, weight loss.

*Intestine:* Absorptive processes in intestine may also be modulated rhythmically. An example is the absorption rhythm of glucose due to the action of several transporters (SGLT-1 in enterocytes and GLUT-2 in the basolateral membrane) which show circadian rhythms. Several authors have revealed that in rats fed *ad libitum*, glucose absorption displays 24 h changes, being lower during the morning hours and higher during the night. Some intestinal enzymes also show synchronization with the feeding rhythm, this is the case of intestinal disaccharidases, especially maltase and sucrase in rats. Their enzymatic activity increases around 1 h before feeding and falls 3 h afterward and it is synchronized by the feeding time. In addition, expression of islet-specific genes such as GLUT-2 and MIF are modulated in a circadian manner, suggesting a potential circadian regulation of pancreatic beta-cells and their implication in insulin production and secretion.

*Liver:* In relation to systemic metabolism, liver is the most important organ implicated in the post absorptive phase of digestion. Most of the liver genes, which encode enzymes or regulatory proteins involved in food processing, display rhythmic expression, for example glycogen metabolism. Glycogen storage changes throughout the day coinciding with changes in the activity of the key enzymes in its storage, such as glycogen synthase, glycogen phosphorylase and glucose-6-phosphatase. Other examples include cholesterol 7 $\alpha$ -hydroxylase (limiting enzyme in the synthesis of bile acids); transcription factors governing fatty acid metabolism, such as PPARs; metabolic enzymes involved in cholesterol metabolism; a number of cytochrome P450 enzymes involved in detoxification and elimination of food components (e.g., coumarin hydroxylase) and many more. Considering that the major function of circadian oscillators in the liver is the coordination of physiological needs during digestive processes, changes in food timing may strongly alter the function of the liver. Besides, the transcriptional regulation of some genes implicated in the hepatic bile acid formation of rats (that consume most of their food during the night) is severely altered when food is provided during the morning. Indeed, in nocturnal animals, feeding during the day inversed the phase of several circadian oscillators in hepatocytes.

## Types of food timing interventions and effect on obesity and metabolic dysfunction

### Calorie restriction and intermittent fasting

Long-term calorie restriction (CR) without malnutrition has been proposed as one of the most consistent dietary interventions to improve health and extend survival across different species. Thus, changes in fasting time and duration, nutrient composition, circadian rhythms, age of interventional onset, and sex of the individuals are all variables that can affect the effectiveness and outcomes of CR. In the last years, evidence suggests that the length (or duration) of fasting, the dietary composition, and the individual chronotype contribute to the effects of CR. In rodents, CR increases health and survival, but most of the studies have involuntarily introduced changes in fasting time that could be affecting results. CR shows low adherence for most humans, therefore, alternative feeding methods have been developed in an attempt to provide the same benefits as CR (Duregon et al., 2021).

*Intermittent fasting (IF):* or periodic energy restriction includes eating patterns in which periods of fasting are followed by periods of *ad libitum* feeding (1–3 days per week). Among the forms of IF includes: (1) periodic fasting (PF), which is an alternative to CR consisting of long but less frequent fasting periods. One form is the fasting mimicking diet (FMD), which combines a plant-based, very-low-caloric diet provided continuously for 4 days, twice a month. FMD after 3-month study has been shown to be effective to decrease blood glucose levels and IGF-1 levels, and increase circulating ketones. (2) The 5:2 intermittent fasting (fasting 2 days each week) is another IF type and lead to greater reduction in body fat and improvement in insulin sensitivity in overweight women after 3-month study than a regular energy reduced diet (DER). The success of these 5:2 intermittent fasting may be related not only to the adherence to the 2 d restriction, but also to the spontaneous restriction of energy intake on non-restricted days. Indeed, authors indicate that the intakes on these days were comparable with those of the DER group. Furthermore, authors discuss that "observation suggests that intermittent dieting does not lead to disordered eating and overconsumption on non-restricted days, however other studies have shown that this could depend on the type of person i.e., emotional eaters or individual chronotype etc." (3)

Alternate-day fasting (ADF) is a continuous sequence of a fast day (100% energy restriction) followed by a feed day (*ad libitum* food consumption) where it shows reduction in body weight, visceral fat and “browning” of WAT in rodents. Moreover, ADF improves insulin resistance and glucose tolerance in rodents for T2D. (4) Time-restricted feeding (TRF, also known as time-restricted eating, TRE), which is defined as the provision of food for up to 12 h during the active phase, and this restriction restores circadian rhythms and imparts pleiotropic metabolic benefits in animal models. Thus, TRF is a form of intermittent fasting that limits the daily food consumption to a period of 4–12 h, which induces a fasting window of 12–20 h per day. However, TRF does not require caloric restriction and it requires a consistent daily eating window.

It has been shown that TRF protects mice against obesity under HFD feeding, insulin resistance, hepatic steatosis and inflammation. Mechanistically, TRF can reprogram the circadian clock in the fasting state via AMPK and in the fed state via mTOR, and TRF increases the amplitude of *cry1* and *per1* in liver of mice fed chow and restored the amplitude of *bmal1*, *cry1*, *per2* and *Rev-erbα* in mice fed HFD. In addition, TRF reduces the pyruvate carboxylase and glucose 6-phosphatase, and increases glucokinase during the active phase, decreasing the glucose production by the liver. TRF also reduces genes related to lipid metabolism in liver during the active phase, reducing the lipid storage and increasing triglyceride hydrolysis. Moreover, TRF protected in knockouts mice (whole-body *Cry1;Cry2* and in liver-specific *Bmal1* and *Rev-erbα/β*) from HFD-induced weight gain, glucose intolerance, hepatic steatosis, and dyslipidemia, providing evidence that daily rhythms in the fasting and feeding cycle is enough to maintain metabolic homeostasis, independently of circadian clocks.

In humans, TRF have been shown to reduce body weight and fat mass, to improve glucose tolerance, and to reduce blood pressure in humans in those with overweight or obesity. Moreover, TRF have shown to reduce plasma triglycerides and inflammatory markers. A recent clinical trial in overweight adults have shown lower glucose levels, increases ketones, cholesterol and gene expression in the whole blood of *SIRT1* and autophagy gene *LC3A* in the morning, while in the evening, there is an increased in the expression of *mTOR* (major nutrient sensing protein), and a tend to increase brain-derived neurotrophic factor (*BDNF*). Besides, TRF also altered diurnal levels of cortisol, and increased the expression of circadian clock genes *BMAL1*, *CRY1*, *CRY2*, and *RORA* in the morning. In the evening, there was a decreased in gene expression of *PER1*, and increased in *CRY1*, and *RORA* in blood, indicating a different circadian pattern under TRF. In addition, TRF in overweight men affects the rhythmicity of serum and muscle metabolites and regulates several amino acid transporter genes and metabolites in muscle, without perturbing core clock gene expression (Lundell et al., 2020). Hence, TRF is recognized as simple and well-tolerated diet with beneficial health effects based on chrononutrition. Nevertheless, the studies to date in humans are limited in size and duration, and the effectiveness and principles acceptability of TRF in the general population remains unclear. Furthermore, one of the key questions related to TRF is the timing of fasting. In this sense, results of a study performed in human adipose tissue culture, which analyzed the circadian changes in the hormone-sensitive lipase (HSL) activity, show that at least 12 h of fasting during the nighttime is able to duplicate the activity of HSL and stimulate body fat mobilization from adipose tissue. Therefore, authors conclude that an easy way to follow a TRF could be advancing dinner timing (for example at 8 p.m.) and delaying breakfast timing (for example to 8 a.m.) achieving a 12 h fasting during night, the natural timing that we are in fasting, (i.e., when we are sleeping). This will facilitate TRF without major changes in individual habits or family and social life.

Commonly, IF represents a dietary approach of interest to reduce body weight and to improve the health by delaying many age-related diseases while improving metabolic markers independently from weight loss. In addition, IF reduces glycemia, improves insulin sensitivity, and decreases systemic inflammatory marker.

### Timing of food intake in nutrigenetics

Nutrigenetics points to understanding how the genetic background of an individual impact on the diet. This novel science involves the heterogeneous response of genetic variants to nutrients and dietary components and may be useful in developing nutraceuticals, which may be designed for specific genetic subtypes. Concerning chronobiology, different SNPs of our circadian system interact with food intake and various behaviors for obesity and metabolic risk variables. *CLOCK* polymorphisms interact with dietary intake of different fatty acids subgroups (for example saturated, or MUFA) to modulate several metabolic syndrome traits such as glucose and insulin sensitivity. One example is the protective effect of the minor allele (G) at rs4580704 in the presence of higher MUFAs intake (more than 13% of total energy intake). Afterward, the same group demonstrated an interaction of the *CRY1* gene and several characteristics of diet for insulin resistance both in a Mediterranean and in a North American population. Authors showed that a higher intake of carbohydrate was associated with higher HOMA-IR and lower QUICKI, only in those individuals homozygous for the minor allele CC (rs2287161) of *CRY1* gene. This finding supports the link between the circadian system and glucose homeostasis in order to develop personalized nutrition programs to prevent insulin resistance in CC carriers of *CRY1* rs2287161. Garaulet et al. (2015) also showed that Melatonin Receptor 1B (*MTNR1B*) rs10830963 risk variant G worsens the deleterious effect of melatonin on glucose tolerance in humans. These findings suggest the importance of genotyping for personalized nutrition programs in subjects consuming melatonin, or in late eaters who are exposed to high levels of melatonin when eating late at night and are carrying allele G for *MTNR1B* (Garaulet et al., 2015) (Table 2).

The timing of food intake (for example eating lunch late) may also interact with our genes for obesity or weight loss effectiveness. Indeed, studies have demonstrated that eating late the main meal of the day, that is lunch in Spain, may be deleterious but not for everybody. Indeed, the deleterious effect only affect a genetic subtype of *PLIN1* (14994A > T variant). Interestingly, among AA carriers, eating late was associated with less weight loss, whereas the time of eating did not influence weight loss among TT carriers.

**Table 2** Effects of melatonin on glucose metabolism.

	<i>Low melatonin</i> <i>Circadian ... light</i> <i>...day ... exposure</i>	<i>High melatonin</i> <i>Circadian ... exogenous</i> <i>...night ... melatonin</i>
Fasting	$\beta$ cell rest 	$\beta$ cell rest 
Postprandial	$\beta$ cell function insulin sensitivity 	$\beta$ cell function insulin sensitivity 

Source: Garaulet et al. (2020).

These results contribute to the development of new strategies for personalized nutrition programs in overweight and obese people based on genetics (Garaulet et al., 2016).

All of these studies show how our habits can interact with our genes and reduce or increase the effect of a specific genetic risk variant. Consequently, as we cannot change our genome, we can change our habits in order to improve the health and prevent the disease.

## Conclusions

In this article, we summarize that changes in “how we eat”, “what we eat” and other daily behaviors such as the timing of food intake can improve our health due to the interaction with our genome. In this sense, experimental studies in mutant’s animals and observational studies in humans revealed the association and putative function of clock genes in relation to obesity and weight loss. Furthermore, eating is an external synchronizer of our circadian system and the “when” we eat might play an important role in obesity and metabolic dysfunction. Thus, we have described the impact of time-related eating patterns on weight-loss treatment, and the differences between early eaters and late eaters. Therefore, changes in our behaviors toward early meals may improve the weight-loss efficiency during the treatment. Finally, epigenetics shows that our behaviors can help to change our genome and decrease the risk of several metabolic diseases.

### Key points

- Cytokines are low molecular weight proteins released mainly from cells of the immune system
- Cytokines are released in response to microbes and tissue injury
- Cytokines act in an autocrine or paracrine manner
- Cytokines include the interleukins, interferons, stem cell growth factors, interferons, tumor necrosis factors and adipokines
- Tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1 and IL-6 have metabolic effects—they induce fever, anorexia, altered metabolism and mobilization of substrates
- Inflammation induces oxidative stress and oxidative stress induces inflammation
- Although part of the host defense mechanism, inflammation can be damaging to the host and must be controlled
- Excessive or uncontrolled inflammation is associated with many diseases including frank inflammatory conditions such as rheumatoid arthritis and also age-related chronic diseases including obesity, type-2 diabetes and atherosclerosis; these are all associated with elevated TNF- $\alpha$ , IL-1 and IL-6
- Long chain n-3 fatty acids can decrease production and action of TNF- $\alpha$ , IL-1 and IL-6
- Through decreasing oxidative stress, antioxidants can decrease production and action of TNF- $\alpha$ , IL-1 and IL-6

### Introduction

Cytokines are a broad family of low molecular weight proteins which are released, mainly, though not exclusively, from cells of the immune system, in response microbes and tissue injury, which might be physical, oxidative or metabolic. Cytokines induce a state of inflammation in the body and modulate the activity of the immune system. Although mainly thought of as immune modulators, cytokine production is not restricted to cells in the immune system but fibroblasts, epithelial and endothelial cells, adipocytes, myocytes and specialized tissues, such as the ovary, all produce cytokines. Although largely influencing immune function, including the inflammatory response, a number of cytokines act as growth factors and lead to the proliferation and differentiation of a wide range of cell types in the body. Cytokines act via receptors and generally act in an autocrine or paracrine fashion. Many cytokines are found circulating in the bloodstream. Cytokines include the interleukins, the interferons, many stem cell growth factors, the chemokine family, the tumor necrosis factor family and the adipokines. There is no single cytokine classification system and cytokines are often grouped in different ways depending upon origin or function. For example, monokines are cytokines released from monocytes, lymphokines are cytokines released from lymphocytes and adipokines are cytokines released primarily from adipose tissue. Chemokines are cytokines that mediate the chemically-induced movement of cells known as chemotaxis or chemoattraction. Representative examples of cytokines are detailed in [Table 1](#). While all cytokines influence the functions of cells of the immune system (see [Table 1](#)), some also exert metabolic effects upon the host. These include the three classic proinflammatory cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- $\alpha$  ([Beutler and Cerami, 1986](#); [Dinarello, 1988](#); [Heirich et al., 1990](#)).

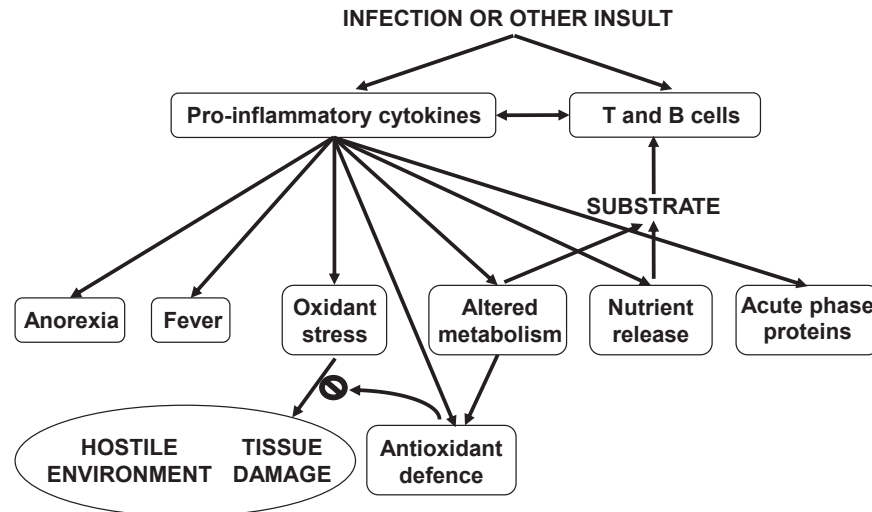

**Table 1** Selected cytokines, their main sources and their functions. Note that the list is not exhaustive.

<i>Cytokine</i>	<i>Main sources</i>	<i>Main function</i>
IL-1 $\beta$	Monocytes/Macrophages	Cell proliferation, differentiation and apoptosis; induces cyclooxygenase-2; causes fever and anorexia; promotes acute phase protein synthesis
IL-2	Helper T cells	Proliferation and differentiation of type 1 helper T cells; maturation of CD8 <sup>+</sup> T cells
IL-4	Helper T cells	Proliferation and differentiation of type 2 helper T cells; promotes IgE production
IL-5	Type 2 helper T cells	Proliferation of B lymphocytes; activation of eosinophils
IL-6	Monocytes/Macrophages	Proliferation of B lymphocytes and IgA and IgG1 production; promotes acute phase protein synthesis
IL-8	Macrophages	Induces acute phase responses
IL-10	Monocytes/Macrophages; T cells; B cells; natural killer cells; neutrophils; Eosinophils; mast cells	Chemoattractant
IL-12	Monocytes/Macrophages	Inhibits production of IFN- $\gamma$ , IL-1, IL-6, TNF- $\alpha$ ; inhibits antigen presentation
GCSF	Monocytes	Promotes type 1 helper T cell responses; induces IFN- $\gamma$
MCSF	Monocytes	Promotes maturation of myeloid cells
GMCSF	Activated macrophages; T-cells	Promotes maturation of monocytes
IFN- $\alpha$ and IFN- $\beta$	Monocytes/Macrophages; virally-infected cells	Promotes proliferation, differentiation and survival of monomyelocyte cells
IFN- $\gamma$	Type 1 helper T cells; natural killer cells	Inhibits viral replication
TNF- $\alpha$	Monocytes/Macrophages	Activation of type 1 helper T cells; activation of macrophages for proliferation and antigen presentation; production of TNF- $\alpha$ and IL-1
TGF- $\beta$	Platelets	Stimulates generalized immune activation as well as tumor necrosis; causes fever and anorexia; promotes acute phase protein synthesis
		Immunoinhibitory but stimulates IgA production and connective tissue growth and collagen formation

Abbreviations: GCSF, granulocyte colony stimulating factor; GMCSF, granulocyte-macrophage colony stimulating factor; IFN, interferon; Ig, immunoglobulin; IL, interleukin; MCSF, monocyte colony stimulating factor; TGF, transforming growth factor; TNF, tumor necrosis factor.

### Some cytokines affect metabolism

Widespread changes occur as a result of pro-inflammatory cytokine production and action (Fig. 1). These seem to be designed to create a hostile environment for pathogens, but are also harmful to the host, especially if they are sustained (Soeters and Grimbale, 2009). Cytokines orchestrate metabolic responses to ensure that during infection, nutrients are provided for the immune system as a result of wasting of peripheral tissues (Douglas and Shaw, 1989). For example, amino acids released as a consequence of increased proteolysis in muscle, skin, and bone, provide substrate for the synthesis of proteins produced as part of the immune response (e.g., antibodies, acute phase proteins). Glutamine, released from muscle, and glucose derived from increased hepatic gluconeogenesis using amino acids as the substrate, are major sources of energy for the immune system. Likewise increased lipolysis in adipose tissue provides fatty acids as metabolic fuels, substrates for regulatory molecules, and building blocks for cell membranes (Grunfeld and Feingold, 1992). In addition, proinflammatory cytokines cause insulin resistance (Grimble, 2002; Wiser et al., 2013) which results in an elevation of plasma triacylglycerol concentrations through a combination of effects: by enhancing free fatty acid efflux from adipose tissue, raising hepatic triacylglycerol synthesis, and inhibiting entry of triacylglycerol fatty acids into adipose tissue by inhibition of adipose tissue lipoprotein lipase activity. One interesting effect of raised plasma triacylglycerols is that bacterial endotoxins are sequestered onto the lipoproteins carrying the triacylglycerols, so protecting the host from the deleterious consequences of endotoxin and also targeting them for elimination by the liver. Zinc, an important cofactor in RNA and DNA synthesis, is released from peripheral tissues by inflammatory cytokines, incorporated into the zinc transporting protein metallothionein in liver and kidney, and subsequently utilized by the immune system. Fever and loss of appetite (anorexia) often occur as a result of increased pro-inflammatory cytokine production due to a direct action of these cytokines on the hypothalamus. Pro-inflammatory cytokines also modify metabolism in the liver. Large increases in the rates of gluconeogenesis, glycogen breakdown, and urea synthesis occur. Blood glucose, urea, and triacylglycerol concentrations may rise. Paradoxically, however, metabolism of xenobiotics is decreased owing to a reduction in the activity of

**Fig. 1** Central role of pro-inflammatory cytokines in the host response to infection. The dark circle with a diagonal line indicates inhibition.

cytochrome P450 enzymes. The profile of export proteins synthesized by the liver is changed: synthesis of albumin is reduced, and the synthesis of a group of proteins closely associated with inflammation called acute-phase proteins is increased (Heinrich et al., 1990). Acute-phase proteins are multifunctional and include ceruloplasmin (an antioxidant and copper transport protein), C-reactive protein (improves macrophage activity), fibrinogen (for blood clotting), complement proteins (for enhanced phagocytosis and pathogen destruction), and metallothionein (a zinc transport protein). Thus, pro-inflammatory cytokines not only affect the immune system, but also alter metabolism in the liver, adipose tissue, muscle and brain, to control the whole body response to infection or insult. All of the metabolic changes may be purposeful in creating a situation in which substrate is more closely tailored to the requirements of the immune system than would occur from the vagaries of habitual dietary intake.

In addition to the changes in metabolism described above, the antioxidant defenses of the body are strengthened by increases in the activities of superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase, and by increases in the hepatic synthesis of the reduced form of glutathione (GSH) (Grimble, 1994). The liver thus becomes the main focus for the synthesis of molecules for the nutrition, support and direction of the immune system, and for the protection of the body from the adverse effects of cytokine action. Indeed when the ability of the liver of patients with sepsis (a severe clinical form of inflammation induced by infection), to extract amino acids from the circulation was assessed, it was found that patients who subsequently died had only half of the ability compared with patients who survived.

A number of molecules synthesized in enhanced amounts when cytokines are produced are part of complex feedback systems which act to limit cytokine production and effects (Fig. 2). These include corticosteroids, GSH and some acute-phase proteins which

**Fig. 2** Some of the feedback control systems for pro-inflammatory cytokine production and action. HSPs, heat shock proteins; IL, interleukin; IL-1ra, IL-1 receptor antagonist; sTNFRs, soluble TNF receptors; TNF, tumor necrosis factor; the dark circle with a diagonal line indicates inhibition.

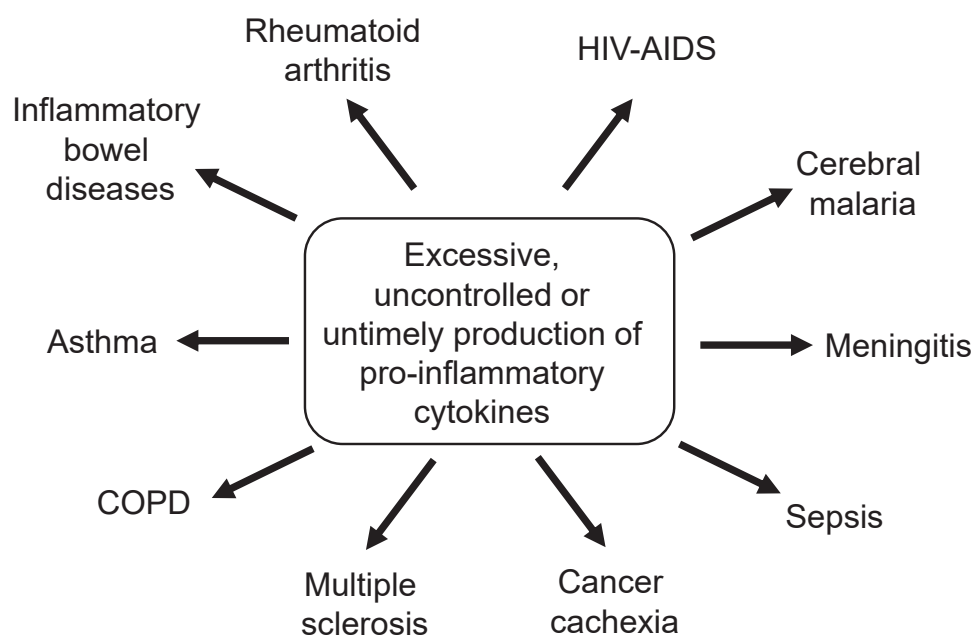

suppress cytokine production, and cytokine receptor antagonist molecules for IL-1 and TNF which inhibit their action. Other molecules also moderate cytokine actions. *Anti*-inflammatory cytokines such as IL-10 and some heat shock proteins exert an *anti*-inflammatory influence in the latter stages of the inflammatory response. This down-regulation of inflammation, once the infectious agent has been defeated, is important for survival since the inflammatory process depletes the body of resource. The balance between the pro-inflammatory and *anti*-inflammatory process is of key importance for return to homeostasis and for survival.

### Role of cytokines in disease

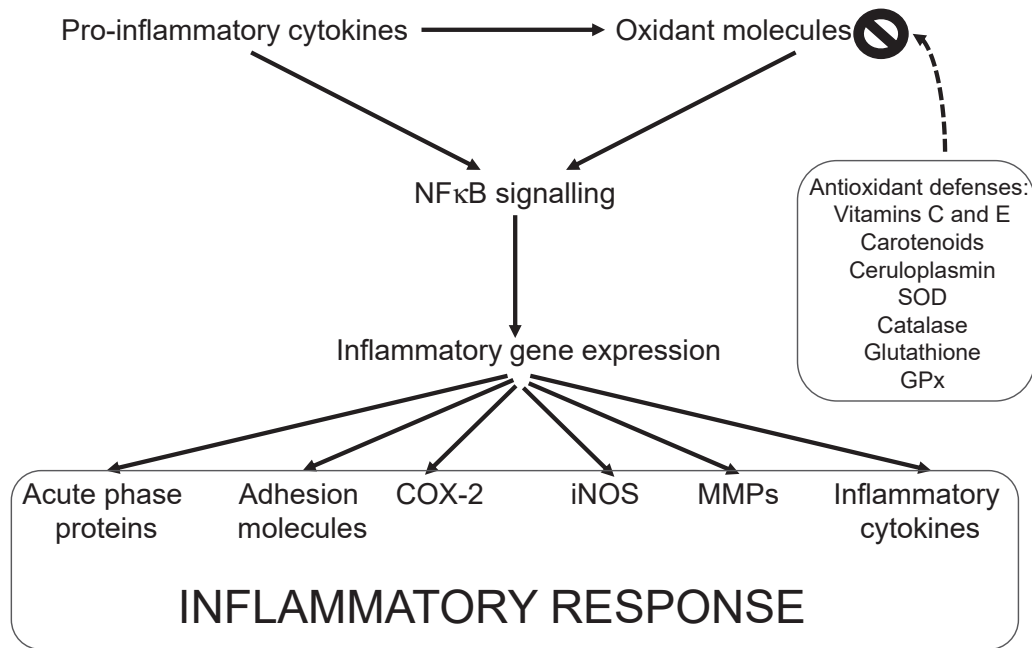

Despite the importance of cytokines in protecting the host from pathogens, these cytokines may have damaging and even lethal effects upon the host (Grimble, 1996; Calder et al., 2009; Soeters and Grimble, 2009). Thus, the response of the host to a pathogen may play as significant a part in the demise of the host as the effects of the pathogen itself. This damaging aspect has sometimes been called the “cytokine storm”. This is why the feedback processes described in Fig. 2 are so important as an infection runs its course. Cytokines can also play a major part in the tissue damage that is seen in chronic inflammatory disease in which no infective agent is involved (e.g., rheumatoid arthritis). Excessive or inappropriate cytokine production has been associated with increased morbidity and mortality in a wide range of diseases and conditions in which inflammation plays a part. These include diseases where the immune system is clearly interacting with invading pathogens, such as in malaria, meningitis, sepsis, and acquired immunodeficiency syndrome and conditions such as asthma, inflammatory bowel disease, rheumatoid arthritis, and cancer where inflammatory disease develops without obvious involvement of pathogens (Fig. 3). Furthermore proinflammatory cytokines are involved in the progression of disease processes such as plaque development in atherosclerosis and demyelination in multiple sclerosis and Alzheimer’s disease. They are now even known to be involved in changes in adipose tissue as obesity progresses (Tilg and Moschen, 2006).

Damage may also be caused to the host by release of free radicals and other oxidant molecules from phagocytic cells in response to an inflammatory stimulus including IL-1 and TNF. Furthermore, oxidant molecules up regulate production of IL-1, TNF and IL-8, among other inflammatory factors, by activation of the transcription factor, nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) (Fig. 4). The factor is normally held quiescent in the cytoplasm owing to attachment to an inhibitory component (IκB). In the presence of either inflammatory stimuli or oxidants, IκB is phosphorylated and dissociates from the rest of NFκB; the now free NFκB migrates to the nucleus and induces the transcription of a large range of genes encoding proteins associated with the inflammatory process (Fig. 4). These include genes encoding inflammatory cytokines, acute phase proteins, adhesion molecules, and enzymes including cyclooxygenase 2, inducible nitric oxide synthase and some of the matrix metalloproteinases. Hence antioxidants, which reduce the production of or quench oxidants, can have an *anti*-inflammatory action (Fig. 4).

The fact that insulin resistance and disordering of lipid metabolism occur in obesity, diabetes mellitus, and during the inflammatory response has led to the investigation of the possibility that inflammation and obesity are somehow interlinked. As adipose tissue expands it becomes infiltrated by monocytes which differentiate into macrophages. It is now known that other immune cells

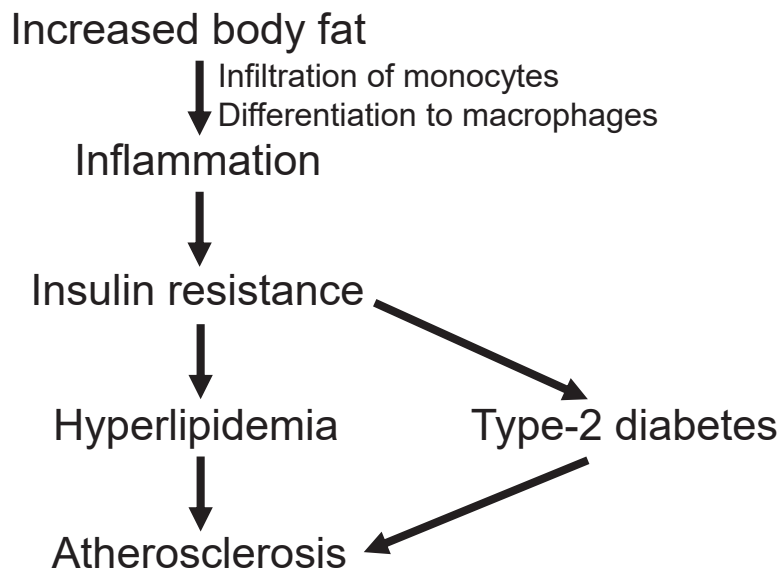

**Fig. 3** The central role of excessive, uncontrolled or untimely pro-inflammatory cytokine production in human disease. COPD, chronic obstructive pulmonary disease; HIV-AIDS, human immunodeficiency virus acquired immunodeficiency syndrome.

**Fig. 4** Interplay between pro-inflammatory cytokines and oxidants in initiating NFκB signaling leading to upregulation of multiple components of the inflammatory response. COX, cyclooxygenase; iNOS, inducible nitric oxide synthase; MMPs, matrix metalloproteinases; NFκB, nuclear factor kappa-light-chain-enhancer of activated B cells; the dark circle with a diagonal line indicates inhibition.

including T and B lymphocytes also infiltrate adipose tissue in obesity. The immune cells interact with adipocytes and an inflammatory environment is created (Hotamisligi et al., 1993; Tilg and Moschen, 2006; Sethi and Hotamisligi, 2021). This most likely contributes to the insulin resistance that occurs in obesity. For example, TNF-α results in insulin insensitivity, indirectly by stimulating stress hormone production and directly by sustained induction of SOCS-3, which has been shown to decrease insulin-induced insulin receptor substrate 1 tyrosine phosphorylation and its association with the p85, the regulatory subunit of phosphatidylinositol-3 kinase, and by negative regulation of PPAR gamma, an important insulin-sensitizing nuclear receptor. Adipose tissue produces and releases inflammatory cytokines including TNF-α and IL-6 and the adipokines leptin and adiponectin; the latter two have opposing actions to one another. Both immune/inflammatory cells and adipocytes produce TNF-α and IL-6 while it is adipocytes that produce leptin and adiponectin. In humans, plasma leptin concentrations are linearly related to body mass index and body fat mass. Thus, compared with people of healthy weight, those living with obesity have higher plasma concentrations of TNF-α, IL-6, leptin, and C-reactive protein and lower concentrations of adiponectin (Calder et al., 2011). This increase in systemic inflammation in obesity may be partly responsible for the co-morbidities that develop in obesity (Fig. 5).

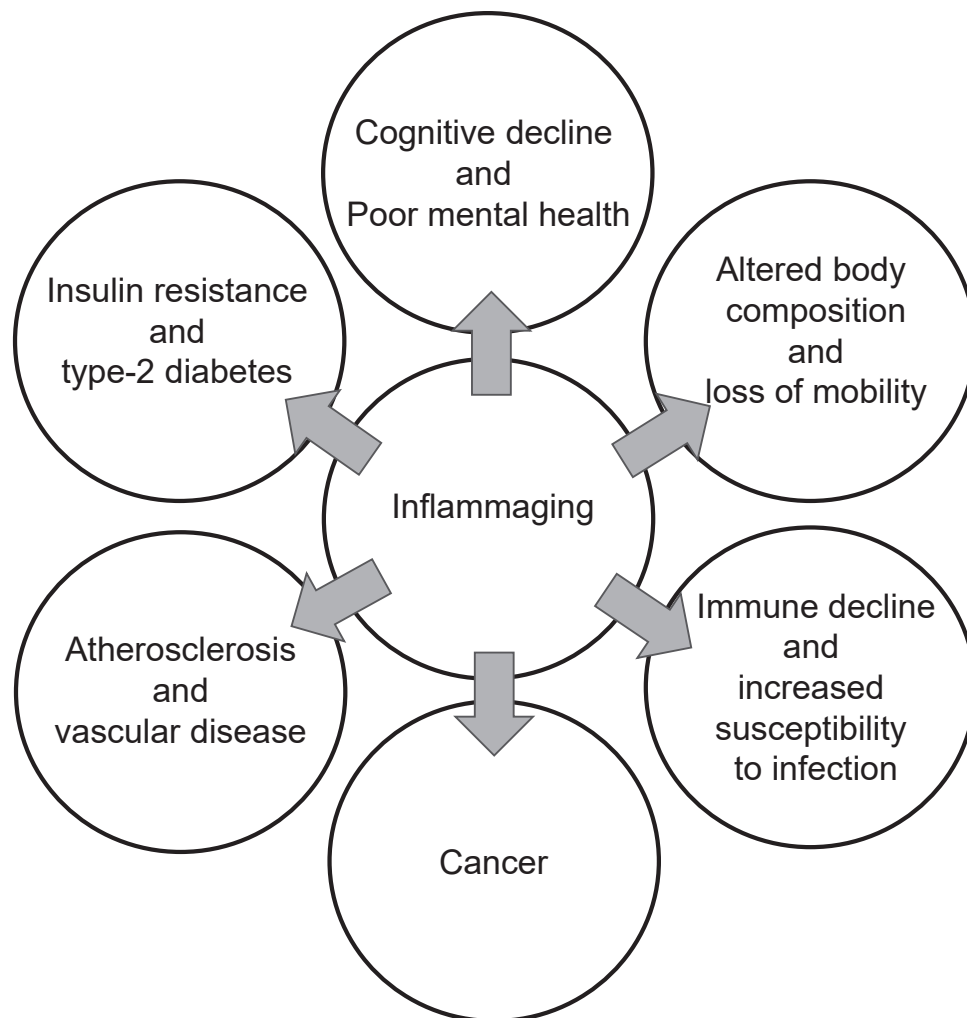

**Fig. 5** Inflammation creates a link between increased body fat (obesity) and the cardiometabolic co-morbidities of obesity.

It is also important to note that as people age they can develop a state of chronic low-grade inflammation, termed inflammaging, which is characterized by elevated levels of pro-inflammatory cytokines, such as IL-6, and of C-reactive protein in the plasma (Calder et al., 2017). Inflammaging may be a link to age-related changes in muscle mass and increases in non-communicable diseases (Fig. 6).

### The interaction of nutrition and cytokines

Proinflammatory cytokines exert widespread effects on metabolism, involving alterations in lipid, carbohydrate, and protein metabolism (see earlier). In addition there are substantial changes in micronutrient metabolism (see earlier). There is a bidirectional interaction with oxidant stress, that is mitigated by antioxidants (see earlier). A number of intracellular signaling pathways are activated by the actions of cytokines on target cells; these include the cyclic AMP and protein kinase C pathways and pathways leading to production of prostaglandins (PGs) and leukotrienes (LTs) from polyunsaturated fatty acids (PUFAs). Thus, there are many levels at which nutrients and nutrient intake can modify the intensity and characteristics of the cytokine response to inflammatory stimuli (Grimble, 1996). The ability of nutrients to modify inflammation has been used in the treatment of diseases with an inflammatory basis, such as rheumatoid arthritis. The interaction between nutritional status and inflammation is also important in public health by determining the effects of infection on growth and well-being of populations with a poor nutrient intake.

The earliest indications that nutritional status could affect cytokine biology came from studies on malnourished hospital patients, where white blood cells had a reduced capacity to produce cytokines. The high mortality rates in these patients suggested the importance of cytokines in the process of recovery from injury and infection. Protein supplements improved cytokine production and decreased the mortality rate. Because these observations were made, a large number of studies have been conducted in

**Fig. 6** The central role of inflammaging in chronic diseases of aging.

animals and humans which show that fatty acids, amino acids, and micronutrients change the ability of mammals to produce and respond to a number of cytokines including IL-1, IL-6 and TNF.

### Influence of fatty acids on inflammatory cytokine production

The production and actions of proinflammatory cytokines are influenced by dietary fatty acids acting through several different, but perhaps interlinked, mechanisms. Central to these mechanisms is the incorporation of the fatty acids into the cell membrane bilayer (Fig. 7). Subsequently, membrane fluidity may be changed, the formation of signaling platforms called lipid rafts in the membrane may be affected, and the types and amounts of lipid mediators including PGs and LTs being produced may be altered (Calder, 2020a). In addition, there seem to be direct effects by which different fatty acids influence inflammatory cytokine production. For example, several fatty acids, but particularly the n-3 PUFA docosahexaenoic acid (DHA), can bind directly to a cell surface G-protein coupled receptor (GPR) called GPR120 on macrophages which initiates signaling that dampens activation of NFκB, so reducing production of TNF-α, IL-1 and IL-6. Furthermore, there is some evidence that certain saturated fatty acids, including lauric, myristic and palmitic acids, bind to the endotoxin receptor (toll-like receptor 4) to directly promote inflammatory signaling activating NFκB, although this action is disputed by some. With regard to lipid rafts, DHA seems to be the most potent raft disruptor in inflammatory cells and this has been linked to less activation of NFκB. The n-3 PUFAs eicosapentaenoic acid (EPA) and DHA act as activators of PPAR-γ which physically interferes with NFκB translocation to the nucleus. Normally, the main substrate for synthesis of PGs and LTs is the n-6 PUFA arachidonic acid (Calder, 2020b). In general, these lipid mediators have pro-inflammatory effects and they are linked with many inflammatory conditions. However, different mediators produced from arachidonic acid can have different effects and sometimes these can be *anti*-inflammatory. For example, PGE<sub>2</sub>, which has many pro-inflammatory actions, actually inhibits the production of TNF-α and IL-1. This is, most likely, an example of the self-regulating nature of the inflammatory response referred to earlier. EPA and DHA decrease production of PGs and LTs from arachidonic acid and give rise to separate families of lipid mediators. EPA is a substrate to PGs and LTs with a different structure to those performed from arachidonic acid and in general these are weakly bioactive. EPA also gives rise to E-series resolvins while DHA gives rise to D-series resolvins, protectins and maresins. The resolvins, protectins and maresins are together termed specialized

**Fig. 7** Summary of the mechanisms by which fatty acids interact with inflammatory processes, including pro-inflammatory cytokine signaling and production. CAMs, cell adhesion molecules; COX, cyclooxygenase; DHA, docosahexaenoic acid; GPR, G protein coupled receptor; iNOS, inducible nitric oxide synthase; LT, leukotriene; MMPs, matrix metalloproteinases; NFκB, nuclear factor kappa-light-chain-enhancer of activated B cells; PG, prostaglandin; PPAR, peroxisome proliferator activated receptor; SFAs, saturated fatty acids; SPM, specialized pro-resolving mediator; the dark circle with a diagonal line indicates inhibition; + indicates activation.

pro-resolving mediators (SPMs) (Chiang and Serhan, 2020). All these bioactive lipid mediators act via cell surface receptors. The SPMs possess *anti*-inflammatory and inflammation resolving capabilities including the ability to decrease the activation of NF $\kappa$ B and the production of TNF- $\alpha$ , IL-1 and IL-6. Thus, in their own right and through their derived mediators EPA and DHA have *anti*-inflammatory and inflammation resolving actions, including the ability to decrease production of the classic pro-inflammatory cytokines. Linked to this, supplements of EPA and DHA have been shown to be of benefit in patients with inflammatory diseases especially arthritis. These effects of n-3 PUFAs might also relate to their ability to reduce risk of chronic non-communicable diseases of aging, especially cardiovascular disease.

### Interaction of inflammatory cytokines with amino acid and protein metabolism

Substantial increases in protein synthesis occur as the result of infection. It has been estimated that approximately 45 g of protein is required each day to produce and maintain the increased quantities of white blood cells, acute phase proteins and antibodies in an infected individual. This demand will have a considerable impact on the availability of amino acids for other processes in the body that involve protein synthesis. In children this has an inhibitory effect on growth, which is worsened by repeated bouts of infection. Understandably infection during pregnancy or lactation can have an adverse impact on offspring growth and development. Output of amino acids from skeletal muscle, skin, and bone provides substrate for the synthesis of cells and proteins associated with the response to infection and other inflammatory insults, as indicated earlier. However, the supply may not always match demand, as is evident from the decrease in plasma concentrations of a number of amino acids. In particular, reductions occur in the concentrations of a metabolically related group of amino acids, including glycine, serine, and taurine. All three are metabolically related with the sulfur amino acids. Glycine and serine, together with the sulfur amino acids, are found in high concentrations in many compounds associated with the immune and inflammatory response, most notably comprising 66% of glutathione, 56% of metallothionein, and up to 25% of many acute-phase proteins. Experimental studies have shown that the production of cytokines, acute phase proteins, and glutathione is influenced by the adequacy of both protein and sulfur amino acid intake. The partitioning of cysteine into glutathione and proteins in the liver may change if dietary sulfur amino acid intake becomes inadequate. This phenomenon is due to the biochemical properties of rate limiting enzymes in the two pathways. Although the  $K_m$  for  $\gamma$ -glutamyl cysteine synthetase (rate limiting for GSH synthesis) is 0.35 mM, that for amino acid activating enzymes (rate limiting for protein synthesis) is only 0.003 mM. This biochemical characteristic means that GSH synthesis will fall below maximal rates at much higher intracellular cysteine concentrations than protein synthesis. Thus, at low sulfur amino acid intakes, antioxidant defenses will become compromised, permitting oxidative and inflammatory stress. Low concentrations of GSH in tissues may have implications for the extent of inflammatory processes in the individual. In animal studies, decreased lung GSH concentrations are associated with accumulation of inflammatory cells in tissues. In studies on patients with human immunodeficiency virus infection given *N*-acetyl cysteine to improve GSH status, a decrease in plasma IL-6 concentrations was noted indicating a reduction in inflammation.

### Modulation of inflammatory cytokine production by micronutrients

Micronutrients play widespread and complex roles in the response to infection and trauma. They are incorporated into structures that are synthesized in increased amounts during the inflammatory response and into components of antioxidant defense, and also modulate immune function. Trace elements are present in several acute-phase proteins and enzymes associated with antioxidant defense. These proteins include metallothionein (Zn), ceruloplasmin (Cu), superoxide dismutases (Mn, Cu, Zn), and glutathione peroxidase (Se). Deficiencies in copper impair the ability to increase superoxide dismutase and ceruloplasmin activities in response to inflammatory stimuli. Deficiencies in zinc impair the ability to increase metallothionein synthesis; furthermore, zinc deficiency has potent suppressive effects on many aspects of the immune response including lymphocyte proliferation. Iron status may influence inflammation and immune function in a number of ways. Normally iron is tightly bound to transport proteins such as transferrin and ferritin. However, following tissue damage and infections, such as malaria which may destroy red blood cells, free iron may be released and exerts a proinflammatory effect by catalyzing free radical production. The latter effect may activate NF $\kappa$ B and up-regulate cytokine production. Indeed, iron dextran infusion has been shown to exacerbate inflammatory symptoms in rheumatoid arthritis, while desferrioximine, an iron chelator, suppresses TNF and IL-1 production by macrophages. Iron deficiency also decreases the ability of such cells to produce cytokines. Impairment of immunological defense is commonly found in iron-deficient animals and human populations including defects in T cell proliferation and in the ability of macrophages to engulf and kill bacteria. The latter defect may relate to the role of iron as part of the NADPH oxidase complex that is responsible for the respiratory burst and generation of hydroxyl radicals that kill bacteria. Myeloperoxidase, which generates hypochlorous acid for bacterial killing is a heme protein which is decreased in activity by iron deficiency.

Vitamins also exert a number of effects upon cytokine biology. These effects may relate to the roles which some of these nutrients play as antioxidants and growth factors. Rats deficient in vitamin E exhibit an enhanced inflammatory response to endotoxin; addition of the vitamin to the diet will suppress this effect. In healthy subjects and smokers, a daily dose of 600 IU of vitamin E for 4 weeks reduced the ability of white blood cells to produce TNF and IL-1. Cigarette smoking enhances cytokine production and raises acute-phase protein concentrations. The extent of the elevation is inversely related to vitamin E status. Strenuous exercise results in a small increase in plasma concentrations of IL-1 and IL-6; vitamin E supplementation can prevent this effect. Vitamin A also influences cytokine production, although the mechanism underlying the effect is unclear. Macrophages taken from Indian children who had received a supplement of 100,000 IU of retinol produced seven times the quantity of IL-1 produced by cells

from children who had not received supplementation. The effect may be more pharmacological than nutritional in nature. Mice given vitamin A, at a dose that was 16 times their requirement, had macrophages which produced twice as much IL-1 upon stimulation than cells from unsupplemented animals. Cells of the immune system express the vitamin D receptor and some cells involved in inflammation, including macrophages, can produce the active form of vitamin D (1,25-dihydroxyvitamin D<sub>3</sub>). 1,25-dihydroxyvitamin D<sub>3</sub> has been shown to have *anti*-inflammatory effects, for example promoting a shift of macrophages and T lymphocytes from a pro-inflammatory to an *anti*-inflammatory phenotype, with decreased production of pro-inflammatory cytokines and increased production of IL-10. Vitamin C, being an *anti*-oxidant, may also decrease pro-inflammatory cytokine production. In accordance with this, incubation of white blood cells from people with severe community-acquired pneumonia with vitamin C decreased oxidative stress and inflammatory cytokine production.

## Conclusions and perspectives

The objective of the response of the body to infection is to disadvantage and destroy invading organisms, but at the same time to protect healthy tissues from the damaging influence of agents produced during the response. Cytokines play a central role, being part of the host defense system and bringing about changes in host metabolism aimed at supporting the immune response. The inflammatory cytokines affect the immune response as well as metabolism in tissues including the liver, muscle, adipose tissue and brain. Some of the symptoms of infection including fever and anorexia are due to pro-inflammatory cytokines. Through their metabolic effects they can impair growth, which can become serious in children if the inflammation is prolonged or repeated too frequently. There is a close interrelationship between proinflammatory cytokines and pro-oxidant molecules, with inflammation inducing oxidative stress and oxidative stress inducing inflammation. Ultimately these processes need to be controlled, balanced and limited. The complex antioxidant system, supported through nutrition (e.g., trace elements, sulfur amino acids), and the potent pro-resolving mediator system, again supported through nutrition (n-3 PUFAs), are both central to the control and self limitation of inflammation.

The essence of survival of an individual or species lies in the ability to prioritize physiological processes, particularly those processes which exert a large metabolic demand. Thus, at various times throughout the life cycle, mammals will focus metabolic processes upon achieving growth, the construction of placenta and fetus, the synthesis of milk components, or the repulsion of invasion by pathogens. For the infected individual, the marshaling of resources to combat the invading pathogen must assume a priority over all other physiological events. These other physiological processes can resume once the invasion has been repulsed and the damage done by the invader repaired. Hence excessive prolongation of the inflammatory response is not desirable.

The production of cytokines and other molecules associated with the inflammatory process carries risks of damage to the host as well as a survival advantage. The risk to the host is minimized by a sophisticated range of feedback control systems and synthesis of substances which protect the host. As discussed above, nutrient intake modulates cytokine biology and the control and protective systems. A wide range of nutrients modulate cytokine biology at the level of production and sensitivity of target tissues. As a consequence of the modulation, the extent of depletion of nutrient stores and the risk of damage during the inflammatory response will be changed. The extent of tissue depletion and risk to the host will thus range from mild and transient in nature, to severe, chronic, or lethal in effect.

### Key points

- The expression of human appetite emerges from a complex bio-psychological system
- The omnivorous nature of humans makes food choice a key feature of appetite control
- Satiety (short term inhibition of eating and hunger) arises from the physiological and psychological effects of food consumption.
- The Drive to Eat (hunger) is under separate control from the choice of what to eat.
- The hedonic aspect of food choice is composed of the processes of liking and wanting for foods which together modulate the processes of satiety.
- There is huge individual variability (physiological and psychological) in the satiety response to different foods which allows the identification of satiety phenotypes (people who vary in the strength of the satiety response).
- The amount of physical activity (and energy expended) a person does, or the degree of sedentariness, can influence the strength of satiety and the amount of food consumed.
- The joint action of the drive to eat (arising from physiological energy requirements) together with satiety adjust the amount of food eaten, and therefore strongly impact energy balance, weight control and obesity.
- The modern technological environment, including issues of processing of foods, food security and sustainability, has a critical impact on the expression of appetite and the strength of satiety.

### Introductory paragraph

There has never been a more important period in which to examine appetite and satiety. The world is currently experiencing a pandemic of the respiratory virus COVID-19, adding to the more longstanding so-called pandemic of obesity. Both pandemics can be treated by modifying behavior and the environment in which it occurs (in addition to medical therapies). For obesity, it is relevant that humans are omnivores with the capability to eat a huge range of materials irrespective of their composition and nutritional value. Obesity is intimately linked to the diet available to people, and to the patterns of eating behavior associated with that diet. Given the negative health consequences of obesity, it is essential that this article addresses the implications of appetite and satiety for the control of body weight.

It is important to recognize that behavior and diet occupy separate domains in the psychobiology of human functioning, but they are inextricably linked. The behavior of eating is the agency through which nutrients enter the body and exert their effects on physiology and metabolism. This means that any factors that influence the behavior of eating have the potential to influence the impact of diet on health. As [Rozin et al. \(1998\)](#) has pointed out “Because behavior is so central to nutrition, the behavioral sciences play an especially important role in the understanding of what we eat and why we eat it. The study of what is in food is extremely important, but all of this knowledge amounts to little if we cannot understand how people eat what is good for

them and avoid what will do them harm". We need knowledge of what is in food and how it affects the body, but we also need an understanding of what makes people eat some foods and not others, and what makes them start and stop eating. This is the essence of the study of appetite.

Diets influence the amount and type of food consumed through behavior which is controlled in a large part by the processes of appetite and satiety. The importance of this is highlighted by the fact that behavior (eating) is the only route through which nutrients enter the body to determine growth and development, and to maintain health. These behavioral processes are not simple linear cause-effect associations; they are complex interactions between physiology and the environment. A starting point for our work will be the recognition of appetite as a representation of a complex system (see Fig. 1) in which the choice of which food to consume is influenced by multiple factors. This article will not attempt to review or summarize everything that has been published on this topic. Our job as authors is to provide a conceptual framework and a structure to allow an understanding of appetite and satiety and to explain principles in the control of food intake. In this role we concur with the expressed view that "the purpose of all explanation must be, ultimately, the illumination of the chaotic world with which we are actually surrounded" (Midgley, 1978).

### **Appetite and satiety (and satiation)**

Appetite is not the opposite of satiety; rather satiety is an important component of appetite control. Appetite refers to the sum of processes that influence food consumption. These include: the drive to eat, food selection, food hedonics, psychological traits, factors that influence the initiation of eating, its duration and termination, and the frequency of eating episodes. Appetite, therefore, forms a system rather than a single entity. Satiety is one important component of the appetite system and can be defined as the inhibition of hunger and eating following a meal. Whereas satiation is the term that refers to the termination of a meal and determines meal size. The post-prandial (after-meal) period is characterized by a sequence of physiological events in the gastro-intestinal tract including gastric distention and the progressive release of enzymes and hormones that control the digestion of nutrients and their management during absorption and eventual assimilation into the body. These physiological events reflect the nature of the foods in the diet consumed, and they are often referred to as satiety signals since they accompany the state of satiety. There is no agreement on whether these signals are biomarkers of satiety or are the actual causes of satiety. However, it can be concluded that there is no single unique satiety signal. The inhibition of eating that is the essence of satiety is therefore associated with a complex pattern of gastrointestinal physiological activity.

Because satiety is an inhibitory process it has a key role in controlling the level of hunger and the amount of food consumed; and therefore, has the capacity to prevent (or to permit) overconsumption that potentially influences body weight. For this reason, weak satiety is regarded as a major factor that can lead to the development of obesity. Conversely, specific (functional) foods or drugs that intensify satiety can inhibit eating and potentially lead to weight loss.

### **Appetite as a complex system**

As noted above, appetite refers to the sum of processes that influence food consumption. Since humans are omnivores there is a huge variety of human eating patterns on the planet, which draws attention to the degree of complexity that arises from this heterogeneity. This complexity was originally recognized in a conceptual model that viewed obesity as a complex problem arising from many interlinked proximal and causal factors. Instead of obesity being regarded as the outcome of a single dominant causal agency (or several such single agencies) acting in a linear fashion, obesity was conceived as the outcome of multiple interrelated factors in continuous interactions (see Fig. 1). These factors could be organized into groups that were each composed of multiple elements including factors that described the psychological world of people, the food environment at the level of the consumer that could be traced to food manufacturing and procurement, the physical environment, the biological system, and the social and cultural milieu.

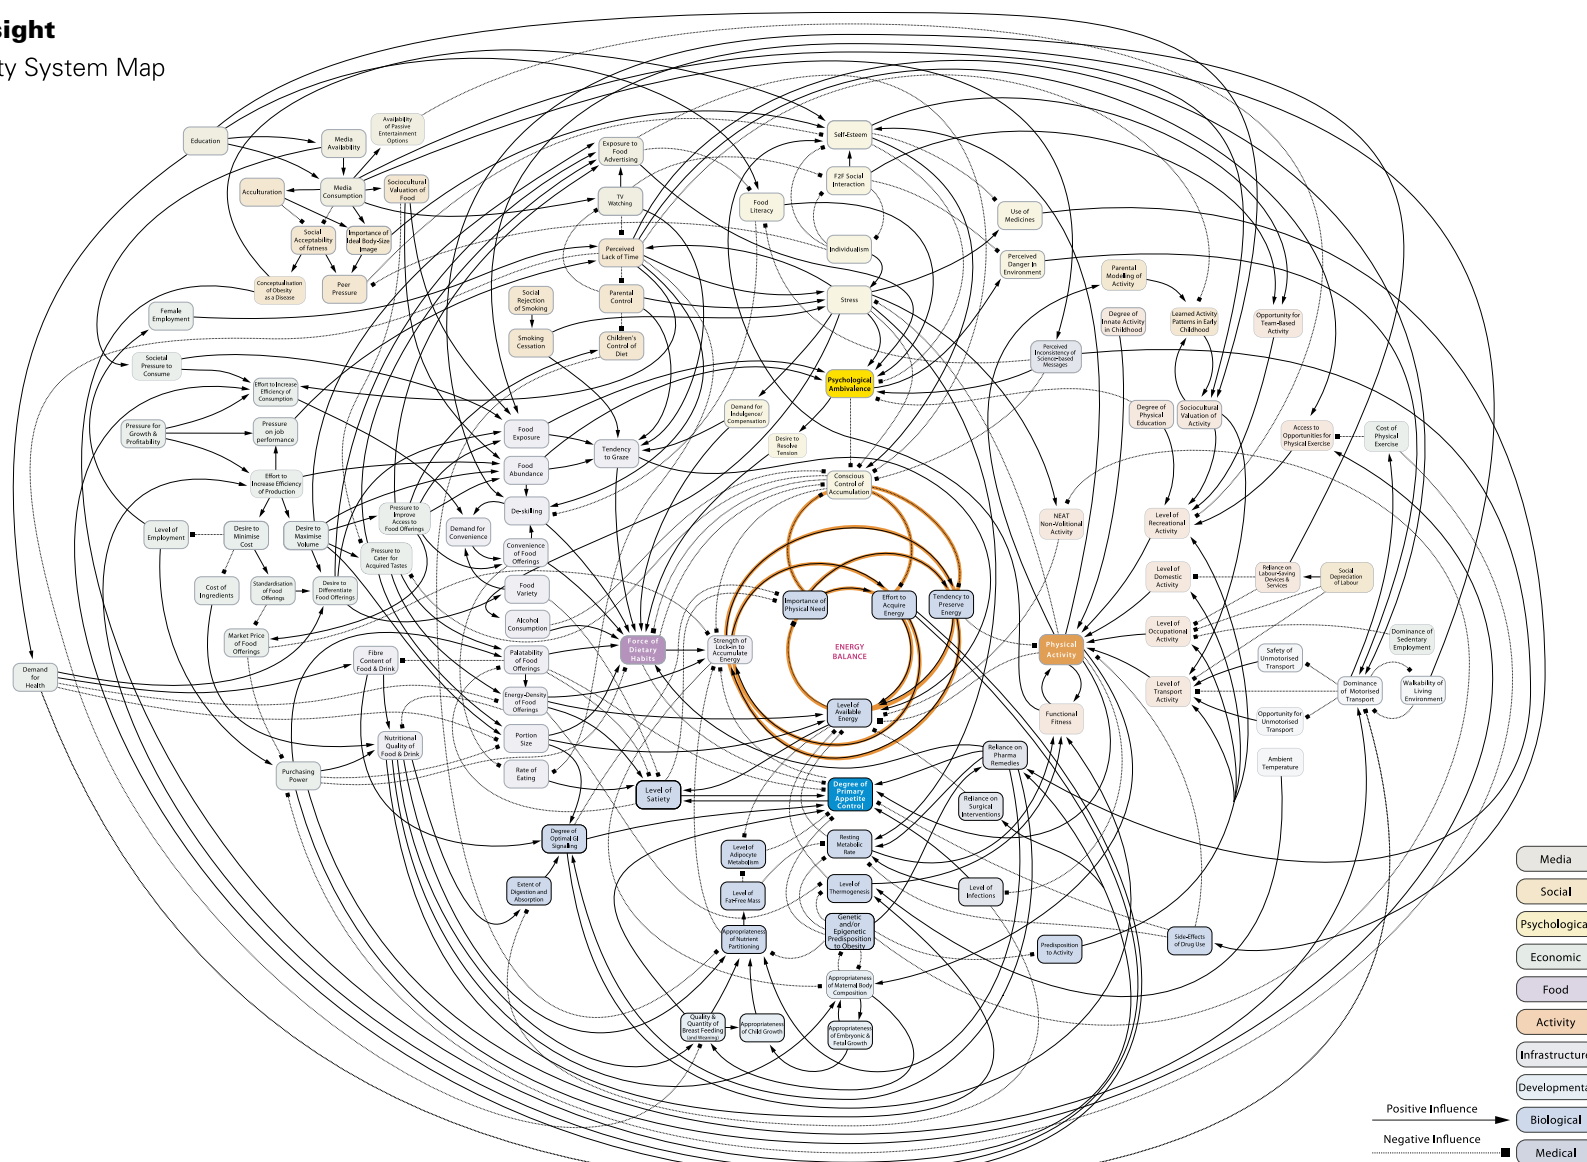

While this conceptual map was developed for understanding the factors that contribute to obesity, it equally describes the multiple factors that influence human appetite. The map is composed of more than 300 variables and over 100 feedback loops across 7 domains (see Fig. 1). At the center of the map is the core or engine upon which the surrounding interplay of variables has been focused. The core ultimately brings about adjustments in patterns of behavior and consequent changes in body composition, in particular fat mass, which in turn are crucial for appetite control. Moreover, the map makes clear that every domain contains elements that directly or indirectly influence eating behavior. It is therefore appropriate that this concept can be extended from the "Obesity Systems Map" to an "Appetite Systems Map" (Fig. 1).

### **The diet – behavior relationship: humans are omnivores**

The fact that humans are omnivores is of huge significance for both behavior and nutrition. Humans are not restricted in their food habits to the same extent as herbivores or carnivores, and consequently they can consume a wide range of nutritional materials. Of course, this ability has been of enormous evolutionary significance and has enabled humans to colonize a wide variety of environments and habitats. Just as different groups of humans can exist on widely divergent types of foods in different parts of the world,

## Foresight

### Obesity System Map

**Fig. 1** The Obesity Systems Map identifies many interlinked proximal and causal factors associated with the development of obesity. The map is composed of more than 300 variables and over 100 feedback loops across seven domains. In addition to understanding the factors that contribute to the development of obesity, the map can also be used to better understand the systems underlying appetite control and therefore may equally be termed the “Appetite Systems Map”.

the patterns of behavior that bring these nutrients into the mouth can also differ widely. It can be appreciated that developing a science that encompasses such complexity is a daunting proposition. A science has therefore developed around a more restricted range of environments and behavioral types focusing on the nutrition and behavioral types relevant to technologically industrialized societies in which we live, and to the preoccupations of people living in these societies. Over the last 50 years the issue of obesity has provided a dominant framework for understanding the intimate link between behavior (appetite control) and diet. This is relevant when considering that behavior can be seen as the agency that mediates in meeting two nutritional demands; namely what to eat, and how much to eat. Both are important for health, and it means that appetite control is a central feature of the relationship between behavior and diet.

### **The drive to eat and food selection**

The distinction between how much to eat and what to eat reflects the difference between two aspects of appetite control: the drive to eat and food selection. The problem of what to eat arises because of a combination of our omnivorous nature and the abundance of foods in the environment. This is the issue of food choice and involves the conscious or automatic selection among potential edible materials. Interestingly this food choice is not strongly programmed biologically but is dependent upon factors such as geography, climate, religion, ethnicity, and culture. The issue of how much to eat has always been conceptualized in regard to homeostatic principles of energy requirements of the body, with a stronger link to biology.

Traditionally the control of appetite has been linked to the regulation of body fat in the so-called “adipocentric” hypothesis in which the maintenance of fat stores has been regarded as a major influence on food intake. However, in the last decade much evidence has accumulated to show that the drive to eat is strongly associated with the lean mass (fat-free mass) of the body and with the metabolic activity of the lean mass. Specifically, the energy requirements generated by high metabolic rate organs such as the heart, liver, brain, and kidneys (as well as skeletal muscle) create an energy demand that drives food consumption (Hopkins and Blundell, 2017). The relationship between the resting metabolic rate and energy intake has been demonstrated in new-born babies, adolescents, adults with and without obesity, and in groups of older people. These observations give rise to the idea that energy expenditure drives energy intake, and reflects fundamental ideas proposed by human nutritionists more than 70 years ago which remained largely ignored for half a century. This concept is of evolutionary significance since it means that food intake is driven by the need to maintain vital organs in the body responsible for growth and survival. The biological basis of this drive to eat generates what can be termed “homeostatic hunger”. Alongside this drive to eat related to lean body tissue, fat tissue has an inhibitory function on the drive to eat mediated by pathways in the brain involving leptin. However, these biological processes determining the strength of the drive to eat are completely unrelated to processes responsible for food selection. In turn, food selection reflects an intimate relationship between the diet and behavior and has a major influence on the processes of satiety and satiation.

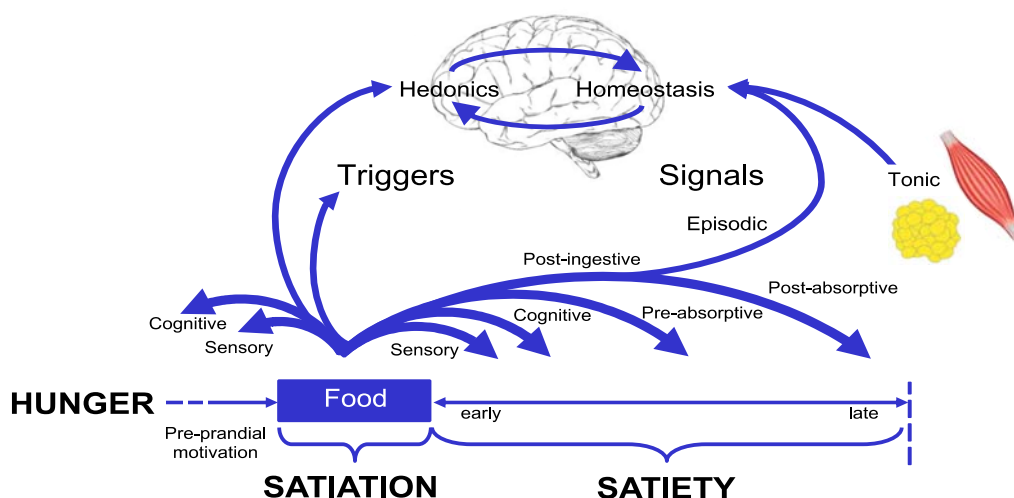

### **Foods and the satiety cascade**

Across the planet the omnivorous habit ensures that humans eat thousands of different foods that comprise an array of distinct dietary patterns. In turn, the foods selected influence the degree of satiation and satiety experienced. The processes responsible can be described in the concept of the “Satiety Cascade”. Fig. 2 depicts a model of the satiety cascade, which provides a framework to understand the mechanisms involved in the short-term control of eating behavior. The satiety cascade demonstrates the distinction between satiation and satiety, and shows how episodic signals arising from sensory, cognitive, post-ingestive, and post-absorptive processes influence the size and frequency of meals. The processes of satiation control meal size through their effect on the duration and termination of an eating episode. These processes, along with the nutritional composition of food being consumed, determine the amount of energy consumed during an eating episode. Following the termination of an eating episode, the motivation to eat is suppressed for a measurable period by the physiological effects of the ingested foods, especially in the stomach, and the hormones released from the gastro-intestinal tract during digestion and absorption of foods (see Box 1 and 2).

The question of whether certain foods or diets possess nutritional properties that are beneficial to enhancing satiety and therefore promoting greater control of appetite has received considerable attention in recent years. While evidence suggests that it is possible to develop diets (and meals) that are beneficial to improving control over satiation and satiety, and by extension to support weight loss, it is a separate (and perhaps more concerning) issue whether people can be motivated to eat such a diet over a prolonged period. In an obesogenic environment, intentions to gain control of eating are often undermined by pervasive pressures to overconsume and the rewarding aspects of food (i.e., food hedonics). Therefore, in the absence of considerable changes to the food environment, it is unlikely that any single food or diet will be able to exert a prolonged effect on the processes depicted in the satiety cascade.

### **Hedonic processes of appetite control**

The hedonic system of appetite control accounts for eating behavior motivated by the appeal of food in the external environment and the sensory appreciation of food as it is consumed. In today’s obesogenic environment, food is a reliable source of pleasure and food hedonics have an important role in the initiation, maintenance, and termination of an eating episode. It is well established that food hedonics is more than simply liking the taste of food or experiencing pleasure from it. Research on non-human animals has

**Fig. 2** The satiety cascade depicts how the size of a meal and the interval between meals is influenced by the processes of satiation and satiety. The cascade also demonstrates the interaction between the homeostatic and hedonic influences on the processes of satiation and satiety. Adapted from [Blundell and Finlayson \(2008\)](#).

### Box 1 Which features of food cause satiety?

Following eating the feeling of fullness (satiety) is generated by several characteristics of the foods consumed including the volume, weight, sensory characteristics (taste, texture, mouthfeel), pleasantness, visual aspects, nutritional composition, non-nutritional components (e.g., fiber) and packaging/labeling.

Consequently, satiety is brought about by the integrated effects of multiple components of the food eaten. Much research has attempted to identify those specific features of foods that have the most potent impact on satiety. These features are of importance to the food industry in developing foods to control hunger and intensify the sensation of fullness. There are indications that a high protein and fiber content can enhance satiety. However, energy density is a major factor, with low energy dense diets generating stronger sensations of satiety. Currently, much interest is focused upon the effects on satiety of highly processed or ultra-processed foods with a suggestion that such foods may weaken appetite control rather than promote satiety.

### Box 2 A note on physiological satiety signals

Since the first investigations of satiety, it has been believed that the effects of food composition are mediated by post-prandial physiological responses. These involve changes in gastric distention, laxation, and emptying together with the release of gastro-intestinal peptides including cholecystokinin (CCK), glucagon-like peptide (GLP-1), peptide YY (PYY), insulin, and others. For many years, CCK was regarded as the unique single satiety signal. It should be noted that all these peptides have other important roles in the management of food within the body through the processes of digestion and absorption, such as the slowing of gastric emptying and the release of bile for the emulsification of fat. Therefore, an effect on satiety may be secondary to these other functions. It remains a point of debate whether gut peptides are biomarkers or the true causes of satiety. Since different foods may have similar effects on satiety but generate quite distinct physiological profiles, it appears that there is no unique pattern underlying satiety. The same degree of satiety may be associated with different post-prandial physiological changes. There is considerable interest in the post-prandial physiological effects of highly- and ultra-processed foods.

demonstrated that the brain structures underpinning food hedonics comprise dissociable affective and motivational subcomponents, termed “liking” and “wanting”, respectively. The “liking” component of food hedonics, refers to the subjective experience of pleasure derived from the sensory perception of food and is associated with the release of endogenous opioids acting on clusters of neurons termed “hedonic hotspots” within the brain. The “wanting” component refers to the motivational value of the food and is associated with the release of dopamine in the brain’s mesolimbic pathway. In studies of human appetite behavior, liking and wanting for food are often viewed as explicit subjective states that refer to the everyday understanding of these terms. Specifically, liking is understood as an appreciation of the sensory characteristics of food that create its hedonic impact while wanting may describe a subjective state of desire or craving. People tend to be good at estimating and reporting their liking for food, however, they are often unable to accurately gauge their implicit wanting for food (i.e., why they are drawn to or are craving one food over another) (see [Box 3](#)).

**Box 3 Measuring food hedonics in human appetite research**

Central to the understanding of food hedonics is the distinction between Liking and Wanting. The approach to measuring liking and wanting in human behavioral studies has incorporated explicit reports of subjective experience to measure liking alongside more implicit assessment of wanting. Liking responses to food can be explicitly reported using VAS ratings by asking individuals to report “how pleasant would it be to taste some of this food right now?” in response to images of food or asking individuals to report how pleasant a food tastes in response to consumed food. Techniques to assess implicit wanting include those that assess people’s willingness to expend effort to obtain a target food over an alternative and those that assess people’s choice between food cues with a time-critical approach related response, where the speed of the response is interpreted as a measure of motivational value (Finlayson et al., 2007).

Palatable food can disrupt appetite control by counteracting the inhibitory effects of short-term satiety signals to increase food intake. Specifically, palatable food appears able to stimulate an orexigenic drive that can override homeostatic signals of satiety and lead to overconsumption. After food is ingested, its sensory qualities are registered by cognitive and sensory processes before it is swallowed. When a highly palatable food is consumed, the reward pathways within the brain are activated leading to the release of the neurotransmitters, dopamine, and endogenous opioids. The reward pathways have connections with the hypothalamus, which stimulate the release of hunger peptides such as NPY and orexins and inhibit the release of satiety peptides such as insulin, leptin, and cholecystokinin. Therefore, when food is highly palatable, an impulse to eat is generated, mediated by hedonic stimulation rather than biological need. This drive can be termed “hedonic hunger”. For this reason, it has been suggested that hedonic processes may exert a more powerful influence over food consumption than homeostatic mechanisms. However, the homeostatic and hedonic systems of appetite control can be considered, to an extent, inseparable as the neural connections between them permit interactions that influences the overall organization of eating behavior.

**Food hedonics influence satiation and satiety**

The effect of liking and wanting on delaying satiation and therefore increasing the amount consumed has been well established over the last four decades. One mechanism by which liking and wanting delay satiation is through an increase in hunger at the start of, and during the early stages of a meal when the processes of liking and wanting are most likely to overlap with the biological drive for energy. This increase in hunger corresponds with a faster rate of eating and increased energy intake. These findings have been well established in the appetite laboratory-based literature and taken together suggest that liking and wanting for food can counteract the inhibitory effect of short-term satiety signals.

Outside of the laboratory conditions, the influence of liking on satiation may be less important when compared to other factors. For example, de Castro (2001) examined factors that influenced meal size and food choice in a sample of participants who recorded their food intake in their natural environments over 7-days. They found that liking for food, or its palatability, explained only 4% of the variance in total food intake after other environmental, psychological, and social factors were taken into consideration. This finding does not minimize the importance of palatability as a driver of energy intake, but highlights that outside of the laboratory, where individuals are free to choose what they eat from a wide range of palatable options, it is highly likely that they will choose to eat something that they like. Therefore, under free-living conditions, liking for food may be less important than food wanting, as food wanting is more vulnerable to being triggered by environmental cues such as availability, advertising, and marketing strategies.

Evidence suggests that greater wanting and increased food craving undermine appetite control by weakening the processes of satiety and promote overeating and weight gain through increased meal frequency, episodes of opportunistic eating (i.e., snacking, grazing behaviors), and may feature in certain forms of disordered eating. Conversely, research examining predictors of weight loss in people following a 1-year weight management program, found that increased improvements in craving control at week 8 was predictive of greater weight loss success over 1-year (Dalton et al., 2017). This suggests that interventions that target food wanting and experience of craving to enhance feelings of control over food may be beneficial for long-term weight management. This has implications in countries where environmental cues to eat are plentiful in the form of pervasive advertising, ultimately undermining attempts to improve appetite control and reduce body weight. This suggests there is a need to move toward more environmental-based interventions for weight management, rather than interventions that focus on the personal responsibility of the individual to make “good” or “small” choices.

**Individual variability in appetite control and satiety responsiveness**

The Obesity Systems Map (Fig. 1) identifies several factors that influence the expression of human appetite, which may render an individual vulnerable to passive overconsumption and weight gain. The diversity in susceptibility to weight gain and obesity can be characterized in terms of a person’s genetics, central or peripheral physiology, psychology and behavioral profile and their physical activity and food environment. More than five decades of research has identified numerous features of the westernized environment and associated diet that interact with factors to increase vulnerability to overconsumption and subsequent weight gain. However,

**Box 4 A note on measuring hunger**

Hunger is a distinct conscious feeling that reflects the drive to eat. It is a subjective sensation that can be converted into a measurable quantitative variable by the use of the Visual Analogue Scale (VAS). The line is anchored at each end by a statement about the strength of hunger. A person marks the line at a point corresponding to the strength of their sensation. This instrument can be used to measure hunger before, during and after a meal to track the course of satiety.

The scale has been validated to show that the ratings correlate well with the amount of food eaten. Three other scales are usually used to provide a more complete representation of appetite sensations: fullness, desire to eat and prospective consumption (how much food do you think you can eat?). Over the course of a whole day, tracking hunger reflects the pattern of eating and the type of food consumed and can clearly identify differences between high and low energy dense diets. See [Fig. 3](#).

not everyone in a westernized environment lives with overweight and obesity, and we can observe individuals habitually consuming quite distinctive diets and maintaining a body weight within the “normal” range and similarly consuming similar diets but displaying wide variations in body weight. Therefore, not everyone is vulnerable to weight gain, and excluding monogenic forms of obesity, it is unlikely that one single factor can account for why some are more vulnerable than others, which has implications for appetite control and the prevention and treatment of obesity.

One approach to characterize individual susceptibility is through the identification and characterization of phenotypes. Of relevance to the current article, is understanding how differences in recognizing and responding to signals of satiety may underlie susceptibility to overconsumption and weight gain. In controlled laboratory settings, appetite sensations have been shown to be a valid and reliable method for measuring the subjective motivation to eat (see [Box 4](#)). However, not everyone reports a good relationship between their sensations of appetite (i.e., hunger and fullness) and their eating behavior, and a weakened satiety response to food may contribute to impaired appetite control. Individuals exhibiting a weakened satiety response may be referred to as the “low satiety phenotype” ([Drapeau et al., 2013](#)). The low satiety phenotype has largely been observed in people with obesity, but evidence suggests that individuals with a healthy weight may also exhibit a weakened satiety response to food therefore making them vulnerable to future weight gain. Research examining the low satiety phenotype has demonstrated that it is characterized by increased disinhibition and hunger scores, lower levels of craving control, greater food wanting and increased energy intake under laboratory conditions ([Drapeau et al., 2013](#)). With regards to weight management, research has found that people low in satiety responsiveness lose less weight, have smaller reductions in central adiposity, report lower craving control and more difficulty in adhering to the dietary program compared to those high in satiety responsiveness.

## Applications of satiety to societal challenges

With increasing rates of overweight and obesity, including those seen during the COVID-19 lockdowns, a high proportion of individuals report engaging in weight management attempts that involve dietary restrictions. Indeed, the US weight management industry is worth an estimated \$72.7 billion per year. However, sustained body weight reductions are challenging, and most individuals regain weight lost within relatively short periods of time.

Hunger is one of the main challenges reported for sustained engagement in weight management attempts ([Stubbs et al., 2012](#)). As such, targeting satiety is one approach to support appetite control in individuals engaging in weight management attempts. Foods that promote satiety have generated large amounts of interest among academics and industry and have received high consumer demand. While technological modifications to food properties associated with satiety are currently under development ([Hetherington et al., 2013](#)), diets rich in low energy dense foods can improve appetite control and support weight management attempts. [Fig. 3](#) shows the profile of subjective appetite sensations reported in a sample of women engaged in a weight management program who, over two separate days and under laboratory conditions, consumed either a low ( $\leq 0.8$  kcal/g) or high ( $\geq 2.5$  kcal/g) energy dense diet over 24 h ([Buckland et al., 2018](#)). Hunger, desire to eat and prospective consumption were significantly lower, and fullness significantly higher following a low energy dense breakfast and lunch compared to high energy dense meals, and these differences in appetite sensations between energy density conditions were sustained throughout post-meal intervals in the morning and afternoon. These appetite sensations corresponded with an average total day energy reduction of 1057 kcal on the low versus the high energy dense day. Furthermore, within this study the participants who were engaged in a weight management program that advocated ad libitum intake of low energy dense foods, lost significantly greater amounts of weight compared to participants engaged in a calorie-restrictive weight management program. While the energy density manipulations in this study were relatively large, they illustrate the powerful role that energy density has on appetite control, and the potential implications for weight management. Other experimental studies with smaller energy density manipulations and observational studies, have also shown energy density to be beneficial for appetite control and weight management, including under free-living natural settings.

Traditionally, weight management programs deliver one program for all. However, given the role of individual differences in appetite control, personally tailored weight management programs may be more effective. Recent big data approaches have integrated genetic, metabolic, physiological and psychological information to develop evidence-based algorithms to inform personalized dietary approaches. Additionally, pilot work has developed a personalized intervention that assesses appetitive traits (e.g. low

**Fig. 3** Hunger profiles reported at pre- and post-meals, and at inter-meal intervals in a sample of women who consumed either a day of low- (LED) or high-energy dense meals (HED) under laboratory conditions. Hunger ratings were significantly higher after a HED breakfast compared to a LED breakfast, and this difference remained throughout the day until post-evening meal (dinner). Similar results were reported for other subjective sensations of appetite (desire to eat, prospective consumption and fullness). Values with +1, +2 and +3 refer to the number of hours after a meal was consumed. “LFPQ” refers to a behavioral task that was completed during the lunch session. Image sourced from [Buckland et al. \(2018\)](#).

satiety responsiveness) and delivers trait-specific support to improve appetite control. Such personalized approaches to weight management are in early phases, and more high-quality trials are needed to confirm their effectiveness. However, provided sufficient resources are available and these strategies are cost-effective, personalized approaches offer a promising avenue that recognizes the role of individual differences in appetite control. Importantly the challenge of dealing with overconsumption is equaled by the challenge of managing the widespread sedentariness and low physical activity that characterizes many modern societies. This is doubly relevant since the interaction between energy expenditure and energy intake means that the degree of physical activity has implications for appetite control (see [Box 5](#)).

In addition to weight management, a further societal challenge relevant to appetite control and diet, which will be briefly covered here, is climate change. Given the high protein content of meat, it is highly satiating and is often incorporated into dietary weight management programs. Yet, meat is resource intensive, and animal livestock contribute 14.5% of human-made greenhouse gas emissions (GHGE). Estimates show that a 50% reduction in meat intake would result in a 25%–40% reduction in GHGE linked with food production. As such, current meat-rich diets need to change. Promisingly, there has been increasing numbers of individuals reporting a reduction in meat and a shift to a favourably viewed flexitarian diet. However, the challenge now is to achieve widespread reductions in meat intake. For a national shift toward reduced meat diets, meat-free alternatives (e.g., pulses, plant-based, and cultured meat) need to be palatable and satiating. While research is growing on this topic, it remains limited. Some studies have reported that compared to meat-based proteins, meat-free alternatives result in similar or favourable appetite sensations, energy intake, appetite hormones and weight loss. However, most studies are limited to acute designs in the laboratory. Therefore, more research, and a systematic review of the available studies is currently needed. Importantly, methods from appetite research can play a key role in ensuring research on sustainable diets is conducted rigorously to allow research findings to inform societal applications for environmentally sustainable diets.

### The impact of ultra-processed foods on satiety

As discussed, low-energy dense foods can improve appetite control and reduce energy intake. A key aspect of low-energy dense foods is that they tend to be minimally processed. The NOVA food classification system comprises four categories that differ according to their level of processing ranging from foods that are unprocessed or minimally processed (group 1) to foods that are defined as being ultra-processed (group 4). Ultra-processed foods (UPFs) often contain high amounts of sugar, sodium, and unhealthy types

#### Box 5 A note on physical activity and appetite: Sedentariness and Satiety

A body of research now shows that there is an intimate interaction between energy expenditure and energy intake. This means that the control of appetite and the amount of food consumed is related to the degree of physical activity performed (and the energy expended). Appetite is better regulated when activity level is high. In contrast satiety is weakened when people are in a sedentary state; this allows overconsumption to occur. Many studies have shown that people in advanced technological cultures spend 60–70% of the working day in a sedentary state (low energy expenditure and often in a sitting posture), and that this is correlated with the degree of adiposity (amount of body fat). Therefore, a sedentary lifestyle is a risk factor for weak satiety and overconsumption leading to an increase in body fat.

of fat and they are often hyperpalatable. The level of processing food undergoes has been associated with differences in glycaemic index and satiating capacity. Specifically, the more processed a food is, the higher the glycaemic response and the lower its satiety potential. Further to this, greater consumption of UPFs has been associated with differences in energy intake and weight gain. A two-week, crossover randomized control trial compared the effect of consuming a diet primarily comprising of UPFs compared to a diet that contained no processed foods. Findings showed that increased consumption of UPFs was associated with greater caloric intake and weight gain of just under 2 lbs in two weeks, while the no processed foods diet was associated with weight loss of a similar amount. Interestingly, participants in this trial did not rate the UPF diet as more palatable compared to the unprocessed diet and neither diet produced differences in subjective sensations of appetite. The UPF diet was associated with greater eating rate (17 kcal/min compared to 7.4 kcal/min). Within the food industry there has been a shift toward the reformulation of food products in response to evidence that UPFs are fueling the obesity pandemic. Reformulation of products has acted to reduce the amount of fat or sugar within a product, however the removed ingredient is often replaced with more sugar or artificial sweeteners, respectively, making the reformulated products no healthier, but often more expensive, than the original. This reformulation approach has been described as “damage limitation” to avoid more evidence-based approaches that include restrictions on food advertising, availability and pricing policies.

It is apparent that the consumption of minimally processed or unprocessed foods can improve appetite control and support weight management attempts by reducing the energy density of the diet and increasing feelings of satiety. Taken together these findings suggest that restricting the consumption, advertisement, and reliance on UPFs and promoting healthy, less processed meals and foods may be a more effective treatment and prevention strategy for obesity. To this end, in 2019, a Framework Convention on Food Systems was proposed and recommended by the Lancet Commission to tackle “Big Food, Big Soda, and Big Alcohol” and the obesity pandemic using lessons learned from tobacco control and reduction of smoking behavior. Understanding the effect that processed foods have on satiety, energy intake and markers of health is an important focus for future human appetite research. Evidence to date is primarily based on correlational research and while the NOVA classification system is commonly used there is no agreed upon definition for what constitutes a high- or ultra-processed food (Gibney and Forde, 2022).

## Conclusion

This article has been written in 2022 at a particular moment relevant to diet and eating behavior. The pandemic of obesity which has existed for over 20 years shows no sign of abating. The world is beginning to emerge from a pandemic of COVID-19, which has been associated with general increases in unhealthy food habits and in the level of obesity. The food supply in many parts of the world is characterized by heavily processed foods or ultra-processed foods which compromise healthy eating. Food companies seek further ways in which the palatability of foods can be enhanced. Wars in various parts of the planet threaten the world’s food supply and will cause food shortages. There is a strong movement toward the development of sustainable diets and the promotion of food resilience. While there is much interest in personalized nutrition, for some people food is unpredictable and precarious. All of these situations have implications for the control of human appetite; simultaneously appetite control has implications for the way in which people can deal with these situations. In this article we have tried to show how a description of the processes responsible for appetite and satiety can help our understanding of the relationship between diet and behavior under challenging environmental conditions, and how this understanding can be applied to change the environment to support healthy and sustainable food choices.

### Key points

- Inflammation is a normal part of host defense against pathogens and is involved in removal of cellular debris and wound repair
- Inflammation involves a number of different cell types, cellular interactions and chemical mediators
- Cells involved in inflammation include neutrophils, monocytes, macrophages, eosinophils and mast cells but on-going inflammation can involve T and B lymphocytes
- Chemical mediators of inflammation include lipids (e.g., prostaglandins, leukotrienes), proteins (e.g., cytokines, chemokines), reactive oxygen species (e.g., superoxide) and amino acid derivatives (e.g., histamine)
- Oxidative stress is part of the inflammatory response
- The acute phase protein C-reactive protein (CRP) is often used as a biomarker of inflammation
- Inflammation is normally self-resolving and resolution of inflammation is an active process
- Failure to resolve inflammation can result in damage to host cells and tissues and can lead to disease
- Diet and dietary components can modulate inflammation
- Healthy dietary patterns and foods including whole grains, nuts and seeds, fruits and vegetables and fish reduce inflammation
- Omega-3 polyunsaturated fatty acids, antioxidant vitamins and many polyphenols reduce inflammation
- The gut microbiota is linked to inflammation and foods or supplements that promote a healthy diverse gut microbiota reduce inflammation
- There is an increase in inflammation after eating a meal (post-prandial inflammation) that is exaggerated by glucose or saturated fatty acids in the meal

### Introduction

Inflammation is a normal defense mechanism that protects the host from infection and other insults. Inflammation initiates the killing of pathogens and is involved in removal of cellular debris as well as tissue repair processes, helping to restore homeostasis at infected or damaged sites. The classic signs of inflammation are redness, swelling, heat, pain, and loss of function. Inflammation involves interactions among many different cell types, movement of cells between body compartments and the production of, and

responses to, many different chemical mediators (Calder et al., 2009). When an inflammatory response does occur, it is normally well regulated and does not cause excessive damage to the host; it is also self-limiting and resolves rapidly. Controlled properly, regulated inflammatory responses are essential to remaining healthy and maintaining homeostasis. Loss of tolerance to normally benign exposures (e.g., food, harmless microbes) or an impairment in regulatory processes (e.g., resolution) can lead to pathologic inflammation (Calder et al., 2009). If this becomes excessive, irreparable damage to host tissues and disease can occur. Typically, diseases or conditions with a well-recognized inflammatory component are treated with general or specific anti-inflammatory pharmaceuticals. Because dietary components may influence various parts of the inflammatory response, diet may play a role in predisposing to inflammatory conditions and altered diet or intake of specific dietary components may be useful in the prevention or therapy of such conditions. This article describes inflammation and the inflammatory response, including resolution, and describes evidence that dietary patterns, specific foods and food components can influence inflammatory processes, and indicates the likely mechanisms of action of these food components.

## The inflammatory response

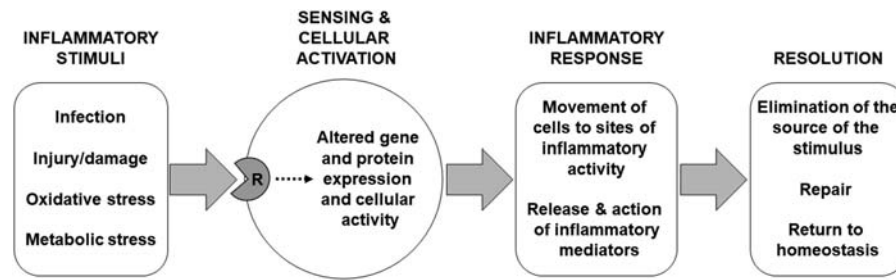

Inflammation is largely orchestrated by leukocytes (neutrophils, monocytes/macrophages, eosinophils, and mast cells) designed to eliminate pathogens and to heal tissue injury using multiple chemical mediators (chemokines, cytokines, adhesion molecules, lipid mediators, growth factors, proteases). Inflammation may be classified as acute or chronic (Calder et al., 2013). Acute inflammation is the initial response of the body to a harmful stimulus and is achieved by the increased movement of plasma and leukocytes (especially granulocytes which include neutrophils, eosinophils and mast cells) from the blood into the injured tissues. A cascade of biochemical events propagates and matures the inflammatory response, involving the local vascular system, the immune system, and various cells within the injured tissue. Prolonged inflammation, known as chronic inflammation, leads to a progressive shift in the type of cells present at the site of inflammation (e.g., monocytes and macrophages become more involved) and is characterized by simultaneous destruction and healing of the tissue from the inflammatory process. Chronic inflammation can eventually involve T lymphocytes and B lymphocytes, the former shaping and sustaining the nature of the on-going inflammatory response and the latter producing antibodies specific to the particular response (Calder et al., 2009, 2013). The features of acute and chronic inflammation are compared in Table 1.

Common to both acute and chronic inflammation are an afferent phase, in which the presence of a “foreign material” is “sensed” by some types of cell and an efferent phase, in which an inflammatory response is generated to eliminate the perceived hostile intruder. The “sensing” of pathogens is carried out by pattern-recognition receptors (PRRs) on the leukocytes that recognize so-called microbe-associated molecular patterns (MAMPs). Toll-like receptors (TLRs) are an example of PRRs. The purpose of the inflammatory response to harmful microorganisms is obvious, and the response is beneficial and necessary to protect the integrity of the body, so long as it does not become unnecessarily destructive or long lasting. Inflammation caused by non-pathogenic agents, which might include damaged host tissues, can also be beneficial, but it may also have negative health effects, especially if it has a long duration. Irrespective of the cause of the inflammation, the response involves four major events: (1) an increase in blood supply to the site of inflammation; (2) increased capillary permeability caused by opening of junctions between endothelial cells, permitting plasma and larger molecules, not normally capable of traversing the endothelium, to do so, thus delivering soluble mediators to the site of inflammation; (3) leukocyte migration from the capillaries into the surrounding tissue and then to the site of inflammation; this process is promoted by release of chemoattractants from the site of inflammation and by the up-regulation of adhesion molecules on the endothelium.; (4) release of mediators from leukocytes at the site of inflammation - these may include lipid mediators (e.g., prostaglandins, leukotrienes), protein mediators (e.g., cytokines, chemokines), reactive oxygen species (e.g., superoxide), amino acid derivatives (e.g., histamine), and enzymes (e.g., matrix proteases), depending on the cell type, the nature of the inflammatory stimulus, the anatomic site, and the stage during the inflammatory response (Calder et al., 2009, 2013). Some of the inflammatory mediators may escape the inflammatory site into the circulation and from there exert

**Table 1** Features of acute and chronic inflammation.

	<i>Acute</i>	<i>Chronic</i>
Causative agent	Pathogens, injured tissues	Continued exposure to pathogens or loss of tolerance to harmless pathogens, other environmental agents, or self
Major cell types involved	Neutrophils and other granulocytes (eosinophiles, mast cells), mononuclear cells (monocytes, macrophages)	Mononuclear cells (monocytes, macrophages, T lymphocytes, B lymphocytes)
Primary mediators	Vasoactive amines (histamine), bioactive lipids (prostaglandins, leukotrienes), chemokines	Cytokines, chemokines, growth factors, reactive oxygen species, hydrolytic enzymes
Onset	Immediate	Delayed
Duration	Hours to days	May be months or years; may be intermittent depending upon exposures
Possible outcomes	Resolution, abscess formation, chronic inflammation	Tissue destruction, fibrosis, necrosis, disease

**Fig. 1** Overview of the inflammatory response. Inflammatory stimuli trigger an inflammatory response after they are “sensed” often by receptors. This initiates cell signaling processes leading to cellular activation, some immediate cell responses and altered gene and protein expression. Cells move to sites of inflammatory action and there is release of, and responses to, a plethora of inflammatory mediators. These aim to eliminate the source of initial trigger, and then during resolution to remove any cell debris and to repair any local tissue damage.

systemic effects. For example, the cytokine interleukin-6 (IL-6) induces hepatic synthesis of the acute phase protein C-reactive protein (CRP), and the cytokine tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) elicits metabolic effects within skeletal muscle, adipose tissue, and bone. Serum or plasma CRP concentration is often used as a biomarker of inflammation. Concentrations of CRP are greatly increased during infection or in people with an active chronic inflammatory disease and are easily measured by enzyme-linked immunosorbent assays. However, in uninfected healthy people, CRP concentrations are low and require measurement using highly sensitive assays; this is sometimes referred to as “highly sensitive CRP”, but it is important to note that this term simply refers to CRP measured using a highly sensitive assay. Using such assays, it has been identified that CRP concentrations (and other circulating markers of inflammation) are elevated with aging (Calder et al., 2017), in those living with obesity (Calder et al., 2011) and in those with cardiometabolic disease; furthermore elevated CRP concentrations are predictive of future cardiovascular disease (Libby and Ridker, 2004).

Fig. 1 provides an overview of the inflammatory response.

## Inflammation and disease

Unresolved inflammation can damage host tissues and is a recognized contributor to the pathology of many conditions (Calder et al., 2009, 2013). In some cases, such as critical illness, rheumatoid arthritis, inflammatory bowel diseases, asthma and psoriasis, the central contribution of inflammation to the pathology of the condition is well recognized. Individuals with these conditions have heavy infiltration of inflammatory cells at the site of disease activity (e.g., joints, intestinal mucosa, lungs, skin), and they have elevated concentrations of inflammatory mediators at those sites and in the systemic circulation. These conditions are treated with varying levels of success by anti-inflammatory drugs. In other cases, such as atherosclerosis and obesity, the role of inflammation has emerged more recently (Hansson, 2005; Tilg and Moschen, 2006), and its contribution to the pathologic features alongside the many other relevant factors is less clear. Individuals with these conditions also show infiltration of inflammatory cells at the site of disease activity (e.g., blood vessel wall, adipose tissue) and have moderately elevated levels of inflammatory mediators and CRP in the systemic circulation (Calder et al., 2009, 2011, 2013). Although inflammation-induced tissue damage occurs in an organ-specific manner (e.g., joints, gut, lungs, skin, blood vessel wall, adipose tissue) in different diseases or conditions, there is some commonality among the responses seen in the different organs (Calder et al., 2009, 2013). In general, the inflammatory response observed is normal, but it occurs in the wrong context; this relates to loss of barrier function (epithelial or endothelial), inappropriate triggering (i.e., a response to a normally benign stimulus equivalent to a loss of tolerance), lack of down-regulation (resolution) to control the response, and tissue destruction with a loss of function. In some cases, the inflammation is the result of exogenous triggers such as microbes or allergens. In other cases, it is the result of loss of tolerance to self, as seen in autoimmune conditions, while in other case it is secondary to tissue damage caused by endogenous molecules such as oxidized low-density lipoprotein. Most, if not all, chronic inflammatory diseases are characterized by overproduction of cytokines (e.g., TNF- $\alpha$ , IL-1 $\beta$ , IL-6), chemokines (e.g., IL-8, monocyte chemoattractant protein (MCP)-1), eicosanoids (prostaglandin E<sub>2</sub>, 4-series leukotrienes), and matrix metalloproteinases. Elevated levels of these mediators act to amplify the inflammatory process (e.g., by attracting further inflammatory cells to the site) and contribute to tissue damage and to the clinical symptoms observed. Many of these mediators are positively regulated through the transcription factor nuclear factor kappa-light-chain-enhancer of activated B cells (NF- $\kappa$ B) (Kumar et al., 2004) or through cytoplasmic protein complexes called inflammasomes (Blevins et al., 2022), and some are negatively regulated through peroxisome proliferator-activated receptors (PPARs) (Wang et al., 2016). Fig. 2 provides an overview of these processes. Entry of inflammatory cells to sites of inflammatory activity is facilitated by up-regulation of adhesion molecules on the endothelium, a process that is promoted by inflammatory cytokines and by a range of inflammatory triggers, frequently acting through NF- $\kappa$ B. The continuous process of tissue injury, healing, and repair, in response to the release of cytokines, chemokines, and growth factors by infiltrating inflammatory cells, as well as resident tissue cells, results in tissue remodeling.

**Fig. 2** A generalized overview of inflammatory signaling. A range of inflammatory stimuli are sensed, often by receptors such as pattern recognition receptors, and initiate cell signaling pathways. These pathways lead to activation of various transcription factors, including nuclear factor kappa-light-chain-enhancer of activated B cells (NF- $\kappa$ B) and activator protein 1 (AP-1), and inflammasomes. Inflammatory gene expression is upregulated and inflammatory proteins (including cytokines, chemokines, adhesion molecules, cyclooxygenase (COX), inducible nitric oxide synthase (iNOS) and matrix metalloproteinases (MMPs)) are produced. Oxidative stress can activate these same inflammatory pathways while the inflammatory response induces production of oxidants creating oxidative stress. AGEs, advanced glycosylated end products; SFAs, saturated fatty acids.

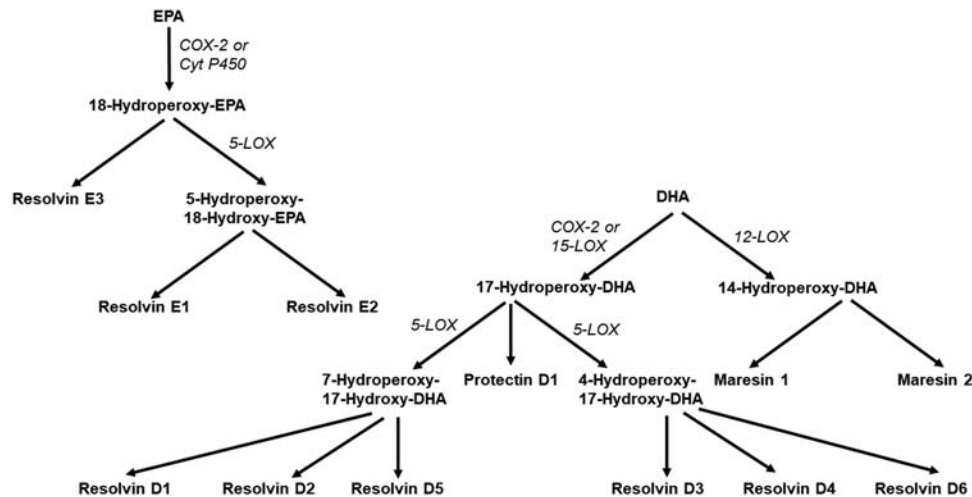

### The importance of resolution of inflammation

As indicated earlier, the inflammatory response can be damaging to host tissues and if this is not controlled pathology and disease can ensue. Therefore, timely resolution of heightened inflammatory responses is critical to prevent such collateral tissue damage. In fact, inflammation is usually self-limiting. It is normally resolved after its purpose is achieved; however, loss of resolution can lead to chronic inflammation, promoting pathogenic processes that lead to the development of major chronic diseases. The self-regulation of inflammation involves the activation of negative feedback mechanisms such as the secretion of anti-inflammatory cytokines (e.g., IL-10), inhibition of proinflammatory signaling cascades, shedding of receptors for inflammatory mediators, and activation of regulatory cells (Barnig et al., 2019; Panigrahy et al., 2021). One interesting aspect of resolution is generation of negative regulators of PRRs (Hedl and Abraham, 2013). These negative regulators include soluble decoy TLRs that interfere with ligand binding or receptor dimerization, and intracellular negative regulator molecules that interfere with recruitment of downstream signaling molecules, or stimulate degradation of signaling molecules. Many of these negative regulators are induced by ligands of PRRs suggesting that PRRs can activate both pro-inflammatory and anti-inflammatory/pro-resolving signals in negative feedback and temporal manners. Another endogenous pathway to promote resolution of inflammation involves the production of lipid mediators, mainly, though not exclusively, from omega-3 polyunsaturated fatty acids (PUFAs) (Chiang and Serhan, 2020). Eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA) and docosahexaenoic acid (DHA) give rise to mediators collectively termed specialized pro-resolving mediators (SPMs) that include resolvins, protectins and maresins (Fig. 3). SPMs seem to be among the most potent and most important pro-resolution molecules.

### Modulation of inflammation by diet and dietary components

#### General mechanisms by which dietary components could influence inflammation

There are a number of mechanisms by which dietary components might influence the inflammatory response. The most obvious would be where a dietary component acts as a direct trigger to inflammation. Perhaps the best example of this is in food allergy where the individual has lost tolerance to (i.e., become immunologically sensitized to) a food antigen; in this case the antigen is termed an allergen (Tedner et al., 2022). Common foods that can cause allergy are cows' milk, hens' egg, peanuts and shellfish. In the case of food allergy, the allergen is recognized by the immune system and there is a rapid and often strong inflammatory response manifested in the skin, the oral cavity, the gastrointestinal tract and, where the allergy has progressed to asthma, the lungs. This reaction may even be fatal with death from anaphylactic shock. Some aspects of the allergic response can be treated by anti-histamines while others require agents targeted at other mediators such as leukotrienes, while anaphylactic shock requires treatment with adrenaline. The most obvious way for a sensitized individual to prevent the occurrence of an allergic response is to avoid the food responsible, although some approaches to immunotherapy seem to be a success. Food avoidance can have adverse nutritional, social and psychological impacts. Another example of an inflammatory response to a food component is seen in celiac disease where the trigger is gluten (Iverson and Sollid, 2022). This is not, strictly speaking, an allergy because the immune-

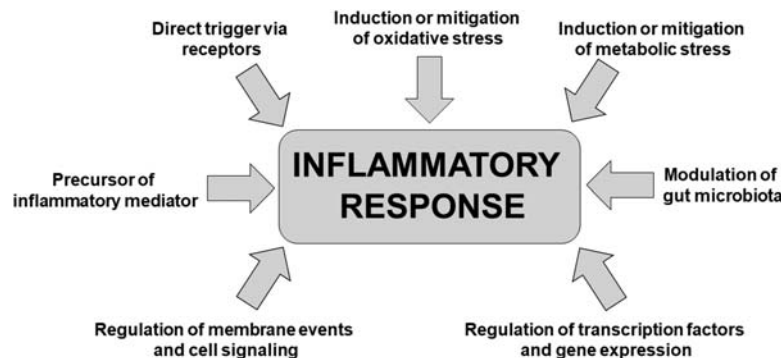

**Fig. 3** Outline of the pathways of biosynthesis of specialized pro-resolving mediators (resolvins, protectins and maresins) produced from the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). COX, cyclooxygenase; LOX, lipoxygenase.

inflammatory response to gluten is different from the response to an allergen. Clearly in food allergy and celiac disease a food component is acting as a direct trigger to the inflammatory response. There is emerging evidence that other food components can also act as inflammatory triggers; one example is some saturated fatty acids which have been demonstrated to bind to TLR-4, the PRR for bacterial lipopolysaccharide, so activating the NF- $\kappa$ B system resulting in an inflammatory response driven mainly by monocytes and macrophages (Hwang et al., 2016). The response that occurs is immunologically very different from the allergic response, and so this should not be regarded as a food allergy, and its intensity is relatively modest, although it may be clinically important over a prolonged period of time.

Advanced glycation end products (AGEs) can be formed in the body by oxidative reactions sometimes promoted by high availability of glucose and by oxidative stress. AGEs can also be derived from food, being formed during cooking and food processing procedures, especially the use of high temperatures. AGEs bind to cell surface receptors (RAGEs), which can facilitate their removal but can also lead to cellular activation, the latter triggering proinflammatory signaling pathways causing activation of transcription factors such as NF- $\kappa$ B and consequent upregulation of inflammatory processes (Twarda-Clapa et al., 2022). This could provide one link between oxidative stress, inflammatory processes and disease. Studies in both healthy subjects and people living with diabetes have reported a positive association between intake of AGEs from the diet and biomarkers of inflammation such as CRP.

Beyond acting as direct triggers to inflammation, food components may have a range of other effects that act to modulate the intensity of inflammatory triggers or the response to inflammatory triggers (Fig. 4). As already mentioned, oxidative stress can activate inflammation partly through the NF- $\kappa$ B system (conversely inflammation induces oxidative stress by promoting generation of reactive oxygen species). Thus, dietary components that favor oxidative stress (e.g., AGEs, oxidized lipids) could promote inflammation while dietary components that reduce oxidative stress (e.g., antioxidant vitamins, carotenoids, polyphenols) could reduce inflammation. Some dietary components can regulate inflammatory signaling by interfering with membrane or cytoplasmic processes that drive activation of NF- $\kappa$ B or the inflammasome. PUFAs are important in this regard. It is important to note that some chemical mediators of inflammation are formed from nutrients once those nutrients are assimilated into cells; well known examples are histamine which is produced from histidine and prostaglandins and leukotrienes which are produced from the omega-6 PUFA arachidonic acid.

**Fig. 4** Overview of the ways in which dietary components can influence inflammation.

## Dietary patterns and inflammation

Greater adherence to the traditional Mediterranean diet (rich in fruits, vegetables, whole grains, legumes, nuts, fish, and low-fat dairy products, with moderate consumption of wine, and with olive oil as the principal source of fat) is associated with lower blood concentrations of inflammatory markers (e.g., IL-6, CRP) in healthy people (Chrysoschoou et al., 2004; Fung et al., 2005). Intervention studies demonstrate that consuming a Mediterranean diet decreases inflammation in healthy subjects, in obese subjects, and in subjects with high cardiovascular risk (Esposito et al., 2004; Estruch et al., 2006; Dai et al., 2008; Schwingshackl and Hoffmann, 2014). Dietary patterns consistent with vegetarianism have been associated with lower concentrations of inflammatory markers in the bloodstream compared with nonvegetarian diets (Purschwitz et al., 2001; Szeto et al., 2004). The healthy eating index, alternate healthy eating index and diet quality score, which are all composite scores reflecting a healthy diet, have all been inversely associated with inflammatory biomarkers such as CRP and IL-6 in several studies (Ford et al., 2005; Fung et al., 2005; Fargnoli et al., 2008). Using data from the Nurses' Health Study, a dietary pattern that was significantly associated with higher concentrations of several inflammatory markers was identified; this pattern was high in sugar-sweetened soft drinks, refined grains, diet soft drinks, and processed meat but low in wine, coffee, cruciferous vegetables, and yellow vegetables (Schulze et al., 2005). In contrast to a prudent diet, which was associated with lower concentrations of several inflammatory markers, a Western diet pattern was associated with higher concentrations of these same markers (Lopez-Garcia et al., 2004a).

## Specific foods and inflammation

Observational studies have reported inverse associations between intake of whole grains, nuts and seeds, fruits and vegetables, fish, and tea and certain blood biomarkers of inflammation, often including CRP and IL-6 (see Calder et al., 2011 and 2017 for references). Regular consumption of small doses of dark chocolate decreased markers of inflammation in healthy subjects (di Giuseppe et al., 2008). Intervention studies with whole grain foods are inconsistent with regard to the effect on inflammation, although some do report a reduction (see Calder et al., 2011 and 2017 for references). Interventions with fruits and vegetables as a food group have been successful at reducing the blood concentrations of inflammatory markers (see Calder et al., 2011 and 2017 for references). However, studies focusing on a single variety of vegetable or fruit have been inconsistent. Soy protein appears not to affect circulating markers of inflammation. Intervention trials of drinking black tea, green tea, or coffee have not yielded a consistent picture regarding a possible anti-inflammatory effect (see Calder et al., 2011 for references).

## Fatty acids and inflammation

### Saturated fatty acids

Experimental studies consistently show that several saturated fatty acids, including lauric (12:0), myristic (14:0) and palmitic (16:0), can directly trigger inflammation via TLRs (Hwang et al., 2016). However, human observational studies investigating the link between saturated fatty acid intake and inflammatory markers have produced inconsistent findings. An intervention study involving feeding diets rich in stearic acid (18:0) or in lauric, myristic and palmitic acids to healthy men for 5 weeks showed higher concentrations of CRP, IL-6 and sE-selectin compared with feeding a diet enriched in oleic acid (18:1n-9) (Baer et al., 2004).

### Trans fatty acids

Experimental studies consistently shown that trans fatty acids, especially those of industrial origin, promote inflammation through a combination of effects on cell membranes, intracellular signaling pathways and NF- $\kappa$ B activation (Valenzuela et al., 2019). Data from the Nurses' Health Study indicated positive associations between the intake of trans fatty acids and the concentrations of all six inflammatory markers assessed, including CRP, IL-6 and three soluble adhesion molecules (Lopez-Garcia et al., 2005). In a 5 week intervention in healthy men, a trans fatty acid-enriched diet resulted in higher CRP, IL-6 and sE-selectin concentrations than diets rich in oleic acid, stearic acid or the combination of lauric, myristic and palmitic acids (Baer et al., 2004).

### Polyunsaturated fatty acids

The key link between fatty acids and inflammation is that eicosanoids, which act as mediators and regulators of inflammation, are generated from 20-carbon PUFAs of both the omega-6 and omega-3 families (Calder, 2020a; Christie and Harwood, 2020). Because inflammatory cells typically contain a high proportion of the omega-6 PUFA arachidonic acid (20:4n-6) and low proportions of other 20-carbon PUFAs, arachidonic acid is usually the major substrate for eicosanoid synthesis. Eicosanoids include prostaglandins, leukotrienes and other oxidized PUFA derivatives, and are generated by reactions catalyzed by cyclooxygenase (COX), lipoxygenase (LOX) and cytochrome P450 enzymes. At least two COX enzymes and several LOX and cytochrome P450 enzymes are expressed in different cell types, according to different conditions; between them, they produce a range of mediators involved in modulating the intensity and duration of inflammatory responses. These mediators have cell- and stimulus-specific sources and frequently have opposing effects. Thus, the overall physiologic (or pathophysiologic) outcome depends on the cells present, the

nature of the stimulus, the timing of eicosanoid generation, the concentrations of different eicosanoids generated, and the sensitivity of target cells and tissues to the eicosanoids generated. Many of the actions of arachidonic acid-derived eicosanoids are pro-inflammatory; those eicosanoids are central to the pathology of several inflammatory diseases including food allergy and asthma and several anti-inflammatory drugs target the synthesis or action of eicosanoids. For these reasons omega-6 PUFAs are generally regarded as pro-inflammatory. While that may be correct in some settings, it is probably an over-simplification. In fact, observational studies have not always reported the anticipated positive relationship between omega-6 PUFA intake or status and inflammatory biomarkers (Innes and Calder, 2018).

The amount of arachidonic acid in inflammatory cells can be decreased by increased consumption of marine omega-3 PUFAs (eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]) found in seafood, especially oily fish, and in fish oil supplements (see Calder, 2015 for references). Thus, less substrate is available for synthesis of inflammatory eicosanoids from arachidonic acid. EPA is also able to act as a substrate for COX, LOX and cytochrome P450 enzymes and produces eicosanoids with a structure slightly different from those formed from arachidonic acid. The functional significance of this finding is that the mediators formed from EPA are typically less potent than those formed from arachidonic acid. Further to this, as previously mentioned, both EPA and DHA, and also DPA, give rise to SPMs, which exert potent anti-inflammatory and inflammation-resolving actions. Thus, one anti-inflammatory mechanism of action of marine omega-3 PUFAs is antagonism of production of inflammatory eicosanoids from arachidonic acid coupled with the generation of less potent EPA-derived eicosanoids and anti-inflammatory SPMs from EPA and DHA. Altered eicosanoid and SPM profiles may have downstream effects because these lipid mediators regulate production of inflammatory cytokines. However, eicosanoid-independent effects of marine omega-3 PUFAs also seem likely (Calder, 2015, 2020b). These PUFAs have been shown to decrease activation of the proinflammatory transcription factor NF- $\kappa$ B and the inflammasome, to activate the anti-inflammatory transcription factor PPAR- $\gamma$ , and to alter key structural and functional aspects of the plasma membrane that reduce TLR-4-mediated inflammatory signaling. In addition, inflammatory macrophages express a G protein-coupled receptor GPR120, through which DHA has been demonstrated to exert anti-inflammatory actions. As a result of these actions, marine omega-3 PUFAs have been shown to reduce leukocyte chemotaxis, adhesion molecule expression, and production of inflammatory cytokines and to increase production of the anti-inflammatory cytokine IL-10. In experimental studies EPA and DHA are able to counter the pro-inflammatory effects of bacterial lipopolysaccharides and saturated fatty acids.

Fig. 5 provides an overview of the mechanisms of anti-inflammatory action of omega-3 PUFAs.

A number of observational studies demonstrated an inverse association between intake or status of marine omega-3 PUFAs and circulating concentrations of several inflammatory markers including CRP, IL-6 and several soluble adhesion molecules (Yli-Jama et al., 2002; Pischon et al., 2003; Lopez-Garcia et al., 2004b; Ferrucci et al., 2006). Intervention studies with marine omega-3 PUFAs showed reduced production of inflammatory eicosanoids and cytokines by isolated inflammatory cells (see Calder, 2015 and 2020b for references). The clinical impact of the anti-inflammatory and inflammation resolving actions of omega-3 PUFAs have been tested in patients with various inflammatory conditions. The strongest evidence of benefit has been in patients with rheumatoid arthritis when high doses of EPA and DHA are used (Miles and Calder, 2012; Abdulrazaq et al., 2017). Anti-inflammatory actions of plant omega-3 PUFA  $\alpha$ -linolenic acid appear to require its conversion to the more biologically active EPA (Baker et al., 2016, 2020).

**Fig. 5** An overview of the mechanisms of anti-inflammatory action of omega-3 PUFAs. AGEs, advanced glycated end products; COX, cyclooxygenase; DHA, docosahexaenoic acid; GPR, G protein coupled receptor; iNOS, inducible nitric oxide synthase; LTs, leukotrienes; MMPs, matrix metalloproteinases; NF- $\kappa$ B, nuclear factor kappa-light-chain-enhancer of activated B cells; PGs, prostaglandins; PPAR, peroxisome proliferator activated receptor; SFAs, saturated fatty acids; SPMs, specialized pro-resolving mediators; the dark circle with a diagonal line indicates inhibition; + indicates activation.

## Antioxidant micronutrients and inflammation

There is a bidirectional interaction between oxidative stress and inflammation. The generation of oxidants (e.g., superoxide radicals, hydrogen peroxide) is part of the host inflammatory response. Oxidants can damage components of host cells. In turn, oxidants and oxidized cell components, acting through transcription factors such as NF- $\kappa$ B, induce inflammation. Thus, dietary components that contribute to oxidative stress (e.g., AGEs and oxidized lipids that result from heating cooking oils to high temperature) could promote inflammatory responses, whereas dietary components that inhibit or quench oxidative stress (various antioxidants) could decrease the strength of inflammatory responses. Antioxidant vitamins act to reduce exposure to oxidants and thereby decrease activation of NF- $\kappa$ B and subsequent production of inflammatory cytokines, eicosanoids, and so on. Inflammatory cells maintain high intracellular concentrations of vitamin C, although these concentrations become depleted during acute activation. In vitro, vitamin E exerts a range of anti-inflammatory actions including decreasing the production of pro-inflammatory cytokines and eicosanoids. Observational studies reported inverse relationships between intake or status of vitamin C, vitamin E and various carotenoids and several markers of inflammation (Kritchevsky et al., 2000; Erlinger et al., 2001; van Herpen-Broekmans et al., 2004; Wannamethee et al., 2006; Wang et al., 2008; Helmersson et al., 2009). Some studies of vitamin C or vitamin E supplements report that they lower CRP and inflammatory cytokines (Devaraj and Jialal, 2000; Block et al., 2004) but findings are not consistent (see Calder et al., 2011 for references).

## Polyphenols and inflammation

Polyphenols are secondary metabolites of plants. They include flavanones, flavones, flavanols, and flavonols. In vitro studies suggest that many polyphenols have anti-inflammatory activity through several mechanisms, including decreasing eicosanoid production through inhibition of phospholipase A<sub>2</sub>, COX and LOX; inhibition of inducible nitric oxide synthase; and inhibition of inflammatory cytokine production. These effects often seem to involve inhibition of activation of key proinflammatory transcription factors such as NF- $\kappa$ B and activator protein-1. A number of polyphenols have benefits in animal models of inflammatory processes. Observational data in humans relating intake of polyphenols with inflammatory markers are inconsistent (see Calder et al., 2011 for references). Human intervention studies investigating the effect of polyphenols on markers of inflammation have often focused on polyphenol-rich foods. For example, the effects of red wine, chocolate and berries on inflammatory markers are believed to result from their constituent polyphenols (see Calder et al., 2011 for references). However, bioavailability of polyphenols is poor, and circulating concentrations are low and are often much lower than those used in the in vitro experiments that demonstrated strong anti-inflammatory effects. Nevertheless, polyphenols may act to regulate inflammation via effects on the gut microbiota, effects which do not require them to be systemically bioavailable.

## The gut microbiota and inflammation

There are believed to be important interactions between the gut microbiota and inflammatory cells present within and beyond the gut wall; these interactions can be chemical or may be by direct cell-to-cell contact. Chemicals involved include short chain fatty acids produced by certain microbes that regulate the activity of inflammatory cells in the gut wall. However, the effects of the gut microbiota extend beyond the gut wall and there is evidence that the microbiota plays a role in defining both local (i.e., gut wall) and systemic inflammatory responses (Samuelson et al., 2015; Verdu et al., 2015). Gut dysbiosis is described in many inflammatory conditions, an observation that is often interpreted to support the role of the microbiota in regulating inflammation. However, reverse causality cannot always be ruled out.

Dietary patterns, specific foods and some dietary components that result in less inflammation often promote a healthy, diverse gut microbiota and it is possible that such patterns/foods/components have dual effects acting both via the gut microbiota and systemically (Wu et al., 2011; Gentile and Weir, 2018; Valdes et al., 2018).

Probiotics are “live microorganisms which when administered in sufficient amounts confer a health benefit to the host” (Hill et al., 2014). Lactic acid-producing bacteria, including lactobacilli and bifidobacteria, are the most commonly used probiotics, although other bacterial genera and some yeasts are also used as probiotics. Several probiotics successfully preserve epithelial barrier function by induction of mucin secretion and maintenance of tight junctions (Ohland and MacNaughton, 2010; Ulluwishewa et al., 2011). This decreases translocation of agents such as bacterial lipopolysaccharides, which can trigger systemic inflammation, from the gut lumen into the bloodstream. Some probiotic bacteria antagonize NF- $\kappa$ B activation in the gut epithelium and thereby decrease production of proinflammatory cytokines, while some interact with gut-residing dendritic cells to induce their maturation and secretion of IL-10, which favors the induction of regulatory T cells that keep inflammation under control (Thomas and Versalovic, 2010). Hence, probiotic bacteria are considered to be anti-inflammatory (Spaiser et al., 2015).

A prebiotic is “a substrate that is selectively utilized by host microorganisms conferring a health benefit” (Gibson et al., 2017). Prebiotics are typically carbohydrates that escape digestion by mammalian enzymes in the small intestine but are metabolized by microbial enzymes in the colon, often to short chain fatty acids. Commonly used prebiotics include fructooligosaccharides and galactooligosaccharides, but it is now recognized that other dietary components including plant polyphenols and marine omega-3 PUFAs have prebiotic actions (Gibson et al., 2017). Prebiotics typically promote growth of lactobacilli and bifidobacteria and hence

they can have effects similar to these probiotic organisms. Some interventions with prebiotic oligosaccharides in humans have been reported to lower the concentrations of inflammatory markers including CRP (Dehghan et al., 2014).

### Postprandial inflammation

During the hours after consumption of a meal there is an increase in blood concentrations of a number of inflammatory mediators including cytokines, chemokines and soluble adhesion molecules, an increase in the number of activated monocytes in the circulation and an increase in expression of some PRRs on monocytes including TLR-2 and -4 (Hansen et al., 1997; Burdge and Calder, 2005). These observations suggest that meal components may have a direct pro-inflammatory action soon after eating the meal. One possibility is that food may contain bacterial lipopolysaccharides that translocate across the gut barrier inducing a transient state of inflammation (Erridge et al., 2007). A second possibility is that the inflammation may be linked to oxidative stress induced by meal components (Burdge and Calder, 2005). Whatever the cause, post-prandial inflammation is believed to increase risk of cardiovascular disease (Bell et al., 2008). Whether postprandial inflammation is due to carbohydrates or fats has been studied. Inducing a state of acute hyperglycemia by infusing glucose resulted in increased blood concentrations of TNF- $\alpha$ , IL-6 and IL-18 and these were shown to be causally related as experimentally induced oscillations in glucose concentration were mirrored by oscillations in the concentrations of the three cytokines (Esposito et al., 2002). Providing a bolus oral dose of glucose increased monocyte activation, assessed as NF- $\kappa$ B activation and TNF- $\alpha$  gene expression, after 1, 2 and 3 h (Aljada et al., 2006), although another study saw no effect of either glucose or fructose on blood concentrations of several cytokines, CRP or three soluble adhesion molecules (Mah et al., 2011). Both these studies reported changes in markers of oxidative stress. A high-fat meal but not a high carbohydrate meal, increased blood concentrations of TNF- $\alpha$ , IL-6 and two adhesion molecules, an effect that was prevented by including vitamins E and C in the meal (Nappo et al., 2002), again suggesting that increased oxidative stress is the mechanism behind post-prandial inflammation. Another study reported that consumption of a high-fat meal was associated with an increase in IL-18 and a decrease in adiponectin concentration in healthy subjects and in patients with type 2 diabetes (Esposito et al., 2003). Interestingly, IL-18 concentration decreased after consumption of a high-carbohydrate, high-fiber meal (Esposito et al., 2003). In another study, both a high-fat meal or glucose resulted in increased concentrations of soluble adhesion molecules in controls and diabetic subjects and combining the high-fat meal with glucose produced a greater overall increase in these markers (Ceriello et al., 2004). Several studies failed to find an effect of meals high in complex carbohydrates on the postprandial concentrations of soluble adhesion molecules and pro-inflammatory cytokines (Nappo et al., 2002; Esposito et al., 2003). Since glucose intake is associated with inflammation but complex carbohydrate intake is not, the magnitude of the change in pro-inflammatory cytokine and soluble adhesion molecule concentrations may be determined by the glycemic response and the associated dynamic changes to lipid and carbohydrate metabolism following a meal. With regards to the effect of a high fat meal on post-prandial inflammation, there is some evidence that it is saturated fatty acids that are responsible (Alayon et al., 2018; Monfort-Pires et al., 2018).

### Dietary inflammatory indexes

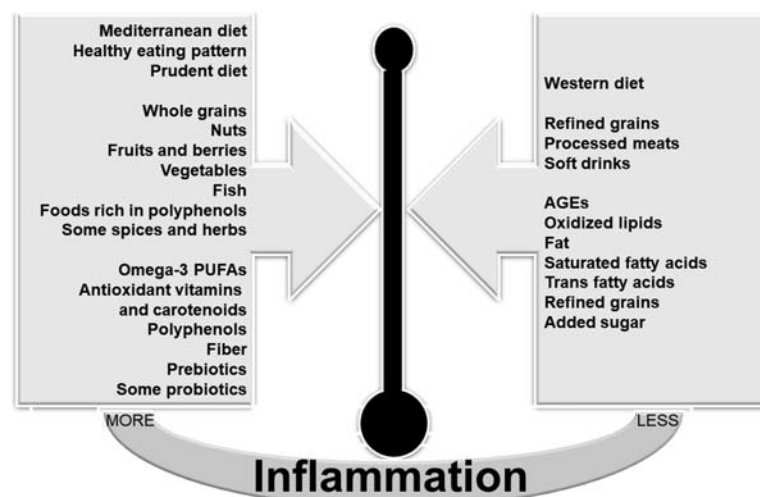

The appreciation that chronic low-grade inflammation contributes to risk of cardiovascular, metabolic and cognitive disease and that these diseases are linked to aging and to diet has led to attempts to classify diets according to the extent to which they are likely to promote inflammation. A number of such classification systems have been proposed. The “dietary inflammatory index” (DII) is a literature-derived nutrient-based index based on published associations of 45 dietary components (energy, macronutrients, fiber, micronutrients, plant polyphenols, herbs, spices) which are each weighted (positively for increasing inflammation and negatively for decreasing inflammation) and blood concentrations of six inflammatory biomarkers (CRP, TNF, IL-1 $\beta$ , IL-6, IL-4 and IL-10); a higher score indicates a more pro-inflammatory diet (Shivappa et al., 2014; Hebert et al., 2019). The “dietary inflammation score” (DIS) is a literature-derived food and supplement-based score based on biological plausibility and published associations of intakes of 18 foods or food groups (e.g., leafy greens and cruciferous vegetables, tomatoes, apples and berries, deep yellow or orange vegetables and fruit, legumes, fish, high fat dairy, low fat dairy, nuts, red meat, added sugars, refined grains and starchy vegetables) and micronutrient supplement use which are each weighted (positively for increasing inflammation and negatively for decreasing inflammation) and blood concentrations of four inflammatory biomarkers (CRP, IL-6, IL-8 and IL-10); a higher score indicates a more pro-inflammatory diet (Byrd et al., 2019). The “anti-inflammatory dietary index” (AIDI) is a literature-derived food-based score based on the associations of intakes of 18 foods or food groups (e.g., total fruits and vegetables, whole grain breads, dry fruits, legumes, nuts, unprocessed red meat) which are each weighted (negatively for increasing inflammation and positively for decreasing inflammation) and plasma CRP concentrations; a higher score indicates a more anti-inflammatory diet (Kaluza et al., 2018). The “empirical dietary inflammatory pattern score” (EDIP) is based on regression models predicting the association of intakes of foods and food groups which are each weighted (positively for increasing inflammation and negatively for decreasing inflammation) and blood concentrations of three inflammatory biomarkers (CRP, IL-6, TNF receptor 2); a higher score indicates a more pro-inflammatory diet (Tabung et al., 2016, 2017). EDIP, DIS and AIDI are all based on whole foods, although they are derived differently, while DII is mainly nutrient based. Although high correlations have been reported between DII and DIS in at least three cohorts, there are low-to-moderate correlations between EDIP and DIS and low correlations between EDIP and DII. EDIP and AIDI seem to be similar although they have not been correlated in a single study.

## Conclusions and perspectives

Inflammation is a stereotypical physiologic response to infection and tissue injury. It initiates pathogen killing as well as tissue repair processes and helps to restore homeostasis at infected or damaged sites. Acute inflammatory reactions are usually self-limiting and resolve rapidly. Resolution involves the activation of negative feedback mechanisms such as the secretion of immunoregulatory cytokines (e.g., IL-10 and transforming growth factor- $\beta$ ) and pro-resolving lipid mediators (resolvins, protectins and maresins), inhibition of proinflammatory signaling cascades, receptor shedding, and activation of regulatory cells. Inflammatory responses that fail to regulate themselves can become chronic and contribute to the initiation, perpetuation and progression of disease. This has been well recognized for “high grade” chronic inflammation where the inflammatory response is central to the pathology and the disease is treated with anti-inflammatory medications. However, in the last two decades “low grade” chronic inflammation has been recognized to underpin atherosclerosis, cognitive decline and loss of muscle mass and to be linked with obesity playing a causal role in its co-morbidities. Dietary choices are likely to be an important factor in determining the extent of low grade inflammation and this is likely one reason why diet is a risk factor for these diseases.

A healthy eating pattern characterized by consumption of whole grains, nuts and seeds, fruits and vegetables and fish is associated with reduced inflammation, a finding suggesting candidate anti-inflammatory dietary components. Indeed, dietary indexes of inflammation have been defined based upon the known impact of foods or food components on circulating inflammatory markers. These observations indicate that diet plays a role in setting inflammatory tone and in determining risk of at least some diseases that involve inflammation. Among food components, there is good evidence that marine omega-3 PUFAs, antioxidant vitamins, plant polyphenols and those components that beneficially modify the gut microbiota all reduce inflammation (Fig. 6). On the other hand, saturated fatty acids, simple sugars, AGEs and oxidized lipids all increase inflammation (Fig. 6). Dietary components that enter the circulation act to influence inflammation through a small number of common mechanisms: they may bind to PRRs to trigger inflammation; they promote or mitigate oxidative stress; they act at the membrane of cytosolic level to promote or mitigate inflammatory signaling for example via NF- $\kappa$ B; they act as substrates for synthesis of chemicals involved in the inflammatory response (see Fig. 4). The gut microbiota is important in determining host inflammatory tone, at both the gut and systemic levels. Thus, foods and food components that modify the gut microbiota making it more or less diverse/healthy can influence inflammation. The composition of this microbiota can be modified by intake of prebiotics or of probiotics. Both modify inflammation and there is some evidence for improvements in certain inflammatory diseases. However, the effects of probiotics are strain and species dependent (Kekkonen et al., 2008) and this is still an area of some uncertainty.

Three areas stand out as being of particular interest in the link between the diet and inflammation and will remain a focus of research over the next period. The first is the role of the gut microbiota in determining inflammatory tone, the extent to which foods and dietary components influence inflammation via the microbiota and the mechanisms involved. The second is the role of post-prandial inflammation in determining cardiometabolic disease risk, the extent to which foods and dietary components influence post-prandial inflammation and the mechanisms involved. The third is the role of diet on promoting or inhibiting resolution of inflammation: tremendous progress has been made in a relatively short time on identifying novel lipid mediators produced from EPA, DPA and DHA that are involved in resolution of inflammation. However, little is still known about these mediators in the human context (Calder, 2020c) and it is not clear what other diet-related factors could be important in regulating resolution of inflammation.

**Fig. 6** The comparative effects of dietary patterns, specific foods and individual food components on inflammation. The dietary patterns, foods and food components on the left push the pendulum of inflammation to the right (i.e., toward less inflammation) while the dietary pattern, foods and food components on the right push the pendulum of inflammation to the left (i.e., towards more inflammation). AGEs, advanced glycosylated end products; PUFAs, polyunsaturated fatty acids.

## Key points

- Interactions between drugs and nutrition occur and may complicate patient care.
- A meal, specific food or diet component, or nutritional status may influence the physiologic disposition and clinical effect of a drug.
- A medication may influence metabolic profile, overall nutritional status, or status of an individual nutrient.
- The presence of a potential interaction requires close monitoring and management as needed.

## Introduction

Medication use is a part of life for many people who make regular use of prescription drugs, non-prescription drugs, and supplements in pharmaceutical form. The oral bioavailability and clinical effect of these drugs are influenced by a variety of factors which together can determine outcome. Although medication-related fatalities occur, less severe outcomes of medication use predominate. These adverse effects include unexpected reactions and drug interactions. In some cases, the adverse reactions and the interactions overlap with or are directly related to nutrition.

Although drug-drug interactions are commonly recognized by clinicians, drug-nutrition interactions are seldom as widely familiar to clinicians, but no less important in their ability to influence patient outcome. Evaluation of a drug may identify multiple influences on nutrition. In turn nutrition plays a role in drug disposition and effect. Whether interactions are positive or negative, they need to be better recognized, understood, predicted and managed as necessary.

This article will define drug-nutrition interactions, explain the different subtypes of interaction and describe their mechanisms using clinical examples. The goal is to provide an appreciation of potential interactions, using some examples, with a focus on mechanistic characteristics rather than attempt exhaustive lists.

## Definitions, recognition and clinical relevance of interactions

Clinicians widely appreciate the influence of interactions between medications on a drug's disposition and clinical effect. Drug interactions with nutrition are no less important than drug-drug interactions (Boullata, 2013). Drug-nutrition interactions result from a physical, chemical, physiological or pathophysiological relationship between a medication and one or more nutrients, food in general, specific foods or food components, nutritional status or metabolic profile (Santos and Boullata, 2005; Boullata, 2013; Boullata and Hudson, 2012; Chan, 2013). Therefore, drug-nutrition interactions can influence the anticipated effect of the drug as well as the patient's nutritional status (Gezmen-Karadağ et al., 2018). As with any interaction, one element of the relationship is considered the "perpetrator" (precipitating factor) while the other is the "victim" (object) of the interaction. The precipitating factor may be the drug, or a nutrient, food or nutritional status, and then another component serves as the targeted object of the interaction.

**Table 1** Types of drug-nutrition interaction.

<i>Precipitating factor</i>	<i>Object of the interaction</i>	<i>Interaction term</i>
Meal	Drug	Food-drug
Diet component <sup>a</sup>	Drug	Diet-drug, nutrient-drug
Nutritional status	Drug	Nutritional status-drug
Drug	Nutritional status	Drug-nutrition (status)
Drug	Metabolic profile	Drug-metabolic (profile)
Drug	Nutrient	Drug-nutrient

<sup>a</sup>Includes those found in dietary supplement products.

Therefore, several subtypes of drug-nutrition interaction exist. They are individually described by their precipitant-and-object as “food-drug” interactions or “drug-nutrient” interactions, among others (Table 1) (Boullata, 2013; Boullata and Hudson, 2012). When classified into subtypes, the systematic approach to identifying, recognizing, and understanding the many interactions is more inclusive and allows evolving interactions to be classified as data become available (Boullata and Hudson, 2012; Boullata, 2013). Despite often being overlooked, drug-nutrition interactions are considered of significant public health relevance (Péter et al., 2017).

Some of the classic drug-nutrition interactions described decades ago are often recognized in isolation rather than within the context of a classification scheme. Examples include the influence of isoniazid on vitamin B<sub>6</sub> metabolism (Biehl and Vilter, 1954) and the influence of iron on tetracycline absorption (Neovonen et al., 1970). Additionally described have been the impact of malnutrition on drug metabolism (Krishnaswamy, 1978) and the influence of drugs on nutrient disposition (Roe, 1985). The effects of food on drug absorption as a result of intraluminal interactions were often the most clinically recognized of the drug-nutrition interactions (Welling, 1977). These food-drug interactions are the most likely interactions to appear in regulator-approved drug product labeling. Even so, using the definition above, many drug products have inconsistent or incomplete drug-nutrition interaction information in their product summaries (Nikolić, 2020). Many electronic medical record systems may have basic built-in alerts to help prescribers and pharmacists identify drug-nutrition interactions in healthcare settings. Unfortunately, the content and capability remain quite limited and do not address much of what is described in this review. Despite their important patient counseling role, community pharmacists’ knowledge about common food-drug interactions was inadequate, requiring greater awareness and education (Radwan et al., 2018). Clinicians continue to rely on summaries of the primary literature in review articles and reference texts.

Recognition of drug-nutrition interactions continues to grow as more comprehensive approaches to systematically identify and classify interactions, describe their mechanisms, and define clinical relevance evolve (Santos and Boullata, 2005; Boullata and Hudson, 2012; Boullata, 2013; Chan, 2002; Mason, 2010; Boullata and Armenti, 2010). For example, a systematic protocol aimed to identify knowledge gaps in and synthesize and evaluate data on clinical characteristics and safety issues for drug-nutrition interactions focused on food-drug interactions (Orellana-Paucar and Vintimilla-Rojas, 2020). The research community continues systematic evaluations using computer modeling, cell culture studies, and literature review to help further build the database. For example, an analysis using high-throughput screening and *in silico* modeling suggested a number of drugs that can inhibit the thiamin transporter (ThTR-2) (Vora et al., 2020). Interestingly, thiamin is also a substrate for other uptake transporters (e.g., OCT1) whose activity is further modulated by genotype. But given the yet unknown gene-protein influences on thiamin disposition itself, the clinical implications for drug interaction at the less specific transporters are not yet known (Jensen et al., 2020). The broad topic of drug-nutrition interactions has been covered in more depth and in the context of specific populations elsewhere (Boullata, 2013; Boullata and Hudson, 2012; Boullata and Armenti, 2010; Boullata, 2010, 2019a, 2021a,b).

Regardless of the object or precipitant, for a drug-nutrition interaction to be considered clinically significant, there is an expectation that nutritional status is compromised and/or therapeutic drug response is modified (Boullata and Hudson, 2012). The change may be recognized by a 20% or greater shift in biomarkers, physiologic indicators, or kinetic parameters from a baseline value or an anticipated effect. The time frame over which the change occurs will vary with the precipitating factor and object. The severity of consequences may vary, with some individuals at higher risk based on their age, genetic variants, organ function, or disease state. As a result, the clinical significance or severity of an interaction may be difficult to predict in the absence of biomarkers for individual predisposition.

The management of an interaction may only require close clinical monitoring in some instances but may require significant changes in eating patterns, nutrient intake or pharmacotherapeutic regimens in others. Clinicians with sharp clinical awareness can recognize or predict drug-nutrition interactions, assess their clinical relevance, and manage them, with a basic understanding of pharmacology, and an appreciation for the mechanisms of interactions. When known, their cellular mechanisms can be intricate.

## Mechanisms

Drug-nutrition interactions essentially occur as a result of two different constructs: (1) the inherent physicochemical properties of drugs, nutrients, and the food matrix, and (2) similarities in the physiologic disposition<sup>1</sup> and physiologic effect of drugs and nutrients.

<sup>1</sup>Disposition refers to the absorption, distribution, metabolism and excretion of a drug or nutrient.

The physical chemistry that is operational for each substance governs their interactions when combined. This occurs in the gut lumen, but also may occur in mealtime dishware or in a nutrition support container prior to consumption/administration. Important properties include the solubility and permeability of a substance, and the viscosity, osmolality, and macronutrient content of a meal (Boullata, 2021b). Physiologically, the processes involved in substrate transport (absorption, distribution, excretion) and metabolism are shared by both drugs and nutrients, at a systemic and cellular level, so an interaction risk always exists (Semen et al., 2020).

Substrate absorption, distribution, and excretion require transporters; metabolism requires one or more enzyme systems; and therapeutic effect requires cellular or molecular targets. These transporters, enzymes, and most targets are proteins coded for by genes. Transporters and enzymes represent products of some of the most highly expressed genes in key tissues (e.g., intestine, liver, kidney). The proteins nearly always require micronutrients for optimal function. The expression of the genes themselves comes under the influence of compounds including nutrients and drugs. Genetic variability and the influence of disease states also need to be considered. Therefore, systems biology models and approaches that incorporate nutrient roles may more efficiently predict potential for interaction than traditional biomarker-based studies. This concept is beginning to evolve within the framework of quantitative systems biology-pharmacology to more closely analyze “-omics” data reflecting broader physiologic roles of these transporters and enzymes including nutrient interaction (Nigam et al., 2020). This will eventually be adapted to better predict drug-nutrition interactions.

The current model of drug-nutrition interactions links an interaction with its physiologic effect and clinical outcome, through differentiating mechanisms (Table 2) (Boullata and Hudson, 2012). Some interactions are based on physicochemical reactions that take place in the lumen of the gastrointestinal tract or ex vivo in a mealtime or nutrition support delivery device. These interactions, referred to as *pharmaceutical* interactions, have the distinct potential to alter the bioavailability of one or more substances (nutrient or drug). An interaction's relevance may be interpreted based on treatment goal. For example, the antiparasitic albendazole must be taken with food in order to create adequate dissolution to support drug absorption and achieve therapeutic blood concentrations (Lange et al., 1988). However, if the therapy with albendazole is only intended for local gut action on helminths, then administration on an empty stomach may enhance that local effectiveness (Humphries et al., 2017). In an example using neurologic agents, the addition of a dose of carbamazepine or escitalopram to an enteral nutrition formula would result in a physicochemical interaction that clogs a feeding tube, thereby limiting delivery and absorption of both drug and nutrients (Klang et al., 2013).

Interactions exist beyond the immediate physicochemical reactions of temporal combinations. Many interactions are the result of encounters at the level of cell membrane transporters and/or metabolizing enzymes, referred to as *pharmacokinetic* interactions. An interaction is based on direct competition for a transporter or enzyme, or an indirect influence often through nuclear transcription factors (e.g., PXR) on protein expression or activity. This is mechanistically similar whether transporters or enzymes are involved. With regard to transporters, short-term/acute regulation involves direct interaction of an agent with the transporter via a ligand-binding site. It may be competitive (via the orthosteric binding site) decreasing substrate transport, or non-competitive (via an allosteric non-overlapping, topographically distinct binding site) that may increase or decrease substrate transport (Domínguez et al., 2021). However long-term regulation involves indirect interactions through a change in transporter expression or modulation through a post-transcription, translation or post-translation level (Rigalli et al., 2016). For example, oleic acid can influence several efflux transporters to decrease P-glycoprotein (P-gp) activity (short-term) and P-gp and breast cancer-resistance protein (BCRP) expression (longer) but increase multidrug resistance-associated protein (MRP2) activity through translocation from intracellular compartments (Domínguez et al., 2021). Potential interactions can occur with drugs that are substrates for any of those transporters.

**Table 2** Mechanisms of drug-nutrition interaction.

Mechanism type	Description	Examples (as cited within the article)
Pharmaceutical	Physicochemical reaction with temporal combination in the gut lumen or nutrition support delivery device	Meal increases (e.g., carbamazepine) or decreases (e.g., indinavir) drug bioavailability; Drug (e.g., ciprofloxacin) chelates nutrient (e.g., calcium) from meal or enteral nutrition formula, reducing bioavailability of both
Pharmacokinetic	Direct competition for transporter or metabolizing enzyme;  Indirect influence on expression or activity of transporter or enzyme;  Obesity and malnutrition alter drug distribution and clearance	Beverage (e.g., grapefruit juice) may increase (e.g., atorvastatin) or decrease (e.g., levothyroxine) drug bioavailability; Drug (e.g., carbamazepine) may decrease nutrient absorption (e.g., biotin) or increase nutrient metabolism (e.g., vitamin D); Nutritional status (e.g., protein-energy malnutrition) increases bioavailability and toxicity risk of a drug (e.g., clarithromycin)
Pharmacodynamic	Therapeutic interference or synergistic augmentation directly at physiologic target site or through indirect targets (e.g., signaling molecules) to alter physiology	Excessive nutrient will interfere with (e.g., vitamin K) or exacerbate (e.g., ubiquinone) the anticoagulant action of warfarin; Drug use (e.g., azole antifungals) may reduce food intake by several mechanisms (gastrointestinal complaints, fatigue, arthralgia, myalgia, tremor)

Although less commonly recognized, pharmacokinetic interactions can also occur through the influence of nutritional status (i.e., body composition variability) on kinetic parameters. For example, systemic drug exposure and toxicity may be increased in protein-energy malnutrition (PEM) as the result of altered drug distribution or clearance of the antimicrobial clarithromycin (Ahn et al., 2003). The potential consequences of all pharmacokinetic interactions are altered bioavailability, distribution, and clearance. The latter can occur through metabolism and/or excretion. This parallels pharmacokinetic drug-drug interactions whose mechanism involves drug transporters alone or along with metabolizing enzymes (Yu et al., 2019).

Still other interactions may take place at target receptors that influence cell signaling, referred to as *pharmacodynamic* interactions, which yield an effect (direct or indirect) on physiologic function, perhaps including nutrient sensing pathways. The potential consequences are altered cellular responses that may translate to a biomarker change or clinical manifestation. Many medications can affect physiologic function to influence food intake. For example, azole antifungal agents may be associated with fatigue, arthralgia, myalgia, tremor, and gastrointestinal complaints (e.g., dry mouth, anorexia, nausea, vomiting, diarrhea, abdominal pain), with potential to decrease food intake and body weight with longer courses of therapy (Boullata, 2021a). Whenever an interaction is sufficient to alter food intake, drug or nutrient disposition, or their clinical effects, it may be considered clinically significant.

## Food-meal

Food is well established for influencing oral drug absorption and bioavailability (Welling, 1977; Boullata and Armenti, 2010; Deng et al., 2017). The potential impact of food on the absorption of a medication is an interaction that all new drug applications to the US Food and Drug Administration (FDA) are required to describe. The potential interaction can occur for a variety of physicochemical and physiologic reasons. This “meal-effect” occurs because the presence of food changes the conditions within the gut lumen into which a drug is administered. Following a meal there are changes in gut pH, viscosity, volume, gastric emptying rates, bile flow and pancreatic secretion that influence drug dissolution, as well as changes to enterocyte permeability, transport, and metabolism. The influences of a meal will be different depending on individual drug properties (e.g., pKa, solubility). There is additionally physiologic variability in drug dissolution and absorption based on the consistency and composition of the meal (Rubbens et al., 2019). Whether the addition of a drug diluted in water to the fed stomach can evade the chyme bolus and be emptied more rapidly is of interest, as this has been noted to differ between orally administered drugs (Schick et al., 2019).

Depending on the drug, altered conditions in the gut may influence the *rate* of a drug’s absorption or the *extent* of drug absorption (i.e., bioavailability). Bioavailability is more clinically relevant than absorption rate and is evaluated by examining the area under the serum drug concentration-time curve (AUC) in the fed state compared to the fasted state. For example, although there is a significant decrease in the rate of absorption for pregabalin when taken with a meal, there is no clinically significant difference in total absorption (i.e., bioavailability), so the drug may be taken without regard to food (Boullata, 2019b).

Well-designed meal-effect studies are useful in recognizing food-drug interactions and designing management strategies. Although not always used in trials, the FDA recommends a “test meal” of ~800–1000 kcal containing ~50% of energy from fat. Clinical significance is noted if the  $AUC_{fed-to-AUC_{fasted}}$  ratio is  $<0.8$  or  $>1.25$ . In the absence of clinical data, a drug’s known physicochemical properties (and susceptibility to removal) can be used to predict drug disposition with a meal. Although complex physicochemical mechanisms are in play, generally, drugs with low solubility but high permeability and significant gut mucosal clearance (e.g., carbamazepine), are expected to have higher bioavailability in the presence of food than in the fasted state, whereas the absorption of drugs with low permeability (e.g., indinavir) is often impaired by food, and those with high solubility and permeability are unaffected (Benet, 2013; Varma et al., 2015; Boullata, 2019b, 2021b). Thus, knowing a drug’s solubility and permeability characteristics may help predict its interaction with food.

Clinical studies can then provide data on the extent to which the change in bioavailability is clinically significant (e.g., AUC change of 20%–25%). Although the bioavailability of one drug may be increased (positive effect) or another drug may be decreased (negative effect) in the presence of food, some drugs exhibit no significant meal-effect and can therefore be administered without regard to a meal. To make an informed evidence-based clinical recommendation, it is important to note what test meal conditions have been used in a study as results may vary with the meal. Varied meal types may have different influences on gut function and therefore drug absorption (Deng et al., 2017). This potential complexity of the meal-effect can be seen with ziprasidone. The drug’s bioavailability is enhanced using the standard high-calorie/high-fat meal, but the effect is seen to a greater extent when a high-calorie/low-fat meal is used but to a lower extent with a low-calorie/high-fat meal (Lincoln et al., 2010; Sutton et al., 2017). Studies that examine the effects of fed vs fasted state on drug bioavailability can also expose significant interpatient variability (Kim et al., 2014).

The alteration in drug bioavailability is especially important for antimicrobials or drugs with a narrow therapeutic index (NTI).<sup>2</sup> Considering antimicrobials, a meal may increase (e.g., cefpodoxime) or decrease (e.g., ampicillin, penicillin, norfloxacin) the extent of drug absorption (Hughes et al., 1989; Eshelman and Spyker, 1978; Minami et al., 1993; Bolme et al., 1995). For the latter agents, administering the drug at least 1 h before or 2 h after food is recommended to improve bioavailability. Sometimes the formulation of a drug may make a difference. For example, azithromycin capsules and tablets are considered bioequivalent in the fasted state;

<sup>2</sup>NTI—drugs for which slight decreases (or increases) in dose or blood concentrations can lead to dose/concentration-dependent therapeutic failure (or toxicity); includes medications whose blood concentrations or biomarker effects are routinely monitored (e.g., carbamazepine, cyclosporine, digoxin, levothyroxine, lithium, phenytoin, tacrolimus, warfarin).

however, a significant meal-effect is noted only with the capsules resulting in decreased bioavailability compared with the tablets (Curatolo et al., 2011). Food may reduce the bioavailability of the antiepileptic phenytoin—at least for some brands of extended-release products (Wilder et al., 2001). Of note, not taking into account the reduced drug bioavailability with a meal may lead to subtherapeutic drug concentrations, risking therapeutic failure and drug resistance in the case of antimicrobials.

The meal-effect may have different outcomes even on agents within the same drug class. For example, the antifungal posaconazole should be administered with food, based on a 3-fold increase in bioavailability regardless of caloric density compared with the fasted state (Lin et al., 2013). While a similar antifungal, voriconazole, needs to be administered on an empty stomach to optimize oral bioavailability (Courtney et al., 2004; Purkins et al., 2003). Mixed findings are also reported for agents to treat tuberculosis where food may reduce the oral bioavailability of isoniazid and pyrazinamide, but not likely of rifampin, so that administration in the fasted state is suggested (Kumar et al., 2017). The administration of a four-component (elvitegravir, cobicistat, emtricitabine, tenofovir) fixed-dose antiviral tablet to healthy subjects in crossover studies under both fed and fasted states revealed drug-specific effects (Shiomi et al., 2014; Yamada et al., 2018). Although bioavailability of cobicistat, emtricitabine, and tenofovir from this product were similar in the fasted, standard breakfast fed and enteral nutrition formula fed states, the bioavailability of elvitegravir was significantly greater in the fed state regardless of nutrient content. As a result, this combination antiviral product is best administered with a meal.

The macronutrient content of a meal may make a difference on the effect. For example, the fat component (percent energy) may have significant influence on oral bioavailability of a drug, as with the antifungal drug griseofulvin. The oral bioavailability increases between 35% and 120% with a meal depending specifically on fat content, compared to its administration in the fasted state (Ogunbona et al., 1985). Bioavailability of ivermectin increased ~2.5-fold when administered with a meal, especially with a high-fat meal (Guzzo et al., 2002; Raman and Polli, 2016) which may be related to altered post-absorptive distribution as well as improved gut dissolution following a high-fat meal (Miyajima et al., 2015). However, administration of ivermectin with a grain-based meal did not alter bioavailability from that in the fasted state (Homeida et al., 2013). Even the content of pectin in a meal may alter drug absorption usually through an influence on permeability in part by bile salt modification (Elshahed et al., 2021).

Beyond test-meal conditions, therapeutic diets prescribed in the clinical setting may influence drug disposition. For example, a modified Atkins diet (78% of energy from fat) has been reported to significantly reduce serum concentrations over time of several antiepileptic drugs (carbamazepine, lamotrigine, topiramate, valproic acid) requiring close therapeutic monitoring (Kverneldend et al., 2015). Interestingly, in the case of irinotecan, dietary protein and energy restriction for just a few days may significantly increase the systemic exposure to the drug's active metabolite (de Man et al., 2021).

There is occasionally an interest in mixing powdered medication directly in with food to facilitate administration in patients unable to swallow intact pills. This needs to be carefully considered. For example, crushing and mixing carbamazepine in yogurt slowed drug dissolution, compared with crushing and mixing in water, which then directly influences bioavailability (Manrique et al., 2014). When ciprofloxacin is crushed and mixed in water, it is much more chemically stable compared with mixing it with any of several common foods and beverages or with enteral nutrition formula (Sadrieh et al., 2005; Wright et al., 2000). The influence of dairy products in reducing the bioavailability of some fluoroquinolones (e.g., ciprofloxacin) by at least 30% is the result of chelation with calcium in the intestinal lumen (Neuvonen et al., 1991).

## Food—diet component

Distinct from the meal-effect, specific dietary components, including those available in dietary supplement products, may also influence drug disposition. The oral bioavailability of medications that are substrates for transporters (uptake or efflux) and/or metabolizing enzymes at the intestinal epithelium, lend themselves to interactions with dietary components that may directly or indirectly influence expression or activity of those proteins (Nakanishi and Tamai, 2015). Uptake transporters include the peptide transporters (e.g., PEPT1) and organic anion transporting polypeptides (e.g., OATP2B1) which both have broad substrate specificity at luminal brush-border membranes, with organic cation transporters (e.g., OCT1) at the basolateral membrane, and efflux transporters P-gp and BCRP, while common metabolizing enzymes include phase 1 cytochrome P450 (e.g., CYP3A) and phase 2 conjugation enzymes (e.g., UDP-glucuronosyl-transferases [UGTs], glutathione-S-transferases [GSTs]) (Wu and Lin, 2019). An individual's susceptibility may in part also depend on the transporter and enzyme genotype.

Administration of oseltamivir, the influenza treatment, with milk reduces initial drug bioavailability by 35% compared to administration with water, possibly the result of competition at the PEPT1 transporter for absorption (Morimoto et al., 2011). Dietary garlic intake at up to 15 cloves per week may reduce protease inhibitor (e.g., darunavir) concentrations enough that HIV plasma viral load increases (Cloarec et al., 2017). This is most likely associated with an increase in garlic-induced expression of gut P-gp efflux reducing drug bioavailability. Cruciferous vegetable intake containing isothiocyanates can within a week significantly induce the activity of CYP1A2, UGT1A1 and GST $\alpha$  responsible for metabolizing a number of drugs (Eagles et al., 2020). Other compounds such as genistein found in soy-based foods or in dietary supplement products, interact with several efflux transporters to modulate their expression and activity (Rigalli et al., 2016). Consistent with the interesting co-localization and apparent coordination between gut metabolizing enzymes and efflux pumps, genistein may activate PXR to induce CYP3A4 as well as efflux transport (e.g., P-gp, MRP2) by increasing expression and activity at typical concentrations.

**Box 1 The grapefruit interaction**

Juice components can influence drug-metabolizing enzymes and drug transporters to increase bioavailability of some drugs and reduce bioavailability of others (Ando et al., 2005; Dolton et al., 2012; Bailey et al., 2013; Hyewon et al., 2013; Fleisher et al., 2015). This seeming dichotomy is explained by differential effects through metabolizing enzymes (e.g., CYP3A) and transporters (e.g., OATPs).

Grapefruit and its juice contain furanocoumarins (including bergamottins) which are metabolized by CYP3A4 in gut enterocytes. The metabolites then bind to and irreversibly inactivate the enzyme making it unavailable to metabolize medication, allowing more of the enzyme-susceptible drug to be absorbed. Given that many drugs are substrates for CYP3A4, there can be widespread increased bioavailability/serum concentrations for drugs as disparate as atorvastatin, budesonide, buspirone, carbamazepine, efavirenz, estradiol, fenofibrate, ibrutinib, lomitapide, lovastatin, saquinavir, sertraline, and simvastatin (Bailey et al., 2013; Boullata, 2019b; De Vries et al., 2015; Lee et al., 1999). But grapefruit juice has no influence on drugs like abacavir, glyburide, phenytoin or prednisone because these are not substrates for CYP3A4 (Kupferschmidt et al., 1998; Kumar et al., 1999; Boullata, 2019b). The effect of the interaction can last up to several days later until sufficient quantity of new enzyme is produced. In other words, the interaction is unrelated to temporal proximity of consumption. Generally, the interaction is more likely to be clinically significant with potential for adverse effects for drugs with a bioavailability <25–50% and significant clearance through CYP3A4. This explains why felodipine bioavailability increases with grapefruit juice but the related drug amlodipine does not (Vincent et al., 2000).

Grapefruit juice also contains flavonoids (e.g., naringin, hesperidin) which can inhibit uptake transporter function (OATP1A2, OATP2B1) at the gut mucosa (Nakanishi and Tamai, 2015; Johnson et al., 2017). Several drugs are substrates for OATP absorptive transport including aliskiren, celioprolol, etoposide, fexofenadine, ivermectin, levothyroxine, sulfasalazine, and talinolol (Kashihara et al., 2017; Glaeser et al., 2007; Lijja et al., 2005; Boullata, 2019b; Dolton et al., 2012). Because the interaction seems to occur through ligand competition at the transporter, the effect is most pronounced when drug is consumed with the juice or up to about 4 h afterward (Dolton et al., 2012). This interaction can generally be avoided by separating drug and juice by at least 4 h.

An individual's susceptibility to grapefruit juice-drug interactions may depend in part on the transporter and enzyme genotype, and concentrations of bioactive components in the juice. Despite much research on juice interactions involving drug-metabolizing enzymes, the effect on transporters continues to develop and both will allow better recognition and prediction of interactions (Dolton et al., 2012).

A number of beverages, containing a wide variety of polyphenols, are known to influence drug bioavailability; apart from any interactions in the gut lumen. For example, fruit juices can serve as the precipitating factor in interactions (Boullata and Armenti, 2010). Grapefruit juice is a commonly recognized example that with typical use can influence a number of drug-metabolizing enzymes and drug transporters to increase bioavailability of some drugs and reduce the bioavailability of others (Boullata and Armenti, 2010) (see Box 1). Similar interactions also occur with other fruit juices to varying degrees, depending on bioactive contents, by altering the bioavailability of vulnerable drugs (Chen et al., 2018a). For example, clementine and mandarin juices inhibit transporters (i.e., BCRP, OATP) to a similar extent as grapefruit juice, but grapefruit is more potent an inhibitor of CYP3A4 and CYP1A2 than are the other two citrus juices (Theile et al., 2017). Aside from interactions at transporters/enzymes caused by specific diet components, the fluid's characteristics may alter drug bioavailability. Beverage (e.g., apple juice) osmolality influences gut lumen fluid volume which then alters drug concentration and impacts absorption by decreasing the concentration gradient, especially for low permeability compounds (e.g., atenolol) (Funai et al., 2019). Given apple juice's ability to inhibit a specific transporter involved in atenolol absorption, multiple mechanisms may be in play (Hyewon et al., 2013).

The widespread use of dietary supplement products is associated with adverse effects including drug interactions (Ronis et al., 2018). Up to 45% of patients using dietary supplements with prescription drugs are at risk of interaction, with as many as 29% considered clinically serious (Peng et al., 2004; Lee et al., 2006; Sood et al., 2008; Loya et al., 2009). Individual nutrients and other isolated bioactive food substances found in dietary supplements can influence drug disposition, due to the effect on transporters and metabolizing enzymes, as well as their clinical effects. The ingredients found at higher concentrations in dietary supplement products are more concerning in some circumstances than food sources with regard to interactions (Egert and Rimbach, 2011).

Supplement products may include compounds isolated from a variety of foods including fruits (e.g., berries) and spices (e.g., turmeric) (Dreiseitel et al., 2009; Sand et al., 2010; Bahramsoltani et al., 2017; Hyrsova et al., 2019). Based on experimental data, several dietary flavonoids can decrease P-gp activity (non-competitively), and the polyphenols gallic acid and ellagic acid decrease P-gp activity (competitive), and curcumin may decrease BCRP activity through an unclear mechanism (Domínguez et al., 2021). A classic interaction with garlic supplements resulted in significant reduction of saquinavir bioavailability (Piscitelli et al., 2002).

Traditional supplements containing macro- and micronutrients are also important. Protein supplements, possibly with source-specific effects, can increase drug metabolism (Boullata and Armenti, 2010; Ronis et al., 2011). Interactions with micronutrients may improve drug outcomes in some cases but be detrimental in others. The potential benefit of vitamin B complex as an adjuvant intervention to fluconazole therapy for *Candida* has been described (Sun et al., 2017). A number of randomized controlled trials have administered vitamin D concurrent with pulmonary tuberculosis treatment accelerating sputum culture conversion in those with multidrug-resistant disease (Jolliffe et al., 2019). Including ascorbic acid, with or without vitamin E, in a triple-antibiotic therapy eradication regimen for *H. pylori* infection improved success rates in randomized trials (Kaboli et al., 2009; Sezikli et al., 2012).

The administration of folic acid supplementation in a patient receiving phenytoin can increase the drug's metabolic clearance over several weeks possibly requiring an increased drug dose to reach a new therapeutic state to avoid breakthrough seizures (Lewis et al., 1995; Berg et al., 1995). These two substances may also compete for similar transporters in the gut and brain. Vitamin

E can increase P-gp and CYP3A expression and activity in vitro (Podszun and Frank, 2014). Supplemental vitamin E could reduce tamoxifen concentrations (pharmacokinetic) in patients with breast cancer, or the drug's inhibitory effect on cancer cell proliferation (pharmacodynamics) (Peralta et al., 2009, 2006). Coenzyme Q<sub>10</sub> (ubiquinone) supplementation increases the bleeding risk in patients using warfarin, whereas vitamin K inhibits the drug's anticoagulant activity (Shalansky et al., 2007). Although vitamin C enhanced the killing of *Candida albicans* in vitro, when combined with fluconazole the activity of the antifungal was significantly reduced (Avci et al., 2016; Wang et al., 2009).

At therapeutic doses, multivalent mineral supplements can interfere with antimicrobial (e.g., ciprofloxacin, levofloxacin, minocycline) absorption due to chelation (Lomaestro and Bailie, 1991; Pai et al., 2006). Co-administration of mineral supplements (e.g., calcium, iron, magnesium, or zinc) also significantly reduces the bioavailability of the antiretroviral drug dolutegravir, unless taken concurrently with a fat-containing meal (Song et al., 2015).

## Nutritional status on drug disposition

The nutritional status of an individual, much like renal or hepatic function, is also a determining factor in drug disposition and effect. Drug distribution and clearance are the elements most influenced by poor nutritional status (e.g., obesity, PEM, micronutrient deficits) (Walter-Sack and Klotz, 1996; Boullata, 2010). Despite the prevalence of obesity and PEM, it is rare for drug product labeling to provide dosing regimen guidance for these patients as there is currently no regulatory requirement to do so (Boullata, 2010; Jacques and Erstad, 2010; Boyd et al., 2016). So clinicians rely on reviews summarizing the limited data available or apply rational principles to their decision-making (Boullata and Armenti, 2010; Boullata, 2010). The factors to appreciating the implications of nutritional status on drug dosing regimens include dose format and body composition.

Dose formats are most often a fixed dose (mg) but may also be weight-based (mg/kg). The fixed dose is established on the clinical effects in patients of otherwise healthy weight. Weight-based dosing most often uses total body weight. For drugs prescribed using weight-based dosing, it can be particularly challenging in a patient with elevated body mass index (Boullata, 2010; Pai, 2012). Neither body surface area nor an "ideal" body weight relative to height is appropriate for drug dosing in these circumstances (Boullata, 2010). The dosing weight to use depends on drug-specific characteristics in obese patients. The total body weight may be appropriate for some drugs; the lean body weight for others. A validated predictive equation for lean weight, which accounted for body composition, may be suitable for weight-based dosing to account for the altered distribution of a drug (Janmahasatian et al., 2005; Beckman et al., 2017). For other drugs an "adjusted" body weight may be more fitting. This value falls between total and lean weight ( $= \text{lean body weight} + [\text{cf}] [\text{total body weight} - \text{lean body weight}]$ ), where the correction factor (cf), when known, represents the fraction of excess weight that normalizes the volume of distribution for that drug in the obese to that in a non-obese patient (Boullata, 2010). This is where body composition comes into play.

Two important kinetic parameters to examine for each drug are the volume of distribution (Vd, in L/kg) and the clearance (Cl, in L/h); the former governs a drug's initial or loading dose, while the latter shapes the maintenance dose and/or dosing interval and both parameters together determine serum and tissue drug concentrations. Using the two-compartment framework, relative to healthy body habitus, absolute content and proportions of lean mass and fat mass are altered as lower and upper extremes of body mass index are approached. A drug's Vd correlates with both anatomic compartments, while its Cl correlates predominantly with lean body mass (Boullata, 2010). So any influence of altered nutritional status on these two parameters can yield unexpected drug concentrations following a "usual" dose. Optimal drug dosing, especially for NTI drugs and antimicrobials, is required to achieve sufficient therapeutic serum concentrations while limiting adverse effects associated with supra-therapeutic concentrations. Generally, the initial (loading) dose is adjusted to account for drug distribution into existing lean and fat mass, and dosing interval is adjusted to account for altered clearance. Best practice, especially for NTI drugs and antimicrobials, is to closely follow clinical effects and serum concentrations in obesity or PEM.

In obesity, the weight-normalized Vd (L/kg) of carbamazepine is lower, and clearance is slightly reduced, suggesting use of an appropriately adjusted (between actual and lean) body weight for initial dosing followed by close monitoring (Caraco et al., 1992, 1995). Unrelated to the lipophilicity of lorazepam, there is no significant difference in Vd for the drug in obesity; however, drug clearance via glucuronidation is increased (Abernathy et al., 1983).

In malnourished children, gentamicin exhibited increased Vd and/or reduced Cl suggesting that larger doses administered less frequently might be appropriate as confirmed in a prospective study (Khan et al., 2006). Conversely, drug concentrations of sulfadiazine increase in PEM because of reduced Vd (Nehru et al., 1988), and Vd is also reduced for quinine and chloroquine (Pussard et al., 1999; Kadam et al., 2016). For antibiotics cleared primarily by renal excretion, some (e.g., cefoxitin, penicillin) are significantly reduced by malnutrition, whereas others (e.g., the aminoglycosides, cotrimoxazole) are insignificantly affected (Bolme et al., 1995; Bravo et al., 1984, 1982; Buchanan et al., 1979, 1980). PEM is associated with increased chloramphenicol concentrations despite increases in renal Cl because of a concurrent decrease in hepatic metabolism (Kohli et al., 1981; Smith et al., 1973). Hepatically cleared drugs will be influenced by any malnutrition-associated alterations in the enzymes of phase 1 (oxidation) or phase 2 (conjugation) metabolism. Rarely there may be a reported increase in drug metabolic Cl (e.g., chloroquine, quinine), but more often overall metabolic Cl is reduced (e.g., chloramphenicol, isoniazid, metronidazole, quinine) (Eriksson et al., 1983; Lares-Asseff et al., 1992; Ashton et al., 1993; Tulupule and Krishnaswamy, 1984; Roy et al., 2010; Treluyer et al., 1996; Salako et al., 1989). Modeling drug disposition based on data from malnourished patients better predicts serum concentrations than

a model derived in non-malnourished individuals (Lares-Asseff et al., 1999). Subsequently, a rational dosing approach can be prospectively evaluated and validated (Lares-Asseff et al., 2016). Following weight loss in obesity or nutritional rehabilitation in PEM, the pharmacokinetics may return toward expected values.

Micronutrient deficits can also influence drug disposition based in part on their roles in the function or stability of enzyme systems involved in drug metabolism (Walter-Sack and Klotz, 1996). For example, inadequate folate status decreases metabolic clearance of phenytoin, and subsequent repletion increases the metabolism (Berg et al., 1995). Carnitine deficiency may also increase phenytoin toxicity (Ling et al., 2012). Selenium deficiency in an animal model decreased the activity of several CYP-isoenzymes relative to controls (Jiang et al., 2020). Magnesium and zinc deficits compound the ototoxicity associated with aminoglycoside use making it potentially irreversible (Gunther et al., 1988; Lautermann and Schacht, 1995).

## Drug-induced alteration in nutrition

In addition to any therapeutic benefit, medication use is associated with potential adverse effects. Among the adverse effects are those that can influence metabolic biomarkers, nutritional status in general, or the status of specific nutrients, all of which are important to consider during patient care (Piccolo and Boullata, 2016). The influence of medication on metabolic profile (e.g., hyperglycemia, hypertriglyceridemia), on overall nutritional status (e.g., weight gain, weight loss), or on the status of specific nutrients (e.g., hyperkalemia, zinc deficiency) can be mechanistically multifactorial (White, 2010; Lombardi et al., 2010). These include long lists of drugs including specific neurologic and antimicrobial agents described elsewhere (Lombardi et al., 2010; Piccolo and Boullata, 2016; Boullata, 2019a, 2021a). Even close analysis of a single drug can identify multiple influences on nutrition—including positive effects (Luciano-Mateo et al., 2017). From a clinician's perspective, drug-induced change in metabolic status is reflected in available biomarkers, alteration of overall nutritional status evaluated by physical exam, and in the case of specific nutrients is assessed through nutrition-focused physical exam and biomarkers.

Common general effects of a drug on metabolic profile or broad nutritional parameters are often available from clinical trials and found in the FDA's product labeling and therefore not specifically cited further in this section (US-FDA, 2021). Specific nutrient biomarkers of interest are rarely available until post-marketing reports surface from case studies. These represent "drug-nutrient" interactions in the strict sense of the term in which a medication alters the disposition of a nutrient. The number of drugs used by an individual has been correlated with deficits/excesses of specific nutrients (Heuberger and Caudell, 2011).

## Metabolic status

Metabolic changes can include hyperglycemia as seen with several antiretrovirals (e.g., abacavir, atazanavir, dolutegravir, lamivudine, saquinavir), other antimicrobials (e.g., posaconazole), and neurologic agents (e.g., aripiprazole, bupropion, escitalopram, lamotrigine, olanzapine, quetiapine). Hypoglycemia may be expected with some drugs (e.g., insulin, glyburide) but also occur with others as an "off-target" effect (e.g., fluoroquinolones). Hypertriglyceridemia and hypercholesterolemia have been reported during treatment with some antimicrobials (e.g., clindamycin, dolutegravir, efavirenz), and neurologic drugs (e.g., mirtazapine, olanzapine, quetiapine).

## Overall nutritional status

The effect on food intake may occur through the central nervous system, more local gut mechanisms, or both. Some medications may indirectly influence intake by altering a patient's capacity to gather, prepare or ingest food. An individual drug may cause several adverse effects that together influence nutritional status—fatigue, loss of appetite, change in taste, and disturbances of gastrointestinal function combined can lead to reduced dietary intake and decreased body weight. The impairment of the ability to gather, prepare, and ingest food may even occur following drug-induced cognitive, visual, movement, or gait disturbances. Many of these are at play in the elderly in particular given their generally high use of medication (Zadak et al., 2013). An influence on appetite or body weight is important to recognize especially for medications used chronically. The effects can be additive if multiple drugs are being used.

Central nervous system effects that may contribute to reductions in food gathering, preparation, and intake can include severe dizziness, fatigue, ataxia, and/or tremor. Visual disturbances (e.g., rifampin) and optic neuritis (e.g., chloramphenicol) may also influence food gathering, preparation, and intake. Peripheral neuropathy and even myositis, myalgia, and/or arthralgia may influence food gathering, preparation, and intake and negatively impact nutritional status over time. The influence on appetite varies, but rarely, a drug may alter impulse control that includes binge eating (e.g., aripiprazole). Reduced appetite has been reported for several unrelated antimicrobials (e.g., aminoglycosides, fluconazole, lamivudine, tenofovir), which with other factors may contribute to weight loss. The influence on weight gain or weight loss may even be indirect through a change in the gut microbiota (Angelakis et al., 2013; Raoult, 2017). This likely involves the gut-brain axis.

Through an effect on the gastrointestinal tract itself (i.e., taste disorders, stomatitis, nausea, vomiting, diarrhea and malabsorption), many medications can impair a patient's overall nutritional status. An influence on oral health which interferes with food intake is possible with several agents. Dry mouth and altered taste as well as glossitis or stomatitis occur with a number of drugs (Lombardi et al., 2010; Piccolo and Boullata, 2016; Boullata, 2019a, 2021a). Furthermore, common gastrointestinal disturbances

(i.e., anorexia, nausea, vomiting, abdominal pain, and diarrhea or constipation) are reported with many medications. Less commonly occurring are dysphagia, liver function abnormalities or hepatitis, and pancreatitis.

Changes in body weight, body composition, or extracellular fluid volume over time are easier to recognize. Weight gain including body fat accumulation (central, dorsocervical) or redistribution with peripheral wasting may occur with several antiretroviral agents (e.g., abacavir, atazanavir, dolutegravir, efavirenz, lamivudine, nevirapine, saquinavir, tenofovir). Weight gain is also associated with several neurologic drugs (e.g., aripiprazole, mirtazapine, olanzapine, quetiapine, and valproic acid), while weight loss is associated with others (e.g., phenytoin, sertraline, topiramate, and venlafaxine). Some drug-associated weight gain (e.g., lamotrigine, trazodone, valproic acid) may be attributed to edema.

### Specific nutrients

The classic term “drug-nutrient” interaction is appropriately applied here for medication that alters nutrient disposition. The absorption, distribution, metabolism and excretion of specific nutrients can be influenced by drugs. When the detrimental effect on a specific nutrient’s status is significant, it may be addressed by supplementation (e.g., pyridoxine administered with isoniazid, folic acid with phenytoin). With the common findings of micronutrient deficits, an undefined proportion of them may result from a drug-nutrient interaction requiring concerted effort to recognize and prevent (Karadima et al., 2016).

Although overt classic nutrient deficiency syndromes are rarely seen, lesser degrees of deficit may still be associated with clinical manifestations noted as adverse drug effects. For example, drug-induced osteomalacia can be caused by influence (e.g., antiepileptic drugs) on vitamin D metabolism (Pascussi et al., 2005; Oscarson et al., 2006; Xu et al., 2006). Carbamazepine increases the catabolism of vitamin D and subsequent association of long-term use with poor bone mineral density (Farhat et al., 2002; Fitzpatrick, 2004; Souverein et al., 2006; Kim et al., 2007). Intervention with vitamin D therapy may improve serum 25(OH) vitamin D concentrations in these patients (Pedrera et al., 2000; Elliott et al., 2007). Treatment for tuberculosis (e.g., isoniazid, rifampin) may decrease 25(OH) vitamin D concentrations by inhibiting 25-hydroxylation and accelerating 24,25-hydroxylation (Brodie et al., 1982). Despite low 25(OH) vitamin D concentrations often found at baseline in HIV infection, efavirenz as part of an antiretroviral regimen is associated with significant vitamin D deficits, increased bone turnover, and risk for osteomalacia (Welz et al., 2010; Orkin et al., 2014; Nylen et al., 2016). This may occur as a result of drug-induced interference with vitamin D metabolism and regulation in osteoblasts (Wegler et al., 2016). Vitamin D supplementation increased serum 25(OH) vitamin D concentrations in these patients and improved biomarkers of bone metabolism (Etminani-Esfahani et al., 2012). Knowing a patient’s vitamin D status may help determine whether supplementation is required as part of these drug regimens.

Drug-induced hepatotoxicity with hyperammonemia (e.g., valproic acid) may result from carnitine deficiency (Van Wouwe, 1995; Werner et al., 2007; Melegh et al., 1987; Opala et al., 1991; Moreno et al., 2005). Reductions in serum carnitine concentrations occur in the face of diminished tissue distribution (Tein et al., 1993). In addition to the inhibition of intracellular transport, deficits are also thought to be related to decreased endogenous synthesis, and decreased renal reabsorption (Farkas et al., 1996; Lheureux et al., 2005; Segura-Bruna et al., 2006).

Sometimes the effect may be through more than one mechanism. For example, carbamazepine impairs biotin status through decreased intestinal absorption and accelerated metabolism to inactive metabolites (Said et al., 1989; Mock and Dyken, 1997). This influences the activity of the biotin-dependent carboxylases that may in turn alter neurologic function noted as an adverse drug effect. Phenytoin has an effect on folate status by inhibiting intestinal conjugases and limiting folate absorption. The drug may also interfere with folate transport, and consume folate during metabolism leading to folate deficits in at-risk individuals (Lewis et al., 1995; Schwaninger et al., 1999; Apeland et al., 2002; Sener et al., 2006). Serum folate decreases significantly in a few weeks, but adding folic acid to the regimen improves folate status and allows for steadier control of drug concentrations (Berg et al., 1995). For other drugs the mechanism of altered nutrient status is less clear.

The classic influence that isoniazid has on pyridoxine metabolism has been well described for decades in the treatment of tuberculosis (Biehl and Vilter, 1954; Clark, 1976). To prevent associated peripheral neuropathy or seizures, or to manage the presenting adverse effect, pyridoxine is administered along with the isoniazid regimen (Minns et al., 2010; Aiwaile et al., 2015). The co-administration of high-dose pyridoxine with isoniazid is not expected to significantly affect overall drug bioavailability (Zhou et al., 2013). The use of highly active antiretroviral therapy was associated with lower folate and vitamin B<sub>12</sub> concentrations in circulation and in breast milk in postpartum HIV-infected women (Allen et al., 2015; Flax et al., 2015). Highly active antiretroviral therapy is also associated with reduced  $\alpha$ -tocopherol concentrations in nearly 20% of patients with long-standing HIV (Kaio et al., 2014). Carnitine deficits have also been suspected as an adverse effect of antiretroviral therapy (Mintz, 1995). Elevated partial thromboplastin time (PTT) and international normalized ratio (INR) with or without bleeding has been associated with azithromycin and with cotrimoxazole despite no history of malabsorption, that responded in each case to vitamin K administration (Stork et al., 2011; Fotouhie et al., 2016). Aminoglycosides may interfere with host selenium (Se-cys) incorporation into proteins (e.g., selenoprotein P) but requires further examination (Renko et al., 2017). Plasma selenium and selenoprotein P can serve as valuable biomarkers in such studies (Wiehe et al., 2016).

Electrolyte abnormalities are associated with a number of medications mostly at the level of excretion. This includes hyponatremia (e.g., carbamazepine, cotrimoxazole, escitalopram, mirtazapine, sertraline, venlafaxine), hypokalemia (e.g., aminoglycosides, amphotericin, caspofungin, flucytosine, posaconazole), hypomagnesemia (e.g., aminoglycosides, amphotericin, posaconazole, caspofungin), and hypocalcemia (e.g., aminoglycosides, amphotericin, posaconazole), and hypophosphatemia (topiramate). Chronic adefovir treatment for viral hepatitis is also associated with renal tubular dysfunction, hypophosphatemia,

and osteomalacia (Chen et al., 2018b). Hyperkalemia (e.g., cotrimoxazole, macrolide antibiotics) and hyperphosphatemia (e.g., macrolides) may also occur. Cotrimoxazole's association with reversible hyperkalemia is likely due to inhibition of renal potassium secretion attributed to the trimethoprim fraction of the combination product (Marinella, 1995).

## Summary

It is given that each person has a relationship with nutrition that supports their growth and development, and with varying degrees of success maintains or improves their health. However, many persons use medication acutely or on a more routine basis, setting up the potential for drug-nutrition interactions. A variety of potential interactions between drug and nutrition may influence a specific outcome and need to be accounted for. Such interactions include the influence of meals, dietary components, dietary supplements, or nutritional status on the disposition and clinical effect of the drug, as well as the potential effect of each drug on metabolic profile, overall nutritional status, or the status of individual nutrients. Depending on the drug and the patient, the pharmaceutical, pharmacokinetic, or pharmacodynamics interactions may have clinically significant effect. Drug-nutrition interactions are becoming better recognized and understood in clinical practice. In cases where enough data are available, interactions may be identified or predicted, and then appropriately managed. With ongoing advances, the expectation is that patient care can be further improved in the context of drug-nutrition interactions.

## Key points

- To understand the nutritional and metabolic origin of eicosanoids, as well as the main aspects of their functions.
- To understand the fundamental biochemical processes involved in platelet aggregation.
- To understand the role of eicosanoids in inflammation and immune responses.
- To know the main pathophysiological implications of eicosanoids.

## Introduction

Given the complexity of multicellular organisms, good intercellular communication is necessary to regulate metabolism, growth and other functions of the various organs and tissues. This is a very complex network of signals that is gradually becoming better understood. Many chemical compounds (e. g. hormones, cytokines and eicosanoids) are involved in intercellular communication. Alterations in the signaling networks cause diseases as important as cancer and diabetes (Johnson et al., 2020).

Eicosanoids are derivatives of polyunsaturated fatty acids of 20 carbon atoms, especially arachidonic and eicosapentaenoic acids. They include many types of molecules, such as prostaglandins, prostacyclins, thromboxanes, leukotrienes, lipoxins, resolvins and

other oxidized compounds. Although they are derived from fatty acids, they are not very lipid soluble and therefore act primarily on membrane receptors (Calder, 2020).

While hormonal signals function in an endocrine fashion, acting on cells far from those that produce them, eicosanoids act in a paracrine (on neighboring cells) or autocrine (on the same producing cell) way (Fredriksson and Schioth, 2005). They are involved in the regulation of numerous physiological processes and are therefore implicated in many pathological alterations (Calder, 2020). Their pharmacological interest is also noteworthy, because there are inhibitors of their synthesis with therapeutic activity (especially anti-inflammatory agents) (Nakahata, 2008; Casati et al., 2021).

The aim of this chapter is to explain the intercellular communication system mediated by eicosanoids.

## Biosynthesis

Eicosanoids are formed from three polyunsaturated fatty acids of 20 carbon atoms: eicosatrienoic or dihomo- $\gamma$ -linolenic (20:3 n-6), eicosatetraenoic or arachidonic (20:4 n-6) and eicosapentaenoic (20:5 n-3) acids (Fig. 1).

The first two are derived from linoleic acid, while the third is derived from  $\alpha$ -linolenic acid. The latter two are essential fatty acids of 18 carbon atoms. The formation of the long-chain polyunsaturated acids from the essential fatty acids takes place by enzymatic processes of desaturation and chain elongation in the liver. Subsequently, these acids are exported by the liver to the rest of the tissues, being incorporated into the membrane phospholipids, preferably in position two. There is a wide variety of stimuli capable of triggering the hydrolysis of the ester bond at position two, so that the corresponding fatty acids are released. From dihomo- $\gamma$ -linolenic acid, series 1 of eicosanoids originate; from arachidonic acid, series 2 of eicosanoids are derived, and from eicosapentaenoic acid, series 3 of eicosanoids (Calder, 2020).

The first eicosanoids investigated were those of a cyclic nature (prostanoids), formed by the activity of cyclooxygenase: prostaglandins (PG), thromboxanes (TX) and prostacyclins (PC). Subsequently, other derivatives of a linear nature were discovered, originating from the action of various lipooxygenases (LOX), among which leukotrienes (LT) and lipoxins (LX) stand out (Biringer, 2020). Figs. 2 and 3 show the formation pathways of the main eicosanoids derived from arachidonic acid (series 2), which are the most important in our usual dietary conditions.

Series 1 and 3 of eicosanoids are structural analogs of arachidonic-derived series 2, with one less and one additional bond, respectively.

Probably, the main mechanism of the regulation of eicosanoid biosynthesis is the availability of arachidonic acid and the other precursors of series 1 and 3, which is very small under normal conditions. Therefore, the action of enzymes that release these acids from the phospholipids that contain them is critical. In turn, these enzymes are influenced by membrane transduction systems in response to a wide variety of hormonal and other stimuli (Biringer, 2020). Most of the receptors related to eicosanoid synthesis operate in connection with G proteins, although, in some cases, these proteins are not well characterized (Fredriksson and Schioth, 2005). As a result of the activation of this system, activation of phospholipase A<sub>2</sub> or phospholipase C occurs.

Phospholipase A<sub>2</sub> (PLA<sub>2</sub>) is an enzyme that acts on various phospholipids, including phosphatidylcholine, and requires calcium ions for its activity. The calcium ions can either come directly from outside the cell (as occurs in the case of physical stimuli on the

Fig. 1 Origin of series 1, 2 and 3 of eicosanoids.

**Fig. 2** Cyclic pathway of eicosanoid synthesis. PG: prostaglandin; TXA<sub>2</sub>: thromboxane A<sub>2</sub>.

membrane) or from the cytosol, once the activation of phospholipase C has occurred (see below). PLA<sub>2</sub> directly releases arachidonic acid from membrane phospholipids. Among the positive effectors is angiotensin II. In contrast, natural corticosteroids (and their pharmacological derivatives) inhibit this enzyme through the induction of a protein called lipocortin or lipomodulin.

Phospholipase C acts on phosphatidylinositol bisphosphate (PIP<sub>2</sub>), releasing diacylglycerols and inositol triphosphate (IP<sub>3</sub>). The latter releases calcium ions from the endoplasmic reticulum into the cytosol, which may result in further activation of PLA<sub>2</sub>. On the other hand, there are lipases that can act on diacylglycerols, leading to the release of arachidonic acid from position two (Fig. 4).

The enzymes of the cyclic pathway of eicosanoid formation are found in the microsomal fraction of numerous tissues. In almost all tissues there is a prostaglandin synthetase or cyclooxygenase, known by the acronym COX-1, which is constitutive in nature, not inducible. Another form of cyclooxygenase, COX-2, is not normally expressed in cells, but can be induced by some growth factors or cytokines. Cyclooxygenase acts in two stages corresponding to two distinct enzymatic activities. First, with the intervention of molecular oxygen, a cyclic endoperoxide called prostaglandin G<sub>2</sub> (PGG<sub>2</sub>) is produced. Subsequently, the hydroperoxide group at position 15 is reduced to hydroxyl by peroxidase activity and the probable assistance of glutathione, giving rise to another cyclic endoperoxide called PGH<sub>2</sub> (Fig. 2). Cyclooxygenase is inhibited by aspirin and other non-steroidal anti-inflammatory drugs. COX-2 also appears to be inhibited by corticosteroids.

The remaining enzymes are not as ubiquitous. Some tissues, such as the lung, contain all of them and can synthesize the full range of prostanoids. In contrast, only D-series prostaglandins and thromboxanes can be synthesized in platelets, whereas the vascular endothelium synthesizes only prostacyclins (Biringer, 2020).

The enzymes of the linear pathway are found primarily in the cytosolic fraction of neutrophils (5-LOX and 12-LOX), eosinophils (15-LOX) and platelets (12-LOX). 5-LOX is the best known enzyme of this group. Its activation requires intracellular calcium ions and an activator protein that allows it to bind to the membrane.

There are three different lipoxygenases capable of synthesizing lipoxins from arachidonic acid: 5-LOX, 12-LOX and 15-LOX. One of the synthesis pathways takes place in platelets and involves the transformation of leukotriene A<sub>4</sub> (LTA<sub>4</sub>) into lipoxin A<sub>4</sub> (LXA<sub>4</sub>) via 12-LOX. Another route involves 15-LOX and 5-LOX in neutrophils, erythrocytes and reticulocytes. In this case,

**Fig. 3** Linear pathway of eicosanoid synthesis. HPETE: hydroxyperoxyeicosatetraenoic acid; LT: leukotriene.

**Fig. 4** Arachidonic acid release from membrane phospholipids. DAG: diacylglycerol; IP<sub>3</sub>: inositol triphosphate; PIP<sub>2</sub>: phosphatidylinositol bisphosphate; PLA<sub>2</sub>: phospholipase A<sub>2</sub>; PLC: phospholipase C.

15-hydroxyperoxyeicosatetraenoic acid (15-HPETE) is obtained from arachidonic acid, which is eventually converted to lipoxins A and B. The other route by which lipoxins can be generated is mediated by the action of aspirin, which gives rise to 15-epilipoxin A<sub>4</sub> (15-epi-LXA<sub>4</sub>) and 15-epilipoxin B<sub>4</sub> (15-epi-LXB<sub>4</sub>), also known as ATL (aspirin-triggered lipoxins) (Chandrasekharan and Sharma-Walia, 2015).

In addition to these compounds, there are biologically active derivatives produced by oxidation of arachidonic acid through the cytochrome P-450 system, although their physiological significance is less clear. On the other hand, there is the possibility of non-enzymatic transformation of arachidonic acid to prostaglandin-like compounds called isoprostanes. These eicosanoids also exhibit biological activity and may play a role in the inflammatory response, since they are formed by the action of free radicals released in this process (Kumar et al., 2020).

In recent years, derivatives of long-chain polyunsaturated fatty acids capable of binding to cannabinoid receptors and referred to as endocannabinoids, have gained special relevance. Anandamide or arachidonyl ethanolamide is an ethanolamide derivative of arachidonic acid and a member of a larger class of N-acyl ethanolamines (NAEs) lipids, and thus also referred to as NAE 20:4. Other endocannabinoids are N-homo- $\gamma$ -linolenoyl ethanolamine (NAE 20:3(n-6)), N-docosatetraenoyl ethanolamine (NAE 22:4(n-6)) and 2-arachidonyl glycerol (Kilaru and Chapman, 2020).

Endocannabinoid signaling has been implicated in a number of physiological and cognitive processes in humans. The endocannabinoids are well-known modulators of various neurological functions such as perception of pain, mood, memory, sleep, appetite etc. Endocannabinoids also play an important role in activation of immune system, pre- and postnatal development, embryo implantation and fertility, among others. Thus, maintaining physiological homeostasis is considered as the primary function of endocannabinoid signaling. The biological consequences of endocannabinoids result from their interactions with several target proteins, including cannabinoid receptors, G-proteins and other downstream effectors. As such, synthesis, receptor activation and degradation of endocannabinoids are all highly regulated and is believed to start "on-demand" via a stimulus-dependent synthesis (Kilaru and Chapman, 2020).

## Mechanism of action

There are membrane receptors for each type of eicosanoid, which have been studied especially in platelets and smooth muscle. It is noteworthy that there can be, however, several types of receptors for the same eicosanoid, even in the same cell membrane. In all cases, membrane signal transduction is carried out by G proteins (Fredriksson and Schiöth, 2005). In some cases, stimulation or inhibition of adenylate cyclase occurs, increasing or decreasing cyclic AMP production. In other cases there is stimulation of phospholipase C, with a consequent increase in diacylglycerols and phosphoinositol bisphosphate. Leukotrienes appear to act through stimulation of phospholipase C, while PGI<sub>2</sub> (prostacyclin) and prostaglandins D and F activate adenylate cyclase.

On the other hand, PGE<sub>2</sub> and thromboxane A<sub>2</sub> (TXA<sub>2</sub>), as well as isoprostanes, oxidized derivatives of eicosanoids, can act through both systems. The action of TXA<sub>2</sub> occurs through its TP receptor that interacts with different G proteins, which causes the activation of different enzymes, such as adenylate cyclase and phospholipases C of type  $\alpha$  and  $\delta$ , as well as the Rho guanine nucleotide exchange protein (Rho-GEF) (Nakahata, 2008). In a very general way it can be said that stimulation of the phosphoinositol bisphosphate system and the subsequent release of calcium ions result in constriction phenomena, whereas the production of cyclic AMP results in relaxation (Fig. 5).

**Fig. 5** Mechanism of action of eicosanoids. cAMP: cyclic adenosine monophosphate; ATP: adenosine triphosphate; PD: prostaglandin E receptor; IP<sub>3</sub>: inositol triphosphate; LT: leukotriene; PIP<sub>2</sub>: phosphatidylinositol bisphosphate; PGE: prostaglandin E; PGI: prostacyclin.

Recently, it has become clear that some eicosanoids can act on nuclear receptors of the peroxisome proliferator-activated receptor (PPAR) type. Calcium-activated PLA<sub>2</sub> can translocate to the nuclear membrane and release arachidonic acid or other polyunsaturated fatty acids, leading to the formation of eicosanoids, such as the prostacyclin PGI<sub>2</sub>, which interact with nuclear transcription factors such as PPARs and retinol receptors (RXRs), which bind to DNA and modulate the expression of numerous genes (Katusic et al., 2012).

Lipoxins exert their action through their interaction with the high-affinity receptor ALX, also known as FPR-2, curiously the same receptor to which the serum amyloid protein binds. When the interaction between lipoxins and their receptor ALX/FPR-2 occurs, their internalization is then triggered, which induces phagocytosis of polymorphonuclear cells, thanks to the regrouping of actin filaments. On the other hand, several intracellular signaling pathways are activated with important consequences, such as inhibition of the action of B-lymphocyte nuclear factor kappa (NF-κB), a key factor in the development of inflammation. In addition, the growth factor EGR-1 (early growth response protein 1) controls the production of proinflammatory cytokines, such as interleukin-2 (IL-2) or tumor necrosis factor-α (TNF-α). This transcription factor is inhibited by another called NAB-1 (Nerve growth factor 1A-binding protein). Several studies have shown that lipoxins secreted by neutrophils are able to potentiate the synthesis of NAB-1 to the detriment of EGR-1 to control inflammation. On the other hand, lipoxins also exert their action on another transcription factor that helps to enhance inflammation: PPAR-γ (Chandrasekharan and Sharma-Walia, 2015).

Lipoxins stop polymorphonuclear leukocyte infiltration and limit dendritic cell migration by inhibiting IL-1 synthesis by antigen-presenting cells (APCs). Likewise, lipoxins cause an inhibition of proinflammatory cytokine production by Th1 cells, resulting in an inhibition of proinflammatory type 1 macrophages. In addition, lipoxins stimulate the recruitment of monocytes and the uptake of apoptotic polymorphonuclears by type 2 macrophages, a process that also involves mediators of inflammation resolution called maresins. Finally, lipoxins inhibit the production of metalloproteases by fibroblasts, limiting their tissue-destroying action (Chandrasekharan and Sharma-Walia, 2015).

## Catabolism

Eicosanoids have a very short half-life, degrading very rapidly once they have been synthesized. In general, inactivation takes place in a first phase by the action of specific enzymes, which act very rapidly on the various types of eicosanoids. In a second, slower phase, the metabolites resulting from the first inactivation continue their catabolism by non-specific enzymes, some of which are those that usually act in the degradation of fatty acids (β-oxidation system). The main site of eicosanoid catabolism is the lung (Yonker et al., 2021).

## Biological effects

As noted above, eicosanoids have a very short half-life, so they act only in the cells that produce them or in their immediate environment. Their biological effects are, in general, broad and intense. It is important to note, however, that these effects are highly variable. There are differences depending on the species, tissue or organ, as well as between the different types of eicosanoids. But there may even be opposing effects, depending on the amounts of a given compound used. The most prominent effects of eicosanoids are described below (Kumar et al., 2020).

### Effects on the formed elements of the blood

As will be described in detail later, PGI<sub>2</sub> inhibits platelet aggregation, while TXA<sub>2</sub> stimulates it. LTB<sub>4</sub> is a potent chemotactic agent on polymorphonuclear leukocytes, monocytes and eosinophils, which contributes significantly to the inflammatory reaction. In addition to activating phagocytes, LTB<sub>4</sub> is involved in the differentiation of T lymphocytes into Th1 and Th2 in the early stages of the inflammatory process and stimulates the adhesion of neutrophils to the vascular endothelium and their transendothelial migration to the inflammatory focus. In contrast, lipoxins act in the opposite way on neutrophils. PGE<sub>2</sub>, at high concentrations, inhibits the differentiation of B lymphocytes and the proliferation of T lymphocytes, thus behaving as an immunosuppressant (Imig, 2020).

### Effects on the cardiovascular system

Prostaglandins are vasodilators in general, especially those of the E series, although exceptions occur in certain vascular areas. Generally, they also lower blood pressure and increase cardiac output. The hypotensive effect is very marked for PGI<sub>2</sub>. In contrast, PGF<sub>2</sub>, LTC<sub>4</sub> and LTD<sub>4</sub> and TXA<sub>2</sub> are vasoconstrictors and hypertensors (Piper and Garelnabi, 2020).

### Effects on the uterine musculature

Prostaglandins of the E and F series, as well as TXA<sub>2</sub>, contract the uterine musculature. In fact, prostaglandins E and F are inducers of labor and can be used in therapeutic abortion (Szczuko et al., 2020).

### Effects on the gastrointestinal tract

PGI<sub>2</sub> and PGE<sub>2</sub> inhibit acid secretion in the stomach. Prostaglandins of the E series also increase mucus secretion in the stomach and small intestine and stimulate intestinal motility.

### Effects on the kidney

PGE<sub>2</sub> and PGI<sub>2</sub> decrease vascular resistance and increase renal blood flow. In addition, PGE<sub>2</sub> inhibits the reabsorption of sodium chloride in the cortical collecting tubes, hinders the action of antidiuretic hormone and stimulates the release of renin. TXA<sub>2</sub>, which is vasoconstrictor, is also produced in the kidney.

### Effects on the bronchial tree

Prostaglandins of the E series relax the musculature of the bronchi and trachea, while those of the F series produce bronchospasm. The bronchoconstrictor action is especially important in the case of the leukotrienes LTC<sub>4</sub> and LTD<sub>4</sub> (Yonker et al., 2021).

### Effects on the central nervous system

PGE<sub>2</sub>, PGI<sub>2</sub> and LTB<sub>4</sub> act on afferent nerve endings, lowering the pain threshold at nociceptors. These compounds can, therefore, amplify the sensation of pain in inflammatory processes.

### Effects on the endocrine system

The prostaglandins of the E series exert a multitude of actions on the endocrine system, being able to emphasize the stimulus on the production of adrenocorticotrophic hormone (ACTH), growth hormone, gonadotropins and prolactin, as well as the inhibition of insulin secretion. On the other hand, 12-hydroxy eicosatetraenoic acid (12-HETE) seems to favor the latter secretion.

### Effects on metabolism

In addition to the effects derived from the action of eicosanoids on the endocrine system, it is interesting to note the direct anti-lipolytic effect on adipose tissue of prostaglandins of the E series.

## Pathophysiological implications

Given the diversity of biological actions of eicosanoids and taking into account the fact that most of the cells of the organism are capable of synthesizing them, it is not surprising that these compounds are involved in numerous pathological processes. In most cases, functional alterations seem to be due to excess production, although there can also be problems due to deficiencies. In this case, the cause may be a deficiency of precursors, but they are often the result of certain drug treatments that prevent their tissue synthesis.

### Eicosanoids, inflammation and anti-inflammatory drugs

Some eicosanoids are important biochemical mediators in the inflammatory reaction. As noted above, LTB<sub>4</sub> has a very marked chemotactic activity on various blood cells involved in this process, especially polymorphonuclear cells and monocytes. Once they have crossed the endothelium, these cells reach the inflammatory focus and can perform their characteristic phagocytic functions. On the other hand, PGE<sub>2</sub> and PGI<sub>2</sub> are responsible for the hyperemia typical of inflammatory lesions due to their vasodilator character and contribute to pain and fever, amplifying the action of other mediators such as bradykinin.

Lipoxins intervene, above all, in the resolution of inflammation, because they impede the flow of neutrophils to the inflammatory focus. Some recently discovered polyunsaturated fatty acid derivatives of the n-3 series, including E-resolvins, derived from EPA, and the docosanoids D-resolvins, protectins and maresins, are also involved in the resolution of inflammation (Chandrasekharan and Sharma-Walia, 2015).

There is a large number of anti-inflammatory drugs, most of which inhibit the synthesis of eicosanoids. Some, such as aspirin and other non-steroidal anti-inflammatory drugs, exert their mechanism of action through the inhibition of cyclooxygenase, which prevents the formation of prostaglandins, prostacyclins and thromboxanes. Others, such as cortisol derivatives, also suppress the formation of the linear series eicosanoids, because they act by inhibiting COX-2 and phospholipase A<sub>2</sub> (steroidal anti-inflammatory drugs). All these drugs are widely used in the symptomatic treatment of inflammation, often on a chronic basis (Kumar et al., 2020).

Logically, the suppression of eicosanoid biosynthesis does not exclusively affect the inflamed regions, but also produces a decrease in this biosynthesis in other organs and tissues, causing the corresponding pathological alterations. The side effects of continuous or high-dose use of anti-inflammatory drugs are particularly evident in the stomach and kidney.

Indeed, prostaglandins, especially PGE<sub>2</sub> and PGI<sub>2</sub>, inhibit the secretion of hydrochloric acid and pepsin and promote mucus formation. Therefore, they can be considered cytoprotective of the gastric mucosa. Inhibition of the synthesis of these prostaglandins by the use of anti-inflammatory drugs can therefore lead to ulceration and bleeding.

In the kidney, PGE<sub>2</sub> and PGI<sub>2</sub> are produced in significant amounts when perfusion decreases, causing compensatory vasodilation. In addition, sodium chloride reabsorption is inhibited and there is an inhibitory effect on antidiuretic hormone, increasing diuresis. On the other hand, these prostaglandins stimulate the release of renin, which represents a potential feedback mechanism. Inhibition of prostaglandin synthesis causes less vasodilation, eventually leading to renal lesions. Blood pressure does not change much because, although there is less diuresis, renin production also decreases. However, the decrease in water excretion leads to edema. And the reduced functioning of the renin-angiotensin system produces hyperkalemia.

### **Eicosanoids and bronchial asthma**

Although the different types of prostaglandins have opposing effects on the bronchial tree (see above), the action of peptidyl-leukotrienes, LTC<sub>4</sub> and LTD<sub>4</sub>, which are very potent bronchoconstrictors, strongly predominates. Their release by sensitized cells, in the anaphylactic process, strongly contributes to the clinical picture, especially during the intercritical periods. Precisely, before their isolation, peptidyl-leukotrienes were called “slow reacting substances of anaphylaxis” (Sokolowska et al., 2021).

### **Eicosanoids and immune response**

Eicosanoids appear to be involved in the regulation of the immune response, although many aspects of this regulation are still unknown. In any case, it is well established that PGE<sub>2</sub> is necessary for lymphocyte proliferation, but it behaves as an immunosuppressant when found in high concentrations, for example, when polyunsaturated fatty acids of the n-6 series are used in parenteral nutrition. This prostaglandin decreases, especially, the effects of IL-1 and IL-2 on T lymphocytes. The immunosuppressive effect is counterproductive in patients undergoing parenteral nutrition, because it favors postoperative infections. However, it can be useful when it comes to slowing down transplant rejection (Calder, 2020).

### **Eicosanoids and bone resorption**

Some tumors that do not affect the parathyroid glands, such as medullary thyroid carcinoma or mammary gland carcinoma, cause hypercalcemia due to bone resorption. It seems likely that the mediator for this effect is PGE<sub>2</sub>, which is released in large quantities from the tumor. This prostaglandin may also be the cause of hypotension and other systemic effects that occur in these conditions. Other sources of PGE<sub>2</sub> that also cause bone resorption are synovial fluid in rheumatoid arthritis and certain dental cysts.

### **Eicosanoids and reproduction**

Prostaglandins of the F series strongly contract the uterine musculature and sensitize afferent pathways for pain. Therefore, prostaglandin synthesis inhibitors are used to relieve symptoms in dysmenorrhea. Conversely, using the same effect on the uterus, structural analogs of these prostaglandins have been tested for therapeutic abortions. There seems to be a relationship between the concentration of prostaglandins in the seminal fluid and male fertility, although the data are not yet incontrovertible. On the other hand, the vasodilator effect of PGE<sub>1</sub> has been used to achieve penile erection by intracavernous injection (Szczuko et al., 2020).

### **Eicosanoids and arteriovenous duct persistence in neonates**

PGI<sub>2</sub> is capable of dilating this duct in newborns. For this reason, it is used palliatively while waiting for surgery, in cases in which pulmonary circulation is affected by the existence of heart disease, thus improving tissue oxygenation. In contrast, prostaglandin synthesis inhibitors are indicated when there is pathological persistence of the arteriovenous duct.

### **Eicosanoids and wound healing**

Among arachidonic acid metabolites, several COX and cytochrome P-450 products have demonstrated a positive effect on skin wound healing through various activities, including modulation of clotting, macrophage polarization, keratinocyte migration, and angiogenesis, and the metabolites produced by the 5-LOX pathway such as LTs delayed the process of skin wound healing partially via the mechanisms of excessive inflammation, including neutrophil recruitment and reduced macrophage polarization to M2 phenotype (Yasukawa et al., 2020).

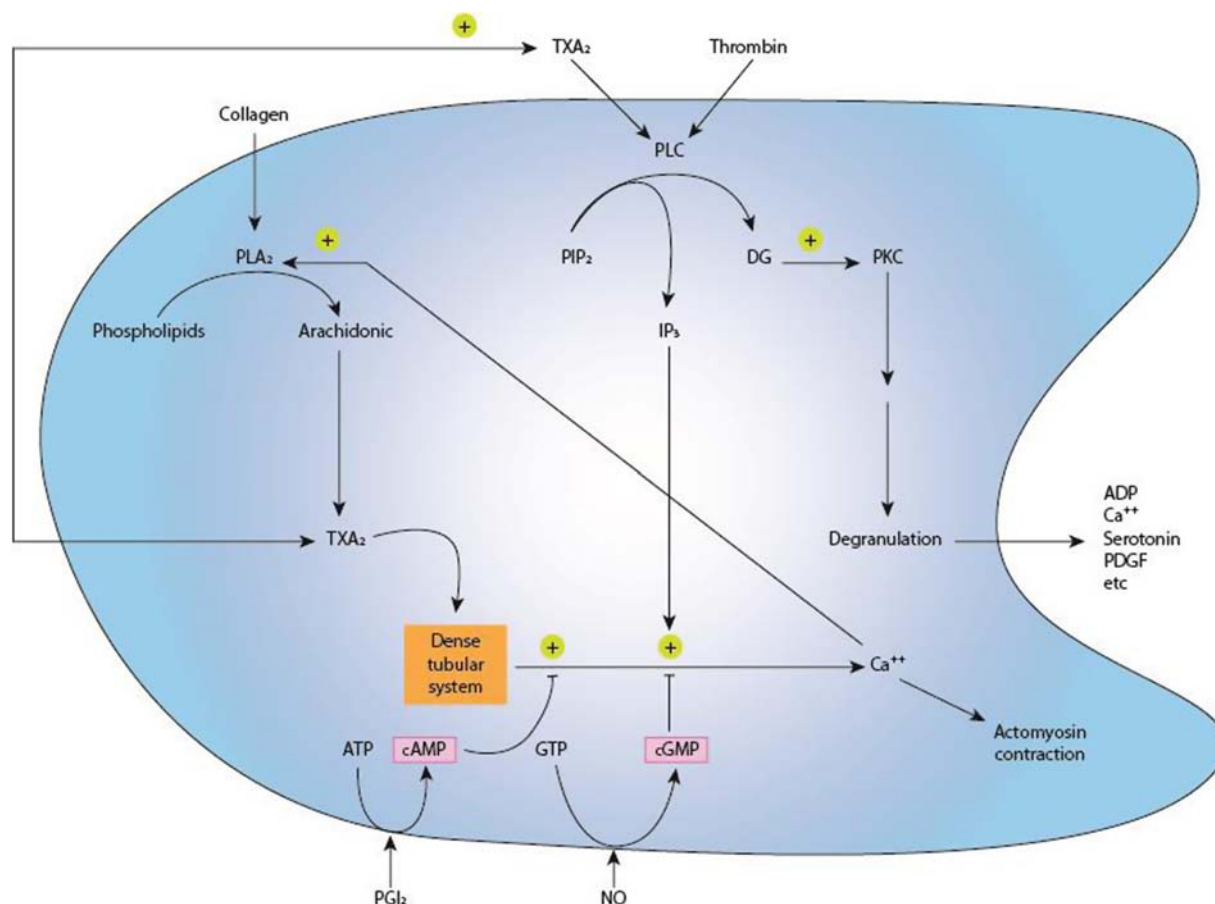

## Eicosanoids and diet

It is important to note that the relative proportions of the different series of eicosanoids in the body depend on the type of diet. The usual diet in the Western world, based on vegetables and terrestrial animals, leads to a preponderance of series 2, derived from arachidonic acid. It should be remembered that this compound, in turn, is derived from linoleic acid, which is abundant in the vegetable world. On the other hand, since  $\alpha$ -linolenic acid is very abundant in algae, aquatic animals are rich in this acid and its long-chain derivatives, including eicosapentaenoic acid (EPA). Therefore, the intake of fatty fish in relatively high quantities leads to a significant increase in eicosanoids of the 3 series in the organism. Series 1 of eicosanoids, i.e., derived from eicosatrienoic acid (20:3 n-6), are not very abundant, unless large amounts of  $\gamma$ -linolenic acid are ingested. This compound, which is found only in some terrestrial plant species, such as evening primrose (*Oenothera biennis*) or borage (*Borago officinalis*), is easily converted to eicosatrienoic acid, which greatly favors the formation of series 1 of eicosanoids.

In general, eicosanoids of series 2, the most abundant in our organism given the characteristics of our diet, are very active. On the contrary, series 3 of eicosanoids tend to have less biological activity. Particularly,  $\text{TXA}_3$  is very little platelet proaggregant and  $\text{LTB}_5$  is very little chemotactic on leukocytes. As has just been pointed out, these compounds originate in certain quantities when the intake is very rich in polyunsaturated acids of the n-3 series, derived from fish and other aquatic animals. Under these conditions, certain pathophysiological processes can be altered, as described below, when studying the regulation of platelet aggregation.

## Regulation of platelet aggregation

Platelets are corpuscles without nuclei derived from the fragmentation of megakaryocytes, which play a fundamental role in hemostasis. Platelet activity is triggered by primary stimuli (collagen, thrombin, adrenaline) and by substances that can be released by activated platelets themselves (serotonin, ADP, calcium ions, platelet activating factor (PAF) and  $\text{TXA}_2$ ). There are also inhibitory factors, such as prostacyclin ( $\text{PGI}_2$ ) and nitric oxide (NO). All these substances appear to have specific receptors on the platelet membrane (Imig, 2020). Fig. 6 summarizes the mechanisms of the platelet response following stimulation of some of these receptors.

**Fig. 6** Regulation of platelet aggregation. DAG: diacylglycerol;  $\text{IP}_3$ : inositoltriphosphate; NO: nitric oxide; PDGF: platelet-derived growth factor;  $\text{PGI}_2$ : prostacyclin;  $\text{PIP}_2$ : phosphatidylinositol bisphosphate; PKC: protein kinase C;  $\text{PLA}_2$ : phospholipase  $\text{A}_2$ ; PLC: phospholipase C;  $\text{TXA}_2$ : thromboxane  $\text{A}_2$ .

The interaction between primary stimuli and platelet substances with receptors results in the release of calcium ions from the dense tubular system into the cytoplasmic space. In this cellular compartment, calcium ions stimulate calmodulin, leading to phosphorylation of the myosin light chains, which finally causes the actomyosinic contraction responsible for platelet shape changes and platelet movements.

The release of calcium ions into the cytosol can be considered the fundamental mechanism for triggering platelet activity. The main stimulus for this release appears to be  $IP_3$ , which is produced when phospholipase C is activated by thrombin, ADP, calcium ions themselves or  $TXA_2$ . This last compound can be considered as the main positive regulator of platelet activity, since it is capable, in turn, of directly intervening in the release of calcium ions from the dense tubular system into the cytosolic space and, in addition, once it is synthesized inside the platelet, it can exit into the plasma and stimulate other platelets. The compounds that trigger thromboxane formation are collagen, PAF and probably calcium ions and ADP. All these effectors activate phospholipase  $A_2$ , arachidonic acid is released from membrane phospholipids and thromboxane is produced as the main product, thanks to the intense activity of thromboxane synthetase in the platelet.

Activation of phospholipase C by thrombin and the other effectors mentioned above produces 2 s messengers:  $IP_3$  and diacylglycerol. The latter activates protein kinase C, which causes phosphorylation of a platelet protein, pleckstrin, which acts on the alpha and dense granules, producing the release of their contents. The dense granules contain, among other substances, ADP, calcium ions and serotonin, all of which stimulate platelet activity. The content of the alpha granules is more related to the coagulation phenomenon (platelet factor 4,  $\beta$ -thromboglobulin, platelet-derived growth factor [PDGF], fibrinogen, etc.). It is worth noting that the release of PDGF plays a key role in the growth of the atheroma, when platelets adhere to it as a consequence of its rupture, since this growth factor acts by strongly stimulating the proliferation of smooth muscle cells.

In the platelet there is also a system for reuptake of calcium ions into the tubular system, a process that is stimulated by cyclic AMP. The synthesis of this nucleotide increases when the adenylate cyclase of the platelet membrane is activated by the action of prostacyclin ( $PGI_2$ ). This eicosanoid is the main product of arachidonic acid in endothelial cells after activation of phospholipase  $A_2$ . Therefore, the release of prostacyclin by the endothelium constitutes a negative regulatory system of aggregation. The role of endothelial cells in the control of platelet activity is not limited to prostacyclin release (Katusic et al., 2012). These cells can also generate nitric oxide, which is capable of interacting with platelets and stimulating the reuptake of calcium ions, in this case through cyclic GMP.

Although the mechanisms are more complicated, it can be concluded that platelet aggregation is largely regulated by the relationship between the concentrations of two eicosanoids: thromboxane and prostacyclin. It is interesting to remember that  $TXA_2$  is also a vasoconstrictor, whereas prostacyclin is a vasodilator. Therefore, any factor that alters the delicate balance between platelet production of  $TXA_2$  and endothelial release of  $PGI_2$  can affect the aggregation process, as well as the state of constriction or dilatation of the corresponding artery. Thus, when the endothelium is subjected to aggression, prostacyclin production decreases and the balance shifts toward aggregation. This is what occurs both in the development of the atherogenic process and in the thrombotic phenomena that trigger clinical problems (Nakahata, 2008).

As previously described, the type of diet can condition the proportion of the different series of eicosanoids in the organism. Thus, the intense consumption of fats of marine origin and, consequently, the increase in polyunsaturated fatty acids of the n-3 series, will give rise to important quantities of eicosanoids of the 3 series. Under these conditions, platelets form  $TXA_3$ , while endothelial cells generate  $PGI_3$ . The latter retains an anti-aggregating activity very similar to that of  $PGI_2$ . In contrast,  $TXA_3$  is very poorly aggregative. As a result, it decreases platelet activity, as evidenced even by the occurrence of spontaneous nosebleeds. In fact, populations that consume many marine animals (such as Eskimos or the inhabitants of certain Japanese islands) have a very low incidence of thrombotic problems.

It is also interesting to note that platelet activity can be decreased by administration of very low doses of acetylsalicylic acid. This drug binds irreversibly and covalently to platelet cyclooxygenase, completely inhibiting its activity. This inhibition prevents the production of thromboxane during the entire platelet lifetime, because, lacking a nucleus, the disabled enzyme cannot be replaced. In contrast, the inhibition of endothelial cyclooxygenase is not permanent, since these cells have the capacity to synthesize new enzymatic proteins. The use of very low doses of the drug allows inhibition of platelet thromboxane synthesis and has little effect on endothelial prostacyclin synthesis, achieving a good antiaggregant effect (Kumar et al., 2020).

## Conclusions

Prostaglandins, prostacyclins, thromboxanes and leukotrienes belong to a large, heterogeneous group of lipid mediators, collectively named eicosanoids, that exhibit a diverse array of physiological activities. Eicosanoids are synthesized by oxygenation and remodeling of their precursor 20-carbon polyunsaturated fatty acids, namely arachidonic acid. Although pivotally involved in many homeostatic processes, eicosanoids are also implicated in the pathophysiology of many chronic disorders. Since the discovery in the mid- 1930s of prostaglandins as a component of human semen that potentially induced uterine contractility, the field of eicosanoid biology has expanded to include other groups such as hydroxyeicosatetraenoic acids, lipoxins, isoprostanes, and the cyclopentanone prostaglandins. Except for the latter two classes, which are generated by nonenzymatic oxidation, synthesis of these mediators is tightly regulated by a number of enzymes. Eicosanoids generally act as paracrine or autocrine agents, in that they exert their biological effects locally, either on the cell from which they were synthesized or on neighboring cells.

### Glossary

**Acidemia** The presence of a low blood pH.

**Acidosis** The clinical term for a state of excess acid in the blood, further defined by its etiology, either metabolic or respiratory in origin.

**Alkalemia** The presence of an elevated blood pH.

**Alkalosis** The clinical term for a state of excess alkali in the blood, further defined by its etiology, either metabolic or respiratory in origin.

**Buffer** Solution of a salt of a weak acid, which is able to bind hydrogen ions.

**Renal tubular acidosis** A group of conditions where metabolic acidosis results from diminished tubular secretion of hydrogen ions by the kidney.

Maintenance of cellular and extracellular pH (hydrogen ion concentration) is essential to life, in view of the exquisite pH dependence of processes such as enzyme function. Hydrogen ions ( $H^+$ ) are generated by cellular metabolism and, to a lesser extent by the ingestion of acids in the diet. Acid–base homeostasis regulates pH between 7.36 and 7.44 (corresponding to a  $[H^+]$  of 36–44 nmol  $l^{-1}$ ) in extracellular fluids, such as blood, whereas intracellular pH is more acidic (pH 6.3–7.4) depending on individual organs and circumstances. The pH of subcellular organelles may be yet more acidic, reflecting their physiological function (e.g., lysosomes). Blood and extracellular fluid pH are tightly regulated by the presence of buffer systems, which effect change as a consequence of acid load. These buffer systems, both extracellular and intracellular, include hemoglobin, other proteins, phosphate, and bicarbonate – the latter being most important. However, the acid load must ultimately be eliminated by subsequent excretion of volatile acids by the lungs and fixed acids by the kidney.

## Definitions, Acids, Bases, and Buffers

### pH

The term pH is an expression of hydrogen ion ( $H^+$ ) concentration (such that pH and  $H^+$  are inversely related)(eqn [1]).

$$pH = -\log_{10}[H^+] \quad [1]$$

### Acids and Bases

Acids are substances that dissociate to donate  $H^+$  (eqn [2]); the stronger the acid, the more readily it dissociates. The dissociation constant ( $pK_a$ ) is the pH at which 50% of the acid is dissociated. At pH values greater than  $pK_a$  more  $H^+$  will dissociate; the lower the  $pK_a$ , the stronger the acid. A base is a substance that accepts hydrogen ions. In the following text, ‘fixed acid’ is used to describe formed acid, and ‘volatile acid’ is used to describe the potential acid load imposed by carbon dioxide ( $CO_2$ ). Where ‘A’ represents an acid, the following applies:

The importance of this relationship in physiological terms is that because the  $pK_a$  of most organic acids is much lower than the pH of extracellular fluids, most organic acids exist in a dissociated state – as acid anion salts – the free  $H^+$  being buffered. In urine, where the minimum achievable pH is approximately 5, most strong acids (with a  $pK_a$  below this value) will be in a dissociated state, necessitating the excretion of  $H^+$  together with urinary buffers.

Acidosis is the term used to describe conditions where pH is low and those where pH would be low were it not appropriately buffered; similarly alkalosis is the term used for a high pH and for a potentially elevated pH that has been appropriately buffered. Acidemia and alkalemia reflect low or elevated blood pH. It is common to describe an acidosis/alkalosis as respiratory or metabolic depending on causation.

### Buffers

Buffering is the ability of weak acids, present in excess, to accept  $H^+$  donated from strong acids, thus limiting changes in free  $H^+$  concentrations and pH changes (eqn [3]):

The principal buffer system in blood (and other extracellular fluids) is based on bicarbonate ( $HCO_3^-$ ), accounting for approximately 70% of the buffering capacity of blood. In blood,  $CO_2$  (the major product of oxidative metabolism) reacts with water, in the presence of the enzyme carbonic anhydrase (CA), to form carbonic acid ( $H_2CO_3$ ). This compound is relatively unstable and tends to dissociate (eqn [4]). The rate of formation of carbonic acid is dependent on the concentration of carbon dioxide and the rate constant of reaction [i]; the dissociation of carbonic acid to generate  $H^+$  and  $HCO_3^-$  is governed by the rate constant of reaction [ii]. In practice, these two reactions can be combined, and the relationship between pH ( $[H^+]$ ), carbon dioxide, and bicarbonate is described by a single equation – the Henderson–Hasselbalch eqn [5]:

$$pH = 6.1 + \log_{10}([HCO_3^-]/K.S.PCO_2) \quad [5]$$

pH reflects  $-\log [H^+]$ ; 6.1 is the value of  $-\log (1/K)$ , K being the equilibrium constant describing the overall eqn [4];  $PCO_2$  is the partial pressure of carbon dioxide; S is the solubility constant for carbon dioxide. K.S. is constant and equal to 0.225 (when  $PCO_2$  is measured in kPa, 0.03 when  $PCO_2$  is measured in mmHg). Table 1 shows the normal range for these parameters in humans.

From eqn [5] the principles of acid–base balance can be appreciated. Acidification may occur in two ways: either by production of  $CO_2$  or by the consumption of bicarbonate (as part of buffering of fixed acid). The excretion of  $CO_2$  is controlled by the lungs, and excretion of fixed acid takes place in the kidney.

**Table 1** Normal ranges

Variable	Normal range
pH	7.36–7.44
Hydrogen ion ( $H^+$ )	37–44 nmol $l^{-1}$
Partial pressure $CO_2$ ( $PCO_2$ )	34–46 mm Hg
	4.5–6.1 k Pa
Bicarbonate $HCO_3^-$	24–30 mmol $l^{-1}$

The Henderson–Hasselbalch equation allows basic understanding of acid–base physiology, in health and disease but has limitations. In the presence of either metabolic or respiratory derangement of acid–base homeostasis it does not allow assessment of the severity of the metabolic derangement, analogous to the respiratory component. It also does not assess the influence of other acids other than carbonic acid. For this reason some authors propose analysis of acid–base physiology using a more complex method based on the principals of physical chemistry. This method proposes that all changes in pH of plasma can be explained in terms of relative concentrations of  $\text{CO}_2$ , relative electrolyte, and weak acid. This concept allows more rigorous interrogation of acid–base disorders and may permit greater insight into their pathophysiology and management.

## Maintenance of the pH of Blood and Extracellular Fluids

### Acid and Alkali Load

The sources of acids (and alkalis) are the diet and metabolism. The major potential source of acid is  $\text{CO}_2$  ('volatile acid') (eqn [4]), generated by oxidative metabolism; a total of 12–20 moles of  $\text{CO}_2$  are produced daily. Other metabolic products include lactic acid, other organic acids, and urea, the synthesis of which produces  $\text{H}^+$ . Because of its role in the metabolism of lactic acid and in the synthesis of urea, the liver plays a major role in acid–base homeostasis that is often not appreciated.

The lungs excrete volatile acid,  $\text{CO}_2$ , whereas the breakdown of sulfur- and phosphorus-containing compounds are 'fixed' acids. For example, cysteine or methionine metabolism leads to production of sulfuric and phosphoric acid ( $\text{H}_2\text{SO}_4$ ,  $\text{H}_3\text{PO}_4$ ), and metabolism of other amino acids (lysine, arginine, and histidine) to hydrochloric acid (HCl). In contrast, organic acids (e.g., lactate, fatty acids) may be completely metabolized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  and thus excreted by the lungs. In addition, absorption of dietary phosphate and fecal loss of bicarbonate represent an additional acid load. In total, the net acid load of fixed acid is approximately  $1 \text{ mmol kg}^{-1} \text{ day}^{-1}$  and may be increased by a high protein intake or reduced by a strict vegetarian diet.

There is surprisingly little information on the direct contributions of individual foods to the acid burden. However, this source of dietary acid is of increasing importance in view of weight reduction diets (e.g., the Atkins diet). The major acids contained in food are citric acid (in fruit), acetic acid (as a preservative, pickles, vinegar), lactic acid (yogurt, fermented foods), malic acid (fruit), oxalic acid (vegetables, that contain smaller amounts of citric and malic acids), and tartaric acid (wine). Oxalic acid precipitates in the gut to form calcium salts, excreted in the stool, and little is absorbed. The others are absorbed but quickly metabolized and present an acid burden in the form of carbon dioxide. The largest source of fixed acid comes from the metabolism of amino acids (particularly those from animal proteins). The significance of this source of acid is readily demonstrated in patients taking a high-protein diet – particularly one rich in animal protein – who have increased urinary acid excretion. Based on studies on the relationship between diet, renal excretion of acid, and urine pH it is theoretically feasible to quantify urinary acid excretion for individual foods. However due to daily variation in diet (and therefore absence of a metabolic steady state) and inherent variation in the composition of food-stuffs, it has not been possible to estimate accurately the effects of diet on renal acid–base metabolism in circumstances reflective of normal dietary intake.

Alkalis are often prescribed to compensate metabolic acidosis and have often been used to neutralize gastric acidity. Milk and milk products are also alkaline but seldom cause any disturbance, unless consumed in great excess. Excessive consumption of milk or alkali is now rarely seen.

## Regulation

Blood and extracellular fluid pH is regulated at three levels: (1) buffering within the blood and tissues; (2) excretion of volatile acids by the lungs; (3) excretion of fixed acids by the kidney. Although buffering is immediate, respiratory compensation occurs over minutes to hours and renal excretion can take from hours to days (Table 2).

### Blood/Extracellular Fluid

Immediate buffering of an acid load, for example by release of lactic acid and  $\text{CO}_2$  by anaerobic and aerobic metabolism in exercising muscle, occurs in blood and other extracellular fluids. Together they contain approximately 350 mmol of bicarbonate buffer. 60–70% of the buffering capacity of blood is accounted for by the bicarbonate buffer system; 20–30% is dependent on direct binding to hemoglobin and to other proteins, including plasma proteins. Blood is in equilibrium with extracellular fluid  $\text{H}^+$ .  $\text{H}^+$  ions move across cell membranes depending on concentration and charge, thus  $\text{H}^+$  ions may move into cells in exchange for  $\text{K}^+$  (and to a lesser extent  $\text{Na}^+$  ions) when extracellular  $\text{H}^+$  is increased. Hence acidosis is often accompanied by increased serum  $\text{K}^+$ , and alkalosis by low  $\text{K}^+$ . Large amounts of  $\text{H}^+$  may be 'buffered' by direct binding to proteins within cells and tissues, particularly bone where  $\text{H}^+$  are also buffered by calcium salts, such as apatite.

### Lungs

The lungs excrete volatile acid ( $\text{CO}_2$ ) by changes in the rate and volume of respiration. This is regulated by respiratory centers in the brainstem, that respond to changes in the pH of cerebrospinal fluid (that is in equilibrium with extracellular fluids elsewhere in the

**Table 2** Buffering and acid–base regulation

Mechanism	Site	Role (time)
Protein (e.g., Hb)	Cell	Rapid binding of $H^+$ (s)
Bicarbonate buffer	ECF	Buffering of $H^+$ (s)
Ventilation	Lungs	Excretion of $CO_2$ , respiratory compensation (h)
Fixed acid excretion	Kidney	Excretion of $H^+$ , reabsorption and regeneration of bicarbonate, renal compensation (h–days)

body), and signals from chemoreceptors in the carotid and aortic bodies that are responsive to changes in pH and  $PCO_2$  of arterial blood (increased  $PCO_2$  or reduced pH cause an increase in respiration). Thus, acidosis leads to an increase in respiratory rate and ventilatory volume (the pattern in severe acidosis being described as Kussmaul breathing) and alkalosis to the opposite effect.

## Kidneys

The kidneys have two major roles in acid–base homeostasis: the recovery of filtered bicarbonate and generation of new bicarbonate; and excretion of fixed acid (Figures 1 and 2; eqn [5]). Blood is filtered in the glomeruli and the glomerular filtrate is subsequently modified in the renal tubules so that the final urine volume is less than 1% of the glomerular filtrate volume. Plasma bicarbonate concentration is approximately  $25 \text{ mmol l}^{-1}$  and glomerular filtration rate (GFR)  $100 \text{ ml min}^{-1}$ , thus 3600 mmol of bicarbonate must be reabsorbed daily. Bicarbonate reabsorption mainly occurs in the proximal convoluted tubule (PCT). 85% of filtered bicarbonate is reabsorbed here, 10% in the thick ascending limb of the Loop of Henle, the remainder being titrated to regulate total acid excretion, in the collecting duct (Figures 1 and 2). As shown, different mechanisms are involved at each tubular site. The enzyme carbonic anhydrase, on the luminal brush border of tubular cells, catalyzes the combination of filtered bicarbonate with  $H^+$ , secreted by the apical  $H^+$ -ATPase and  $Na^+/H^+$  exchangers on tubular cells, to generate  $CO_2$ .  $CO_2$  then diffuses into the tubular cells down its concentration gradient. Within the tubular cell, carbonic anhydrase catalyzes the reverse reaction, which generates  $H^+$  and  $HCO_3^-$ . Hydrogen ions are then recycled to the tubular lumen and bicarbonate is secreted into the extracellular fluid by basolateral anion exchangers or  $Na^+-HCO_3^-$ , cotransporters. Tubular cells are also exposed to  $CO_2$  in the extracellular fluid and will continue to generate  $H^+$  even in the absence of filtered bicarbonate. This  $H^+$  is then buffered by other buffers in the glomerular filtrate including  $HPO_4^{2-}$  and, to a lesser extent, creatinine. Strong acids, (e.g.,  $H_2SO_4$ ) with low  $pK_a$  values will dissociate in the urine (pH range 5–8), and be buffered whereas weaker acids may be excreted intact. In the presence of alkalosis, cellular transporters

**Figure 1** Recovery of filtered bicarbonate in the proximal convoluted tubule.

**Figure 2** Excretion of acid in the collecting duct.

and their function may be reversed so that  $\text{H}^+$  secretion occurs on the basolateral membrane and  $\text{HCO}_3^-$  on the brush border of tubular cells resulting in alkaline urine.

Classically, the final mechanism by which the kidney can excrete  $\text{H}^+$  is by generation of ammonium ( $\text{NH}_4^{2+}$ ) from metabolism of glutamine by glutaminase (Figure 2), a process that is stimulated by low pH and increased  $\text{PCO}_2$ . Excretion of  $\text{H}^+$  as part of ammonium accounts for approximately  $70 \text{ mmol day}^{-1}$ , increasing several-fold (albeit over a period of days) in the face of an acid load. Whether this is truly a urinary buffer is the subject of some debate as ammonium ( $\text{NH}_4^{2+}$ ) is generated directly from glutamine rather than accepting additional protons. There are alternative mechanisms for the role of  $\text{NH}_4^+$  in overall acid–base homeostasis that involve the liver. After being pumped into the glomerular filtrate,  $\text{NH}_4^+$  may be reabsorbed by the tubule and used by the liver to synthesize urea, generating free  $\text{H}^+$  ions. Thus, there is no net loss of  $\text{H}^+$ . Thus, the overall role of  $\text{NH}_4^+$  in acid–base balance is dependent on the balance between tubular reabsorption of  $\text{NH}_4^+$  and the hepatic synthesis of urea. The latter function may also be directly influenced by extracellular pH.

### Liver and Bone

The liver also plays additional roles in acid–base balance that may be underestimated. For example, the liver metabolizes lactate and ketoacids; the rate of metabolism is dependent on pH (e.g., ketogenesis is suppressed at low pH) and may be exceeded at higher concentrations of lactate or in liver disease. The synthesis of urea from ammonium and carbon dioxide (see Section on Kidneys) results in genesis of two protons, and is reduced in the presence of acidosis. Some buffering also occurs in bone due to slow exchange of bone calcium carbonate for extracellular phosphate.

### Measurement of Urinary Acid Excretion

Urinary pH can be measured by commercially available ‘dipsticks’ or by using a pH meter on a fresh sample of urine. Loss of  $\text{CO}_2$  or the production of  $\text{NH}_4^+$  from urea-splitting organisms in infected urine will alter the pH with time. The excretion of fixed acid can be determined by chemical titration of urine to pH 7.4, and is commonly termed ‘titratable’ acidity. The amount of  $\text{NH}_4^+$  is usually estimated from the difference between the most abundant cation ( $\text{Na}^+$ ,  $\text{K}^+$ ) and anion ( $\text{Cl}^-$ ) concentrations in the urine.

### Effects of Acid–Base Disturbance

In addition to the adaptive changes occurring in acidosis, a range of metabolic and pathophysiological changes occur; alkalosis tends to produce opposite but milder effects. Metabolism of carbohydrate is altered; both glycolysis and gluconeogenesis are

inhibited in the liver. Delivery of oxygen to the tissues is increased by the reduced ability of hemoglobin to retain oxygen in an acid environment (the Bohr effect). Consciousness is impaired, leading to coma in severe cases. However, the most important effects from a clinical perspective are cardiovascular: vasodilatation occurs in peripheral tissues, cardiac contractility is impaired resulting in reduced blood pressure and, when severe, in reduced tissue perfusion. These adverse effects of acidosis contribute to the high mortality of conditions like septic shock. Conversely, in critically ill patients, often after surgery, severe alkalosis may be equally or more dangerous, particularly in the event of cardiac arrest, where resuscitation is extremely difficult.

## Abnormalities in Acid–Base Balance

Disturbances in acid–base balance are classified either as ‘acidosis’, indicating an excess of  $H^+$  ions in the blood (reduced pH) or ‘alkalosis’, indicating the opposite. In practice, acidosis is often the more common, varied, and serious problem, although profound alkalosis can be life threatening in the critically ill. Disturbances in acid–base balance are usually labeled according to their origin. For example, respiratory acidosis reflects a primary problem in gas exchange with impaired excretion of  $CO_2$ , whereas metabolic acidosis reflects over-production of fixed acid or loss of bicarbonate. Compensation refers to the body's ability to offset the primary problem. Thus, the response to a primary metabolic acidosis is to increase excretion of  $CO_2$ ; respiratory compensation. In a primary respiratory acidosis, increased  $H^+$  is secreted by the kidney with increased bicarbonate generation; metabolic compensation. If the pH returns to normal the problem is said to be ‘fully compensated’ whereas most disturbances tend to only be partially compensated (Table 3). Additionally in some circumstances, a mixed respiratory and metabolic acidosis may be present (e.g., septic shock in a patient with underlying respiratory disease affecting gas exchange).

### Metabolic Acidosis

The main causes of metabolic acidosis are excessive acid production, inappropriate urinary loss of bicarbonate or failure of the kidney to excrete fixed acid. Although the Henderson–Hasselbalch equation provides mathematical information concerning the equilibrium of bicarbonate species, in practice it provides little information regarding the nature of the underlying cause of the acid–base disorder and the concept of ‘anion gap’ is useful in assessing cause of metabolic acidosis. This is derived from the principle of electroneutrality and is calculated thus (eqn [6]):

$$([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) \quad [6]$$

The anion gap represents an artificial disparity between the concentrations of these cations and anions routinely measured in clinical practice, therefore signifying concentration of unmeasured anions such as proteins (the most important in healthy subjects), sulfate, phosphate, and other unmeasured anions. The normal anion gap is  $10\text{--}18\text{ mmol l}^{-1}$  although recent calculations using more sensitive measurements estimate this as  $6\text{--}12\text{ mmol l}^{-1}$ . This concept has limitations but is useful for dividing metabolic acidoses into those characterized by an increased anion gap as a marker of excess generation of organic acids and those with a normal anion gap due to decreased excretion of acid or external losses of bicarbonate. There are exceptions to this rule for example, the acidosis of chronic renal failure but nonetheless, it remains a useful concept in clinical practice. Classification of the causes of metabolic acidoses according to presence of an increased or normal anion gap is shown in Table 4.

### Diabetic Ketoacidosis

The absence of pancreatic insulin secretion in insulin-dependent diabetes results in increased plasma glucose and reduced tissue uptake and utilization of glucose. In place of glucose, there is increased utilization of nonesterified fatty acid (NEFA) as an alternative source of energy that is metabolized to acetyl coenzyme A (acetyl-CoA). Under normal circumstances this substance is further metabolized in the liver *via* the tricarboxylic acid (TCA) cycle to carbon dioxide and water. In diabetic crises this cycle cannot accommodate the excess acetyl-CoA that is instead converted to acetoacetic acid, which can be further reduced to  $\beta$ -hydroxybutyric acid or

**Table 3** Changes in blood and ECF during acid–base disturbance, the mechanism and degree of compensation

Problem	$[H^+]$	$HCO_3^-$	$PCO_2$	Compensation
<i>(a) Metabolic</i>				
Acidosis	↑	$1^\circ \downarrow$	$2^\circ \downarrow$	Partial respiratory
Alkalosis	↓	$1^\circ \uparrow$	$2^\circ \uparrow$	Partial respiratory
<i>(b) Respiratory</i>				
Acidosis	↑	$2^\circ \uparrow$	$1^\circ \uparrow$	Complete renal
Alkalosis	↓	$2^\circ \downarrow$	$1^\circ \downarrow$	Complete renal

↑, increase; ↓, decrease;  $1^\circ$ , primary;  $2^\circ$ , secondary.

**Table 4** Causes of metabolic acidoses according to the presence of an increased or normal anion gap

<i>Increased anion gap</i>	<i>Normal anion gap</i>
Ketoacidosis	Decreased renal acid excretion
Diabetic	Distal renal tubular acidosis
Starvation	
Alcoholic	
Inborn enzyme defects of metabolism	
Lactic acidosis	Loss of alkali
	Diarrhea
	Ureterosigmoidostomy (urinary conduit)
Renal failure	Increased renal bicarbonate loss
	Proximal renal tubular acidosis
	Azetazolamide
	Renal tubular damage
Intoxication	Increased HCl production
Salicylates	Ammonium chloride ingestion
Methanol	Increased catabolism of lysine, arginine
Ethylene glycol	
Paraldehyde	

decarboxylated to acetone. These metabolites are known as 'ketone bodies' and their accumulation results in metabolic acidosis. In diabetic ketoacidosis, homeostatic compensation is to increase ventilation and  $\text{CO}_2$  excretion, leading to the characteristic pattern of Kussmaul breathing.

### Lactic Acidosis

Reduced tissue perfusion, or perfusion that is inadequate to meet the metabolic demands of tissues (such as exercising muscle), results in an inadequate supply of oxygen and a change from oxidative metabolism (the end products of which are  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) to anaerobic metabolism. The end product of anaerobic glycolysis is lactic acid, which is normally metabolized (to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ) by the liver or used in synthesis of glucose (gluconeogenesis). The normal plasma lactate concentration is less than  $1 \text{ mmol l}^{-1}$  but may increase 10-fold in extreme exercise. When the ability to metabolize lactate is exceeded, either by increased production, or reduced delivery to the liver (in, for example, circulatory shock) or in the presence of impaired liver function, accumulation results in metabolic acidosis. Thus, lactic acidosis may occur in a variety of conditions, including both overt circulatory shock and conditions leading to circulatory shock (for example, septic shock), severe diabetic ketoacidosis, as a consequence of drugs (e.g., the oral hypoglycemic agent metformin that inhibits gluconeogenesis and lactate transport), chronic liver disease and poisoning (including ethanol and methanol).

### Excess Bicarbonate Loss

The secretion of acid into the stomach is neutralized by intestinal alkaline secretions. It follows that excessive loss of pure intestinal secretions (e.g., due to an enteric fistula) may lead to acidosis. A more common circumstance is a urinary diversion procedure such as an ileal conduit where the ureters are implanted into an isolated loop of intestine, which is then externalized (a 'urinary conduit'). The delivery of urine rich in chloride to the isolated intestine leads to exchange of  $\text{Cl}^-$  for  $\text{HCO}_3^-$ , and thence to excessive loss of  $\text{HCO}_3^-$  in the conduit, resulting in metabolic acidosis. Historically ureterosigmoidostomies performed for similar clinical indications tends to provoke a more severe metabolic acidosis by the same mechanism.

There is also a group of conditions known as renal tubular acidosis (RTA). These are mostly inherited but may be acquired, for example as a consequence of recurrent infection. There are two major forms – proximal and distal – reflecting the site of the tubular defect in the nephron. In distal tubular RTA (Type 1)  $\text{H}^+$  secretion is impaired resulting in impaired  $\text{H}^+$  excretion, whereas in proximal RTA (Type 2)  $\text{HCO}_3^-$  reabsorption is impaired (usually as part of multiple tubular abnormalities) leading to net loss of bicarbonate. Both cause acidosis, with low pH and hypokalemia as a result of increased distal tubular  $\text{H}^+/\text{K}^+$  exchange. The precise causes of these conditions are not known but is likely to reflect genetic defects on individual transporter subtypes, for example those of the  $\text{Na}^+/\text{H}^+$  exchanger (Figure 1).

A third form of RTA (Type 4), also called hyperkalemic RTA, is the result of generalized transport abnormalities of the distal tubule. Electrolyte transport of sodium, chloride, and potassium are impaired. This form differs from classical distal and proximal RTA because there are high (not low) levels of potassium in the blood. Type 4 RTA occurs with deficiency of the hormone aldosterone or when the kidneys fail to respond to it. Aldosterone acts *via* the kidneys to control levels of sodium, potassium, and chloride

in the blood. Type 4 RTA also occurs when tubular transport of electrolytes such as sodium, chloride, and potassium is impaired due to an inherited disorder or use of certain drugs (e.g., spironolactone, nonsteroidal anti-inflammatory drugs or angiotensin-converting enzyme inhibitors) and in diseases which alter kidney structure and function (e.g., diabetic nephropathy, sickle cell disease, urinary tract obstruction, lupus, or amyloidosis). Treatment is directed at the underlying cause; in aldosterone deficiency, fludrocortisone, a mineralocorticoid is used.

### Renal Failure

In progressive renal failure, renal clearance of all substances is progressively impaired, reflecting progressive loss of individual nephron function. Reduced excretion of fixed acid leads to bicarbonate consumption in extracellular fluids and to acidosis. Tubular recovery of  $\text{HCO}_3^-$  may also be impaired (see *Excess bicarbonate loss*), as may production of tubular  $\text{NH}_4^+$ , and be associated with over-production of urea in the liver, although this is unlikely to be a major concern to excess urea production in clinical practice.

### Drugs and Other Causes

Many drugs can cause metabolic acidosis, generally in overdose. A classic example is aspirin (acetylsalicylic acid). Lactic acidosis is also associated with oral hypoglycemic agents (specifically metformin, used in treatment of noninsulin dependent diabetes), paracetamol, alcohol, and ethylene glycol (antifreeze) poisoning.

### Compensation

The body's response to metabolic acidosis is a compensatory increase in ventilation to excrete excessive  $\text{CO}_2$ , restoring equilibrium in the Henderson–Hasselbalch equation (eqn [5]). This respiratory compensation is usually incomplete, resulting in pH values or  $\text{H}^+$  concentrations at, or marginally outside, the limits of 'normal' (Table 3). Complete compensation depends on renal excretion of excess  $\text{H}^+$ , or resolution of the underlying condition.

### Treatment

Treatment of metabolic acidosis is essentially that of the underlying condition: correction of tissue hypoxia in lactic acidosis; correction of fluid depletion and insulin therapy in diabetic ketoacidosis; dialysis in renal failure. Rapid correction of pH can be achieved by administration of intravenous sodium bicarbonate if necessary with the caveat that in a mixed respiratory and metabolic acidosis caution should be exerted as sodium bicarbonate can increase  $\text{CO}_2$  levels. The treatment of chronic metabolic acidosis (e.g., in chronic renal failure or RTA) may be achieved by the administration of oral sodium bicarbonate. In uremia the prescription of a low protein diet will reduce acid load and may prevent uremic symptoms.

### Metabolic Alkalosis

Metabolic alkalosis may be caused either by excessive loss of acid or intake of alkali. The latter may be iatrogenic or factitious, with the excessive intake of prescribed antacids (such as sodium bicarbonate for heartburn or peptic ulcer disease) – the 'milk-alkali' syndrome. The loss of acid-rich gastric secretions in severe vomiting for example, in cases of gastric outlet obstruction (due to pyloric stenosis, or a consequence of peptic ulcer disease), also leads to alkalosis. Administration of alkali only causes significant metabolic alkalosis when the absorption is considerable and sustained such as transfusions of citrated blood or sodium bicarbonate therapy for metabolic acidosis due to circulatory arrest in the presence of oliguric renal failure. Compensation is by reducing ventilation to promote retention of  $\text{CO}_2$  and thus balance the Henderson–Hasselbalch equation. Treatment is usually of the underlying condition. In the case of severe metabolic alkalosis in critically ill patients with associated coma or arrhythmia where alternative treatment (hemodialysis or filtration) has failed or is contraindicated, administration of intravenous hydrochloric acid *via* a central vein can be beneficial.

### Respiratory Acidosis

Impaired ventilation, reduces  $\text{CO}_2$  excretion, increases  $\text{PaCO}_2$  and thus lowers pH. This may occur acutely or chronically. Causes of respiratory acidosis include factors that interfere with the neurological 'drive' for respiration (e.g., head injury, cardiac arrest, opiate, and anesthetic drugs), diseases of the respiratory muscles (e.g., poliomyelitis, Guillain–Barré syndrome), or primary lung diseases (acute-pulmonary edema or pneumonia; chronic bronchitis, emphysema). In acute conditions, pH may fall dramatically, whereas in chronic conditions, such as chronic lung disease, pH is generally nearer normal. In chronic conditions complete compensation occurs in the kidney where elevated  $\text{PaCO}_2$  levels are offset by the increased generation of bicarbonate and excretion of fixed acid by the kidney, to balance the Henderson–Hasselbalch equation.

### Respiratory Alkalosis

Respiratory alkalosis occurs as a result of inappropriately increased ventilation and increased excretion of CO<sub>2</sub>. This may occur as a transient response to pain or hysteria. Such stimuli tend to be short-lived and can be offset by analgesia, sedation or short-term re-breathing of expired air. Additional causes include the early phases of aspirin poisoning (where the respiratory centers are activated), hypoxia, sepsis, hepatic failure, stroke, and other conditions affecting brainstem respiratory control centers. Most causes of respiratory alkalosis are short-term and, although adaptive responses would be expected to require excretion of bicarbonate to balance the Henderson–Hasselbalch equation, resolution usually occurs with treatment of the underlying condition.

### Transporter Mechanisms: Physiology and Pathophysiology

Developments in molecular biology have led to major improvements in our understanding of the physiology, and pathophysiology of renal tubular function. It is now possible to subdivide the various types of renal tubular acidosis for example, by the precise biochemical defect rather than simply the tubular location. Thus, distal (or type 1) RTA may be a consequence of impaired distal tubular H<sup>+</sup> excretion, either due to increased permeability to H<sup>+</sup> or to impaired secretion, the latter – in turn – being a consequence of a variety of defects that include carbonic anhydrase type 2 deficiency, mutations in anion transport protein AE1, or deficiency of collecting-duct proton transport ATPase. Although specific knowledge of the molecular defect is not necessary to either diagnose or manage these disorders, it is likely that future classification of acid–base disorders will change to recognize the underlying defect.

### Key points

- The major energy supplying fuels in the body are glucose, lactate, fatty acids, ketone bodies, some amino acids and ethanol, with minor contributions from fructose, galactose, glycerol and limited amounts from short chain fatty acids produced by the colonic microbiota.
- During metabolism the energy in the fuels is converted by specific pathways to a number of end products but the useable energy is conserved in reducing equivalents (NADH and FADH<sub>2</sub>) and primarily acetyl CoA.
- The only anaerobic pathway of energy metabolism is glycolysis, the breakdown of glucose (and other sugars) to lactate which only yields 2 ATP per glucose metabolized. When this occurs in the presence of oxygen the process is termed aerobic glycolysis. Most cells however can continue the breakdown of glucose by oxidation in the mitochondria a process yielding 27–29 ATP per glucose.
- Acetyl CoA is itself oxidized in the Tricarboxylic Acid Cycle (a central pathway for the final stages of catabolism of all fuels) releasing the carbon as carbon dioxide and producing NADH and FADH<sub>2</sub>.
- NADH and FADH<sub>2</sub> are oxidized in the process of oxidative phosphorylation in the inner membrane of mitochondria where electrons flow along a transport chain to the final electron acceptor, molecular oxygen, to produce water. At key stages along the electron transport chain protons are pumped out of the mitochondrial matrix to concentrate in the inter-membrane space. These protons flow back into the matrix driving the ATP synthase complex to produce ATP.
- During the absorptive phase the major fuel utilized is glucose and extra glucose and dietary fatty acids are stored as glycogen and triglycerides respectively. During the post-absorptive period fatty acids are mobilized and used as fuel by most tissues, but not by the brain. Within the liver fatty acids undergo partial oxidation to produce ketone bodies which can be used as fuel by most tissues including the brain. During this time blood glucose concentrations are maintained by the release of glucose from liver glycogen stores and then from gluconeogenesis (the synthesis of new glucose).
- In the post-absorptive period and starvation the utilization of fatty acids and ketone bodies as fuels by different tissues replaces much of the need for glucose utilization and is known as “the glucose sparing effect of fat derived fuels”. But since most of the glucose in starvation is made from amino acids derived from the breakdown of proteins, this could also be referred to as “the protein sparing effect”.

### Glossary

**Acidosis** In this text referring to metabolic acidosis, a disturbance of plasma acidity with a drop in pH and bicarbonate levels. Arising from an accumulation of acids such as acetoacetic acid and β-hydroxybutyric acid (the ketone bodies)

**Acyl** Referring to the fatty acid group in a compound for example, the acetyl and palmitoyl groups in acetyl CoA and palmitoyl CoA may simply be referred to as acyl CoA

**Acyl CoA** A fatty acid linked by a thio-ester bond to Coenzyme A (CoASH)

**Anabolism** The synthetic part of metabolism, the building up of cellular components and storage of fuels

**ATP, ADP, AMP** Adenosine Triphosphate, Adenosine Diphosphate, Adenosine Monophosphate. ATP is the final energy containing compound derived from the breakdown of macromolecules in cells. The third phosphate bond is used to provide energy for other reactions with the production of ADP. Further breakdown to AMP yields more useable energy

**$\beta$ -oxidation** The breakdown of fatty acids by removal of 2 carbon units, ultimately yielding acetyl CoA or ketone bodies

**BAT** Brown adipose tissue that contains Uncoupling protein 1 (UCP 1) which generates heat by allowing protons to re-enter the mitochondrial matrix without the synthesis of ATP

**Cellular Respiration** The biochemical process by which the energy in fuels is released as ATP by the process of oxidative phosphorylation (also known as oxidative respiration)

**CoASH** Coenzyme A (derived from vitamin B5, pantothenic acid). The SH indicates a thiol group that is used to link to acyl groups by a thio-ester bond

**Chylomicrons** Large triglyceride rich lipoprotein complexes formed in the enterocytes and released to carry dietary lipids around the body via the lymph and peripheral blood circulation

**Catabolism** The breaking down of fuels and cellular components

**Carnitine Palmitoyl Transferase** The enzyme that replaces the CoA moiety of Acyl CoA with carnitine enabling the acyl (fatty acid) group to enter the mitochondria for oxidation

**Coupled respiration** The coupling of electron transfer to ATP synthesis

**Dehydrogenase** Enzymes that carry out reduction (and oxidation) reactions usually involving  $\text{NAD}^+/\text{NADH}$ ,  $\text{NADP}^+/\text{NADPH}$ , or  $\text{FAD}/\text{FADH}_2$

**De novo** Synthesis of a compound from basic components, for example de novo fatty acid synthesis is the synthesis of fatty acids from glucose

**Electron Transport Chain** A series of electron acceptors embedded in the inner mitochondrial membrane that passes electrons from  $\text{NADH}$  and  $\text{FADH}_2$  to the final electron acceptor oxygen

**FAD,  $\text{FADH}_2$**  Flavin adenine dinucleotide (oxidized and reduced) redox related coenzymes. In this text referring to the production of  $\text{FADH}_2$  in the TCA cycle and its oxidation to FAD in the electron transport chain

**Free fatty acid** Otherwise known as non-esterified fatty acids, meaning the fatty acid is not bound to other compounds and is present as the free acid

**Fructose** A six carbon sugar that comprises 50% of sucrose (table sugar). Almost exclusively catabolized in the liver

**Galactose** A six carbon sugar comprising 50% of lactose and found exclusively in mammalian milk. Almost exclusively catabolized in the liver

**Gluconeogenesis** The synthesis of glucose from non-glucose precursors including, lactate, pyruvate, amino acids, glycerol and propionate. Gluconeogenesis only occurs in the liver and kidneys

**Glucose** A six carbon sugar that is the principal sugar in the body and is the preferred fuel of most tissues in the fed/absorptive state. In healthy individuals blood glucose concentrations are held within very tight limits

**Glycerol** A three carbon alcohol that is the backbone of triglycerides. It is released during lipolysis and can be used for gluconeogenesis

**Glycogen** A polymer of glucose mainly stored in liver (for release as glucose into the circulation) and skeletal muscle (for use as a local fuel for muscle contraction)

**Glycolysis** Glycolysis occurs in the cytosol and is the breakdown of glucose to two lactates, an anaerobic process. When this occurs in the presence of oxygen it is called aerobic glycolysis. In most cells however, the pyruvate formed from glucose is further oxidized in mitochondria and the process of glucose to pyruvate in the cytosol is simply referred to as glycolysis

**Glyceroneogenesis** The formation of glycerol 3-phosphate for esterification with 3 fatty acids to form triglycerides from non-glucose precursors such as lactate

**Hexokinase** The enzyme that phosphorylates glucose to glucose 6-phosphate. In liver a unique form, glucokinase, is employed

**Isomerase** An enzyme that rearranges the structure of a molecule from one isomer (form) to another. For example glucose 6-phosphate to fructose 6-phosphate

**Ketone bodies** The ketone bodies, often referred to simply as ketones, are acetoacetate,  $\beta$ -hydroxybutyrate and acetone. They are water soluble end products of fatty acid oxidation in the liver. Acetone is highly volatile and is lost from the body in expired air. Ketones rise in the circulation in the post-absorptive period and continue to rise as starvation develops. They are used as an alternative fuel by most tissues including the brain, but not the liver. Very high levels of ketones may occur in Type 1 diabetes resulting in keto acidosis. Lower levels of ketones arise on consuming high fat, very low carbohydrate diets, otherwise known as ketogenic diets

**Kinase** An enzyme that adds a phosphate group from ATP (or GTP) to a substrate

**Lactate** Also known as L-lactic acid. A three carbon hydroxy acid that is the end product of the anaerobic pathway of glycolysis. It is readily converted to and from pyruvate in most tissues, and also to alanine (via pyruvate) in a number of tissues. Lactate can also be used directly a fuel in some tissues

**Lipolysis** The hydrolysis of neutral lipids such as triglycerides to yield free fatty acids

**NAD<sup>+</sup>, NADH** Nicotinamide adenine dinucleotide (oxidized, reduced) the major redox related coenzyme. Since it donates H<sup>+</sup> in many reactions, including the synthesis of ATP, it is often referred to as “reducing equivalents”

**NADP<sup>+</sup>, NADPH** Nicotinamide adenine dinucleotide phosphate (oxidized, reduced) a redox related coenzyme mainly involved in donating H<sup>+</sup> in cytosolic synthetic reactions

**Oxidative phosphorylation** The process by which ATP is produced in mitochondria by the passage of electrons from NADH and FADH<sub>2</sub> along the electron transport chain

**Pentose Phosphate Pathway/Hexose Monophosphate Shunt** A cytosolic pathway that is, in part an alternative to glycolysis. The purpose of the PPP is to produce NADPH for synthetic reactions and the ribose phosphate required for the synthesis of nucleic acids

**Pi** Inorganic phosphate, released together with ADP when ATP is hydrolyzed

**PPi** Pyrophosphate released together with AMP when ATP is used in some reactions

**Propionate** A three carbon fatty acid, produced from the oxidation of odd carbon chain fatty acids or as a fermentation product of the colonic microbiota. It can be used as a gluconeogenic substrate

**Proton** In chemistry proton refers to the hydrogen ion H<sup>+</sup> and a reaction where a proton is donated to form a product is termed a reduction. Conversely the removal of a proton is an oxidation

**Proton Motive Force** The build up of protons in the inter-membrane space of the mitochondria that can be used to drive the ATP synthase to synthesize ATP from ADP and Pi

**Substrate level phosphorylation** The transfer of a phosphate directly from a substrate to form ATP. An example is the transfer of phosphate from phosphoenolpyruvate to form ATP and pyruvate in glycolysis. Such a process does not require oxygen

**Thio-ester bond** An ester bond where sulfur replaces oxygen. The best known example is acetyl CoA where acetate is linked by a thioester bond to Coenzyme A (CoASH)

**Thiolase** An enzyme that hydrolyzes thioester bonds as in the terminal reaction of both de novo fatty acid synthesis and fatty acid  $\beta$ -oxidation where a thiolase releases palmitoyl CoA and acetyl CoA respectively

**Tricarboxylic Acid Cycle, Citric Acid Cycle, Krebs Cycle** The central pathway whereby the final products of catabolism are metabolized releasing CO<sub>2</sub> and NADH, FADH<sub>2</sub>, and GTP. Parts of the TCA cycle are also involved in a number of other pathways such as fatty acid synthesis and gluconeogenesis

**Triglyceride (triacylglycerol)** A neutral lipid consisting of three fatty acids bound to a glycerol. It is the major component of dietary lipids and is the major form of storage lipid in the body

**Transamination** A reaction whereby an amino group (NH<sub>2</sub>) is transferred to a keto group (C=O) forming a new amino acid and a new keto acid catalyzed by a transaminase (aminotransferase). An example is alanine transaminase whereby pyruvate (keto acid) and glutamate (amino acid) transaminate to yield alanine and  $\alpha$ -ketoglutarate. Such reactions involve pyridoxal phosphate (vitamin B6) and are usually freely reversible

**Uncoupler** A compound that uncouples electron transport and oxygen consumption from ATP production

**VLDL** Very low density lipoprotein. A triglyceride rich lipoprotein that is the major transporter to move triglycerides, cholesterol and other lipids throughout the body

## Introduction

The first law of thermodynamics states that “energy can neither be created nor destroyed”. Thus, when we refer to energy metabolism in the body we mean the conversion of the potential energy contained in food into the kinetic energy required to maintain life. The major fuels in the body are glucose, lactate, fatty acids, ketone bodies, some amino acids, and ethanol, with minor contributions from fructose, galactose, glycerol, and limited amounts from short chain fatty acids produced by the colonic microbiota. This section will consider how these fuels are used to release energy through the process of intermediary metabolism (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004). Most fuels undergo a series of reactions often resulting in the production of reducing equivalents (H<sup>+</sup>) in the form of NADH that can be used to reduce other metabolites or undergo further oxidation (Fig. 1). Ultimately, most of the energy released from macronutrient metabolism will yield ATP, the universal energy containing intermediate within the cell. The synthesis of ATP can occur by two mechanisms, substrate level phosphorylation and oxidative phosphorylation, the latter requires mitochondria and yields considerably more ATP than substrate level phosphorylation. The body turns over ATP at an amazing rate of the order of 40 kg per day (much more if you are doing hard physical labor). This translates to 10<sup>21</sup> ATP per second per body, or 3 × 10<sup>4</sup> ATP per second per mitochondria.

**Fig. 1** The energy in the major fuels is broken down to acetyl CoA and NADH and used to produce ATP. Most fuels undergo catabolism and ultimately form Acetyl CoA plus NADH. The Acetyl CoA is then further metabolized in the TCA cycle releasing the carbons as carbon dioxide and forming additional NADH. The NADH then passes to the electron transport chain to be oxidized with oxygen to form water which is coupled to ATP formation (oxidative phosphorylation).

It is important to realize that different tissues and cells show differences in their metabolism (**Table 1**). Some tissues can use most fuels but a few are very specific in their fuel usage. Of particular importance is the brain which usually just oxidizes glucose but can use ketone bodies if they are available, and possibly lactate under certain conditions. Notably the brain does not utilize fatty acids as fuel. Since the brain uses about 20–25% of the body's energy per day and it completely oxidizes glucose it must be supplied with about 120 g of glucose per day. Furthermore, the brain is not able to obtain sufficient glucose once the circulating

**Table 1** Tissue specific fuel metabolism.

Brain	Normally completely oxidizes only glucose. If ketone body concentrations are elevated they can be oxidized decreasing the use of glucose. Under some conditions the brain also can oxidize lactate in place of glucose
Liver	The liver is important in the utilization (glucose, fatty acids, amino acids, glycerol and alcohol), interconversion (synthesis of fatty acids, triglycerides, ketone bodies and glucose) and storage of fuels (glycogen). Ethanol is almost totally metabolized in the liver. The liver is not able to use ketone bodies or to carry out the initial reactions of branched chain amino acid metabolism.
Skeletal muscle	Different types of muscle will use different fuels, mostly fatty acids and glucose, with some metabolism of branched chain amino acids. In starvation most muscles can use ketone bodies.
Cardiac muscle	Mainly fatty acids, but during the absorptive period can use lactate or glucose. During starvation ketone bodies also may be used.
Red blood cells	Since these cells lack mitochondria they are only able to use glucose which is fermented to lactate via glycolysis.
Kidney	Can use most fuels but also is able to carry out gluconeogenesis.
Proliferating cells (e.g., Tumors)	Very high rates of glucose metabolized to lactate (Warburg effect) and high rates of glutamine utilization.

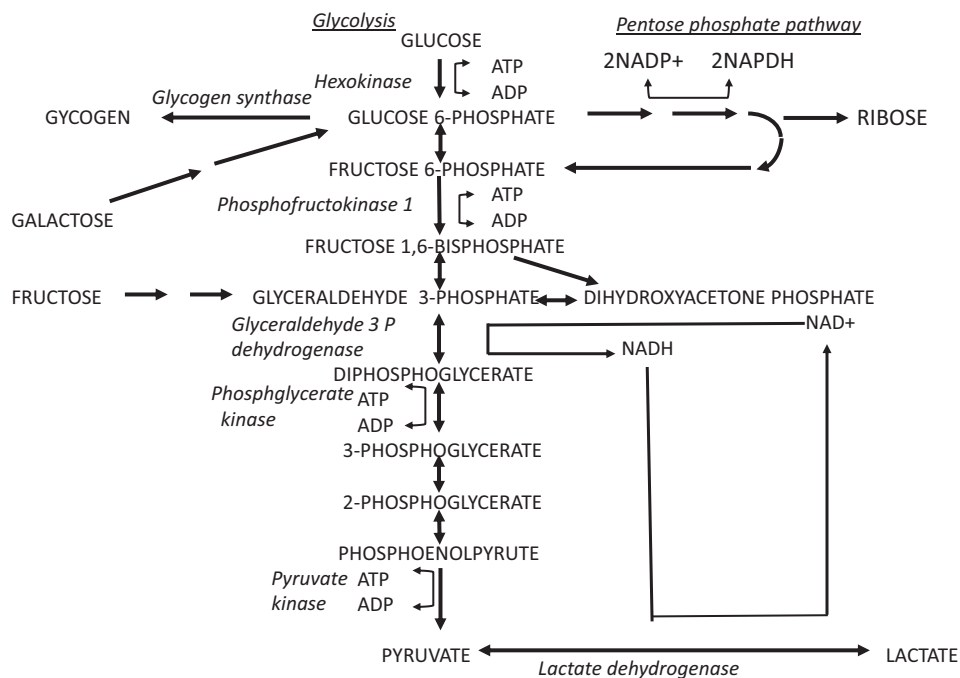

glucose concentration drops below about 3 mg/dL (60 mg/dL) and therefore blood glucose is maintained at around 4.4–5.0 mM (80–90 mg/dL). The careful balance of the utilization of the different fuels enables the body to provide different tissues with sufficient energy from the absorptive state after a meal through the postabsorptive state and into starvation (Cahill, 2006; Watford, 2015).

## Carbohydrates

The end products of the digestible carbohydrates (starches and simple sugars) are glucose, fructose and galactose. Some may be metabolized in the cells of the small intestine but most will enter the portal vein for direct delivery to the liver where, under normal dietary loads, all the fructose and galactose will undergo metabolism. The rise in blood glucose after a meal will trigger the release of insulin from the beta cells of the pancreas and this will have a number of important effects to maintain glucose homeostasis. It will increase glucose uptake into skeletal muscle and adipose tissue via the stimulation of the glucose transporter GLUT 4. Equally importantly insulin also shuts down glucose output by the liver and the release of fatty acids from lipolysis in adipose tissue (Frayn and Evans, 2019). This means that glucose is now the major fuel available and, not surprisingly, insulin signals to many cell types to increase glucose utilization. There are essentially three separate pathways for glucose utilization, glycolysis, the pentose phosphate pathway (hexose monophosphate shunt), or storage as glycogen (Fig. 2) (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

## Glycolysis

Strictly speaking glycolysis is a fermentation, it does not require oxygen, and the penultimate product, pyruvate, is converted to lactate (which has the same oxidation state as glucose). Most cells however, are capable of taking the pyruvate into the mitochondria where is oxidized to  $\text{CO}_2$  and water. There is some confusion in biochemistry texts regarding the use of the terms aerobic and anaerobic glycolysis. In this text the metabolism of glucose to pyruvate with further oxidation will be referred to simply as glycolysis. Many cell types will convert glucose to lactate regardless of oxygen availability and this will be referred to as aerobic glycolysis. The classic example of such a cell is the mammalian red blood cell which, lacking mitochondria, is unable to carry out oxidative metabolism. A number of other tissues such as some muscles, the renal cortex, and a number of other cell types, including tumors, also exhibit high rates of aerobic glycolysis, widely known as the Warburg effect.

**Fig. 2** Fate of glucose in the cell. Glucose is phosphorylated by hexokinase to glucose 6-phosphate which can then be used for glycogen synthesis, the pentose phosphate pathway or glycolysis. Glycolysis results in the formation of pyruvate which can be transported into the mitochondria for oxidation or simply reduced to lactate. Fructose and galactose are metabolized to feed into the glycolytic pathway. The pentose phosphate pathway is used to make ribose for nucleic acid synthesis or it can be used to produce NADPH for use in synthetic and anti-oxidant reactions with the carbon skeleton feeding back into the glycolytic pathway. Hexokinase, Phosphofructokinase 1 and Pyruvate Kinase are irreversible steps in glycolysis.

Within the cytosol glucose (a six carbon sugar) undergoes phosphorylation by the enzyme hexokinase (glucokinase in liver) to yield glucose 6-phosphate (G6P) with the phosphate donated from ATP (**Fig. 2**). An isomerase will convert G6P to fructose 6-phosphate, then to fructose 1,6-bisphosphate (F1,6P2) in another reaction requiring ATP catalyzed by phosphofructokinase 1 (PFK 1). Thus, two ATPs have been used in these initial reactions. The F1,6P2 is split by an aldolase to yield 2 three carbon compounds which progress along the pathway via a series of intermediates to pyruvate. Glyceraldehyde 3-phosphate dehydrogenase will yield NADH and two substrate phosphorylation steps, phosphoglycerate kinase and pyruvate kinase, are linked to the synthesis of ATP. Since each three carbon unit yields 2 ATPs the total yield is 4 ATPs but because two ATPs were utilized in the first part of the pathway the net yield is two ATP per glucose plus two pyruvates and 2 NADH. To maintain flux in the pathway, and to keep using glucose, this NADH must be oxidized back to  $\text{NAD}^+$ . In oxidative cells the reducing power of the NADH can be transferred to the mitochondria but if this is not possible the NADH will be used by lactate dehydrogenase to reduce the pyruvate to lactate limiting the ATP yield to 2 per glucose metabolized. Sugars such as fructose and galactose can enter the glycolytic pathway after being phosphorylated by specific isozymes of hexokinase and metabolized to intermediates, triose phosphates for fructose and glucose 6 phosphate for galactose, that feed into the glycolytic pathway.

If however, the pyruvate is destined to be fully oxidized in the mitochondria then the NADH formed in the cytosol also must be transferred to the mitochondria. The mitochondrial membrane, however, is impermeable to NAD and NADH and shuttles exist to transfer the reducing power ( $\text{H}^+$ ) in NADH into the mitochondria for oxidative phosphorylation. There are two possible shuttles one that yields NADH within the mitochondria and one that yields  $\text{FADH}_2$ .

An additional pathway of glucose metabolism is the pentose-phosphate pathway (hexose-monophosphate shunt) (**Fig. 2**). This takes G6P and produces the ribose required for RNA and DNA synthesis. Alternatively the pathway can produce NADPH which is the reducing power required by a number of cytosolic synthetic pathways, such as de novo fatty acid synthesis. NADPH is also used to reduce oxidized glutathione the major cellular antioxidant. When used for NADPH production the carbon re-enters the glycolytic pathway as fructose 6-phosphate.

### Pyruvate metabolism

Within the mitochondrial pyruvate is metabolized by pyruvate dehydrogenase, a multi-subunit complex, to yield acetyl CoA (**Fig. 3**) ([Jeoung and Harris, 2010](#)). The first reaction, a thiamine dependent decarboxylase yields a 2 carbon (acetyl) group that is transferred to CoASH forming acetyl CoA. In so doing a lipoate group is reduced which must be re-oxidized to allow continued flux through the complex. This is achieved by transferring the reducing power from the lipoate to NAD to form NADH via a  $\text{FADH}_2$  intermediate. The reaction is highly regulated mainly by phosphorylation (inhibition) and dephosphorylation (activation) of the decarboxylation step. Regulation of PDHC is extremely important at times of limited glucose availability (when glycogen stores are becoming depleted) since it is possible to synthesize glucose (gluconeogenesis) from pyruvate (3 carbons) but not from acetate (2 carbons).

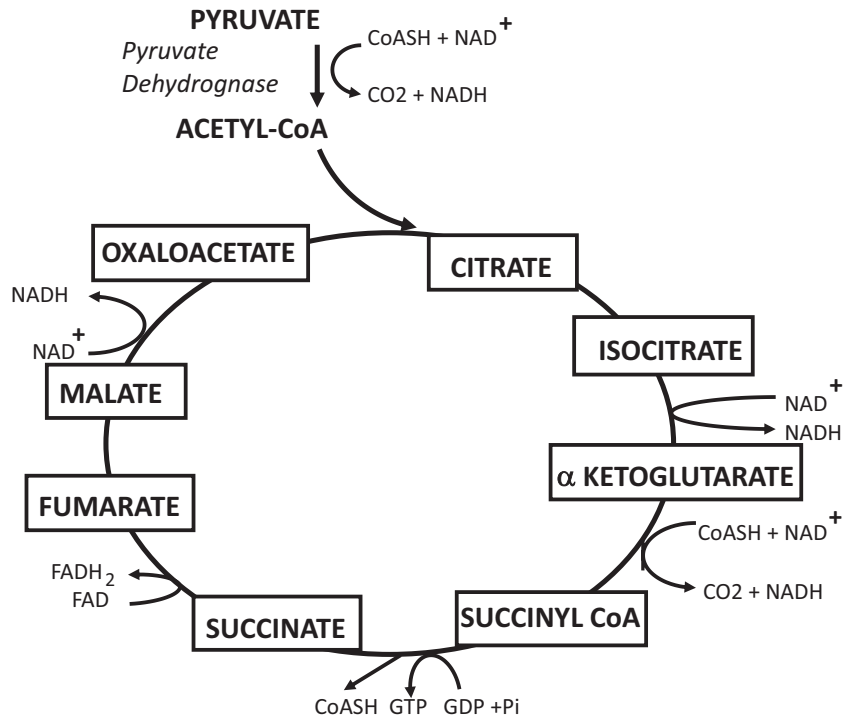

The acetyl CoA formed can now enter the TCA cycle (**Fig. 3**). Alternatively, the acetyl CoA can enter the pathway of fatty acid synthesis (**Fig. 4**) which is important in producing cell membranes and other lipids. In humans however, although theoretically possible, there is very little de novo fatty acid synthesis for storage ([Aarsland et al., 1997](#); [Acheson et al., 1988](#); [Hellerstein et al., 1996](#)). Note, this does not mean if you eat carbohydrates you will not get fat. As with any overeating of calories you will become obese, it just means that most of the fat you store will be derived from the diet.

### Fat catabolism

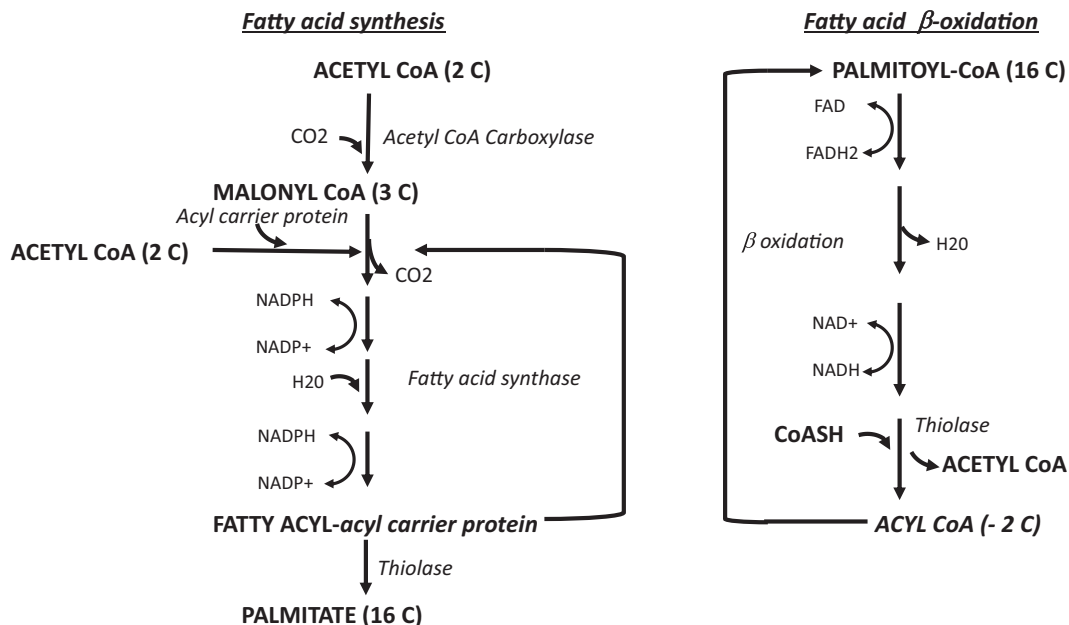

Fat in the diet is predominantly in the form of triglycerides (three fatty acids esterified to a glycerol). The end products of digestion are free fatty acids and monoglycerides. These are absorbed in the enterocytes where they are resynthesized to triglyceride and then packaged with a number of specialized proteins into large lipoprotein complexes, chylomicrons. The chylomicrons pass into the lymph system to be transported to the thoracic vein where they are released into the blood circulation. This process is much slower than the digestion of carbohydrates and dietary lipids do not appear in the blood circulation until a number of hours after a meal. On reaching the target tissues the triglycerides in the chylomicrons are hydrolyzed to fatty acids and glycerol by lipoprotein lipase present on the exterior of the cells. Similarly, fatty acids released by the liver in the form of VLDL (very low density lipoproteins) are also hydrolyzed by lipoprotein lipase. The fatty acids can then enter the cells where they can be oxidized to liberate the energy or re-esterified to triglyceride for storage.

As indicated above lipids are transported between tissues as triglycerides (neutral lipids) and a limited amount of free fatty acids. The latter are transported in the circulation bound to the protein albumin since a free acid group is potentially toxic. Usually most dietary lipids are stored for at least some time but when glucose levels fall and insulin levels drop there is an increase in lipolysis (the release of the fatty acids from triglycerides). In adipocytes the triglycerides are stored in a one large lipid droplet, comprising about 80% of the cell volume. This droplet is surrounded by a number of proteins with perilipin being the most important in terms of lipolysis. When lipolysis is stimulated, for example by norepinephrine, perilipin can be phosphorylated and this then allows access of a number of lipases to release the fatty acids from triglycerides. Both free fatty acids and glycerol are released from the cell to be taken up by other tissues.

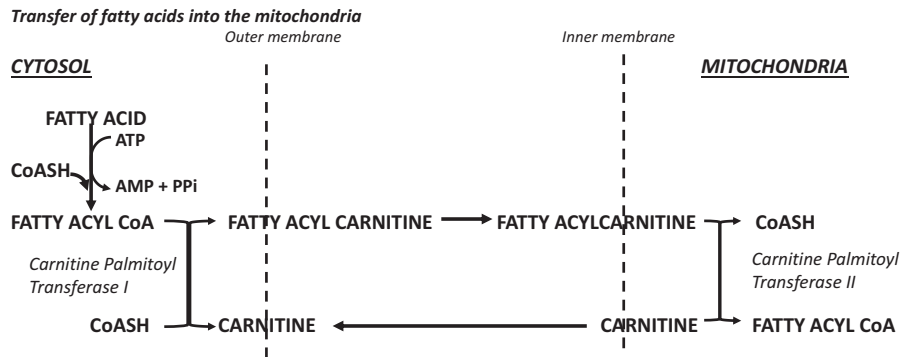

On being taken up by cells the fatty acids are esterified to CoASH to form a fatty acyl-CoA involving the breakdown of ATP to AMP plus  $\text{PPi}$  (**Fig. 4**). It is at this stage that the fate of that acyl CoA may be re-esterification with glycerol-3-phosphate to

**Fig. 3** Pyruvate dehydrogenase and the TCA cycle. Within the mitochondria pyruvate is decarboxylated to form Acetyl CoA which, together with Acetyl CoA from the catabolism of other fuels, enters the TCA cycle. Acetyl CoA (2 C) combines with oxaloacetate (4 C) to form citrate (6 C). In a series of reactions two carbons are lost as  $\text{CO}_2$  with the production of 2  $\text{NADH}$ , 1  $\text{FADH}_2$  and a  $\text{GTP}$  to regenerate the oxaloacetate.

**Fig. 4** Fatty acid synthesis and fatty acid  $\beta$  oxidation. Acetyl CoA carboxylase forms malonyl CoA which binds to an acetyl CoA linked to the acyl carrier protein of fatty acid synthase. Within the cytosol, after a decarboxylation, a series of reductions by  $\text{NADPH}$ , and a hydration, the resulting four carbon acyl group is bound to the acyl carrier protein (ACP) in fatty acid synthase. The process repeats utilizing a new malonyl CoA until the final product, palmitate (16 carbons) is formed and this is released by hydrolysis from the ACP by a thiolase. The palmitate can be further modified by elongation and/or desaturation. Within the mitochondria fatty acyl CoA (e.g., palmitoyl CoA) will be catabolized releasing a  $\text{FADH}_2$  and a  $\text{NADH}$  in a process equivalent to the reverse of fatty acid synthesis. The final step is the release of acetyl CoA by a thiolase leaving a fatty acyl CoA that is two carbons shorter than the original. The process then repeats until the final acetyl CoA is released. In liver the end product is usually ketone bodies. See Fig. 6.

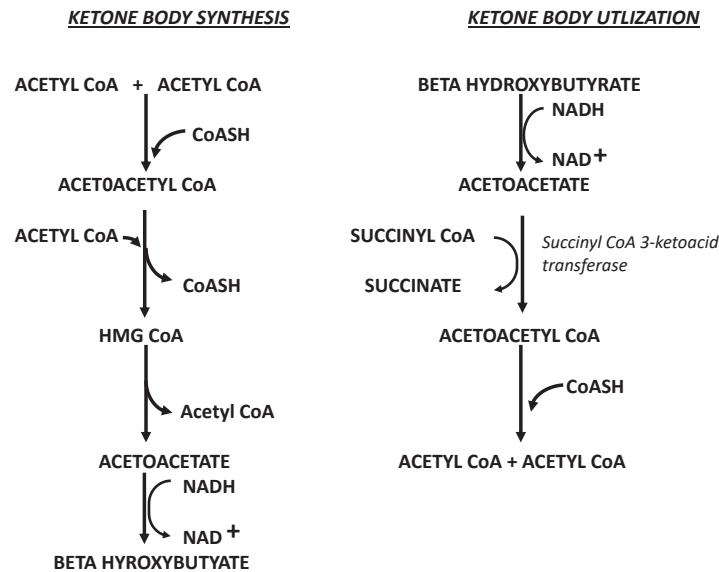

**Fig. 5** The Carnitine shuttle. Fatty acids are activated by the addition of CoASH in the cytosol. At this stage the fatty acyl CoA could be used to synthesize triglyceride. If the fatty acid is to be oxidized it must enter the mitochondria but fatty acyl CoA cannot cross the mitochondrial membrane. Carnitine Palmitoyl Transferase I (CPT 1) on the outside of the outer mitochondrial membrane transfers carnitine to the acyl group to replace CoASH. The fatty acyl carnitine now enters the mitochondria where CPT II will reverse the reaction transferring CoASH to the acyl group and liberate carnitine that can return back to CPT 1.

triglyceride for storage in the cytosol or oxidation in the mitochondria. If the fatty acid is to be oxidized the fatty acyl group from the fatty acyl CoA is transferred to carnitine to form a fatty acyl-carnitine by the action of palmitoyl carnitine transferase 1 (CPT 1) (Fig. 5). This occurs on the outer mitochondrial membrane and the fatty acyl-carnitine is transported into the mitochondrial matrix in exchange for free carnitine. Once within the matrix the fatty acyl group is transferred back to CoASH to yield the fatty acyl-CoA that can enter the pathway of  $\beta$  oxidation. CPT1 is strongly inhibited by malonyl CoA which is abundant in the cell at times of high rates of glucose metabolism and therefore inhibits fatty acid oxidation. The  $\beta$  oxidation of fatty acids (Fig. 4) involves a dehydrogenase producing  $\text{FADH}_2$ , followed by a hydratase (addition of water), a further dehydrogenase producing NADH and finally a thiolase to release the acetyl CoA leaving a fatty acyl CoA that is two carbons shorter than the original substrate. The complete process then repeats removing two carbons at a time until the final acetyl CoA is produced. The oxidation of unsaturated fatty acids requires two additional steps to remove the double bond (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

In the liver fatty acids do not undergo complete oxidation to acetyl CoA rather the end products are acetoacetate,  $\beta$ -hydroxybutyrate and acetone (Fig. 6). Collectively these are known as the ketone bodies, although only acetone is actually a ketone. Within the liver two acetyl CoA molecules are linked to yield acetoacetyl CoA that is elongated by the addition of another acetyl CoA group and then lysis to yield acetyl CoA and the free acetoacetate. Acetone, produced by the spontaneous decarboxylation of acetoacetate, is relatively unstable and most is lost in the urine and in expired air. Acetoacetate however can be reduced to  $\beta$ -hydroxybutyrate and these two products circulate throughout the body to be used as a fuel by a number of tissues, including the brain. Ketone bodies are metabolized in non-hepatic tissues by reacting with succinyl CoA to form acetoacetyl-CoA that is cleaved to yield two acetyl CoA (Fig. 6). Essentially all ketone bodies are made in the liver but the liver cannot use them since it lacks the succinyl CoA 3-ketoacid CoA transferase activity required to initiate their breakdown (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

## Protein and amino acid metabolism

The end products of protein digestion are free amino acids and a mixture of di- and tri-peptides. Once these enter the enterocyte however, the peptides are immediately hydrolyzed to yield the amino acids. Some amino acids (notably glutamine and glutamate) are metabolized within the enterocyte but most others simply enter the circulation via the portal vein. After a meal there is a rise in the circulating concentrations of amino acids which is accompanied by a general increase in protein synthesis in most tissues. Any amino acids in excess of immediate needs for protein synthesis and non-protein functions, are predominantly metabolized by the liver. Notable exceptions are the branched chain amino acids (BCAA), leucine, valine and isoleucine (usually 25% of the amino acids in a meal). They are not metabolized to any great extent by the intestine or the liver but are degraded in tissues such as skeletal muscle, adipose tissue and kidney. The first step in degradation of the BCAA is a transamination whereby the amino group is transferred to  $\alpha$ -ketoglutarate to form glutamate yielding a branched chain keto acid. Some of these keto acids can undergo further degradation within the tissues but large amounts are released into the circulation to be further broken down in the liver. The end products of BCAA metabolism are acetyl CoA and propionate (isoleucine) propionate (valine) and acetoacetyl CoA and acetyl CoA (leucine). Since leucine does not yield a three carbon product leucine cannot be used as a gluconeogenic substrate. Similarly, lysine cannot be used for gluconeogenesis since the end product of lysine metabolism is also acetyl CoA (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

**Fig. 6** Ketone body metabolism. In the liver the end products of fatty acid  $\beta$ -oxidation, acetyl CoA, are joined to make Acetoacetyl CoA. An additional Acetyl CoA is added to form HMG CoA when then cleaved to release acetyl CoA and form acetoacetate. Acetoacetate can be reduced using NADH to form  $\beta$ -hydroxybutyrate. Acetoacetate and  $\beta$ -hydroxybutyrate are released into the circulation as fuel for other tissues. Some amino acids can also give rise to acetoacetate. When ketone bodies are oxidized the  $\beta$ -hydroxybutyrate is first oxidized to aceto acetate followed by the addition of CoASH from succinyl CoA releasing succinate. The acetoacetyl CoA is then split to form 2 acetyl CoA. The liver is unable to use ketones as a fuel since it does not express the succinyl CoA 3-oxoacid transferase.

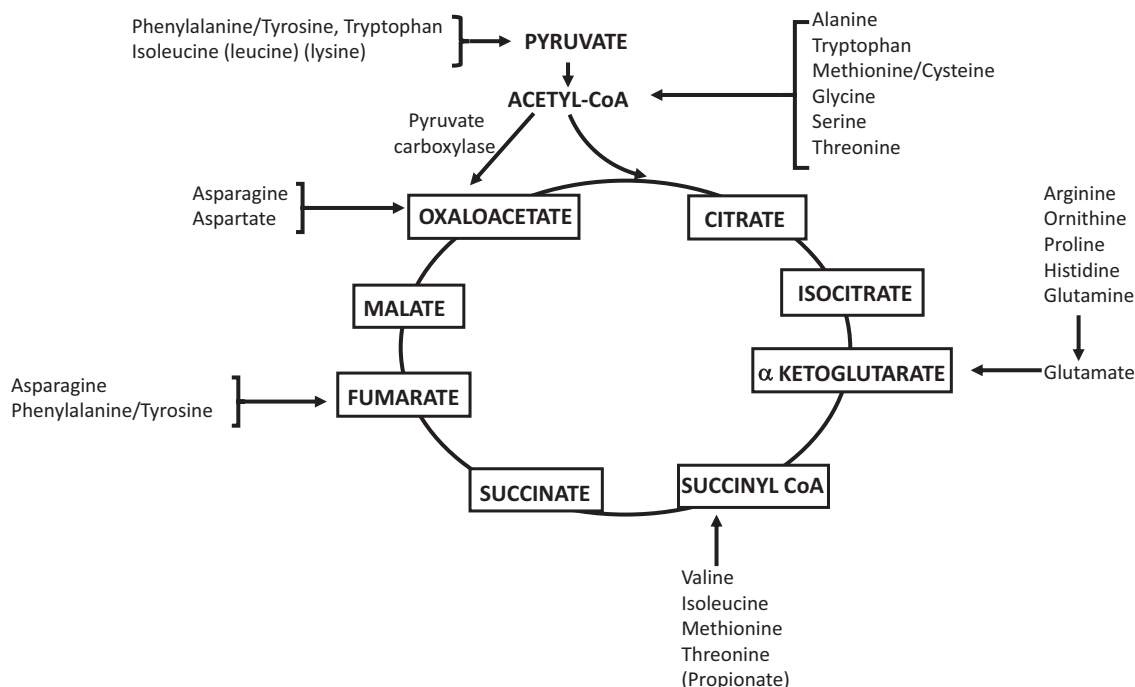

Although the pathways of catabolism are different for every amino acid they do follow a common sequence. Usually the nitrogen is removed, often by transamination, although a few do undergo direct hydrolysis with release of the nitrogen as ammonia. The carbon skeleton will then be further metabolized to acetyl CoA, ketone bodies, propionate and a number of other products that can feed directly into the TCA cycle (Fig. 7). In the liver the nitrogen is converted to urea to be excreted and the bulk of the carbon skeletons will be used for gluconeogenesis (replenishing hepatic glycogen stores in the absorptive state) (Watford, 2020a). Similarly, the degradation of glutamine in the kidney is linked to the provision of urinary ammonia to correct acidosis with the carbon skeleton being recovered as glucose through renal gluconeogenesis (Watford, 2020b). Certain cell types, notably those that are replicating and proliferating rapidly, or are very short lived, for example, cells of the immune system, enterocytes, and cancer cells, utilize large amounts of glutamine as their major respiratory fuel through metabolism of the carbon skeleton through parts of the TCA cycle (Watford, 2020b). Such cells also show limited glucose oxidation with high rates of lactate formation (aerobic glycolysis).

## Ethanol

Humans express considerable alcohol dehydrogenase the main enzyme of ethanol metabolism. Most is in the liver with some evidence of limited expression in the stomach. On entering the cell alcohol undergoes reduction to yield acetaldehyde and NADH in the cytosol. The acetaldehyde enters the mitochondria where a further reduction occurs to form acetate and NADH. The acetate may be further metabolized within the liver or released to be used by other tissues.

## The tricarboxylic acid cycle and oxidative phosphorylation

As can be seen above the major product arising from macronutrient metabolism is acetyl CoA (even if the initial pathway yielded ketone bodies or glucose). Thus the fate of acetyl CoA is important in all cells that possess mitochondria and acetyl CoA will enter the TCA cycle, also known as the citric acid cycle or the Krebs cycle (Fig. 3). As implied from the name the pathway is cyclic in nature with a four carbon compound, oxaloacetate (OAA), being the starting point. Acetyl CoA condenses with OAA to form citrate (6 carbons). This then converts to  $\alpha$ -ketoglutarate with the release of  $\text{CO}_2$  and production of NADH. The  $\alpha$ -ketoglutarate (5 carbons) undergoes a reaction similar to PDHC, with the release of another  $\text{CO}_2$  and NADH and yields succinyl CoA. The CoASH from succinyl CoA is released involving a substrate level phosphorylation of GDP to GTP (an ATP equivalent) to produce succinate (4 carbons). Further metabolism to fumarate yields  $\text{FADH}_2$ , and then to malate followed by another dehydrogenase yielding another NADH and regeneration of the OAA. The TCA rotates twice for each glucose molecule (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

**Fig. 7** Entry of carbon skeletons into the TCA cycle. In addition to acetyl CoA for oxidation the TCA can use acetyl and other substrates for oxidation or as part of other pathways such as gluconeogenesis. Leucine and lysine are shown in parentheses since these amino acids only give rise to acetoacetate (a 4 carbon molecule equivalent to two acetyl CoA) and therefore cannot be used for gluconeogenesis. The entry of propionate (3 carbons) is also shown since this is the only fatty acid that can be used for gluconeogenesis.

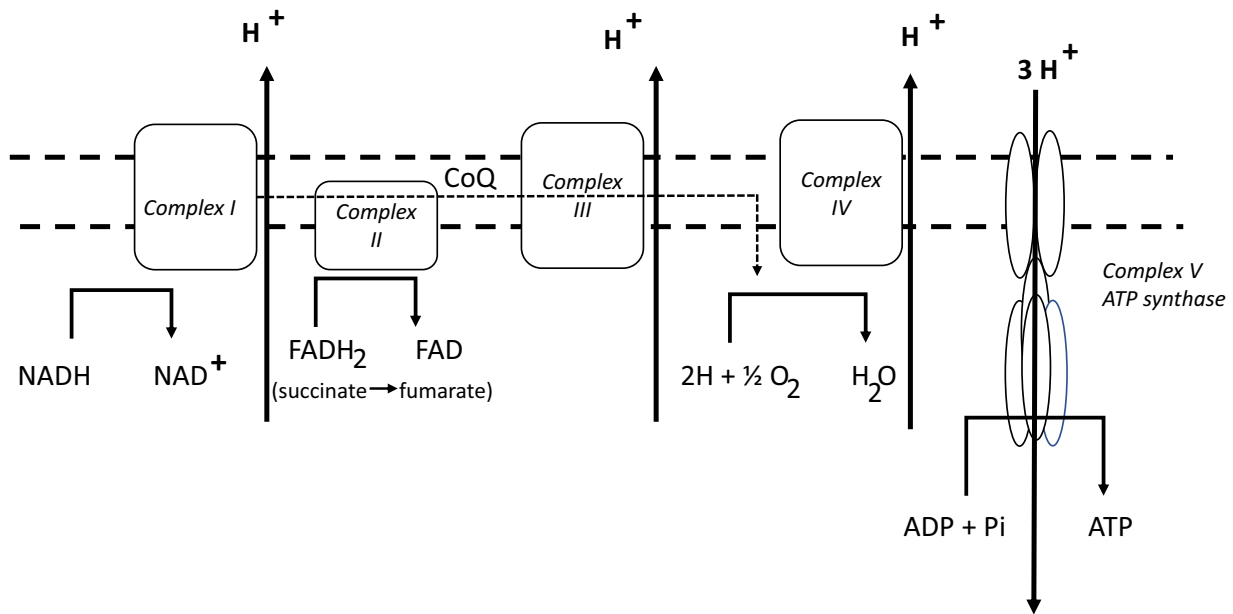

Thus at the end of glucose oxidation the mitochondrial matrix accumulates 8 NADH, 2 FADH<sub>2</sub> and a GTP from the TCA cycle, 2 NADH from PDHC, plus 2 NADH (shuttled in from cytosolic glycolysis) and the release of 6 CO<sub>2</sub>. The NADH/FADH<sub>2</sub> is now used to generate ATP via the process of oxidative phosphorylation.

As stated earlier the hydrogen of NADH is generally referred to as “reducing power” or “reducing equivalents” since it is extensively used to reduce other metabolites. Within the mitochondria these hydrogens dissociate into protons (H<sup>+</sup>) and electrons (e<sup>-</sup>). The electrons pass along what is known as the electron transfer chain within the inner membrane of the mitochondria (**Fig. 8**). NADH enters at complex 1 where it is oxidized to NAD<sup>+</sup> with the H<sup>+</sup> transferring to FADH to yield FADH<sub>2</sub>. At this step a number of protons are pumped from the mitochondrial matrix into the inter-membrane space. The FADH<sub>2</sub>, both from NADH oxidation and pathways such as  $\beta$ -oxidation and the TCA cycle, is oxidized at Complex II by reduction of ubiquinone (coenzyme Q), and then on to the cytochromes each one being reduced and then re-oxidized as it reduces the next one. At complexes III and IV more protons are pumped into the inter-membrane space. The cytochromes, named because of their coloration, contain a reactive ferric ion that becomes reduced to ferrous and then finally is re-oxidized at Complex IV by cytochrome oxidase (a copper containing enzyme) with the electrons passed along to the final acceptor oxygen to yield water. Thus the oxidative metabolism of acetyl CoA yields CO<sub>2</sub> and water as the end products. The result of this process is a buildup of protons in the intermembrane space (crista space) forming a what is known as the proton-motive force. These protons then re-enter the matrix via complex V, the ATP synthase. In so doing they drive a “motor” subunit in the matrix that powers the formation of ATP from ADP and Pi ([Berdanier and Berdanier, 2015](#); [Bronk, 1999](#); [Frayn and Evans, 2019](#); [Salway, 2004](#)). The number of protons pumped per NADH oxidized is commonly accepted as 10. From this textbooks usually state that total oxidation of glucose will yield 36–38 ATP. It is now realized that NADH oxidation does not yield 3 ATPs and the actual ATP yield from glucose oxidation is 27–29 ATPs ([Bronk, 1999](#); [Rich, 2003](#)). The process is generally known as oxidative phosphorylation due to the coupling of the electron transport chain with ATP synthesis and the mechanism as the chemiosmotic theory.

### Uncoupling and brown adipose tissue

A number of metabolic poisons work by interfering with oxidative phosphorylation. Cyanide will bind to the copper in cytochrome oxidase, while rotenone inhibits electron transfer. Another group of poisons are uncouplers, of which dinitrophenol (DNP) is perhaps the best known example. Uncouplers simply punch holes in the membrane and allow large amounts of protons to leak back into the matrix without ATP synthesis in so doing they do generate considerable amounts of heat. In the 1920s DNP was sold as a weight loss supplement but was withdrawn from the market due to severe side effects, often as severe as death.

**Fig. 8** Oxidative phosphorylation. Within the mitochondria the protons and electrons from NADH and FADH<sub>2</sub> are split and the electrons pass along the electron transport chain (shown as the dotted line) embedded in the inner membrane to the final electron acceptor molecular oxygen to produce water. At complexes I, III and IV protons are pumped out of the matrix into the inter-membrane space. This establishes the proton motive force (a build up of protons in the inter-membrane space). The protons then re-enter the matrix at Complex V driving the ATP synthase reaction to phosphorylate ADP to ATP. The process is also referred to as coupled respiration but some compounds, and the Uncoupling protein 1, can allow the protons to reenter the matrix without passing through Complex 5 with the energy released being dissipated as heat.

Unfortunately, with the rise of the internet, DNP has recently re-appeared as a weight loss supplement and is resulting in a rising number of deaths ([Grundlingh et al., 2011](#)). Some uncoupling also occurs naturally in mitochondria in most cells which again decreases the ATP yield from electron transfer.

Most adipose tissue is classified as white, due to its color, and is the major site of energy storage in the body. A different form of adipose tissue, known as brown adipose tissue (BAT), also exists which functions to produce heat ([Siddosis and Kajimura, 2015](#)). Unlike white adipose tissue BAT contains numerous mitochondria (hence the brown color) and many lipid droplets. But BAT also expresses a unique protein, uncoupling protein 1 (UCP 1). As its name implies, it is an uncoupler and allows protons to re-enter the matrix and bypass the ATP synthase dissipating the energy as heat. For many years it was assumed that BAT was only present in humans as babies and was not found in adults. By using sophisticated imaging techniques however, the presence of BAT was detected in adults but it is only detectable when active, i.e., in the cold. The everyday response to cold is to shiver but activation of BAT allows non-shivering thermogenesis (heat production). BAT is more common in northern climates, more common in winter, higher in women than men, and lower in obese subjects. Once cold is detected lipolysis within BAT increases the concentration of fatty acyl CoA that activates UCP1 and heat is produced. White adipose cells and brown adipose have very different cell origins and recent work has shown that some of the UCP1 containing cells in adult humans are derived from the same lineage as white adipose cells. Such cells are not as brown as pure BAT and are termed beige.

## Energy storage and fuel use in the post-absorptive state

The previous sections have dealt with how fuels are catabolized releasing their energy to do useful work. Two of the fuels, carbohydrates and fats are also stored in the body to be used between meals and longer periods of starvation, or during exercise ([Cahill, 2006](#); [Watford, 2015](#)). There is no purely storage form of protein since all proteins have unique functions other than as a fuel. Similarly, there is no storage of ethanol and the metabolism of ethanol is actually prioritized over all other fuels by the liver.

### Triglycerides

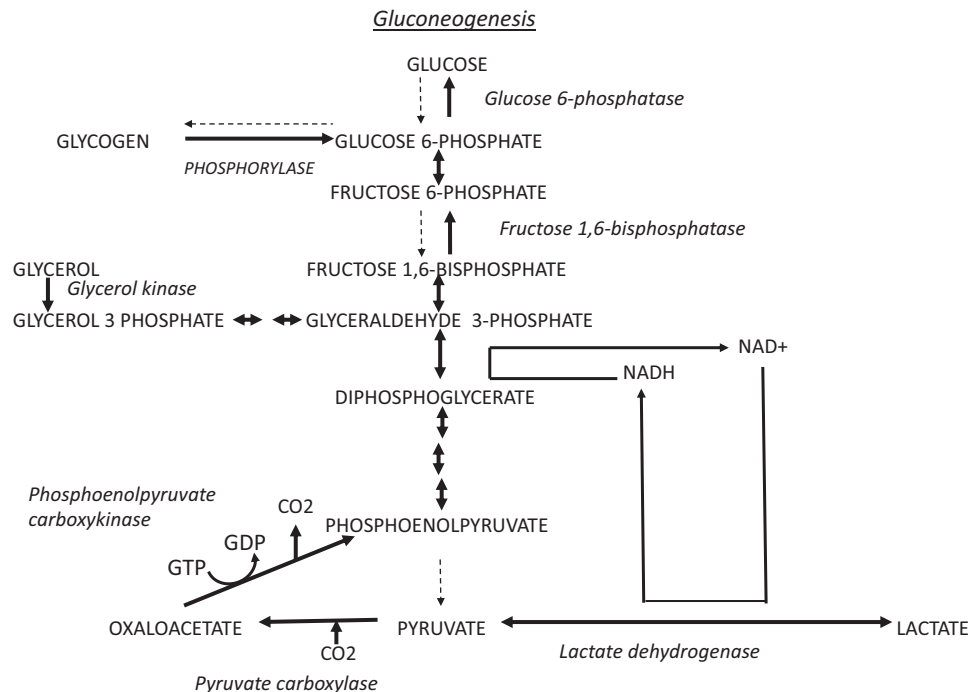

In humans white adipose tissue is the most important site of triglyceride storage. Most fatty acids stored as fuel are derived from the diet. A minor contribution will arise from de novo fatty acid synthesis ([Fig. 4](#)) that occurs in the cytosol from acetyl CoA which is converted to malonyl CoA followed by a series of reactions in the fatty acid synthase enzyme complex ([Berdanier and Berdanier, 2015](#); [Bronk, 1999](#); [Frayn and Evans, 2019](#); [Salway, 2004](#)). In a reversal of  $\beta$ -oxidation acetyl CoA (2 carbons)

are sequentially added as malonyl CoA until the chain length is 16 carbons which is then released as palmityl CoA. This can then undergo elongation and desaturation to form the variety of long chain fatty acids. Within the cytosol the high levels of malonyl CoA will block CPT1 preventing the fatty acid from entering the mitochondria to be oxidized. Therefore any long chain fatty acids, from de novo synthesis or taken up by the cell, will be esterified to glycerol 3 phosphate to form triglyceride (a neutral lipid) and then stored in the lipid droplet. The glycerol 3-phosphate can arise from glucose via glycolysis or from lactate by the pathway of gluconeogenesis. In addition, the liver expresses glycerol kinase that enables the glycerol released from lipolysis in other tissues to be phosphorylated and either used for triglyceride synthesis or as a substrate for gluconeogenesis. In the post-absorptive state insulin levels drop which activates lipolysis in adipose tissue and the free fatty acids become available as fuel for other tissues.

## Glycogen

During the absorptive phase the blood glucose concentration rises and any in excess of immediate needs will be stored as glycogen mainly in liver and skeletal muscle through the action of glycogen synthase (Fig. 2). Glycogen is a polysaccharide (a polymer of glucose with extensive branching), sometimes called animal starch. Glycogen is synthesized from glucose 6-phosphate derived from glucose in muscle and both from glucose and gluconeogenesis in liver. Glycogen is mobilized by release of glucose 6-phosphate by the enzyme (glycogen) phosphorylase (Fig. 9) (Berdanier and Berdanier, 2015; Bronk, 1999; Frayn and Evans, 2019; Salway, 2004).

Muscle glycogen stores are of the order of 300 g and muscle glycogen functions as a local, intracellular, fuel. Stimulation of the muscle to contract releases calcium within the cell and this stimulates glycogen breakdown and glycolysis and so provides the ATP for contraction. White (Type 2b) muscles possess high levels of glycogen which fuels glycolysis to lactate (anaerobic metabolism) yielding very high power (ATP formation) but limited endurance. Glycogen levels in muscle are also important in aerobic exercise, where the oxidation of glucose yields twice the power (rate of ATP production) compared with the oxidation of fatty acids. Thus, the more glycogen present in muscle longer the endurance at maximal aerobic metabolism and endurance athletes develop

**Fig. 9** Glycogen breakdown and gluconeogenesis. In the liver excess glucose can be stored as glycogen (see Fig. 2). In the post absorptive state this glycogen is broken down by phosphorylase to yield G6P that can be hydrolyzed by glucose 6-phosphatase with the resulting glucose being released into the circulation to maintain blood glucose levels. As liver glycogen becomes depleted blood glucose levels are maintained by the process of gluconeogenesis. The main substrates are lactate (together with pyruvate and alanine), glycerol and amino acids (see Fig. 7). Glycerol is phosphorylated by glycerol kinase and enters the pathway at glyceraldehyde 3-phosphate. The other substrates all enter the pathway within the mitochondria where they give rise to oxaloacetate. The oxaloacetate then transfers to the cytosol via shuttles and is converted back to phosphoenolpyruvate by phosphoenolpyruvate carboxykinase (PEPCK). The PEP then essentially reverses the glycolytic pathway to yield free glucose. Three irreversible steps (shown as dotted arrows) in glycolysis are reversed by gluconeogenic specific enzymes: Pyruvate Kinase, reversed by Pyruvate carboxylase and PEPCK, Phosphofructokinase 1 reversed by fructose 1,6-bisphosphatase, Glucokinase (Hexokinase) reversed by glucose 6-phosphatase. Gluconeogenesis also occurs in the kidney where it is predominantly linked to the production of ammonia from glutamine at times of metabolic acidosis.

specific dietary regimes to maximize their muscle glycogen stores (Frayn and Evans, 2019). The phenomenon of “hitting the wall” in a marathon, when the runner can no longer maintain high intensity, is believed to occur when the muscle glycogen reserves have been depleted and the muscles must rely of fat oxidation.

### Glycogen breakdown and gluconeogenesis provide glucose to the body

Liver glycogen is an important source of circulating glucose in the post-absorptive state (Fig. 9). This is possible since liver expresses glucose 6-phosphatase which enables the release of free glucose to be released into the circulation on stimulation by glucagon. Liver glycogen stores are of the order of 100 g in an adult but the turnover of glucose is approximately 10 g per hour which would mean that liver glycogen stores would be rapidly depleted. But as insulin levels fall in the post-absorptive state lipolysis in adipose increases and the availability of free fatty acids in the circulation can replace some of the glucose utilization in most tissues. Nevertheless, given that the brain continues to fully oxidize 120 g of glucose per day liver glycogen stores can only maintain the brain for less than a day. In addition to stimulating glycogen breakdown glucagon also stimulates gluconeogenesis in liver (Cahill, 2006; Watford, 2015).

Gluconeogenesis (Fig. 9) is the synthesis of glucose from non-carbohydrate precursors and will increase during the post-absorptive period and early starvation to keep blood glucose concentrations stable. Glucose can only be formed from 3 carbon substrates and not from 2 carbon units such as those in fatty acids and ketone bodies. The substrates for gluconeogenesis are lactate (pyruvate and alanine), glycerol from triglyceride lipolysis, amino acids, and propionate (see Fig. 7). The last is the product of fermentation of dietary fiber by the colonic microbiota and is of little importance during prolonged starvation. Lactate, pyruvate and most alanine are derived from pyruvate that is itself derived from glucose in peripheral tissues. Therefore, the use of these three substrates for gluconeogenesis simply recycles the carbon skeletons and does not contribute “new” glucose for other tissues. This means that glycerol and amino acids are the only gluconeogenic substrates that can provide glucose for the brain to oxidize. From day one of starvation glycerol, derived from lipolysis of triglycerides, contributes approximately 20 g of new glucose. Therefore, once hepatic glycogen stores have been depleted gluconeogenesis from amino acids must provide 100 g of glucose. It has been estimated that it takes 180 g of amino acids to make 100 g of glucose which would require the breakdown of this much protein (approximately 800 g of muscle tissue) each day. Clearly this cannot be maintained for long and during starvation ketone bodies and fatty acids become the dominant oxidative fuels for most tissues. This is known as “the glucose sparing effect of fat derived fuels” or as the protein sparing effect. As ketone concentrations rise the brain will begin to oxidize them instead of glucose thereby further reducing the requirement for glucose. In very long starvation however, the brain still utilizes some glucose but even the metabolism of most of that is restricted to glycolysis to lactate, so conserving the glucose carbon skeletons. During prolonged starvation the high levels of ketone bodies produces an acidosis which is titrated by as ammonium salts with the ammonia being synthesized in the kidney from glutamine. The carbon skeleton of glutamine is further metabolized within the kidney as a substrate for renal gluconeogenesis (Watford, 2015, 2020a).

### Summary

Within the body different tissues show distinct patterns of fuel use to provide the ATP that is required for optimal function. In the absorptive state glucose is plentiful which increases insulin secretion and thereby increases glucose uptake into cells, suppresses hepatic glucose output, and inhibits the release of fatty acids from triglyceride stores. Insulin also increases the utilization of glucose both for energy production in most cells and storage as glycogen in liver. Similarly, dietary fats are stored, as triglycerides, in adipose tissue. Excess proteins will be degraded with the carbon skeletons used for gluconeogenesis (glycogen storage). During the post-absorptive period blood glucose levels decrease slightly and insulin levels fall. This removes the inhibition of lipolysis which then releases the fatty acids to be oxidized in place of glucose. Glucagon rises to stimulate the mobilization of hepatic glycogen to provide glucose to those tissues, such as the brain, that continue to use glucose. As hepatic glycogen stores become depleted blood glucose levels are maintained by gluconeogenesis, mainly in the liver using glycerol (from triglycerides) and amino acids (from protein degradation) as substrates. The partial oxidation of fatty acids in the liver results in increasing ketone body levels that will be utilized by the brain in place of glucose. Together the utilization of fatty acids and ketones as fuels is known as the “glucose sparing effect of fat derived fuels” (Randle et al., 1963). An alternative description is, the protein sparing effect, since the glucose would have been made from amino acids released from protein breakdown. This well-orchestrated pattern of fuel metabolism maintains fuels (glucose and ketones) to the brain and fatty acids and ketones to other tissues from the absorptive period into starvation (Cahill, 2006; Watford, 2015).

## Key points

- Humans can adapt energetically to changes in body weight through autoregulatory control systems that operate through an intrinsic (internal) control of body energy partitioning between lean and fat tissues (lean-fat partitioning) and through adaptive thermogenesis (regulated heat production); these contribute to energy conservation during energy deficit or increased energy dissipation during energy surplus.
- Even under standardized conditions of experimental overnutrition (weight gain) or undernutrition (weight loss), there is a large inter-individual variability in lean-fat partitioning and in adaptive thermogenesis, both of which contribute to the large inter-individual variability in weight gain during overfeeding or weight loss during underfeeding.
- The available evidence suggest the existence of two distinct control systems for adaptive thermogenesis: a relatively rapid reaction system that respond to energy imbalance and a relatively slow reaction system responding to changes in the body's fat reserves *per se*.
- Adaptive thermogenesis may occur in any of the components of daily energy expenditure, and could hence result in altered efficiency of energy utilization in the resting and/or non-resting states, whether during weight gain, weight loss or after the dynamic phase of weight change.
- There may hence be considerable inter-individual differences among humans in metabolic strategies to conserve in response to energy deficit or dissipate some of the excess energy in response to energy surplus.
- Subtle variations between individuals in lean-fat partitioning and in adaptive thermogenesis, cumulated over the long-term amid a fluctuating body weight, can be important in determining long-term weight maintenance over months and years in some individuals and in provoking the drift toward obesity in others.
- These energy adaptations are relevant as much to the etiology of obesity and in undermining therapeutic slimming as to the difficulties in regaining a healthy body composition (and functional capacity) during nutritional rehabilitation after disease cachexia or perturbed growth.

 SPA Spontaneous physical activity

## Introduction

Current notions about how humans adapt energetically to food deficit or surplus have origins in seminal works that were conducted in the late 19th and early 20th centuries.

First, it has long been advocated that the body's fat reserves play a critical role in ensuring the energy needs of the individual during long periods of food scarcity, while protecting the functional integrity of the lean mass (and vital organs). Indeed, an inverse association between the contribution of the body's protein as fuel during starvation and the initial (pre-starvation) degree of fatness was observed from inter-species studies more than a century ago. It was only several decades later (in the 1980s) that this lean-fat interrelationship in response to energy deficit became firmly established in humans. This was notably through (i) the work of Gilbert Forbes on the "companionship" of the lean and fat compartments of the body in response to dietary-induced alterations in body weight, and (ii) that of Marinos Elia in his remarkable analysis of human body composition data pertaining to the effect of starvation and very low calorie diets on protein–energy interrelationships. These publications have formed the basis of mechanistic models to help explain human variability in maximum percentage of body weight that can be lost and in predicting survival duration during prolonged starvation.

Second, in early human investigations into physiological adaptations pertaining to protein-energy metabolism during starvation, Francis Benedict's documentation of the day-to-day changes in basal oxygen consumption during the course of prolonged fasting revealed a greater-than-expected fall in basal metabolic rate (BMR) relative to the loss in body weight, thereby suggesting the possible existence of an adaptive energy conservation phenomenon in response to food deficit. This notion was strongly supported a few decades later in men subjected to 6 months of semistarvation in the classic Minnesota Starvation Experiment directed by Ancel Keys, and subsequently extended to people with obesity undergoing therapeutic dieting. This phenomenon of energy conservation during weight loss, nowadays often referred to as "metabolic adaptation", thus accounts for some of the less-than-expected weight loss from the prescribed dietary regimen and/or exercise therapies, and can hence influence the short- and long-term outcomes of weight loss interventions.

Third, the notion that certain individuals can offer considerable resistance to weight gain during overeating through the ability to burn the excess calories also has a long history. Carl Voit, in his 1881 theory of plethora, suggested that excess calories may be converted directly to heat, a phenomenon which Rudolf Neumann later referred to as "Luxus Konsumption". This term was replaced by "thermogenesis" several decades later in mid-1960 when Miller and Mumford discussed the potential importance of variations in heat production in the etiology of obesity. In subsequent discussion of their "Gluttony experiments" in university students, they attributed the large inter-individual variability in weight gain to varying capacity in disposing of excess calories as heat, and introduced the term "dietary-induced thermogenesis". This was later shortened to "diet-induced thermogenesis" and abbreviated as "DIT". To-day, the variations in heat production that serve the purpose of buffering body weight against energy imbalance—whether when referring to DIT in response to energy surplus or to "metabolic adaptation" in response to energy deficit—are embodied in the concept of regulated heat production or adaptive thermogenesis.

Given the famine-and-feast lifestyle that has characterized human evolutionary history, it is conceivable that these phenomena of energy adaptations—through adaptive thermogenesis and the management of the body's main energy-containing (protein and fat) compartments—evolved as key control systems in the regulation of body weight and body composition. This article provides an overview of current concepts about the nature of these control systems, and their modes of operation in enabling the human body to adapt to nutritional stresses and to achieve weight homeostasis.

## Energy adaptation: beyond mass action

Understanding how long-term weight homeostasis is achieved is still challenging for human research today. It is nonetheless recognized that the regulation of body weight results from a complex integration of genetic, epigenetic, physiological and behavioral factors which are mediated by numerous hormonal, metabolic and neural signals. In individuals in whom body weight is tightly regulated in the face of widely varying levels of food intake and energy expenditure (EE), this is achieved through autoregulatory feedback control systems that enable the precise matching of energy intake and EE in order to achieve long-term energy balance.

In fact, it has long been realized that there is a built-in stabilizing mechanism into the overall regulatory system that enables weight homeostasis. Any imbalance between energy intake and energy requirements will eventually lead to a change in body weight which, in turn, will alter the maintenance energy requirements in a direction that will tend to counteract the original imbalance and restore body weight to its original level. In this context, the system exhibits "dynamic equilibrium". For example, an increase in body weight will be predicted to lead to an increase in EE due to the extra energy needed for synthesis and maintenance of additional lean

and fat tissues. This will tend to produce a negative energy balance and thus a subsequent decrease in body weight toward its “set” or “preferred” value. Conversely, a reduction in body weight will lead to a reduction in EE due to the loss in lean and fat tissues, which will tend to produce a positive energy balance and a subsequent return toward the “set” or “preferred” weight. In reality, however, the homeostatic system is more complex than this simple effect of mass action as the efficiency of metabolism—through the extent of lean-fat partition and adaptive thermogenesis—can also change following alterations in body weight.

The most compelling evidence in support of a role for adaptive thermogenesis in the adjustments of daily EE following altered body weight derives from the “weight-clamping” experiment in which the subjects were made to lose or gain 10% of their habitual body weight, and which they had to maintain for several weeks prior to the determination of their daily EE. Subjects who were deliberately maintaining body weight at 10% above their habitual level showed an increase in daily EE of 15% on average even after adjusting for changes in body weight and body composition. Conversely, in subjects who were deliberately made to maintain body weight at 10% below their habitual level, daily EE, after adjusting for the losses in weight and lean tissues, was lower by about 15% on average. These compensatory changes in daily EE reflect changes in metabolic efficiency (i.e., adaptive thermogenesis) that oppose the maintenance of a body weight that is above or below the “set” or “preferred” body weight, and were observed in both men and women, and in subjects with or without obesity.

### Energy adaptation: inter-individual variability

Another important outcome of the above-mentioned “weight clamping” experiment is that it also underscored a wide inter-individual variability in the ability to readjust daily EE following weight gain or weight loss. Some individuals showed little or no evidence for adaptive thermogenesis while some others exhibited marked ability to decrease or increase EE through adaptive thermogenesis that was estimated to correspond to as much as  $2 \text{ MJ day}^{-1}$ .

Indeed, a large inter-individual variability in weight gain under standardized overfeeding conditions or in the efficiency of weight gain (i.e., the amount of weight gain per unit of excess energy consumed) has been observed in virtually all experiments of human overfeeding that ranged in duration from a few weeks to a few months. These differences could be attributed in part to inter-individual variability in the gain of lean tissue relative to fat tissue (thus reflecting variability in lean-fat partitioning), and in part to variability in the capacity for DIT. A subsequent detailed reanalysis of data from some 150 men and women who participated in overeating experiments conducted in the second half of the 20th century suggested that more than 40% of these overfed subjects must have exhibited an increase in DIT, albeit to varying degrees.

An important role for genetic factors in accounting for some of the human variability in metabolic susceptibility to weight gain has in fact been established from an overfeeding study in identical twins. The demonstration of intra-pair resemblance in their gain in body weight, body fat and lean mass have strongly suggested that genes play an important role in lean-fat partitioning of the excess energy consumed and in EE responses. Conversely, a role for genes in determining the large inter-individual variability in the amount and composition of weight lost, and in variability in the estimated increase in metabolic efficiency during therapeutic slimming has been suggested by intrapair resemblance during weight loss on a very low calorie diet in female identical twins with obesity.

Taken together, these studies suggest that in addition to the control of food intake, changes in lean-fat partitioning and in metabolic efficiency (adaptive thermogenesis) play an important role in the regulation of body weight and body composition, and that the magnitude of these adaptive changes is strongly influenced by genetic factors.

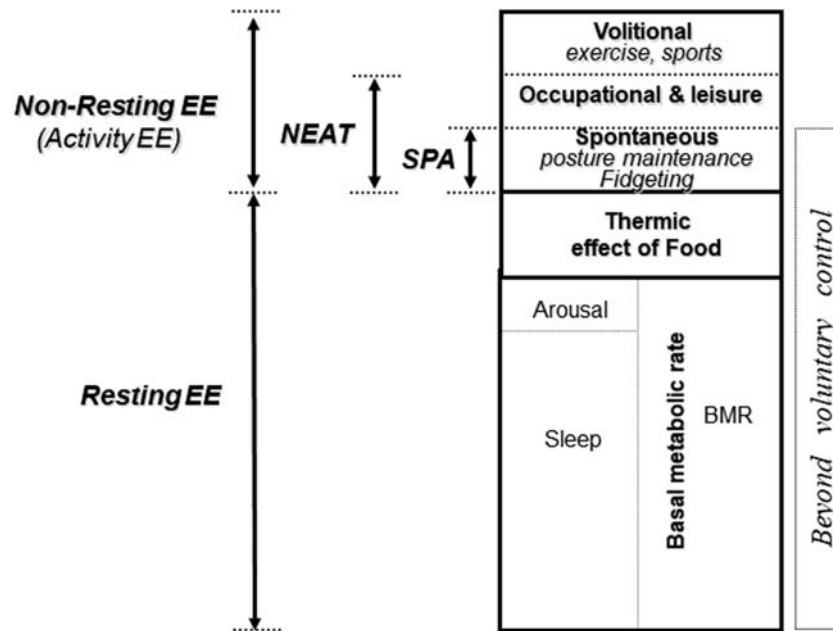

### What constitutes adaptive thermogenesis?

The quantification of adaptive thermogenesis during different states of weight changes remain challenging, amid several lines of evidence indicating that it could be occurring in any of the various components and subcomponents of daily EE, i.e., within the resting and/or non-resting state (Fig. 1).

#### Adaptive thermogenesis in the resting state

The majority of studies investigating the existence of adaptive thermogenesis pertaining to weight regulation have assessed EE only as BMR or resting EE (REE), which constitutes the largest component of daily EE in most sedentary humans typical of modern societies. In response to underfeeding or overfeeding, the changes in mass-adjusted BMR or REE, i.e., changes in EE that are greater than those predicted by changes in fat-free mass (FFM) and fat mass, can be quantified with the use of regression models to calculate the residuals (measured-predicted) values. The latter “residuals” (hence deviations from the predicted values) are considered to reflect changes in metabolic “efficiency” due to adaptive thermogenesis.

Reports of increases in mass-adjusted BMR, as well as in the thermic effect of food (expressed as % of meal energy) during experimental overfeeding is equivocal, and may be influenced by protein intake or the inclusion of exercise in the overfeeding protocol. By contrast, most studies of experimental starvation or hypocaloric dieting have reported reductions in mass-adjusted BMR or REE, with average values in the range of  $0.4\text{--}1 \text{ MJ day}^{-1}$ . Based upon the application of imaging techniques to assess the contribution of

**Fig. 1** Schematic representation of daily energy expenditure components and sub-components. Daily energy expenditure (EE) can be divided into resting and non-resting components from which resting EE is the larger component in sedentary, light-activity individuals; these various components or sub-components can be assessed by ventilated canopy or facemask indirect calorimetry or in a respiratory chamber. The compartment of resting EE comprises all measurements of EE generally made at rest—the basal metabolic rate (BMR), sleeping EE and the thermic effect of food (TEF)—and which are essentially beyond voluntary control. Non-resting EE (often referred to as activity EE) comprises both involuntary and voluntary physical activities; it is divided into volitional and non-exercise activity thermogenesis (NEAT), which in turn is subdivided into occupational/leisure activity and spontaneous physical activity (SPA), the latter being essentially involuntary and subconscious. Adapted from Dulloo, A.G., Jacquet, J., Montani, J.P., Schutz, Y., 2012. Adaptive thermogenesis in human body weight regulation: more of a concept than a measurable entity? *Obes. Rev.* 13 (Suppl. 2), 105–121.

the loss of individual organ mass to the decline in REE following weight loss on a low-calorie diet in women who were overweight or with obesity, more than a-third of the fall in REE could be attributed to adaptive thermogenesis.

A reduction in mass-adjusted BMR or REE has also been shown in subjects with obesity following weight reduction programs that involved dieting in combination with intense exercise and in which the loss of FFM is prevented or minimal. The most spectacular reductions in mass-adjusted REE were observed in “The Biggest Loser” nationally televised weight loss competition in which the participants who showed severe obesity (lost more than a-third of their body weight during a weight loss program consisting of diet restriction and vigorous exercise for 30 weeks. Despite a relative preservation of FFM, exercise did not prevent the dramatic reduction in mass-adjusted REE ( $\sim 2 \text{ MJ day}^{-1}$  on average) observed several months later.

A lower thermic effect of food (expressed as a % of meal energy) measured under resting conditions has also been reported after weight loss. Post-prandial thermogenesis, assessed during a test of oral glucose tolerance, has been reported to be reduced by more than two-thirds following weight loss in patients with obesity, while the thermic response to a mixed meal has been shown to be markedly lower after weight loss in subjects who were no longer obese compared to lean controls who never developed obesity.

Overall, these studies suggest that energy conservation through adaptive thermogenesis can occur both in the post-absorptive (BMR) and postprandial (thermic effect of food) components of EE; these being consistent with the reduced circulating levels of thyroid hormones and diminished sympathetic nervous system (SNS) activity that characterize energy sparing following weight loss.

### Adaptive thermogenesis in the non-resting state

Adaptive thermogenesis can also occur in various sub-components of non-resting EE (Fig. 1). While it is well established that the efficiency of muscular contraction during dynamic exercise is low ( $\sim 25\%$ ), that of spontaneous physical activity (SPA)—including fidgeting, muscle tone and posture maintenance, and other low-level physical activities of everyday life—is even lower since these essentially involuntary activities comprise a larger proportion of isometric work which is simply thermogenic. Since the actual work done on the environment during SPA is very small compared to the total energy spent on such activities, the energy cost associated with SPA has been referred to as movement-associated or SPA-associated thermogenesis. Because SPA is primarily a biologically-driven, involuntary (subconscious) behavior, a change in the level or amount of SPA in a direction that defends body weight may also constitute autoregulatory changes in EE. In this context, a decrease in SPA occurring following weight loss or an increase in SPA during overeating, also constitute adaptive changes in thermogenesis in the non-resting component of daily EE.

### Variability in spontaneous physical activity

The potential importance of SPA-associated thermogenesis in human weight regulation has in fact been underscored by the findings that even under conditions where subjects are confined to a respiratory chamber, the 24 h EE attributed to SPA (as assessed by radar) was found to vary widely (between 0.4 and 3.3 MJ day<sup>-1</sup>), and to be predictive of subsequent weight gain. This notion of a role of SPA in the etiology of obesity received considerable support by the findings that about two-thirds of the increase in total daily EE in experimentally overfed subjects could be attributed to non-exercise activity thermogenesis (NEAT), in which SPA is an important subcomponent (Fig. 1), and that NEAT was the most significant predictor of resistance to body fat gain. The more recent findings that overfeeding resulted in an increase in physical activity after adjusting for changes in weight and body composition, is consistent with the notion that an elevation in low-level physical activities and SPA might contribute to DIT, although there seems to be considerable inter-individual variability in this behavioral response to overfeeding. Conversely, evidence that diminished SPA contributes to adaptive thermogenesis following underfeeding can be derived from data obtained from the participants of the Biosphere 2 experiment, a self-sustaining ecologic “miniworld” and prototype planetary habitat built in Arizona several decades ago. Following an unexpected shortage of food, their losses in body weight (ranging between 8% and 25%) over a 2 year period were found to be accompanied by a markedly lower SPA than controls, which along with their reduced mass-adjusted 24 h EE (assessed in a respiratory chamber), was found to persist several months later after substantial weight recovery. In more recent years, diminished physical activity EE (including SPA), after adjustment for the change in body mass, has also been found to be reduced after several months of modest caloric restriction. Thus, in addition to suppressed thermogenesis in the resting component of EE, reduced SPA may contribute importantly to adaptive reductions in thermogenesis following caloric restriction.

### Efficiency of muscle work

Although changes in SPA can constitute an adaptive response to under- or over-nutrition, significant alterations in SPA have not always been found to be a main component of adaptive changes in non-resting EE. Indeed, in the “weight-clamping” experiment in which the participants maintained their body weight at 10% above or below the habitual level, the reported adaptive thermogenesis which was found to occur primarily in the non-resting component of EE (estimated by the difference between total daily EE and REE), could not be explained by changes in the amount of time spent in physical activity assessed by accelerometry. Instead, changes in the mechanical contraction efficiency of skeletal muscle following weight loss or weight gain have been shown to account for about a-third of the change in daily EE associated with physical activity. The notion that weight loss leads to increased muscle contraction efficiency is consistent with other reports of a lower (net) energy cost of walking or cycling exercise after weight reduction in subjects with or without obesity, in female dieters exercising at different workloads or in chronically undernourished subjects—all of which would contribute to further reduce energy needs after weight loss. They are also consistent with diminished circulating leptin, thyroid hormones and SNS activity that characterize energy sparing following weight loss.

### Interactions and compensations across components of EE

It should be underlined that the separation of adaptive thermogenesis into resting and non-resting states is arbitrary, and that potential interactions across these two components of EE cannot be disregarded (Fig. 1). For example, sleep EE, which is generally classified as EE at rest, also comprises a non-resting component due to spontaneous movements (i.e., SPA) that occur during sleep, the frequency of which appears to be highly variable between individuals. In addition, non-resting EE and NEAT could also include EE resulting from the impact of physical activity (exercise or SPA) on postabsorptive or postprandial EE. There is indeed some evidence that relatively low-intensity exercise can potentiate the thermic effect of food and that the effect of physical activity on EE can persist well after the period of the physical activity. There is also considerable interest in the phenomenon of exercise-induced “energy compensation” whereby the increases in EE that occur during moderate-to-intense exercise activities may not necessarily all translate into an increase in daily EE because of at least partial compensatory reductions of EE in NEAT or when at rest over subsequent day(s). Diminished post-exercise stimulation of EE has also been proposed as a mechanism for energy conservation in individuals who are considered to be chronically-energy deficient since childhood.

Overall, any change in metabolic efficiency in resting or non-resting state that would tend to *attenuate energy imbalance* or to *restore body weight and body composition* toward its “set” or “preferred” value constitute adaptive changes in thermogenesis.

### Autoregulation of body weight and body composition

Based upon a series of re-analyses of classic longitudinal studies of human starvation, refeeding and overfeeding, the available evidence suggests that the mechanisms of energy adaptation for optimal survival in an environment of famine-and-feast are embodied in three distinct autoregulatory control systems. These comprise an intrinsic (internal) control of partitioning between protein and fat (i.e., the control of lean-fat partitioning) and two distinct control systems underlying adaptive thermogenesis—the latter being depicted in the conceptual diagram shown in Fig. 2. One control system is a direct function of changes in dietary energy intake and responds relatively rapidly to energy deficit. Its effector mechanisms are suppressed early during starvation, restored rapidly as a function of energy re-availability, and are further activated if hyperphagia occurs during refeeding. Since the efferent limb of this control system—which is primarily under the control of the SNS—is dictated not only by the dietary energy intake but also by a variety of other environmental factors such as diet composition, specific nutrient deficiencies, ambient temperature,

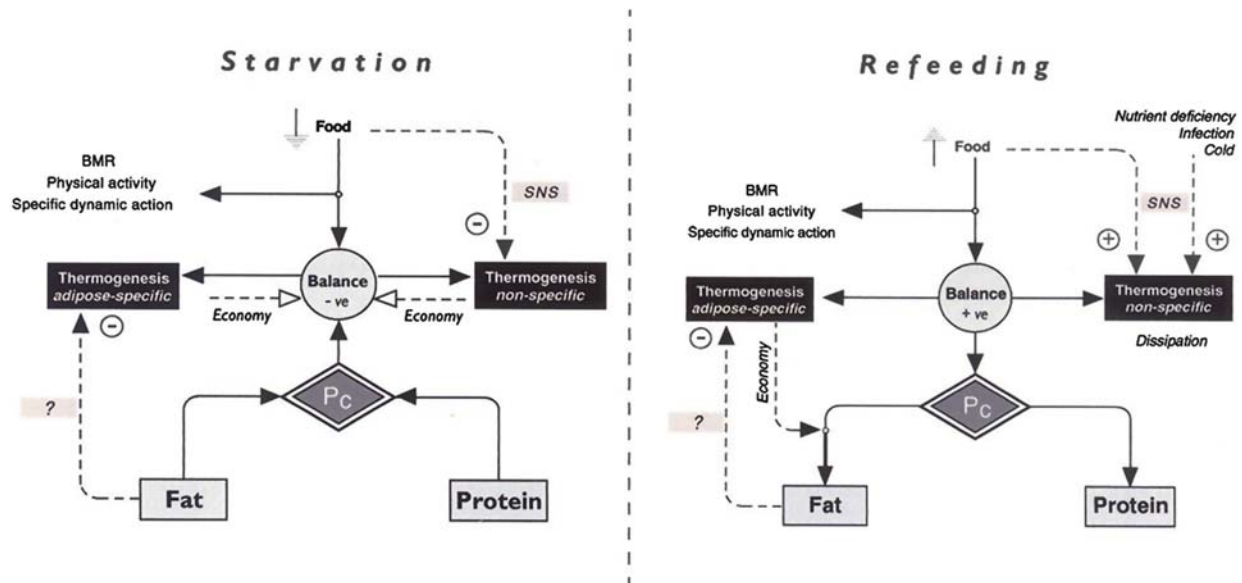

**Fig. 2** Schematic representation of the concept of two distinct control systems underlying adaptive thermogenesis during prolonged starvation and subsequent refeeding. One control system, which is a direct function of changes in the food energy supply, responds relatively rapidly to the energy deficit. Its effector mechanisms are suppressed early during the course of starvation, and upon refeeding they are restored relatively rapidly as a function of energy re-availability (levels 1–4), and are activated further if hyperphagia occurs during refeeding (level 4). Because, (as depicted in Fig. 3) the efferent limb of this control system is primarily under the control of the sympathetic nervous system (SNS) whose functional state is dictated by overlapping or interacting signals arising from a variety of environmental stresses including food deprivation, deficiency of essential nutrients, excess energy intake and exposure to cold or to infections, it is referred to as the *non-specific* control of thermogenesis; it is likely to occur primarily in organs/tissues with a high specific metabolic rate (e.g., liver, kidneys, brown adipose tissue). The other control system, by contrast, is independent of the functional state of the SNS, has a much slower time-constant by virtue of its response *only* to putative signals (denoted by symbol “?” in Fig. 3) arising from the state of depletion/repletion of the fat reserves; it is therefore referred to as the control system operating through an *adipose-specific* control of thermogenesis. While suppression of this *adipose-specific* thermogenesis during starvation and during refeeding leads to energy conservation, the energy thus spared during refeeding is directed specifically at the replenishment of the fat reserves, resulting in an accelerated fat recovery—a phenomenon that could contribute to the disproportionately rapid rate of fat relative to lean tissue recovery during refeeding after substantial fat reserves depletion. Adapted from Dulloo, A.G., Jacquet, J., 2001. An adipose-specific control of thermogenesis in body weight regulation. *Int. J. Obes.* 25 (Suppl. 5), S22–S29.

psychological stress, etc., it has been referred to as the *non-specific* control of thermogenesis. By contrast, the other control system has a much slower time-constant as it responds to signals arising from the state of depletion/repletion of body fat reserves; it has therefore been referred to as the control system operating through an *adipose-specific* control of thermogenesis. Thus, these control systems are distinct in their responses to signals reflecting changes in energy balance and the fat reserves.

### A compartmental model

An integration of these control systems in the autoregulation of body weight and body composition during a cycle of weight loss and weight recovery is discussed using a schematic diagram presented in Fig. 3. This diagram embodies the findings that the intrinsic control of body energy-partitioning between protein and fat (i.e., lean-fat partitioning) is an individual characteristic and that the intrinsic lean-fat partitioning characteristic ( $P_c$ ) of the individual during weight loss is relatively conserved during weight recovery. It also takes into account the two distinct control systems of adaptive thermogenesis which can function independently of each other.

During starvation, the intrinsic control of partitioning determines the relative proportion of protein and fat to be mobilized from the body as fuel—the individual’s  $P_c$  being, to a large extent, dictated by the initial body composition (i.e., initial body fat%). The functional role of the control of lean-fat partitioning is to meet the individual’s fuel needs in such a way that the energy-reserve component in both the fat and protein compartments (i.e., the part that can be lost without causing death or irreversible damage) would reach complete depletion simultaneously. Such a strategy would ensure the maximum duration of survival for a given individual during long-term food shortage. Furthermore, the energy conservation resulting from suppressed thermogenesis is directed at reducing the energy imbalance, with the net result that there is a slowing in the rate of protein and fat mobilization in the same proportion as defined by the  $P_c$  of the individual. Indeed, the demonstration in lean individuals that the proportion of fuel energy derived from protein (i.e., the  $P$  ratio) remains relatively constant during the course of prolonged fasting implies that suppressed thermogenesis is not directed at sparing specifically protein or specifically fat, but at sparing both protein and fat compartments

**Fig. 3** Schematic representation of a compartmental model for the regulation of body weight and body composition during a cycle of weight loss (prolonged starvation) and weight recovery (refeeding). In this model, the two distinct control systems underlying adaptive thermogenesis—the non-specific control and the adipose-specific control—are integrated with the more “basal” control of lean-fat partitioning between the body fat and protein compartments as determined by the partitioning characteristic ( $P_c$ ) of the individual. During weight loss (starvation), the energy economy resulting from a reduction in thermogenesis is directed in such a way as to spare (non-specifically) both the lean and fat compartments as defined by the  $P_c$  of the individual. In contrast, during weight recovery, the energy economy resulting from a reduction in thermogenesis is specifically directed at replenishing the fat compartment, with the net result that fat is deposited in excess of that determined by the  $P_c$  of the individual during weight recovery. The existence of these two distinct forms of adaptive thermogenesis provides an explanation for the co-existence of a hypermetabolic state (e.g., in response to infections, nutrient deficiencies, cold exposure) and the suppression of thermogenesis specific for accelerating fat replenishment. SNS = sympathetic nervous system; ? = unknown signal(s) (see legend of Fig. 2). Adapted from Dulloo, A.G., Jacquet, J., 2001. An adipose-specific control of thermogenesis in body weight regulation. *Int. J. Obes.* 25 (Suppl. 5), S22–S29.

simultaneously. During the course of prolonged starvation therefore, the functional role of the two control systems underlying suppressed thermogenesis is to reduce the overall rate of fuel utilization, i.e., to conserve energy that would reduce the rate at which both lean and fat energy reserves are being depleted.

During refeeding, the control of lean-fat partitioning operates in such a way that protein and fat are deposited in the same relative proportion as determined by the individual's  $P_c$  during starvation, thereby restoring the individual's pre-starvation surviving capacity. In addition, the increased availability of food energy would lead to rapid withdrawal of the suppressed *non-specific* (SNS-mediated) control of thermogenesis. In contrast, the suppression of thermogenesis under *adipose-specific* control is slowly withdrawn as a function of fat recovery, so that the energy that continues to be spared is directed specifically toward replenishing the body's fat reserves. The net effect is that fat is deposited in excess of that determined by the individual's  $P_c$ , thereby contributing to the disproportionate rate of fat recovery compared to that of lean tissue. This phenomenon of preferential catch-up fat has often been observed during nutritional rehabilitation in adults as well as during catch-up growth in infants or children. A role for thrifty (energy conservation) mechanisms underlying this catch-up fat phenotype has been proposed as a key link between fetal or neonatal growth retardation, catch-up growth and risks for developing type 2 diabetes and cardiovascular diseases later in life.

### Biological significance of a dual control system for adaptive thermogenesis

Such an adaptive phenomenon that accelerates the restitution of the fat reserves rather than diverting the saved energy toward a compensatory increase in body protein synthesis (an energetically costly process) would have survival value in an ancestral life-style of periodic food scarcity. This is because, by virtue of the fact that body fat has a greater energy density and a lower energy cost of synthesis/maintenance than protein, it would provide the organism with a greater capacity to rapidly rebuild an efficient energy reserve, and hence to cope with recurrent food shortages.

Thus, the functional role of the *adipose-specific* control of thermogenesis during weight recovery is to accelerate specifically the replenishment of the fat stores when food availability improves following severe food deficit and marked depletion of body fat reserves. It provides an alternative mechanism to accelerate the recovery of survival capacity in the absence of food abundance and hyperphagia. But equally important for mammalian survival during weight loss and weight recovery is the need to retain the ability to increase heat production (i.e., to activate thermogenesis) in response to a number of other environmental stresses namely: (i) for increased thermoregulatory needs in cold environments, (ii) for generating fever upon exposure to infections or (iii) for increased heat production as an adaptation to nutrient-deficient diets.

Indeed, a re-analysis of human data on experimental overfeeding studies conducted between 1965 and 1999 demonstrated that subjects who were overfed diets almost deficient in protein (<3% of energy intake) showed the highest energy cost of weight gain, and were hence most likely exhibiting a substantial level of DIT. From an evolutionary perspective, the capacity to increase DIT in the face of nutrient-deficient diets probably had survival advantage of “homeostatic waste” because it allows individuals to overeat relatively large amounts of poor quality food in order to obtain essential nutrients without depositing excess, non-essential energy in the form of fat. Excessive weight gain is thought to interfere with optimal locomotion, hunting capabilities and the ability to perform the “fight or flight” reaction. It has in fact been proposed that DIT may have evolved as a means of regulating the metabolic supply of essential nutrients (protein, minerals, vitamins) with only a secondary role in regulating energy balance and body weight.

Whatever the exact functional significance of DIT, however, it is clear that in a context of weight recovery, an increased efficiency for catch-up fat can be shown to persist even under conditions of hypermetabolism (a net increase in thermogenesis) induced by hyperphagia or nutrient-deficient diets. To explain this apparent paradox, the model presented in Fig. 3 provides a structural framework that illustrates how suppressed *adipose-specific* thermogenesis which drives the acceleration of fat deposition during refeeding (with the energy sparing postulated to occur in the skeletal muscle) persists under conditions when the *non-specific* control of thermogenesis is activated in organs/tissues recruited by the SNS (liver, kidneys, heart, brown adipose tissue). Such differentially-regulated control systems for adaptive thermogenesis may thus have arisen during the course of mammalian evolution as dual-adaptive processes that can satisfy the need for energy conservation during weight loss, or for catch-up fat during weight recovery, even under conditions of environmental stresses when activation of heat production by the SNS has equally important survival values. This concept of dual-control system for adaptive thermogenesis has received considerable support from studies in rodent models of refeeding after caloric restriction, and is also supported by some studies in humans (see section below). Furthermore, using animal models of semistarvation and controlled refeeding, considerable progress has been made in elucidating the postulated role of diminished skeletal muscle thermogenesis in the effector mechanisms of the “adipose-specific” control of thermogenesis. These include reductions in the rate of muscle protein turnover and other energetically costly substrate cycles, reductions in subsarcolemmal mitochondria, diminished ratio of white to red muscle fibers and slowed muscle contraction/relaxation cycle—all of which can be related to a state of skeletal muscle hypothyroidism resulting from altered activity of muscle deiodinase enzymes. Still to be unraveled, however, are the sensors and signals of the feedback loop between adipose tissue fat depletion and suppressed skeletal muscle thermogenesis.

### Energy adaptation during a longitudinal human study of large weight fluctuations

The existence and functions of this dual-control systems for adaptive thermogenesis in humans are consistent with the temporal changes in BMR and body composition during the longitudinal study of semistarvation, refeeding and subsequent overeating in men participating in the Minnesota Starvation Experiment—the most tightly controlled domiciled feeding study ever conducted in humans. The pattern of changes in food intake and body weight, together with kinetics of altered thermogenesis (BMR adjusted for FFM and fat mass, and expressed as a percentage of baseline BMR) are presented in Fig. 4; the data on altered thermogenesis being derived from a re-analysis of data from this experiment.

- First, during the phase of weight loss, the operation of the two control systems for adaptive thermogenesis is suggested by the fact that reduction in thermogenesis is *biphasic* in nature, with an initial rapid reduction in adjusted BMR at week 4, corresponding to 10% of baseline BMR, followed by a slower reduction in adjusted BMR, corresponding to 20% and 25% of baseline BMR at week 12 and 24, respectively. At these latter time-points during semistarvation (at S12 and S24), the magnitude of reductions in adjusted BMR was found to be associated with the reduction in fat mass—i.e., the greater the degree of depletion of the fat reserves, the greater the suppression of thermogenesis.
- Second, during the phase of weight recovery, the functioning of the two control systems for thermogenesis is also suggested by the following:
  - (a) the relationship between the degree of depletion of fat reserves and suppressed (*adipose-specific*) thermogenesis persisting at week 12 of restricted refeeding, at which time-point (R12) the mean adjusted BMR was still about 10% below baseline BMR level, the body fat was 80% recovered, while the recoveries of body weight and FFM were less than 50%, and
  - (b) during the subsequent period of *ad libitum* refeeding, the development of hyperphagia was accompanied by a rapid (*non-specific*) increase in thermogenesis, as evidenced by increases in adjusted BMR corresponding to about 20% of baseline BMR at week 14 of refeeding.
- Third, during the phase of weight overshoot, it is noticeable that by week 20 after the onset of refeeding (at R20), when FFM has been recovered to almost 100% and body fat has exceeded the baseline (pre-starvation) level by more than 50%, the adjusted BMR remained significantly higher (by about 10% on average) above baseline (pre-starvation) values despite the fact that hyperphagia was no longer present and FFM was normalized. This sustained rise in thermogenesis after post-starvation overfeeding is consistent with a feedback mechanism existing between thermogenesis and body fat, and may well have contributed to the subsequent slow return of the “overshoot” body weight toward the baseline (pre-starvation) level.

It should be pointed out that the data available for the re-analysis of the Minnesota Starvation Experiment only allowed the analysis of adaptive thermogenesis in the BMR component of daily EE, and that no measurements were performed pertaining to the thermic effect of food or to the energy cost of physical activity. Nonetheless, the authors observed that there was a profound decrease in

**Fig. 4** Pattern of changes in body weight, food intake, and adaptive thermogenesis during the various phases of the longitudinal Minnesota Experiment of human semistarvation and refeeding. The changes in adaptive thermogenesis at the various time-points are assessed as changes in basal metabolic rate (BMR) after adjusting for changes in fat-free mass (FFM) and fat mass, and expressed as a percentage of the baseline (control, C) level. C = end of control (baseline) period; S12 and S24 = week 12 and week 24 of semistarvation, respectively; R12 and R20 = week 12 and week 20 after onset of refeeding. Drawn from data of: (i) Keys, A., Brozek, J., Henschel, A., Mickelson, O., Taylor, H.L., 1950. *The Biology of Human Starvation*. Minneapolis: University of Minnesota Press, 1950; (ii) Dulloo, A.G., Jacquet, J., 1998. Adaptive reduction in basal metabolic rate in response to food deprivation in humans: a role for feedback signals from fat stores. *Am. J. Clin. Nutr.* 68, 599–606.

physical activity of the subjects, especially during second 12 week period (S12-S24) of semistarvation, thereby suggesting that adjustments in EE occurred importantly in both resting and non-resting EE. Indeed, further evidence in humans in support of the adipose-specific suppression of thermogenesis driving catch-up fat can be derived from:

- (i) the demonstration of an association between mass-adjusted REE and the recovery of fat mass during nutritional rehabilitation of patients recovering from non-neoplastic gastrointestinal disease, and
- (ii) the findings of persistently low mass-adjusted 24 h EE (including in sleeping EE and SPA) during weight recovery that was primarily as body fat after 2 years of sustained caloric restriction in the above-mentioned Biosphere 2 Experiment.

### Energy adaptations and susceptibility to leanness and fatness

In addressing the issue of energy adaptation in human susceptibility to leanness and fatness, it must be emphasized that even in individuals who appear to maintain a relatively stable body weight over decades, there is no absolute constancy of body weight over days, weeks and months. Instead, body weight tends to fluctuate or oscillate around a mean constant value, with deviations from a “set” or “preferred” value being triggered by events that are cultural (week-end parties, holiday seasons), psychological (stress, anxiety or emotions), intentional (multiple attempts to lose weight but resulting in repeated weight regain, i.e., weight cycling), and pathophysiological (ranging from minor health disturbances to more serious disease states). Within such a dynamic state in which weight homeostasis occurs, it is likely that long-term constancy of body weight is achieved through a network of regulatory systems and subsystems through which autoregulatory changes in food intake, body composition and EE are interlinked.

The above-described autoregulatory control systems—operating through the intrinsic control of lean-fat partitioning and through the two distinct control systems underlying thermogenesis—can play a crucial role in attenuating and correcting deviations of body weight from its “set” or “preferred” value. The extent to which these adjustments are made depends on the environment (e.g., diet composition), and varies greatly between individuals, largely due to the individual’s previous nutritional status and genetic variations. They probably conferred different abilities to defend the body’s lean mass and fat reserves in an ancestral hunter-gatherer lifestyle of famine-and-feast, but now underlie our different metabolic susceptibilities to fatness in societies where palpable foods are abundant throughout the year. The resultant subtle variations between individuals in lean-fat partitioning and in adaptive thermogenesis can, over the long-term, be important in determining constancy of body weight in some and in provoking drift toward obesity in others. This may have particular relevance in explaining the findings of numerous prospective studies which suggest that repeated dieting to lose weight and subsequent weight regain (weight cycling) is a risk factor for later obesity. Indeed, using a mathematical model of weight cycling that integrates these autoregulatory control systems regulating body composition—including those underlying the preferential catch-up fat phenomenon leading to fat overshooting—it could be predicted that in lean individuals, the cumulative amount of fat overshoot over several weight cycles would ultimately result in obesity.

Furthermore, with particular relevance for obesity management, the adaptive responses to energy deficits, discussed so far, primarily in the context of weight recovery after experimental starvation in normal-weight (lean) individuals, also occur in individuals in whom obesity has developed spontaneously, and contribute the defense of the obese state once acquired. Indeed, several studies conducted in subjects with obesity have shown that mass-adjusted reductions in REE and/or in non-resting EE persist in the stable weight loss maintenance phase (i.e., in the weight reduced state) for months to years after weight loss. For example, in a follow-up study of the “Biggest loser” competition, the reduced mass-adjusted REE ( $2 \text{ MJ day}^{-1}$  on average) after losing about 40% of their weight during the competition, persisted some 6 years later despite having regained more than two-thirds of their lost weight. Taken together, these studies suggest that people with obesity respond to weight loss therapy by conserving energy through adaptive thermogenesis (in the resting and/or non-resting components of EE) well beyond the dynamic phase of weight loss and into the weight-reduced state and during weight regain.

These results support the notion that suppressed thermogenesis in response to food deprivation is a factor that reduces the efficacy of therapeutic regimens, and contributes to the relapse of obesity. In addition, since the initial body composition (% body fat) is the most important determinant of energy partitioning between lean and fat tissue (i.e.,  $P_c$  of the individual) during weight loss and weight recovery, the higher %body fat (i.e., the more obese the individual), the lower the fraction of energy mobilized as protein, and hence the greater the propensity to mobilize fat during weight loss and to subsequently deposit fat during recovery. The low  $P_c$  of the individual with obesity, coupled with sustained (adipose-specific) suppression of thermogenesis in response to their relative state of body fat depletion, will contribute to the relapse of obesity.

## Concluding remarks

Given the famine-and-feast lifestyle that has characterized much of human evolutionary history, it is conceivable that what constitutes normal physiology of weight regulation evolved within the constraints of large fluctuations in body weight and body composition. In this context, the autoregulatory control systems that regulate body composition must have evolved to optimize not only the survival capacity of the individual during prolonged periods of food scarcity, but also the recovery of this survival capacity whenever food availability improves (in readiness for the next period of food scarcity), and in some situations to exhibit DIT in the face of abundance of nutrient-deficient diets to avoid excessive weight gain. These multiple control systems therefore constitute the “energy adaptations” which nowadays manifest themselves to varying degrees in proneness to obesity and in undermining obesity therapy and disease-cachexia rehabilitation.

## Key points

- While perceived hunger is the drive to consume in response to a biological need, several other influences can impact how much and when a person eats.
- Within the homeostatic appetite system, excitatory and inhibitory signals shape the overall expression of hunger and satiety.
- Hunger is a key component of the relationship between energy expenditure and energy intake.

## Glossary

**Food reward or food hedonics** Thoughts about food and sensory appreciation of certain food attributes that determine food preference and choice. Comprises of two distinct components: liking and wanting for food. Liking is the sensory pleasure elicited by contact with food and wanting is the motivation to consume a specific food, manifesting explicitly (craving/desire) or implicitly (food cue responsiveness)

**Hunger** The drive to consume, a subjective experience that stimulates and sustains a behavioral event, eating. It has a strong learned component and can be triggered by physiological need or environmental stimuli. Hunger usually predicts subsequent eating behavior, and is suppressed by that ingestion, an effect that depends on the sensory, cognitive, gastric, gastrointestinal, and metabolic consequences of ingestion and learned associations with specific foods

**Satiation** The within-meal processes that bring eating episodes to an end, predominantly driven by cognitive factors and learned associations, the physical and sensory characteristics of the meal, the bulk of that meal in the stomach, and the rate of gastric emptying

**Satiety** The suppression of hunger and eating behavior after a meal. Often referred to as a state sustained by numerous post-ingestive and post-absorptive mechanisms, triggered as food is digested and nutrients are absorbed and metabolized

## Introduction

The term “hunger” is used in more than one sense by both scientists and the public. One traditional use refers to insufficient food availability, as it may occur in poor regions of the world. Most experts, however, prefer to use the term “food insecurity” to refer to situations of food scarcity. In the context of this article, hunger describes the drive or the motivational force that urges us to seek and consume food. It is the expression of a biological need to sustain growth and life. Hunger is therefore a purposeful experience that possesses a clear biological function (Blundell, 1979). Therefore, in traditional motivation theory, hunger is a biological drive to satisfy a physical need. In true homeostatic fashion, the drive to consume reduces and that need is satisfied (sated).

There are two components to hunger within nutritional science. Hunger is inferred from directly observable and measurable events. In this way, by inferring increased or high levels of hunger from a long period of food deprivation or an increased willingness to expend effort in order to obtain food, hunger becomes a mediating concept or an intervening variable. However, linked to these

directly observable behavioral events are a collection of conscious feelings or sensations that are linked to a desire to obtain and eat food. This is the sense in which lay people understand the term hunger. It is through these objectively observable behavioral events and the vigorous measurement of these subjective feelings, by means of rating scales and other measurement devices, that researchers attempt to capture changes in hunger motivation.

Early investigators used questionnaires which asked people to note the presence of physical sensations in a number of bodily areas, together with moods, urges to eat, and preoccupation with thoughts of food and of the everyday experience of hunger (Monello and Mayer, 1967; Friedman et al., 1999). It was found that the observation, "I feel hungry," was typically based on the perception of bodily feelings, which at times are very strong. Gastric sensations, a hollow feeling or stomach rumbling, are frequent indicators of hunger, although people also report sensations in the mouth, throat, and head. These accompany more diffuse feelings of restlessness and excitability as well as an urge to eat. The consumption of food changes both the pattern of physical sensations and the accompanying emotional feelings, with unpleasant and aversive sensations becoming replaced by more pleasant ones. Thus, as classic drive reduction theory would suggest, hunger is associated with unpleasant feelings, and food consumption eases these. For example, an aching stomach becomes relaxed, and the feeling of excitement and irritability is replaced by one of contentment.

Despite this commonality, subsequent study has shown a great deal of variability both within and between individuals. In other words, hunger demands neither the consistent presence of sensations before every act of eating nor that these sensations occur in every person sitting down to eat. However, even with this variability, people are able to, and frequently do, make judgments regarding their state of hunger, partly through reference to these sensations.

## The measurement of hunger

The process of measuring hunger is not straightforward. There is an inherent mistrust of subjective reports of appetite. Critics point to the variability in response between individuals and the absence of any objective "standard" by which internal experience can be calibrated. This has driven many to use biological proxies (the release or inhibition of particular hormones or activation of certain brain areas) as "biomarkers" for appetite in the hope that these may be more reliable indicators of behavior. However, hunger must be seen in a wider individual and situation context and cannot rest in the fluctuations of any single biological system or biomarker. The issues of "validity" and "reliability" are more complex than criticism suggests.

The two most common methods for quantifying hunger are fixed-point rating scales and visual analog scales. Fixed-point scales are quick and simple to use, and the data they provide are easy to analyze. Past examples of these scales show that they vary considerably in complexity. In considering the appropriate number of points to be included in this type of scale, the freedom to make a range of possible responses must be balanced against the precision and reliability of the device. Research seems to indicate that scales with an insufficient number of fixed points can be insensitive to subtle changes in subjective experience. In addition, the fixed points are important determinants of the way in which people use the scales and distribute their ratings. One way of overcoming some of these failings is to abolish such points. Thus, visual analog scales are horizontal lines; these lines should be at least 100 mm long (or longer to allow the freedom to make a range of responses), unbroken and unmarked, except for word anchors at each end (Flint et al., 2000). The user of the scale is instructed to mark the line at the point that most accurately reflects the intensity of the subjective feeling at that time. The researcher measures the distance to that mark in millimeters from the negative end (no hunger), thus yielding a score of 0–100 (in the case of 100 mm lines). This is done either by hand or automatically if presented by a computer screen (the latter method ensures that they are completed at designated times during a study day). By doing away with all the verbal labels except the end definitions, visual analog scales retain the advantages of fixed-point scales, while avoiding many of the problems with uneven response distributions.

An important aspect of these methods concerns the interpretation of differences between the fixed points or intervals on a visual analog scale. For example, it cannot be assumed that the difference between 20 and 30 mm on a hunger scale is perceptually the same as the difference between 80 and 90 mm. Nor can a hunger rating of 80 mm be said to represent a feeling of hunger that is twice the intensity of that rated at 40 mm. The variation of scores on these scales represents the fluctuations in the perception of feeling and not absolute change of some physical commodity. Individuals will use these scales idiosyncratically (each individual may interpret the scale and gauge their response differently) but generally consistently on repeated occasions (they will tend to scale any changes in response within their own parameters, producing a reliable record of alterations in an individual's appetite). One example of this is the problem of "end effects." This refers to the reluctance of a minority of subjects to make ratings away from the upper or the lower end points of the scale, despite clear instructions. Despite these limitations, data from such scales are often analyzed using parametric statistical procedures, such as analysis of variance, and in general, this appears to be a satisfactory approach.

## Hunger and satiety

If hunger is that feeling that drives us to seek food and to consume, then eating eventually relieves hunger, albeit until the next snack or meal. The capacity of a food to reduce the experience of hunger can be termed "satiating power" or "satiating efficiency" (Kissileff, 1984) and can be quantified by the satiety quotient (Green et al., 1997). This power is the product of the body's handling of the

nutritional composition and structure of the food eaten. It follows that some foods will have a greater capacity to maintain suppression over hunger than other foods. This will depend on their sensory impact, physical characteristics, energy density, and macronutrient composition (Holt et al., 1995; Kirkmeyer and Mattes, 2000).

The distinction between hunger and satiety is both conceptual and technical. As hunger diminishes, satiety rises. However, it is useful to further separate those events that occur across the course of a meal (prandial) from those between meals (pre- and postprandial). In this way, the prandial process of satiation can be clearly distinguished from the postprandial state of satiety. Satiation can be regarded as the process that develops during eating and that eventually brings a period of eating to an end. Accordingly, satiation can be defined in terms of the measured size of an eating episode (such as its energy, weight, or volume). Hunger declines as satiation develops, and usually reaches its lowest point at the end of a meal. Satiety is defined as the state of inhibition over further eating that follows at the end of a meal and that arises from the consequences of food ingestion. The intensity of satiety can be measured by the duration of time until eating starts once more or by the amount consumed at the next meal. The strength of satiety is also measured by the time that hunger is suppressed, but as satiety subsides, hunger is restored.

In examining the mechanisms responsible for suppressing hunger, it is clear that they range from those that occur when food is initially sensed to the effects of metabolites on body tissues following the digestion and absorption of food (across the wall of the intestine and into the bloodstream). By definition, satiety is not an instantaneous event but occurs over a considerable time period. Sensory effects are generated through the smell, taste, temperature, and texture of food, and it is likely that these factors have effects on eating in the very short term. Cognitive influences represent the beliefs held about the properties of foods, and these factors may also help inhibit hunger in the short term. These will start to affect hunger even before consumption has commenced and continue to suppress it over the course of the meal.

Post-ingestive processes such as gastric distension and rate of emptying, the release of hormones such as cholecystokinin, peptide-YY, glucagon-like peptide-1, and the stimulation of certain receptors along the gastrointestinal tract increasingly suppress hunger and, as the meal terminates, further inhibit its rebound during early post-meal satiety. The postabsorptive phase of satiety comprises those mechanisms arising from the action of metabolites after absorption into the bloodstream. These include the action of glucose and amino acids, which act directly on the brain after crossing the blood-brain barrier and which influence the brain indirectly via neural inputs following stimulation of peripheral chemoreceptors. These will continue to suppress hunger late into the postprandial period.

### Hunger is driven by energetic needs

As that feeling that drives us to seek food, it makes sense from an evolutionary perspective that hunger should arise from the need to replace the energy used by the body. Our body's basic energy needs are reflected by the resting metabolic rate, largely influenced by lean or fat-free mass, which includes all high-metabolic-rate organs of the body such as the heart, liver, kidneys, brain, muscles, etc. Studies have shown that fat-free mass and resting metabolic rate are associated with hunger ratings and energy intake (Blundell et al., 2020). Being physically active and performing essential daily behavioral tasks also contribute to a person's energy needs and constitute another drive for energy from food (albeit to a smaller degree than resting metabolic rate). Thus, both metabolism and behavior are involved in generating hunger as a functional response to energy needs. It is therefore of interest to examine how habitual physical activity affects hunger and satiety. This is different from the effect of acute exercise on hunger: high-intensity exercise has been shown to suppress hunger, but this effect is transient (<1 h) and does not appear to subsequently affect food intake. This will not be discussed further. Rather, habitual physical activity level, i.e., the degree to which someone performs physical activity over a long period of time, has been shown to be non-linearly related to energy intake in a J-shaped relationship (Beaulieu et al., 2018). This means that in people with higher levels of physical activity, daily energy expenditure and energy intake are closely matched, but in those with lower levels of physical activity, this coupling is lost, such that daily energy intake exceeds expenditure. Additionally, lower levels of physical activity appear to be accompanied by higher levels of adiposity. This J-shaped relationship between physical activity level (daily energy expenditure) and energy intake suggests that higher levels of physical activity are associated with more sensitive appetite control. This better matching between intake and expenditure could be due to enhanced satiety signaling. In contrast, lower levels of physical activity (being inactive/highly sedentary) are associated with dysregulated appetite and a reduction of energy expenditure which does not downregulate hunger and food intake. Consequently, this results in overconsumption relative to energy requirements and weight gain. This overconsumption may be related to greater hedonic and psychocognitive inputs increasing the susceptibility to overconsumption at lower levels of physical activity. The effect of physical activity on hunger and satiety can be conceptualized by a "dual-process action" on appetite whereby an increase in fasting hunger with greater levels of physical activity occurs in conjunction with an enhancement in satiety signaling (King et al., 2009).

### Other physiological determinants of hunger

According to Rogers (1999), even before food reaches the mouth, potent physiological signals are generated by the mere sight or smell of food, or even learned contextual cues such as location and time of day. These signals, produced in response to exposure to external stimuli, comprise the "cephalic phase" of appetite. This cephalic response is expressed in several parts of the gastrointestinal tract and acts to anticipate food ingestion. Later, stomach distension and the detection of macronutrients such as fat or protein

within the gut are all powerful satiety cues. They bring a meal to an end and, for a time, inhibit further consumption. Eventually, hunger again prevails and food intake follows. The flux between hunger and satiety is episodic and underpins the expression of our eating behavior throughout the day. However, it is not just the absence of episodic satiety cues (e.g., stomach distension and intestinal or absorbed nutrients) that influences the expression of hunger. Reduction in blood glucose levels or in the levels of the circulating adipose tissue hormone leptin indicates a deficit in available energy and in energy reserves. Such events are linked with feelings of hunger. Fluctuation of these factors indicates the metabolism and storage of the body's energy reserves. These are a tonic class of physiological signals that also influence the expression of appetite. Like episodic satiety signals, these tonic signals normally act on inhibitory mechanisms with the hypothalamus (anorexogenic circuits). Their absence elicits an active feeding response. Other tonic factors that indicate the body's energy status, such as adiponectin, cytokines, and gonadal hormones, also appear to act on energy regulator centers within the brain, particularly the hypothalamus, mainly to suppress hunger. Again, their absence serves to unleash appetite.

However, not all physiological signals, episodic or tonic, inhibit hunger. For instance, blood levels of the gut hormone ghrelin have been shown to increase before a meal. Subsequent intake has been shown to suppress ghrelin release. Further studies have shown that ghrelin infusions increase food intake. Thus, this is a hormone that acts to promote food intake. Interestingly, ghrelin receptors are found in various hypothalamic locations that form part of the orexigenic circuits promoting food intake. These circuits contain many neuropeptides, such as neuropeptide Y, orexins, melanocortin concentrating hormone, and galanin, which all stimulate food intake. The precise nature of the physiological and neurobiological regulation of appetite is discussed elsewhere in this encyclopedia.

Finally, it should be noted that the biological mechanisms critical to the expression of hunger are not independent of psychological ones. Indeed, the sensory and cognitive cues that stimulate hunger produce physiological changes that anticipate the ingestion and metabolism of energy and subsequently aid these processes. This gives rise to the psychological factors critical in the expression of appetite. Furthermore, the taste and thoughts of foods can generate sensations resembling hunger, sometimes called "hedonic hunger" (Lowe and Butryn, 2007). This other concept of hunger arises from the hedonic appetite system, which interacts with the homeostatic appetite system in the expression of our motivation toward and desire to eat certain foods. It has been argued that the concept of hedonic hunger actually represents a form of implicit wanting and is simply a reflection of food reward (Beaulieu and Blundell, 2020). The food reward components of liking and wanting can override homeostatic satiety signals and lead to overconsumption by increasing the size of a meal (overriding satiation) and by "eating in the absence of hunger" during the postingestive period (overriding satiety). It is important to make the distinction between hunger as a biological drive and implicit wanting as a component of the hedonic system as separate but interacting entities.

## Learning and hunger

As the classical work of Pavlov demonstrates, hunger responses can be easily entrained to specific stimuli. Omnivores, like carnivores, are meal eaters (in contrast to grazers); however, their dietary decisions are more complex. One of the essentials for an omnivore faced with a variety of new and different foods is the capacity to learn. It is not possible for an inborn preference or aversion to guide the choice of every possible food. Therefore, we learn which foods are beneficial (and which are not) by eating them. If the consequence of consumption is normal satiety, the pleasant postingestive signals this generates serve as a positive experience that can lead to learned preferences, as studied by Birch (1999). Alternatively, if consumption leads to an association between that food and negative gastrointestinal consequences such as nausea, then a conditioned aversion to that food (or even other similar tastes and flavors) is likely to develop. The learning process involves the association between the sensory and the postabsorptive characteristics of foods. In this way, the sensory characteristics of foods act as cues and come to predict the impact that foods will later have. Consequently, these cues should suppress hunger according to their relationship with subsequent physiological events. It is possible to demonstrate experimentally how human beings adapt their eating to a food's energy content. A distinctively flavored food that contains "extra" hidden energy, presented on several occasions, will result in a change in eating and in preference. When deprived of food, subjects' preference for the taste increases with gained experience. If presented when satiated, preference for the taste decreases. This process is also observable in young children, who eat smaller meals following a taste previously associated with a high-energy snack, and larger meals following a taste previously associated with a low-energy snack. Our hunger can thereby be potentially reduced by the learned associations of satiety.

In environments where food sources remain limited and dietary variety is controlled, learned responses may effectively control subjective feelings of appetite. However, when there is distortion, variation, or extreme complexity in the relationship between sensory characteristics and nutritional properties, then the conditioned control of hunger is weakened or lost. In such a scenario, hunger may become less controllable. In many respects, the variety of foods available to us represents a cacophony of different sensory characteristics and has the added complication of ingredients that preserve the sensory qualities while altering their nutritive value. Learned hunger therefore is a relatively less important factor when the food supply contains many food items with identical tastes but differing metabolic properties.

## Hunger and eating behavior

If hunger is biologically useful and a subjective experience that indicates a depleted nutritional state, then a close correspondence between hunger and eating would be expected. Hunger should be either a necessary or a sufficient condition for eating to occur. However, this is not invariably the case. Instances of people deliberately refraining from eating in spite of hunger (fasting for moral or political conviction) show hunger not to be a sufficient condition. People can, and regularly do, resist the drive to consume. As aforementioned in relation to food reward, examples, from both research and daily experience, of eating a tempting food when otherwise satiated show hunger not to be necessary for eating to take place. In the laboratory, merely changing the food on offer, or increasing its palatability, can encourage eating beyond the limits of normal satiety. Many of us have experienced festive overconsumption or had our interest tweaked by the dessert trolley. However, although the relationship between hunger and eating is not based on biological inevitability, they are not entirely uncoupled and under many circumstances they remain closely linked.

The lack of a one-to-one correspondence between hunger and eating is repeatedly used to question the validity of hunger ratings. But should a high correlation between hunger ratings and subsequent food intake be expected in all circumstances? The previous examples show that in certain circumstances the two can be disengaged. Thus, for example, eating can occur when hunger is low (such as when highly palatable food is offered unexpectedly) and not at other times when hunger is high (when food is unavailable or other activities have priority). The proximity to food cues can have dramatic, instantaneous effects on appetite expression. For some individuals, this responsiveness to food cues overwhelms normal appetite control and the normal rhythm of hunger. For others, eating in the absence of hunger is a component of their natural eating repertoire. It is clear that hunger ratings cannot be used simply as a proxy measure for food intake. Equally, when such factors are taken into account, there is good evidence that self-report ratings of hunger correlate statistically and meaningfully with eating.

In questioning the relationship between hunger and eating, we are also forced to place the action of hunger within a broader context of social and psychological variables that moderate food choice and eating behavior. Eating patterns are maintained by enduring habits, attitudes, and opinions about the value and suitability of foods, and an overall liking for them. These factors, derived from the cultural ethos, largely determine the range of foods that will be consumed and sometimes the timing of consumption. The intensity of hunger experienced may also be determined, in part, by the culturally approved appropriateness of this feeling and by the host of preconceptions brought to the dining table. Fluxes in hunger over time are therefore only one portion of the range of determinants of eating in any given situation.

## Disorders of hunger

The clinical eating disorders anorexia nervosa and bulimia nervosa are commonly believed to encompass major disturbances of hunger. Yet the role that hunger may play is not entirely clear. Contrary to the literal meaning of the term, “anorexia” is not experienced as a loss of appetite. Rather, clinicians recognize that people with anorexia may endure intense periods of hunger during their self-restricted eating. For some, their strength in resisting intense episodes of hunger provides a feeling of self-mastery and control that is absent in other areas of their lives. Research suggests that people with anorexia restricting food intake (compared with those who binge) have the greatest blunting of hunger response, and that this disturbance in hunger is not a product of other areas of perceptual confusion (Halmi and Sunday, 1991).

There is evidence that under conditions of total starvation, hunger may become temporarily diminished. This circumstance is extremely rare and obviously relatively brief. Once eating is recommenced, hunger returns rapidly and with extreme intensity. The accounts of the male volunteers who submitted to a 6-month period of semistarvation during World War II (the “Minnesota Experiment”) are a testament to the extreme power of hunger (Keys et al., 1950). Referred to as semistarvation neurosis, these men’s activities were shaped by their need for food, and their hunger experience was extreme. Nearly two-thirds reported feeling hungry all the time and a similar proportion experienced physical discomfort due to hunger. Participants described a marked increase in what was referred to as “hunger pain.” For some, this was mildly discomforting and vaguely localized in the abdomen. For others, it was extremely painful. This account is especially useful in reminding us why energy-reduced diets aimed at achieving weight loss are often difficult to maintain and easy to abandon.

Like anorexia, bulimia finds its literal meaning in changed hunger—“ox hunger.” Again, however, the term is imprecise. Close analysis of the precursors of binge episodes shows hunger to be lower than it is before a normal meal. In addition, although the urge to eat may be strong during a binge, the large amount of food consumed implies some defect in satiation rather than in hunger. Moreover, bingeing is often a well-practiced behavior that develops and changes with time. As with people with anorexia, it is likely that a stable eating pattern is necessary in order to normalize the experience of hunger, a process that may take a long time to establish.

The question of whether obesity reflects a disorder of hunger is now regarded as largely redundant. There is hardly any evidence of heightened levels of hunger contributing to excessive energy intake in people living with obesity. However, an exception to this is the rare disorder Prader–Willi syndrome. Genetically determined and characterized mainly by intellectual disability, obesity is a well-recognized feature of the syndrome. Research suggests that the excessive levels of food intake are associated with both a delayed reduction in hunger while eating and a more rapid return to premeal states when eating has finished. It has been postulated that tonic inhibitory signals such as leptin and insulin are weakened at higher levels of adiposity due to leptin and insulin resistance, also affecting episodic satiety signaling, which may promote overconsumption and further weight gain in people living

with obesity. Clearly, a better understanding of the biological events that accompany such aberrant eating patterns will strengthen understanding of the psychobiological framework that supports hunger.

## Conclusion

Hunger is a universal human experience and sensation. The sensation of hunger as a motivational drive to eat can be measured using validated tools and be quantified in its intensity. This intensity oscillates on a daily basis in response to food intake and inversely with satiety. Hunger is related to a fundamental process in human biology in order to replenish energy used up in metabolic processes and during activity. However, other intervening variables such as food reward, learned responses, culture and the environment can influence its intensity and periodicity as well as shape its expression.

## Role of Thirst in Water Balance

Approximately 70% of the lean body mass of an individual is composed of water, with approximately two-thirds of the total body water (TBW) volume being held within the cells of the body (intracellular pool), with the remaining one-third (extracellular pool) divided between the circulating blood plasma (intravascular pool) and the fluid-filled spaces between the cells (interstitial pool). The volume and distribution of the body fluids are mainly determined by the amounts of body water and sodium. In humans, the TBW content is regulated daily to within approximately 0.2% of the lean body mass under normal, temperate conditions by factors that control input and output. The kidneys regulate water excretion in excess of the evaporative loss and the fecal and obligatory urine losses. Water intake occurs in the form of food and drink, with the sensation of thirst underpinning drinking behavior.

The mechanisms that monitor the body's hydration status also interact with the thirst control centers in the brain to regulate the desire to drink. This article focuses on the physiological factors that govern the perception of thirst and how this is altered by drinking.

## Perception of Thirst

Thirst is a sensation that is best described as the desire to drink. The reason for drinking may not be directly involved with a physiological need for water intake, but can be prompted by habit, ritual, taste, nutrients, craving for alcohol, caffeine, or other drugs in a beverage, or a desire to consume a fluid, which will provide a warming or a cooling sensation. Much of the perception of thirst is a learned or a conditioned process, with signals such as dryness of the mouth or throat initiating drinking, whereas a feeling of fullness of the stomach can stop ingestion before a fluid deficit has been restored.

Currently, the thirst response is thought to be regulated by neural modulators that operate as a reward mechanism, integrating the effective requirement for water intake with the sensations of taste and pleasantness of the fluid ingested. Thus, when the individual is hypohydrated multiple areas of the brain are activated, promoting the intensity of the thirst sensation. As the water deficit is restored, the feeling of thirst diminishes and this subjective sensation correlates well with a reduction in neural activation. However, areas of the brain associated with taste, which are activated by water when thirsty, remain active following drinking to satiety when water is ingested.

Although it is true that thirst in humans is a poor indicator of acute hydration status and that daily fluid intake is normally in excess of obligatory water loss, the preservation of the TBW volume under a variety of environmental and nutritional stresses is remarkably robust and is mainly due to the drive to drink that the sensation of thirst chronically induces.

## Assessment of Thirst

In humans, two main techniques have been used to identify the perception of thirst and its alleviation by drinking. The first method is to monitor the volume of drink voluntarily ingested by an individual within an allotted time period and to compare the amount consumed with the volume of fluid required to restore a given water deficit or other imbalance of the body water pools. The other method is to assess the individual's perceived rating of thirst by asking them to record on a visual analog scale their responses to

a series of questions that are thought to relate to the sensation of thirst (Figure 1). The questionnaire technique has the advantages that it allows a series of measurements to be made before, during, and following the period of drinking, and appears to provide an indication of the relative strength of a given stimulus. Although in many studies both methods are used to gauge the sensation of thirst and the responses have been correlated to a number of physiological parameters that are known to influence the drive to drink, it is widely recognized that at present there is no consistently reliable measure of the thirst sensation.

A more recently introduced technique has been the use of noninvasive methods of imaging to identify the specific regions of the brain that are activated during the genesis and satiation of the thirst response. Different techniques are used to image brain activation. Both Positron Emission Tomography (PET) and functional Magnetic Imaging (fMRI) are used to visualize brain activation by detecting either temporal changes in blood flow or in the chemical composition of regions in the brain that occur when individuals are exposed to specific stimuli. The number of brain regions, their specificity, and the intensity of activation have also been correlated with the subjective perception of thirst.

### The Physiological Regulation of Thirst

As thirst is the major factor controlling water intake, the physiological regulation of thirst is associated with the need to maintain a relatively stable volume of TBW. Although water is lost from the body continually, albeit usually in relatively small amounts, and hence the body is almost always developing a water deficit, water intake is intermittent. The amount of fluid usually ingested is in excess of that required to replace the losses incurred since the last water intake. The factors that initiate, maintain, and end the drinking response are various and are not fully understood. However, as the regulation of the volume and composition of the various water pools of the body play an essential role in controlling the perception of thirst, an understanding of the homeostatic mechanisms involved has provided us with the best insight we have into the complexities of the perception of thirst.

**Figure 1** Subjective responses to a series of five questions assessed by visual analog scale ratings from 24-h water-deprived individuals before and during a 60-min rehydration period. The data are shown as differences (in centimeters) from the initial values and significant differences are indicated by filled symbols. Reproduced from Rolls BJ, Wood RJ, and Rolls ET (1980) Thirst: The initiation, maintenance, and termination of drinking. *Progress in Psychobiology and Physiological Psychology* 9: 263–321.

The total volume, distribution, and composition of body fluids must be regulated within narrow limits for normal cellular function to be maintained. Body water is passively distributed between the extracellular and intracellular pools according to osmotic, oncotic, and hydrostatic forces as shown in **Figure 2**. The sodium and chloride contents of the extracellular fluid constitute the two greatest osmotically active components of this fluid and are therefore important in maintaining its volume. Potassium, phosphate, and protein play a similar role in regulating the intracellular fluid volume. The distribution of water between the intravascular and the extravascular pools is dependent on the balance of hydrostatic and oncotic pressures across the capillaries and post capillary venules.

Variation in the water to solute ratio of a body fluid pool results in changes in the tonicity and hence effective osmolality of the fluid. As the various body water pools are in dynamic equilibrium with each other (**Figure 2**), there is a tendency for adjustments to occur throughout the body as water moves from regions of low solute concentration to those of higher solute concentration. Changes in plasma osmolality are relatively easy to monitor; therefore, there is a tendency to consider changes in the circulation as the effector of fluid balance control. It is, however, important to remember that any alteration in one body pool will affect the others and that receptors that initiate responses affecting water balance may reside at sites far removed from the circulation.

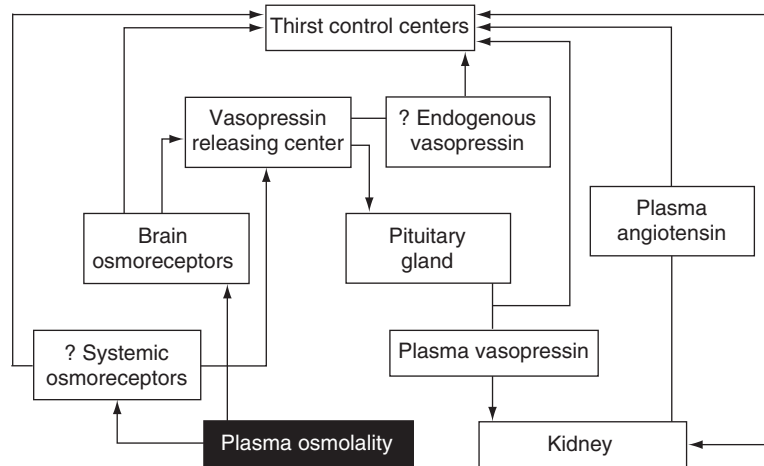

Loss of water from the body or an increase in the circulating solute concentration causes an increase in the osmolality of primarily the extracellular fluid; water then moves into the extracellular space from the cells, producing a reduction in cell volume. Changes in plasma osmolality are therefore thought to be signaled to the effector mechanisms by changes in the cell volume of specific specialized cells, collectively termed osmoreceptors. As the main solute determining the tonicity of the extracellular fluid is sodium, there has been some debate as to whether the receptor cells detect changes in osmolality or changes in the sodium ion content. The evidence to date suggests that at least the majority of the receptors respond to osmolality rather than to sodium concentration. These osmoreceptors play a regulatory role not only in the perception of thirst but also in the maintenance of the circulating levels of hormones that regulate the excretion of water and solute by the kidneys (**Figure 3**). As increases in the extracellular osmolality effectively decrease the volume of the cells in the body, this form of dehydration is termed cellular dehydration.

Alteration in the volume of the extracellular fluid pool without change in its osmolality also affects the fluid balance hormone concentrations and the sensation of thirst. Changes in blood volume affect the blood and capillary pressures and atrial filling pressure. The effect on capillary pressure will tend to redistribute body water and help to adjust the circulating fluid volume, and the change in venous return to the heart will alter the cardiopulmonary and arterial stretch receptor (baroreceptor) activity. The level of afferent activity from these baroreceptors directly affects both the sensation of thirst and the secretion of some fluid balance hormones. Additionally, modifications to the arterial blood pressure can directly affect renal perfusion, which, together with baroreceptor activity to the kidneys, regulates the renin–angiotensin system (**Figure 4**). Although the effect on the kidneys can influence the perception of thirst, the main renal response is to regulate urine water and solute excretion. A decrease in the volume of the extracellular pool with no concomitant change in plasma osmolality is termed extracellular dehydration.

When humans are given access to fluids after the development of a water deficit, their drinking response usually follows a pattern of rapid ingestion of more than 50% of the total intake, followed by intermittent consumption of relatively small volumes of drink over a longer period. Although initiation of the response to drink is due mainly to osmotic or blood volume (volemic) changes, other mechanisms appear to be involved in the control of the continuation and satiety responses. Receptors in the mouth, esophagus, and gastrointestinal tract appear to be major factors in the acute regulation of thirst satiation, with the effects that the volume and solute content of the ingested drink have on restoring the fluid deficits controlling the chronic regulation of thirst (**Figure 5**). There is a close relationship between eating and drinking, with approximately 70% of daily fluid intake normally being associated with meals (**Figure 6**). The desire to drink while eating is probably produced by a series of responses including the mechanochemical composition of the food before absorption, the neuroendocrine response to digestion, the movement of water into the intestine during digestion, and the osmotic solute load that occurs following absorption. The intake of minerals is essential to replace that lost from the body and for growth. The majority of mineral intake is supplied by the food ingested, and indications of a desire or appetite for ingesting specific minerals have been shown in animals and humans. Although sodium appetite has been linked to the sensation of thirst, anatomically and functionally, the controlling mechanisms are distinct and separate.

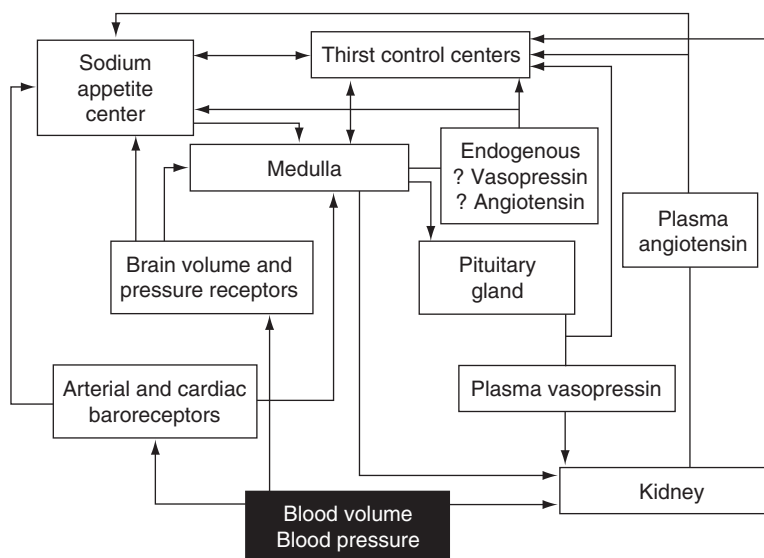

**Figure 2** Diagrammatical representation of the forces that regulate the distribution of the body water pools. The volumes given are those determined in a single male subject with a lean body mass of 75.8 kg.

**Figure 3** Schematic representation of the main factors proposed in osmotically induced regulation of the sensation of thirst and their interaction with the control of diuresis. An increase in plasma osmolality will tend to stimulate greater excitatory activity, whereas a decrease in osmolality will activate more inhibitory inputs. Neural pathways are indicated by  $\rightarrow?$  and hormonal input by  $\rightarrow$ .

### Mechanisms of Thirst Regulation

The sensation of thirst is regulated separately both by the osmotic pressure and by the volume of the body fluids and as such is closely related to the control mechanisms that are responsible for the secretion of the fluid balance hormones, which affect water and solute reabsorption in the kidneys and play a role in blood pressure control. These hormones, arginine vasopressin, atrial natriuretic peptide, oxytocin, and the renin–angiotensin–aldosterone system, are central to the regulation of thirst. Regions of the brain, in the hypothalamus and the forebrain, appear to be the main areas involved in the control of thirst and antidiuresis, and collectively, these parts of the brain have been termed the thirst control centers. Neurons that are responsive to changes in osmolality, intravascular volume (volemia), and blood pressure are found within these areas of the brain, as are other receptors that are responsive to many of the fluid balance hormones. Neural pathways from the thirst control centers and the kidneys may allow some direct integration between the control of thirst and excretion, whereas within the brain, all of the major fluid balance hormones are present as neurohormones. Afferent input from systemic receptors monitoring osmolality, circulating sodium concentration, and changes in intravascular volume and pressure also play roles in controlling the feeling of thirst. Therefore, there appears to be a complex integrated system for both monitoring the status of the body water pools and controlling intake and excretion (Figures 3 and

**Figure 4** Schematic representation of the main factors proposed in volumic-induced regulation of the sensation of thirst and their interaction with the control of diuresis and sodium appetite. A decline in circulating blood volume will decrease baroreceptor activity, which will increase excitatory activity, whereas an increase in volume will have the opposite effect. Reduction in blood pressure will decrease renal perfusion, which will activate the renal renin–angiotensin system. Neural pathways are indicated by  $\rightarrow$  and hormonal input by  $\rightarrow$ .

**Figure 5** Schematic diagram depicting the proposed onset, duration, and overlap of various inhibitory signals to continue fluid ingestion following initiation of drinking in response to a fluid deficit. Reproduced from Verbalis JG (1990) Inhibitory controls of drinking: Satiation of thirst. In: Ramsay DJ and Booth DA (eds.) *Thirst: Physiological and Psychological Aspects*. ILSI Human Nutrition Reviews, pp. 313–330. London: Springer-Verlag.

4). Much of the regulatory mechanisms controlling water balance appear to overlap, with several stimuli appearing to subserve the same response; however, it is assumed that this effect is required in order to ensure that the blocking of one type of stimulus will not prevent homeostatic control.

### Osmotic Regulation of Thirst

The osmolality of circulating plasma is normally maintained within a very narrow limit of between 270 and 295 mosmol kg<sup>-1</sup>, with the circulating levels of the antidiuretic hormone arginine vasopressin playing a major role in its homeostatic regulation. An increase of as little as 2–3% in plasma osmolality is sufficient to produce a strong sensation of thirst and a significant increase in circulating arginine vasopressin concentration (Figure 7). The osmoreceptors that monitor the tonicity of the body pools appear to reside mainly in the subfornical organ (SFO) and organum vasculosum of the lamina terminalis (OVLT), an area of the brain that lacks a blood–brain barrier; therefore, they appear to respond mainly to the changes that occur in the osmolality of the blood rather than in the cerebral interstitium. Although the changes in the circulating levels of arginine vasopressin and the perception of thirst appear to parallel one another, it is unlikely that the same receptors are responsible for both responses; it is likely that there are different neurons that react to the same stimulus. However, there may be some neuro-hormonal interaction between the osmotically

**Figure 6** Changes in body weight during 13 h in the desert. The majority of the volume of drink ingested was associated with food intake. Sweat loss varied from 150 to 700 ml h<sup>-1</sup>; the total fluid intake was 3.05 l. At the end of the period, body mass was essentially the same at the beginning and end of the day; therefore, water intake and output were equal. Reproduced from Adolph ED (1947) *Physiology of Man in the Desert*. New York: Interscience.

**Figure 7** The relationship of plasma vasopressin (○) and thirst (×) with plasma osmolality in a volunteer during an infusion of 5% saline. Reproduced from Robertson GL (1984) Abnormalities of thirst regulation (Nephrology forum). *Kidney International* 25: 460–469.

activated thirst centers and the ‘vasopressin releasing center’ in the brain, and arginine vasopressin-responsive neurons have been detected within the thirst centers (Figure 3).

The current theory of the osmotic control of thirst suggests that there is a constant output of both inhibitory and excitatory neural activity from the respective osmoreceptors to the thirst centers and the arginine vasopressin-releasing centers. Within the normal range for plasma osmolality, the inhibitory and excitatory activities in the thirst centers effectively cancel out one another and there is neither a sensation of thirst nor satiety. However, at this level of activity, there is release of a basal level of arginine vasopressin, which is sufficient to maintain a state of half-maximum antidiuresis. An increase in plasma osmolality above the normal level stimulates greater excitatory output, causing an increase in the feeling of thirst and higher levels of circulating arginine vasopressin. Elevated levels of arginine vasopressin increase the concentrating ability of the kidneys. A decrease in plasma osmolality below the normal range increases the inhibitory output, producing a feeling of satiety, and arginine vasopressin release is suppressed, allowing urinary dilution (Figure 3).

Cells and fibers within the brain have been shown to contain several hormones, including angiotensin and vasopressin, within the same cell. Although neurons associated with the thirst centers can be activated *in vitro* by vasopressin, it is not clear at present whether either peripheral- or neural-generated arginine vasopressin levels do influence the perception of thirst.

### Volemic Regulation of Thirst

The receptors that initiate hypovolemic thirst are generally thought to be the cardiovascular baroreceptors, which respond to under-filling of the circulation by reducing their inhibitory nerve impulse activity to the thirst centers. However, in areas of the brain associated with the thirst centers, there are neurons that are separately responsive to volemic, pressure, and osmotic changes. This suggests that at least part of the response to changes in blood volume originates in the brain. It is thought that changes in blood pressure and osmolality are monitored mainly within the brain, whereas variations in blood volume are principally sensed by the peripheral baroreceptors, with a degree of overlap between the different receptors. The mechanisms that respond to changes in intravascular volume and pressure appear not to be as sensitive as those responsive to osmotic changes, for example, a decrease of approximately 10% of the plasma volume is required to initiate hypovolemic thirst. As fairly large variations in blood volume and pressure occur during normal daily activity, such as postural changes and physical activity, this apparent lack of sensitivity presumably prevents overactivity of the volemic control mechanisms. As with osmotic thirst, the control of volemic thirst is thought to be a balance between continuous inhibitory and excitatory neural activity, although in this system, the basal level appears to be essentially inhibitory. Another difference in the basic control mechanism between the two systems occurs due to the requirement for

both solute, mainly sodium, and water to restore the extracellular volume. Therefore, extracellular dehydration causes an initial thirst and a delayed increase in sodium appetite.

Reduction in the intravascular volume sufficient to lower cardiac output and arterial blood pressure decreases afferent activity from the low- and high-pressure cardiovascular baroreceptors to the thirst centers and increases sympathetic activity to the kidneys. As afferent input from the baroreceptors to the thirst centers is inhibitory, a decrease in activity produces a reflex increase in the perception of thirst and also appears to directly stimulate arginine vasopressin release. The increase in sympathetic activity to the kidneys directly promotes greater renal renin release. In addition, reduction in blood pressure lowers the renal perfusion pressure, which stimulates renin release both as a direct pressure effect and by decreasing the delivery of sodium to the kidneys.

Increased activation of the renin–angiotensin–aldosterone system also helps regulate hypovolemic thirst. Although circulating levels of both vasopressin and aldosterone affect water and sodium reabsorption in the kidneys and thereby control water and solute loss, angiotensin acts directly on the thirst and sodium appetite centers to stimulate their respective responses. Neurons that are stimulated by angiotensin are found in areas of the brain that lack a blood–brain barrier; therefore, circulating angiotensin has direct access to both centers. In addition, the release of neurally generated angiotensin is promoted by suitable neuron activity responding to sensory stimuli (Figure 4).

There are therefore a variety of neural and hormonal responses that interact to modulate and control both thirst and urine excretion. A number of other hormones including oxytocin, atrial natriuretic peptide, tachykinins, neuropeptide Y, thyroid hormones, corticotrophin releasing factor, and steroid hormones have also been shown experimentally to affect the drinking response. Under normal conditions of water and solute loss, both osmotic and volemic dehydration occur; therefore, stimuli from receptors for both systems are usually involved in the sensation of thirst. Increases in extracellular osmolality appear to be more effective than hypovolemia in promoting the thirst and hence the drinking response. Greater than 70% of the stimulus to drink appears to be generated by increased osmolality.

### Sensory Regulation of Thirst

The sensations of a dry mouth or the desire for a specific taste or effect also generate the desire to drink while there may be no physiological requirement to drink. A dry mouth promotes changes in neural activity in the parahippocampus, amygdala, thalamus, cingulate, insula, allocortex, and transitional cortex of the brain. This finding has strengthened the hypothesis that the perception of thirst is a primitive vegetative function that appeared long before vertebrates evolved.

Drinking water activates areas of the anterior insular and frontal opercular cortex that are also involved in the perception of taste. Areas of the orbitofrontal cortex are also activated by the ingestion of water or sweet or salty tastes, but here, activation is greatest when the subjects are thirsty and it diminishes when the subjects have drunk water to satiety. This has been interpreted as functionally separated areas of the brain, one of which responds to taste stimuli that are not diminished following drinking to satiety, whereas the other is highly active during drinking when water is physiologically required but that reduces as the need for water is met.

### Mechanisms for Terminating the Sensation of Thirst

Although undoubtedly decreasing osmolality and increasing extracellular volume promote a reduction in the perception of thirst by reactivating inhibitory neuron activity, usually, there is a decrease in the perception of thirst and termination of drinking before circulating osmolality, volume, and hormonal levels have returned to pre-dehydration levels. Although it could be argued that receptors in the brain may be responsible for the early cessation of the perception of thirst, the majority of the evidence suggests that it is receptors in the upper gastrointestinal tract that promote the early termination of drinking. Although the nature and neural connections of these proposed receptors have not been fully characterized, most appear to have an inhibitory response. It has been suggested that as much of the thirst and drinking response is behavioral, an individual learns what volume of drink is required to restore a given water deficit. Termination of drinking therefore could be a learned response, which anticipates a future fluid deficit or matches a known current level of dehydration. The stimuli for gauging the current level of dehydration may be the same as that which initiates the sensation of thirst.

The mere presence of a liquid, particularly cold liquid, in the mouth reduces the perception of thirst. Receptors in the mouth and esophagus responding to different chemical, tactile, pressure, and temperature stimuli are thought to be part of the mechanism that influences the relative intensity of the perception of thirst. Although the neural activity involved in swallowing, and perhaps oropharyngeal and gastric receptors are thought to be effective in sensing or metering the volume of liquid ingested, distension of the stomach tends to inhibit drinking due to increased gastric stretch receptor activity, although this response does not always reduce the perception of thirst. Taste and other psychological factors can have a stimulatory effect on consumption of a drink that is considered to be palatable.

The continuation and termination of the acute sensation of thirst is regulated by a series of stimuli that operate before all of the drink consumed has been absorbed and before disturbances in the body water pools have been corrected. A variety of receptors located from the mouth to the upper part of the small intestine and probably neural control from the higher centers of the brain appear to monitor and regulate the initial volume consumed. After absorption, if restoration of body water pools does not occur, the

sensation of thirst is once again initiated, presumably by the same homeostatic stimuli that initially induced the feeling of thirst, and drinking restarts. The integration of the pre- and post-absorptive stimuli modulates the sensation of thirst and finally the volume of drink consumed.

## Fluid Requirements

Renal reabsorption can reduce the volume of water and solute loss, and hence slow the rate of progress of a fluid deficit, but it cannot stop its development. Intake of fluid either as food or drink is required to restore a fluid deficit. Daily fluid intake is highly variable between individuals and the rate of loss is dependent on factors such as environmental temperature, physical activity, sweating rate, antidiuretic function, and dietary solute load. A representative normal daily water turnover in a sedentary individual living in a temperate climate and eating a typical western diet is approximately 2–3 l, and a minimum daily fluid intake of approximately 1.7 l is necessary to conserve fluid balance. The water content of the typical western diet approximates to approximately 1 l and metabolically derived water produces in the order of approximately 300 ml, which together almost offsets the daily obligatory water loss. Therefore, in many situations, the requirement for fluid intake can actually be very low.

There are conditions in which water loss is greater than that indicated above and replacement obviously requires a compensatory increase in the daily fluid intake (Figure 6). Urine volume is related to the solute content of the diet, with a minimum volume of approximately 500 ml being necessary to eliminate the usual daily solute load. Diets rich in protein or foods with a high sodium content require a greater obligatory urine output for excretion. The renal concentrating ability at maximum antidiuresis determines the minimum urinary water loss for a given dietary solute load. Normally, there is a wide range of urinary osmolality such that the same solute load can be excreted in 500 ml of urine with an osmolality of 1400 mosmol kg<sup>-1</sup> or in 23 l of urine with an osmolality of 30 mosmol kg<sup>-1</sup>. This feature of renal excretion allows body water balance to be maintained while fluid intake volume is varied.

Prolonged relatively intense muscular activity, elevated ambient temperature, and fever all increase the rate of evaporative sweat loss. Individual sweat rates are highly variable, with average exercise-induced losses usually in the order of 1 l h<sup>-1</sup>, but daily losses of between 10 and 15 l have been recorded. Daily fecal losses associated with a western diet are usually between 100 and 200 ml; however diarrhea, particularly infectious diarrhea, can produce prodigious fecal water losses that are potentially fatal.

Inappropriate fluid intake can be produced following lesions or development of tumors in regions of the brain associated with the thirst centers. Diabetes insipidus promotes an increase in the volume of fluid ingested, which is caused by a lowering of the basal threshold set point for osmotic thirst. A similar, although less pronounced, lowering of the osmotic thirst threshold occurs during pregnancy. In both the young and the elderly, the thirst response can be blunted and inappropriate drinking habits may occur. Psychogenic disturbances in the sensation of thirst and hence fluid intake have also been reported for a variety of clinical conditions.

### Key points

- Indirect calorimetry assesses the rate of metabolic heat production based on the rates of consumption of oxygen and production of carbon dioxide and nitrogen waste products.
- In nutrition, indirect calorimetry typically referring to a measurement of respiratory gas exchange across the lungs.
- Indirect calorimetry is used to optimize nutrition therapy of hospitalized patients and determine the cardiovascular fitness of otherwise healthy athletes during training or cardiac patients before and during rehabilitation.
- Indirect calorimeters are attached in small carts for transport to individual patients and can be designed to be small enough to hand carry to testing facilities.
- When used under unstable clinical conditions, the interpretation of results from indirect calorimetry should be done carefully to avoid misinterpretation.

### Glossary

**Bicarbonate** The chemical form of carbon dioxide when dissolved in body water

**Total body water** The sum of all water within and between the tissues of the body

**Doubly labeled water** A field method of indirect calorimetry to measure energy expenditure over one to three weeks based on the elimination of stable isotope-labeled water from body water

**Resting metabolic rate** The energy expended while completely at rest. It is the energy expended in breathing, circulating blood, sustaining organ function, and supporting neurological function

**Indirect calorimetry** A method to measure the metabolic heat produced by an organism calculated from the rates of oxygen consumption and/or carbon dioxide production usually by monitoring respiratory gas exchange as gases enter and exit the lungs

**Metabolic cart** A common term for a portable, table-mounted indirect calorimeter

**Respiratory Exchange Ratio (RER) or Respiratory Quotient (RQ)** The ratio of the amount of carbon dioxide produced to the amount of oxygen consumed, used to calculate rates of carbohydrate versus fat catabolized to support energy metabolism

**VCO<sub>2</sub>** The rate of CO<sub>2</sub> production, often expressed in ml (mL) min<sup>-1</sup>

**VO<sub>2</sub>** The rate of O<sub>2</sub> consumption, often expressed in ml (mL) min<sup>-1</sup>

## Introduction

All living organisms require a source of energy for survival. Among aerobic animals, this energy is provided in the form of chemical energy in the macronutrients they consume, which are converted to carbon dioxide and water through oxidative phosphorylation. This conversion is subject to the same laws of thermodynamics that govern all energy systems. The first law of thermodynamics states that energy can neither be created nor destroyed; it can only be exchanged from one form to another. Hence, the chemical energy consumed in the form of macronutrients in food is converted into mechanical energy for work performed by the body, heat energy lost to the environment or retained by raising body temperature, or stored as chemical energy in tissues such as fat, protein, or carbohydrates (glycogen). This conservation of energy can be stated mathematically as:

$$\text{Energy}_{\text{in}} = \text{Energy}_{\text{work}} + \text{Energy}_{\text{heat}} + \text{Energy}_{\text{stored}}$$

The sum of energy converted to work and heat is defined as metabolism, which includes synthesis of biochemicals, smooth muscle contractions involved in breathing and blood circulation, generation and maintenance of ion gradients the synthesis and catabolism of biochemicals. Although life-sustaining metabolic functions constitute thousands of chemical reactions occurring at the same time throughout the body that cannot readily be individually measured, their sum can be measured as the sum of work and heat energy or, in the absence of any measurable work, just the rate of heat production by the body. This assumes that all cellular events ultimately result in heat production.

Calorimetry, therefore, is defined as the measurement of heat production by the body during oxidative combustion of the macronutrients from food. At the cellular level, each macronutrient is ultimately combined with oxygen to produce carbon dioxide, water, and heat as described by the following general equation:

These chemical reactions are virtually the same as those that would be observed if the nutrient were combusted in a flame, except the reaction in the body is an enzymatic process that does not produce a flame. Still, the chemical reaction is the same;  $\text{O}_2$  is a necessary reactant, and  $\text{CO}_2$  is an end product of reactions that constitute metabolism. The term “indirect” calorimetry is used when heat production is calculated by measuring rates of oxygen consumption ( $\text{VO}_2$ ) and carbon dioxide production ( $\text{VCO}_2$ ) over time. After  $\text{VO}_2$  and  $\text{VCO}_2$  are measured, the Weir equation (Table 1) or similar equations can be used to calculate the rate of heat production, which is commonly called energy expenditure. In addition, the ratio of  $\text{VCO}_2/\text{VO}_2$ , which is termed the respiratory exchange ratio (RER) when measured on a whole-body basis. The RER, in addition to its use in calculating heat production using the Weir equation, provides useful information about which macronutrient (carbohydrate, lipid, or protein) has been oxidized. The metabolism of these macronutrients consumes oxygen and produces carbon dioxide. When used to calculate nutrient utilization, the whole-body RER is referred to as the global respiratory exchange ratio (RER) as it is the oxygen consumed and the carbon dioxide produced by the total of macronutrients metabolized. The first step in calculating the three individual rates of macronutrient oxidation is to calculate protein oxidation. Protein is the most difficult to describe on a chemical basis because a protein is made from a mixture of amino acids and, for each dietary protein, the number and composition of amino acids differ, and this is also influenced by

**Table 1** Respiratory gas exchange constants and calculation of energy expenditure.

	$\text{VO}_2$	$\text{VCO}_2$	Heat	RER
Substrate	$\text{L g}^{-1}$	$\text{L g}^{-1}$	$\text{kcal g}^{-1}$	$\text{VCO}_2/\text{VO}_2$
Carbohydrates <sup>a</sup>	0.829	0.829	4.2	1.00
Fat	2.019	1.427	9.5	0.71
Protein	0.966	0.794	4.4	0.82
Nitrogen	6.037	4.963	—	0.82
Variable	Formula			
$\text{VO}_2$ ( $\text{L min}^{-1}$ )	$=V_i (\text{FiO}_2) - V_e (\text{FeO}_2)$			
$\text{VCO}_2$ ( $\text{L min}^{-1}$ )	$=V_e (\text{FeCO}_2) - V_i (\text{FiO}_2)$			
$\text{NPVO}_2$ ( $\text{L min}^{-1}$ )	$=\text{VO}_2 - 6.037\text{Nu}$			
$\text{NPVCO}_2$ ( $\text{L min}^{-1}$ )	$=\text{VCO}_2 - 4.963\text{Nu}$			
Full Weir equation ( $\text{kcal min}^{-1}$ )	$=3.941 \text{VO}_2 + 1.106 \text{VCO}_2 - 2.17\text{Nu}$			
Modified Weir equation ( $\text{kcal min}^{-1}$ )	$=(3.94 + 1.11 \text{ RER}) \text{VO}_2$ ( $\text{L min}^{-1}$ )			

$\text{VO}_2$  = rate of  $\text{O}_2$  consumption  $\text{L min}^{-1}$ ;  $\text{VCO}_2$  = rate of  $\text{CO}_2$  production  $\text{L min}^{-1}$ ,  $V_i$  = volume of inspired air  $\text{L min}^{-1}$ ,  $V_e$  = volume of expired air  $\text{L min}^{-1}$ ,  $F_i$  = fraction of inspired  $\text{O}_2$  or  $\text{CO}_2$ ,  $F_e$  = fraction of expired air that is  $\text{O}_2$  or  $\text{CO}_2$ ,  $\text{NPV}$  = Volume of non-protein gas  $\text{L min}^{-1}$ ,  $\text{Nu}$  = urinary nitrogen  $\text{g min}^{-1}$ .

<sup>a</sup>Starch or glycogen.

variation in the fractions of nitrogen excreted as urea, ammonia, and creatinine. The breakdown of the standard dietary protein, however, can be described by the following chemical reaction:

In this example, 86.6 molecules of  $\text{CO}_2$  are produced whereas 104 molecules of  $\text{O}_2$  are consumed when one molecule of protein is oxidized ( $\text{RER} = 0.83$ ). Although this RER value is intermediate between carbohydrate and fat, protein is unique among the three energy substrates because it is the only one to contain the element nitrogen. As such, urinary N (g/min) can be assayed to obtain an estimate of protein oxidized by an individual. Because protein is the only macronutrient containing nitrogen, the oxidation of protein can be calculated from the rate of urinary nitrogen excretion. When greater accuracy has desired the sum of urinary nitrogen production plus and change in the amount of urea circulating in the blood. Assuming circulating urea does not change, protein oxidation is calculated as follows:

$$\text{Protein oxidation}_{\text{g/min}} = 6.25\text{N}_{\text{urineg/min}}$$

After calculating protein oxidation, the  $\text{VO}_2$  and  $\text{VCO}_2$  due to protein oxidation can be calculated in units of mL/min for each g/min of urinary nitrogen, and these subtracted from the global  $\text{VO}_2$  and  $\text{VCO}_2$  to yield the nonprotein  $\text{VO}_2$  and  $\text{VCO}_2$  (Table 1).

To calculate the percentage of carbohydrate versus fat being used to support energy expenditure. For example, one molecule of sugar (glucose) breaks down as follows:

In this reaction, six molecules of  $\text{CO}_2$  are produced and six molecules of  $\text{O}_2$  are consumed. Thus, the ratio of  $\text{CO}_2$  produced to  $\text{O}_2$  consumed (RER) has a value of 1.0. When one molecule of fat (tripalmitin) is broken down completely, the chemical reaction is as follows:

When this molecule of fat is completely oxidized, 57 molecules of  $\text{CO}_2$  are produced whereas 80 molecules of  $\text{O}_2$  are consumed ( $\text{RER} = 0.71$ ).

Physiologic nonprotein RER values generally range between 0.71 (100% fat oxidation) and 1.00 (100% carbohydrate oxidation). Thus, an RER of 0.85 reflects approximately 50% carbohydrate and 50% fat oxidation supporting energy expenditure.

Urinary  $\text{N}_2$  is often not measured and therefore results from indirect calorimetry often use the abbreviated Weir equation to calculate rates of energy expenditure (Table 1), which assumes protein oxidation supports 12% of total energy expenditure.

A healthy individual consuming an average mixed diet of carbohydrates, fat, and protein will usually have an RER between 0.80 and 0.85. For example, assume a healthy male consumes 350 mL  $\text{O}_2 \text{ min}^{-1}$  and produces 298 mL  $\text{CO}_2 \text{ min}^{-1}$  on average throughout 24 h. That individual will be expending 1.7 kcal  $\text{min}^{-1}$  (using the abbreviated Weir equation in Table 1). This equals a 24 h energy expenditure of approximately 2448 kcal  $\text{day}^{-1}$  (1.7 kcal  $\text{min}^{-1} \times 1440 \text{ min}$ ). An  $\text{RER} \geq 1.00$  usually indicates whole body de novo lipogenesis (endogenous synthesis of fatty acids) but can also result from hyperventilation during respiratory gas analysis. High-intensity exercise will also result in an RER above 1.00 as the accumulation of lactic acid in the blood is buffered by the body bicarbonate pool, resulting in additional  $\text{CO}_2$  output.

## Laboratory methods

The first calorimeters developed in the early 1800s directly measured the rate of body heat production of an animal in a thermally isolated chamber (direct calorimetry). Antoine Lavoisier was one of the first to perform such direct calorimetry. He placed a guinea pig inside a chamber surrounded by ice and then measured the rate of melting of the ice to obtain a measure of the animal's rate of heat production. By burning a small amount of coal equal in mass to the mass of carbon in the  $\text{CO}_2$  produced by the guinea pig, he demonstrated that animal respiration was, in fact, combustion of the chemicals provided by food in a manner that is chemically identical to what occurs when macronutrients were burned in a flame. Modern direct calorimeters are complex to construct but are both an accurate and precise method for measuring energy expenditure. The disadvantage is that RER is not measured and thus no information on which substrates are being oxidized. As such most clinic and calorimeter research is performed using indirect calorimeters. A detailed account of the history and theory of calorimetry can be found in the further reading section at the end of the article. This material on laboratory and field indirect calorimetry techniques commonly used in most clinical and research settings is, however, briefly described below.

## Whole body indirect calorimetry

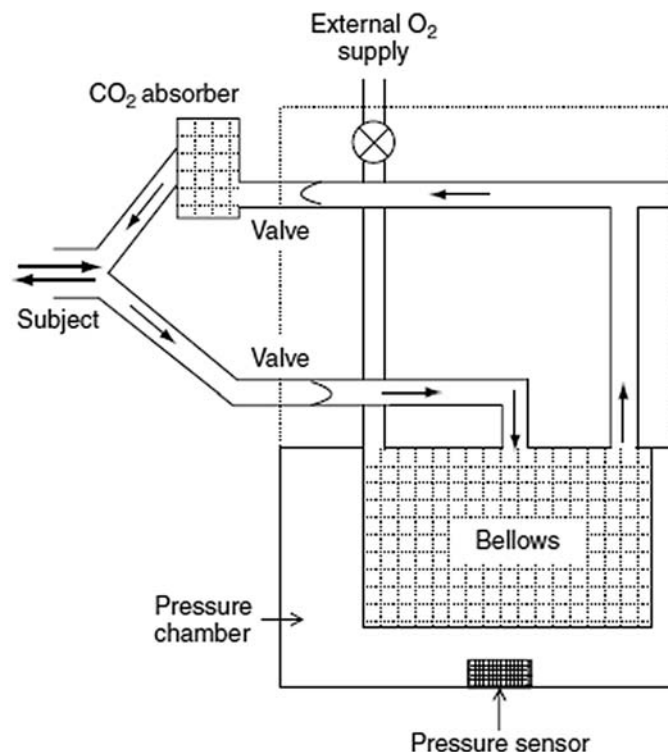

The advent of indirect calorimetry was a significant event in the history of animal and human nutrition. In whole-body indirect calorimetry, a person is housed in a small, sealed room with controlled ventilation, often referred to as a metabolic chamber. It is a small chamber, but similar to a studio (one room) living environment and hence a little more representative measurement

of free-living energy expenditure. The chambers in use today are typically furnished with a bed, a chair, desk or table, toilet, sink, TV/computer, telephone, and an airlock used for passing food and physiologic specimens between subjects and study personnel with minimal leakage of air into or out of the chamber.

Two common types of whole-body indirect calorimetry systems have been constructed. One is closed-circuit indirect calorimetry involves the recirculation of the same air through the sealed chamber. The recirculated air is kept breathable by removing and measuring  $\text{CO}_2$  produced by the subject and replacing it with  $\text{O}_2$  to be consumed by the subject. As the subject consumes  $\text{O}_2$ , a sensor detects the decrease in volume, and a signal is sent to an external source to release calibrated pulses of  $\text{O}_2$  back into the system to restore the  $\text{O}_2$  concentration to its original level. The rate of  $\text{O}_2$  consumption by the subject is measured by recording the amount of  $\text{O}_2$  that is added to the air during recirculation. The  $\text{CO}_2$  produced by the subject is removed from the recirculated air by an absorber and is measured from the increased weight of the absorber (Fig. 1).

The more common type is the open-circuit indirect calorimetry involves a system in which both ends of the breathing system are open to the atmosphere (Fig. 2). Outside air is drawn into the chamber at a constant flow rate while maintaining a slight negative pressure inside the chamber. At the same time, the composition of this outside air is measured by  $\text{CO}_2$  and  $\text{O}_2$  gas analyzers. Well-mixed expired chamber room air is drawn out at a constant flow rate and also analyzed for  $\text{O}_2$  and  $\text{CO}_2$  composition. The difference in  $\text{O}_2$  and  $\text{CO}_2$  composition of the outside air and chamber room air is used to calculate the energy expenditure and macronutrient oxidation of the subject using the equations in Table 1.

A limitation of room calorimeters is that the volume of the room is large, often over 10,000 L, and that the flow rate of air through the chamber is usually between 50 and 100 L/min. Thus, the room requires many hours to respond to changes in the rate of the subject's gas exchange rates. One means to obviate this limitation is to measure not only the difference in  $\text{O}_2$  and  $\text{CO}_2$  as it enters and leaves the chamber but to add to this the changes in the volumes of  $\text{O}_2$  and  $\text{CO}_2$  in the chamber itself—e.g.,  $\text{VO}_2 = \text{flow rate} (V_e(f_{\text{eO}_2}) - V_i(f_{\text{iO}_2}) + (\text{chamber volume}) * ((f_{\text{O}_2})_{t=i} - (f_{\text{O}_2})_{t=0}))$ . During the 1990s, the precision of the  $\text{O}_2$  and  $\text{CO}_2$  analyzers was modest, and minute to minute variation in the measured gas concentrations only allowed investigators to measure energy expenditure over a period of one to 4 h. Improvements in the performance of the gas analyzers since then have improved the time resolution of modern room indirect calorimeters is such that energy expenditure can be measured over intervals as short as minutes and thus it is whole room indirect calorimeters to measure individual bouts of light to moderate physical activity, the energy costs of daily life (dressing, food preparation, playing video games), or the changes in energy expenditure when nutrients are ingested or infused.

**Fig. 1** Closed-circuit metabolic chamber in which the subject's oxygen consumption is measured to calculate the corresponding energy expenditure. The change in volume of air in the system is constantly monitored by the sensors and a measured quantity of oxygen is added back to the system. Carbon dioxide is taken out of the recirculated air by a  $\text{CO}_2$  absorber.

**Fig. 2** An open system respiration chamber is illustrated above. The 2.5 m<sup>2</sup> area is large enough to contain a bed, small table, wall mounted computer/TV station, toilet, and stationary exercise bike (or treadmill). A door is provided for access, and windows to provide contact with the outside world. Air is continuously drawn into the sealed chamber. The volume of air is measured along with the concentrations of oxygen and carbon dioxide entering and exiting the chamber.

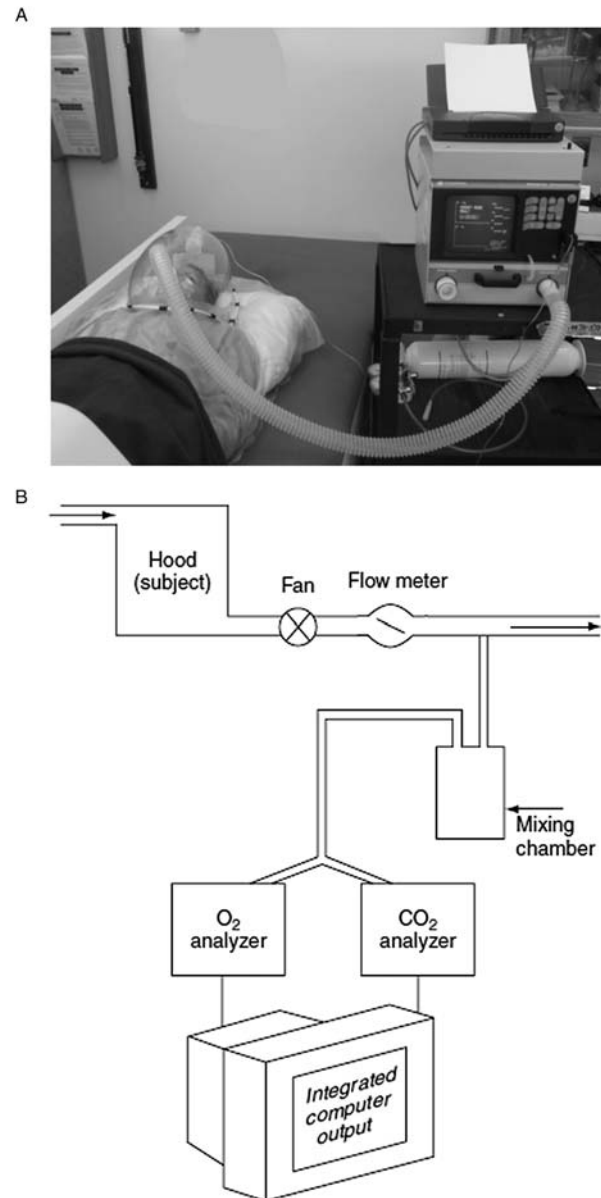

### Metabolic carts

The concept of indirect calorimetry is often applied on a scale smaller than a whole room in many research and clinic settings. Many smaller indirect calorimeters have been developed over the years. The instrumentation used for each varies in complexity and the degree to which they restrict the subject's movement.

Metabolic cart is a common name for a respiratory gas analyzer that has been made small enough to be placed on a cart with wheels so that it can be rolled to different locations within a building. Two designs are generally available: the ventilated hood (canopy) and the mouthpiece systems. The ventilator hood system is an open-circuit indirect calorimeter that usually consists of a pliable plastic or rigid Perspex hood placed over the subject's head with latex or thin plastic apron providing a rough seal around the neck or chest. These allow air to be drawn across a subject's face while in a reclining or lying position. For longer-term measurements, ventilated plastic tents are available that cover all or part of the patient's bed. Because these hoods operate on a suction principle, a tight seal of the hood is not required. For field measurements, whole body transparent plastic ventilated boxes have been used successfully in infants. Many of the ventilatory hoods are constructed by researchers from the components according to the requirements of their study. The components include a pump, a flowmeter, and a means of regulating the airflow. Samples of the air drawn from the hood can be directed to gas analyzers, which are usually connected in series to the hood. Respiratory gas exchange is calculated from the difference in O<sub>2</sub> and CO<sub>2</sub> concentration between the air entering and exiting the hood times the known controlled airflow (Figs. 3A, B).

Instruments have been developed to operate in adult and pediatric modes and differ with respect to flow rates and internal volume because metabolic rates, and corresponding gas exchange rates, of children, are up to five smaller than that of an adult. With adult and pediatric systems, the expired air enters a mixing chamber within the instrument to eliminate concentration variation resulting from the normal inspiration and expiration phases associated with breathing. The mixed sample enters O<sub>2</sub> and CO<sub>2</sub> analyzers and the concentration differences between the air entering and exiting the hood or canopy. For state-of-the-art instruments, the data are input into a microprocessor providing a minute-by-minute calculation of the O<sub>2</sub> consumption, CO<sub>2</sub> production, RER, and energy expenditure. These instruments are generally used for measurements of subjects at rest as part of nutritional studies of energy expenditure and macronutrient utilization. These units can also be connected to mechanical ventilators for use in hospitalized patients.

When measured in the absence of movement or skeletal muscle contraction, the rate of energy expenditure is termed the resting metabolic rate (RMR). Time since the last consumption of nutrients, ambient temperature, and arousal are controlled and recorded. The measurement of RMR under near basal conditions requires an overnight fast of about 15 h, absence of vigorous exercise in previous 24 h, minimal physical activity of any intensity in the previous 30 min, thermal neutrality (20–27 °C for individuals without excess body fat), absence of noise or talking and dim lighting and referred to near basal, fasting or in older literature basal RMR.

**Fig. 3** (A, B) Ventilatory hood system showing a hood that is placed on the subject's head, a mixing chamber, and O<sub>2</sub> and CO<sub>2</sub> analyzers. A fan maintains a slight negative pressure in the hood to pull room air into the chamber and prevent the escape of expired air from the system. The expired air is mixed in the mixing chamber and is analyzed for oxygen and carbon dioxide by the respective analyzers. Results are calculated by the computer.

Mouthpiece systems are similar to ventilated hood systems in principle, but instead of placing a hood over the subject's head, the subject wears a mouthpiece connected to the analyzer and nose clips to prevent breathing through the nose. The mouthpiece is connected to a one-way valve system that allows the subject to breathe in atmospheric air while directing the exhaled air to the gas analysis system. The expired breath is again subjected to analysis of O<sub>2</sub> and CO<sub>2</sub> concentration, but rather than passing the breath through a mixing chamber to smooth out the changes in a concentration gradient of these gases from the start to the end of an exhalation, the concentration profile is measured in real-time along with the rate of gas flow from the exhalation. Again, the data are logged into a microprocessor for calculation of O<sub>2</sub> consumption and CO<sub>2</sub> production, but in this case, the calculation is performed on a breath-by-breath basis. Results are averaged over time, usually provided as minute-by-minute averages of O<sub>2</sub> consumption, CO<sub>2</sub> output, and the rate of energy expenditure. The mouthpiece systems are generally used for studies of gas exchange and energy metabolism during exercise. The mouthpiece and nose clip used with some of the instruments make long-time measurements highly cumbersome. Also, breathing through the mouthpiece often causes untrained subjects to involuntarily hyperventilate leading to inappropriate O<sub>2</sub> and CO<sub>2</sub> rates. It is also often difficult with mask systems to obtain an airtight seal without excessive pressure at the site of contact with the mask and face. The use of mouthpiece systems is often employed for

measures made when the subject is exercising as part of an exercise tolerance test to diagnose exercise limitations in patients with chronic disease or to assess safe limits of exercise in patients before they begin rehabilitation after an adverse metabolic event. A measure of maximal  $O_2$  consumption during exercise is used to measure cardiovascular fitness and training in athletes.

Different types of metabolic carts or monitors are available that are designed for various applications ranging from nutrition to exercise science. Most have built-in gas analyzers and data processing computers, making them highly user-friendly, easy-to-use tools for the measurement of energy metabolism. They generally provide accurate and reliable data but do require periodic calibration. Ventilated hood systems often use a combination of gases with known concentrations and weighed ethanol or methanol burns for such calibration, whereas breath-by-breath systems use a combination of large volumetric syringes and gases of known  $O_2$  and  $CO_2$  concentration.

### Field methods

As for whole-body indirect calorimetry, ambulatory and portable systems measure the respiratory gas exchange with the  $VO_2$  and  $VCO_2$  measurements. Ambulatory methods and less refined laboratory methods often dispense with the measurement of  $CO_2$  to avoid the need for two gas analyzers. The error incurred by assuming a  $CO_2$  production rate is several percentage points, which many researchers and clinicians are prepared to compromise on. When only  $O_2$  consumption is measured, however, it is not possible to compute macronutrient-specific oxidation rates. The accuracy of ambulatory and portable methods is generally between 4% and -2%. Field methods involve the collection of expired air over a fixed period of time as in the Douglas bag or small online analysis systems that sample inspired and expired air through a mouthpiece.

Field methods discussed below are used to measure the energy expenditure of individuals performing a specific task such as agricultural jobs or other manual labor for the estimation of the energy requirements or costs of the jobs being performed so that appropriate supply of food is provided, and the costs of the labor can be calculated. This may be part of an ergometric study, or for planning the logistic requirements for an exploration or military project.

#### Douglas bag

The Douglas bag method is a classic example of how expired air can be collected to measure energy expenditure in the field during both rest and physical activity. It consists of a gas-impermeable bag with a capacity of 100 L. A classic Douglas bag is made of either a rubber sheeting cemented between two layers of canvas or plastic material lined by PVC or aluminum with welded seams. The rubber bags are subject to slow leakage of  $CO_2$  by diffusion, which is unavoidable, but PVC and metalized bags reduce this loss. If the bags are filled to their capacity and analyzed with 20 min of collection, the effects of diffusion are minor. The subject wears a nose clip and mouthpiece or a face mask. Outside air or its equivalent is inhaled through a one-way valve and exhaled into a Douglas bag for a precise period of time. It is important that the mouthpiece and connecting tubing provide minimal resistance to airflow, or the cost of breathing will increase the energy expenditure. The volume of air collected in the bag or tank is measured and a sample of exhaled air is obtained to measure the  $O_2$  and  $CO_2$  concentrations using gas analyzers. The volume of oxygen consumed, and carbon dioxide produced are calculated by analyzing the gas from the Douglas bag for the precise time period during which it was collected. This method is relatively simple and inexpensive yet gives reliable results. It is suitable only for short durations of field measurement, because wearing the mask and nose clip for the whole duration of the study may be cumbersome, interfere with daily activities, and is socially undesirable to the subject. Spirometers were used in the past for the measurement of the volume of the respired air. With the advent of continuous flow electronic analyzers and superior gas flowmeters, spirometers are now rarely used. Ambulatory methods also consist of a mouthpiece incorporating light action-sensitive but robust one-way gas valves, corrugated tubes, and three-way taps. The volume of air and the concentrations of  $O_2$  and  $CO_2$  in the expired air are measured using  $O_2$  and  $CO_2$  gas analyzers. These small analyzers have replaced the systems used in the past such as the Haldane system or micro-Scholander chemical gas analyzers, which used reagents to absorb  $CO_2$  and  $O_2$ , with the weight of absorbents measured before and after use.

#### Max Plank/Kofranyi-Michaels respirometer

A Max Plank respiration gas meter is a small, compact, and lightweight backpack-mounted respirometer (Fig. 4). It combines a gas volume meter and a sampling device for continuous sampling of each breath of expired air. The Max Plank respirometer consists of a dry, bellow-type gas meter for measuring the total volume of expired air during activity. The subject breathes through a low-resistance valve and the expired volume is monitored. A measured quantity of expired air is removed continuously (0.3% or 0.6%) by an aliquoting device to be sent to a small butyl rubber bag. This rubber sampling bag can be connected directly to the oxygen analyzer, eliminating the need for the transfer of samples to gastight syringes for analysis. The respirometer is suitable for flow rates between 15 and 50 L min<sup>-1</sup> or for a period of 110 min on a slow flow rate and 55 min on a faster rate. It is smaller, more compact, and lighter than the Douglas bag apparatus.

In addition, several miniaturized systems have been developed that have been made possible by miniaturization or the development of novel new chemical sensors. Such devices help to extend the use of indirect calorimetry to a field site requires because they are lighter and easily carried to remote locations for measurement of exercise load during mountain climbing, endurance athletes, and laborious tasks in non-industrialized countries. Such devices require validation against established indirect calorimeters to ensure that the gas collection attachments do not restrict breathing and cause hyper- or hypoventilation, are not subject to

**Fig. 4** A Max Plank type respirometer is illustrated above. The subject is fitted with a mask covering the mouth and nose. A pair of one-way valves on the mask allows the subject to inhale and directs the exhaled breath into the flowmeter and oxygen analyzer. The flow rate and oxygen concentration data are transmitted to a data logger for storage.

leakage during breath collection, meet the requirements for accuracy and precision of the application, and are rugged enough to survive transport and use in remote locations.

Calibration of metabolic carts and portable indirect calorimeters remains important to obtaining accurate measurements of RMR and RER. Both the flow and gas sensors that comprise the components of the  $O_2$  and  $CO_2$  must be periodically confirmed or adjusted. With some instruments, the two can be done at the same time by measurement of the area under the curve on gas concentration and time by measuring the amount of  $O_2$  consumed or  $CO_2$  recovered from the utilization of a known quantity of material. An example of this is the combustion of a known quantity of alcohol, which will consume a known volume of  $O_2$  and produce a known volume of  $CO_2$  based on the stoichiometry of the chemical reaction. This does require that the analyzers are impervious to damage from incomplete combustion and that combustion can be performed without issues arising from the open flame. The frequency of calibration depends on the specific instrument being calibrated and its susceptibility to the drift of its response to the gas being analyzed. Calibration can also be performed using a combination of the infusion of gas of known  $O_2$  and  $CO_2$  concentration and calibrated flow generator such as a 1 or 3 L calibrated syringe or a calibrated flow sensor. Gases of known  $O_2$  and  $CO_2$  concentration and flow calibrators are available from many vendors. It should also be remembered that gases must be dried because when water vapor is added to expire air, it will dilute the  $O_2$  and  $CO_2$  and create a measurement artifact. Lastly, the volumes of  $O_2$  and  $CO_2$  gas need to be corrected to standard temperature and pressure for accurate calculation of RMR and RER.

### Tracer methods of indirect calorimetry

A third category of techniques has gained popularity among investigators during the past two decades. These techniques provide a measure of  $CO_2$  production through the use of dilution techniques using isotopic tracers. These are the labeled bicarbonate method and doubly labeled water. These methods do not measure  $O_2$  consumption, and the RER must be assumed or estimated in the calculation of energy expenditure. When used for periods of days, the error in estimating RER is small as the RER is usually close to the food quotient (ratio of  $CO_2$  produced to  $O_2$  consumed if all of the food is completely metabolized). The error incurred by any difference between true long-term RER and assumed or estimated RER is 0.9% for each 0.01 RER unit and such differences have a standard deviation of 0.03 units except under conditions of large ( $>500$  kcal/d) energy imbalance or low ( $<10\%$  of energy) carbohydrate or fat diets. These techniques have been used to study the causes and treatment of obesity, the establishment of energy requirements, or the prevention of malnutrition.

#### Labeled bicarbonate

A constant infusion-labeled bicarbonate method is useful in estimating the net  $CO_2$  production and hence energy expenditure in animals and humans. This method is based on an isotopic dilution technique whereby the administered label is diluted by the  $CO_2$  produced endogenously by the body. The extent of this isotope dilution is used to measure the rate of  $CO_2$  production and then, to estimate the energy expenditure of the individual. A micro-infusion of  $^{13}C$  or  $^{14}C$  labeled bicarbonate is given to an individual and the specific activity or enrichment of his or her physiological fluids, especially breath or urine, are measured to estimate the rate of label elimination and hence the rate of endogenous  $CO_2$ . Thus, variation in the endogenous  $CO_2$  production rate will be reflected in the dilution of the body pool and consequently in the breath samples. These measurements are subject to the effects of label

sequestration over shorter periods. Sequestration refers to trapping, or fixation, of the label in tissues that utilize bicarbonate/CO<sub>2</sub> for their metabolic functions. A shorter duration of collection of breath samples requires a correction for the fraction of the label that is sequestered. This is based on the assumption that similar amounts of the label are sequestered in various individuals. When breath samples are collected over longer durations, the sequestration is often assumed to be negligible.

Some investigators have used a bolus bicarbonate administration rather than the continuous infusion. These investigators measured the rate at which the label concentration decreases with time as a measure of CO<sub>2</sub> turnover and the initial concentration as a measure of the body's bicarbonate pool size. Taken together, these provided a measure of energy expenditure during a short period of constant physical activity.

### Doubly labeled water (DLW)

The doubly labeled water (DLW) technique, discussed in detail in the next article, uses isotope dilution wherein deuterium and heavy oxygen-labeled water (DLW) are given to individuals and timed urine samples are collected to measure the elimination rates of <sup>2</sup>H and <sup>18</sup>O in the urine. The <sup>2</sup>H label from DLW mixes with the body water and is eliminated as water in the urine. Similarly, the <sup>18</sup>O label from DLW is eliminated as water, but it exchanges with the oxygen in circulating bicarbonate and is also eliminated in the breath as CO<sub>2</sub>. The difference in turnover rates of isotopic <sup>2</sup>H and <sup>18</sup>O-labeled water is proportional to CO<sub>2</sub> production. DLW is technically a method of indirect calorimetry even though respiratory gas exchange measurements across the lung are not made. Energy expenditure, oxygen consumption, water intake, and metabolic water production can be calculated using standard indirect calorimetry equations with an estimated RER. Unlike the majority of the other methods, the DLW method provides a measure of average energy expended over a period of 3–21 days, which provides a measure of habitual, free-living energy expenditure.

Since the predictive equations of energy requirement are subject to inaccuracies, more reliable methodologies are fundamental for investigating metabolism in conditions of health and disease. Due to advances in technology, portability, handling, and affordability, IC has been applied to optimize nutrition therapy through the individualization of nutrition support, maximizing its benefits, and thereby, improving the treatment outcome (Haugen et al., 2007; Oshima et al., 2017). This is readily achievable because IC can provide real-time energy expenditure data, and when combined with measures of urinary nitrogen excretion, also assesses substrate utilization and when combined with energy intake an assessment of the patients' energy balance (Lam and Ravussin, 2017).

One of the most important applications of the IC is to assess the near basal RMR, which comprises between 50% of total daily energy expenditure (TEE) in highly active individuals to 85% of TEE in hospitalized individuals who are restricted to bed. Among healthy individuals, measurement of near basal RMR is used to describe an individual's energy budget in terms of the fraction of daily energy expenditure used to support life functions, process foods, support physical activity, calculate physical activity energy expenditure by difference from TEE, with or without adjustment for the energy expended in the processing of macronutrients from meals (thermic effect of meals).

The time course of the changes in RMR among hospitalized individuals is such that energy requirements can change daily and normalize with a week or less after hospitalization. Therefore, monitoring the metabolism, in subjects in the Intensive Care Unit (ICU), has been shown crucial for the recovery of the patient (McClave et al., 2013). Conditions that significantly modifying RMR, the difficulty of maintaining or restoring body weight due to inadequate nutrition support based on predicted energy requirements, and acute disease associated with intense changes of metabolic stress level are strongly benefited with the RMR measurement (Delsoglio et al., 2019). Other chronic conditions as obesity, cancer, chronic kidney diseases, chronic obstructive pulmonary disease, diabetes, neuromuscular degenerative diseases, and anorexia, also significantly affect the RMR, therefore, an individual nutrition therapy benefits from measuring RMR (Delsoglio et al., 2019). Benefits include the prevention of malnutrition or over-nutrition which can worsen an individual's health during treatment.

### Interpretation of indirect calorimetry results

Even being an easy handling device to use in health or critical illness conditions, misinterpretation of IC results can lead to erroneous prescriptions. Less reliable IC measurements are observed under unstable clinical conditions, therefore, the RMR should be assessed within the first 24–48 h to reflect the metabolic evolution caused by the illness. Standard values of VO<sub>2</sub>, VCO<sub>2</sub> are reported to be 120 mL min<sup>-1</sup> m<sup>-2</sup> and 100 mL min<sup>-1</sup> m<sup>-2</sup>, respectively. The RMR varies between individuals and can be between 25 and 40 kg<sup>-1</sup> day<sup>-1</sup>. During an individual 30 min measurement, RMR measurements can vary from minute to minute and the coefficient of variation of up to 10% is acceptable. The measurement of RER also has diagnostic value. A normal range is ~0.7–1, while a value over 1.0 indicates overnutrition which increases the work needed for breathing and can lead to fat accumulation in the liver, and a value below 0.8 indicates undernutrition and can result in reductions in immune function. Other illness conditions as hyper-metabolism, hyperventilation, metabolic acidosis, excessive carbohydrate intake, sepsis, and hemodialysis can cause high values of VCO<sub>2</sub> and/or RER. On the other hand, hypometabolism, hypoventilation, starvation, fasting, ketosis, hypothermia, and paralysis can induce low values of VCO<sub>2</sub> and/or RER (Mtaweh et al., 2018). Respiratory gas exchange constants and equations to estimate the energy expenditure are summarized in Table 1.

## Clinical cases

Analyzing clinical cases provides insight into the understanding of the proper use of an IC device, the interpretation of IC results, and the decision-making process to apply its results for a proper prescription of nutrition support. Here we discuss two clinical cases adapted from Achamrah et al. (2021), where more details about IC use in clinical care can be found.

Case 1: A 25-years-old man weighing 75 kg was admitted to Intensive Care Unit due to a traumatic brain injury. He was on mechanical ventilation, with a  $\text{FiO}_2$  of 60% and positive end expiratory pressure (PEEP) of 8 cm  $\text{H}_2\text{O}$ , with intracranial pressure monitored by ventricular drain and cerebrospinal fluid drainage. He was under sedation with propofol and pain controlled with morphine, without vasoactive agents. In the unit, continuous enteral nutrition of 1500 kcal  $\text{day}^{-1}$  was initiated. Measurements of IC were taken on the second day after admission for 30 min, on which he was showing normal body temperature, but was in an agitated state. The IC results were:  $\text{VO}_2 = 490 \text{ mL min}^{-1}$ ;  $\text{VCO}_2 = 350 \text{ mL min}^{-1}$ ;  $\text{RER} = 0.75$ ;  $\text{RMR} = 3560 \text{ kcal day}^{-1}$ ; The minute-to-minute coefficient of variation (first 5 min) was 14% for  $\text{VO}_2$  and  $\text{VCO}_2$ . Interpretation: The coefficient of variation is out of acceptable limits for  $\text{VO}_2$  and  $\text{VCO}_2$  ( $>10\%$ ), which could be caused by the physical agitation, therefore, this IC measurement is not reliable. Additionally, the measurement was performed in the early phase of the acute illness, on which the energy needs are covered by endogenous energy stores, therefore, to avoid overfeeding, the use of a weight-based equation ( $20\text{--}25 \text{ kcal kg}^{-1} \text{ day}^{-1}$ , with an energy target of  $1875 \text{ kcal day}^{-1}$ ) for the first 5 days of ICU admission would be prescribed and adjusted after the 3–4th day of ICU admission, based on a new IC measurement.

Case 2: A 21 years-old woman with a BMI of  $13.3 \text{ kg m}^{-2}$ , FM (2 kg, 6.3%), and FFM (30 kg, 93.7%) measured by DEXA, was assisted at the Nutrition Outpatients Clinic. The RMR measurement was conducted using a canopy mode, in a quiet room, with a stable temperature and humidity, in the morning and after an overnight fast. The IC results were:  $\text{VO}_2 = 119 \text{ mL min}^{-1}$ ;  $\text{VCO}_2 = 95 \text{ mL min}^{-1}$ ;  $\text{RER} = 0.85$ ;  $\text{RMR} = 900 \text{ kcal day}^{-1}$ ; Coefficient variation (first 5 min) = 5% for  $\text{VO}_2$  and  $\text{VCO}_2$ . Interpretation: the IC measurements were collected in an appropriate environment and the coefficient variation was within acceptable limits for  $\text{VO}_2$  and  $\text{VCO}_2$  ( $<10\%$ ). A blood urea nitrogen (BUN = 4 mg/dL) and blood creatinine (0.65 mg/dL) were measured to assess the BUN to creatinine ratio (BCR = 6:1) and support an overview of the protein metabolism. Interpretations: the IC measurements were collected in an appropriate environment and the coefficient variation was within acceptable limits for  $\text{VO}_2$  and  $\text{VCO}_2$  ( $<10\%$ ). The RER value and a value of BCR below the normal range (10:1 and 20:1) indicates predominant use of protein as a fuel source, thus a need for increased energy intake from carbohydrates and lipids sources to reduce protein catabolism. Protein turnover and patient needs can be assessed by measuring 24 h urinary nitrogen excretion or estimated by measuring urinary urea excretion, which represents 85% of total nitrogen in humans. Considering the extreme malnutrition, more than  $900 \text{ kcal day}^{-1}$  should be prescribed to achieve a positive energy balance and weight gain, however, to avoid the refeeding syndrome the energy prescription should start at  $10 \text{ kcal kg}^{-1} \text{ day}^{-1}$ .

## Conclusion

Max Kleiber's 20th century, seminal textbook is entitled *The Fire of Life* in recognition of the discoveries made by Antoine Lavoisier. The measurement of the intensity of that metabolic fire using indirect calorimetry provided and continues to provide great insight into the metabolic processes that form human and animal metabolism. The metabolic rate assessed by measuring oxygen and carbon dioxide exchange is the largest component of daily energy expenditure and hence the major (50–85%) contributor to an individual's energy requirement. The ratio of carbon dioxide production to oxygen consumption or RER indicates the relative contributions of macronutrients being combusted and further illuminate information on metabolism and is valuable in understanding physical performance as well as alterations in metabolism that underlie various acute disease states.

### Key points

- To describe the presented microbiota in the intestine
- To understand the biology of the microbiota
- To know the physiological functions of the microbiota
- To mention some aspects in personalized nutrition that are related to the gut microbiota

### Introduction

The microbiome is defined as the collective genomes of the microorganisms in a particular environment, and microbiota is the community of microorganisms themselves. Approximately 100 trillion microorganisms (most of the bacteria, viruses, fungi, and protozoa) exist in the human gastrointestinal tract; the gut microbiome is now best thought of as a virtual organ of the body. The human genome consists of about 23,000 genes. In contrast, the microbiome encodes over three million genes producing thousands of metabolites, which replace many of the functions of the host, consequently influencing the host's fitness, phenotype, and health (Valdes et al., 2018).

The gut microbiota acts as a barrier against harmful microbes using competition for nutrients and ecological binding site occupancies, and the production of antimicrobial substances. Numerous antimicrobial compounds, such as defensins, cathelicidins, and C-type lectins, are produced by eukaryotic cells in the gastrointestinal tract. The presence of commensal bacteria or their structural components, as well as the presence of products of bacterial metabolism, can induce the expression and activation of these antimicrobial substances, contributing to host protection against invading pathogens and preventing the overgrowth of the commensals themselves. Induction can be mediated through various signaling pathways (Kelly et al., 2017).

Gram-positive anaerobic fecal isolates have been reported to exhibit a greater inhibitory effect on the growth of enteric pathogens in vitro than Gram-negative anaerobic isolates. The competitive activity between commensal microbes has been shown to vary between individuals, as well as from different time points in the same individuals, highlighting the interindividual variations of the gut microbiome and its dynamic fluctuations over time (Kelly et al., 2017).

Most human pathogens enter the body across a mucosal surface, e.g., in the intestine. Indeed, the intestinal immune system is the main and most complex part of the immune system (Gomez-Llorente et al., 2010). In addition to its continuous contact with dietary and environmental antigens, the adult human intestine is home to a huge number of commensal bacteria. How the host distinguishes between commensal and non-pathogenic bacteria is still not well understood (Gomez-Llorente et al., 2010).

The immune system can be classified into innate and adaptive systems. The adaptive immune response depends on B- and T-lymphocytes, which are specific for particular antigens. In contrast, the innate immune system responds to common structures, called pathogen-associated molecular patterns (PAMP), shared by the vast majority of pathogens. The primary response to

pathogens is triggered by pattern recognition receptors (PRR), which bind PAMP. PRR comprises Toll-like receptors (TLR), nucleotide-binding oligomerization domains, adhesion molecules, and lectins (Gomez-Llorente et al., 2010; Valdes et al., 2018). The present article aims to describe: (1) The biology and biogeography of the gut microbiota with detailed information about physiological functions. (2) The gut microbiota metabolites and their effects on the host; and (3) Gut microbiota influences the development of several diseases and personalized nutrition.

### Human microbiota of the gastrointestinal tract: biology and biogeography

Microbiota composition in the gastrointestinal tract reflects the physiological properties in a given region and is stratified on both a transverse and longitudinal axis. The density and composition of the microbiota are affected by chemical, nutritional and immunological gradients along the gut. There are typically high levels of acids, oxygen and antimicrobials, and a short transit time in the small intestine. These properties limit bacterial growth, such that only rapidly growing, facultative anaerobes with the ability to adhere to epithelial/mucus are thought to survive. In mice, the small-intestine microbial community is largely dominated by *Lactobacillaceae*. In contrast, colonic conditions support a dense and diverse community of bacteria, main anaerobes with the ability to utilize complex carbohydrates, which are undigested in the small intestine. In the colon *Prevotellaceae*, *Lachnospiraceae* and *Rikenellaceae* have been reported to dominate (Thursby and Juge, 2017).

In contrast with the differing microbiota composition between varying gastrointestinal organs, the microbiota of different colorectal mucosal regions within the same individual is spatially conserved in terms of composition and diversity. This feature is apparent even during periods of localized inflammation. On the other hand, the fecal/luminal and mucosal compositions are significantly different. For example, the abundance of the phylum *Bacteroidetes* appears to be higher in fecal/luminal samples than in the mucosa. In contrast, the phylum *Firmicutes*, specifically *Clostridium* cluster XIVa, are enriched in the mucus layer compared with the lumen. Interestingly, experiments in mice colonized with a diverse specific pathogen-free microbiota show that the outer mucus of the large intestine forms a unique microbial niche and that bacterial species present in the mucus exhibit differential proliferation and resource utilization compared with the same species in the intestinal lumen. These observations highlight the need for careful consideration in choosing a sampling method when analyzing the microbiota composition (Thursby and Juge, 2017). Inter-individual differences in the species and subspecies arrangement are proposed to outweigh differences in the community arrangement within an individual. Suggestions have been made of the presence of a “core microbiota,” proposed to be a set of the same abundant organisms present in all individuals. However, more similarity can be observed in the repertoire of microbial genes present between individuals than the taxonomic profile, suggesting that the core microbiota may be better defined at a functional rather than organism level (Thursby and Juge, 2017).

### Microbiota of the intestine: physiological functions

Alteration of the microbial structure and function (dysbiosis) is associated with the pathogenesis of various disorders. Fermentation is the process by which anaerobic bacteria (*Firmicutes* and *Bacteroidetes*) break down indigestible carbohydrates to lactate, short-chain fatty acids (SCFAs; acetate, propionate, and butyrate), and other metabolites collaborating with species specialized in oligosaccharide fermentation (e.g., bifidobacteria). Butyrate and propionate can regulate intestinal physiology and immune function, while acetate acts as a substrate for lipogenesis and gluconeogenesis. The gut microbiota regulates immune homeostasis via the induction of regulatory T cells and Th17 cells. In addition, butyrate has strong anti-inflammatory effects, possibly through the inhibition of histone deacetylase activity. Metabolic products generated by the gut microbiota, such as SCFAs, gamma-aminobutyric acid (GABA), tryptophan, serotonin, and catecholamine, transmit signals to resident cells in the gut (Andoh, 2016).

Furthermore, gut microbiota might interfere in nutrient sensing and signaling from the gut to the brain, where the information is processed to control energy homeostasis. This gut-microbiota-brain crosstalk or axis is mediated by different metabolites such as SCFAs, secondary bile acids, or amino acid-derived metabolites. Besides, some bacterial components participate in this gut-brain crosstalk influencing metabolic homeostasis (Romani-Perez et al., 2021).

An overwhelming number of reports demonstrate that disruptions in gut microbiome taxonomy and functional potential relate to numerous pathological phenotypes. The majority of studies in humans and animals are observational and lack experimental mechanistic data. However, as revealed by the genetic repertoire of the human gut microbiome, the trillions of commensal or mutualistic bacteria and *Archaea* are an immense chemical factory that can synthesize a multitude of compounds needed for their existence and survival with their host.

### Gut microbiome and development of disease

The microbiome is the collection of all intestinal microbial genes from bacteria, archaea, bacteriophages, eukaryotic viruses, and fungi, which are living on human surfaces and in all body cavities (Fig. 1). Most of these microorganisms are influenced by the mode of birth, lifestyle, infant feeding, medication, and host genetics. The gut microbiome has significant roles in training host immunity, regulating gut endocrine function, digesting food, and neurological signaling, modifying drug action and metabolism,

**Fig. 1** Microbiota of the intestine: physiological functions. Abbreviations: GLP-1, Glucagon-like peptide 1; GPCRs, G-protein-coupled receptors; PYY, Peptide YY; UCP-1, Uncoupling protein 1; TGR5, G-protein-coupled bile acid receptor.

eliminating toxins, and producing numerous compounds that affect the host. Hence, host-microbe interactions are determined by the complexity of the human body and the diversity of the microbiome. In this context, the gut microbiota has a deep role in the development of intestinal lymphoid tissue, affecting the balance between Th1 and Th2 responses and inducing Th17 responses. Furthermore, the gut microbiota affects the enteroendocrine system and modulates gut hormones production, such as glucagon-like peptide 1 (GLP-1), which promotes insulin sensitivity in peripheral tissues and modulates the intraepithelial lymphocytes and gut transit. Likewise, work in mice and humans reveals that the gut microbiota composition oscillates with the circadian clock, implying that it may be important to standardize sampling procedures. In general, alterations of the composition of the human gut microbiome is linked to several diseases, including human metabolic diseases such as obesity; type 2 diabetes (T2D), cardiovascular diseases (CVD), cancer, liver disease, allergy, brain disorders, and irritable bowel disease (IBD), establishing causality with some experiments in animals. Nevertheless, the underlying mechanisms remain unclear (Wu et al., 2015; Fan and Pedersen, 2021) (Fig. 2).

### Gut microbiota and obesity

Obesity affects 650 million adults worldwide, and 39% of the world population has overweight, increasing the risk of insulin resistance, glucose intolerance, and T2D, non-alcoholic fatty liver disease (NAFLD), several types of cancer, including breast, endometrial, and colorectal cancer, obstructive sleep apnea, and dyslipidemia with subsequent CVD. Research has increasingly focused on the role of gut microbiota and its metabolites in the pathogenesis of obesity and associated comorbidities, with important microbial produced metabolites including the microbial formed trimethylamine (TMA) and its oxidized form TMAO, lipopolysaccharide (LPS), secondary bile acids, and the discovered association of phenylacetylglutamine (PAG) and its role in thrombosis, among others.

**Fig. 2** Microbiota and its effects on different organs. Abbreviations: IBD, inflammatory bowel disease; IBS, irritable bowel syndrome; NAFLD, non-alcoholic fatty liver disease.

Gut microbiota composition seems to change in time, varies among individuals despite a similar diet and depends on age, genetics, and environment. The most commonly described change in gut microbiota ecology is the fluctuations in the relative abundance of the bacterial phyla of *Bacteroidetes* as compared to *Firmicutes* in individuals with obesity, and the increased *Firmicutes*-to-*Bacteroidetes* ratio as a predictor of obesity and cardiometabolic disease, observed in both murine models as well as in human studies. Evidence is accumulating for the role of the gut microbiota in mediating some of the environmental effects in obesity pathogenesis. After the discovery in 2006 that a transferrable obesity-associated microbiota could induce weight gain in lean mice, epidemiological studies showed differences between the gut microbiota of individuals with obesity and lean individuals. Thus, at the species level, twin studies revealed that the abundance of SCFA producers such as *Eubacterium ventriosum* and *Roseburia intestinalis* is associated with obesity. In contrast, butyrate producers such as *Oscillospira* spp. and the methanogenic archaeon *Methanobrevibacter smithii* may be associated with leanness. Besides, a metagenome-wide association study of lean individuals and individuals with obesity displayed that the abundance of *Bacteroides thetaiotaomicron*, a glutamate-fermenting commensal, is markedly decreased in individuals with obesity and is inversely correlated with serum glutamate concentration. Furthermore, gavage of mice with *B. thetaiotaomicron* protected against adiposity, pointing to possible future modalities for obesity intervention targeting the gut microbiota with potential probiotic or microbial compounds. Analyses of gut microbial pathways and gene families suggest that obesity is associated with a decreased capacity for unidirectional conjugation. Observational studies of fecal microbiota transplantation (FMT) demonstrate that transfer of stool from twins discordant for obesity into germ-free mice, in a diet-dependent manner, shifts the phenotype of the human donor to the recipient animal, establishing a link between gut microbiota and whole-body metabolism. Interestingly, a case report has revealed a significant weight gain in a woman receiving FMT from a healthy donor with overweight as a treatment for *C. difficile* infection, suggesting that obesity may also be transmissible in humans.

Obesity promotes a reduced fecal microbiota richness, which is linked to increased inflammation and decreased insulin sensitivity. A large-scale twin study showed that the abundance of *Christensenellaceae* was highly correlated in monozygotic twin pairs and associated with a lean phenotype. FMT of an obese-associated microbiota supplemented with a cultivable member of the *Christensenellaceae* caused reduced weight gain and altered gut microbiota composition in the recipient mice, demonstrating a strong relationship between heritable microbial taxa and host metabolic regulation. Therefore, the development of bacterial taxa as novel probiotics may be useful to target obesity and associated metabolic disease.

Concerning bariatric surgery as the most successful long-term treatment for obesity, it is worth highlighting that this process alters the human gut microbiota, promoting an increase in *Enterobacteriaceae*, and microbiota richness in the short term up to 6 months after surgery. Moreover, by colonizing germ-free mice with stools from the patients, it has been demonstrated that the

surgically altered microbiota promoted reduced adiposity in recipient mice. In addition, the mice exhibited a lower respiratory quotient, indicating decreased utilization of carbohydrates as a fuel. These findings suggest that gut microbiota may play a direct role in reducing adiposity observed after bariatric surgery (Zwartjes et al., 2021; Wu et al., 2015).

### Gut microbiota and type 2 diabetes

The gut microbiota is altered in T2D, and the production of butyrate and secondary bile acids may be important for insulin sensitivity. Mechanistic studies in rodents have reported that hyperglycemia might increase intestinal barrier permeability through a GLUT2-dependent transcriptional reprogramming of intestinal epithelial cells and alteration of tight junction integrity, causing a leaky mucosa. Indeed, a leaky mucosa promotes translocation of whole bacteria, bacterial products such as metabolites, and bacterial wall components into the circulation and distant tissues, contributing to remote organ injury in T2D and other metabolic diseases. Besides hyperglycemia, the T2D phenotype often exhibits dyslipidemia with high circulating levels of triacylglycerols and low-density lipoprotein cholesterol, hypertension, and an increased tendency for platelet aggregation. Recent epidemiological studies have focused on elucidating the link between the gut microbiota and T2D by the drug-naïve early stages of T2D, called prediabetes. In fact, in individuals with prediabetes, the gut microbiota shows a loss of butyrate-producing taxa, a decrease in abundance of *Akkermansia muciniphila*, and an increase in the abundance of bacteria with pro-inflammatory potentials.

Among the drugs that are frequently prescribed for T2D, metformin, an anti-hyperglycemic compound, seems to promote shifts of multiple genera and species in the gut microbiota such as *Escherichia* and *Intestinibacter*, and enhancement of several microbiome functional potentials, such as propionate and butyrate production that induces intestinal gluconeogenesis.

On the other hand, T2D has been associated with high levels of *Lactobacillus* and low levels of *Roseburia* in both European and Chinese populations, showing that some consistent features may be linked to T2D independent of geographical and dietary differences. Additionally, FMT from lean individuals into patients with metabolic syndrome improved insulin sensitivity over a 6-week period. This has also been linked to higher levels of *Roseburia* in the fecal microbiota and of another butyrate producer, *Eubacterium hallii*, in the microbiota from the small intestinal mucosa (Zhang et al., 2021; Wu et al., 2015).

### Gut microbiota and cardiovascular disease

CVD, in particular arteriosclerosis, is one of the leading causes of morbidity and mortality in the western world. People who have atherosclerosis frequently had prior silent metabolic dysfunction such as elevated circulating concentrations of glucose, insulin, and lipids, insulin resistance, and low-grade inflammation. Hence, an aberrant gut microbiota on early-stage metabolic perturbations from an imbalanced gut microbiota is escalating the pathogenesis of ischemic heart disease. On top of this situation, people with the cardiometabolic disease usually are, like in T2D, heavily medicated making it challenging to tease apart authentic arteriosclerosis signals in the gut microbiota from signatures induced by complex medication and pre-morbidities and co-morbidities. Individuals with cardiometabolic disease exhibit in their gut microbiota enriched abundances of *Enterobacteriaceae*, including *Escherichia coli*, *Klebsiella* spp., and *Enterobacter aerogenes*, as well as an increased abundance of oral cavity species when compared with healthy subjects. However, individuals with the cardiometabolic disease show a lower abundance of *Bacteroides* spp. and anti-inflammatory *Faecalibacterium prausnitzii*. Furthermore, ischemic heart failure is associated with a dysbiotic gut microbiota with a higher abundance of *Ruminococcus*, *Acinetobacter*, and *Veillonella* spp., and a decreased abundance of *Alistipes*, *Faecalibacterium*, and *Oscillibacter* spp. Overall, cardiometabolic disease patients show a more inflammatory and less fermentative microbiome. Other studies have focused on showing how microbial metabolism of dietary such as phosphatidylcholine and L-carnitine to TMA may be involved in atherosclerosis and CVD, through a mechanism involving oxidation of TMA to TMA-N-oxide (TMAO) in the liver, establishing a link between TMAO and CVD. Hence, microbial metabolism in combination with diet interactions might be involved in the development of CVD (Wu et al., 2015).

### Dysbiosis of gut microbiota in NAFLD

Non-alcoholic fatty liver disease (NAFLD) is a hepatic manifestation of the metabolic syndrome that generally occurs in many countries with a prevalence of 20–40% of the adult population. Disrupted gut microbiota is one of the essential factors in the pathophysiology of NAFLD and non-alcoholic steatohepatitis (NASH), an aggressive inflammatory form of NAFLD. Thus, subjects with NAFLD have an augmented abundance of species assigned to *Clostridium*, *Anaerobacter*, *Streptococcus*, *Escherichia*, and *Lactobacillus*, whereas *Oscillibacter*, *Flavonifractor*, *Odoribacter*, and *Alistipes* spp. are less abundant. Furthermore, children with steatosis or NASH are depleted in *Oscillospira* spp. accompanied by a higher abundance of *Dorea* and *Ruminococcus* spp. compared with normal-weight children.

Gut microbiota in NAFLD patients is more enriched in ethanol-producing bacteria such as *E. coli*; therefore, it has been hypothesized that the altered gut microbiome of individuals with NAFLD may produce more ethanol than microbiomes of healthy individuals, as evidenced by increased concentrations of intrinsically generated ethanol in the circulation and breath. Furthermore, ethanol activates nuclear factor- $\kappa$ B (NF- $\kappa$ B) signaling pathways, causing tissue damage by impairing gut barrier function and

contributing to portal endotoxemia. In the liver of individuals with NALFD, the detoxification pathway is weakened, providing a constant source of reactive oxygen species that potentially cause oxidative damage to the hepatocytes, which in turn may induce hepatic inflammation and steatohepatitis. Similarly, liver cirrhosis drives an altered microbiota, including enrichment of *Proteobacteria* and *Fusobacteria* phyla (Fan and Pedersen, 2021).

## Diet and gut microbiota

Diet influences the human gut microbiota, displaying the potential of therapeutic dietary strategies to manipulate microbial diversity, composition, and stability. Energy intake and the macronutrient composition of the diet affect human health and influence the composition of the human gut microbiota. However, the gut microbiota responds rapidly to dietary interventions, both short-term and long-term. Generally, a metabolically healthy microbiota is mainly achieved by a high-fiber, low animal fat, and low animal protein diet. On the contrary, microbial dysbiosis is induced by a high-fat diet, characterized by high amounts of fat and protein, and sedentary life, smoking, alcohol intake, and relatively infrequent defecation might cause a leaky mucosa, inflammation, and reduced production of SCFAs. Of note, a dysbiotic microbiota is often associated with a prolonged colonic transit time, resulting in a shift in colonic metabolism leading to increased microbial proteolysis. Furthermore, the gut microbiota of people consuming high amounts of protein and animal fat is dominated by the *Bacteroides* genus and lower amounts of *Firmicutes* genus, while the *Prevotella* genus dominates the gut microbiota of people consuming more fiber and carbohydrates (Fan and Pedersen, 2021; Zhang et al., 2021). Diet-gut microbiota interactions and their impact on human physiology have been extensively reviewed in the article “Microbiota of the intestine: Dietary interactions”.

## Personalized nutrition and gut microbiota changes

Personalized nutrition is defined as an approach that counts on details of individual characteristics to evolve a package of nutritional counsel, products, or services, explained as a perspective “assists individuals in achieving a lasting dietary behavior change that is beneficial for health.” Diet is increasingly appreciated to impact numerous aspects of the host’s biology tremendously, both in health and disease. Dietary content and timing are also central in shaping the gut microbiome and contribute to its taxonomic and functional diversity. Thus, personal variations lead to consider that host and gut microbiome features might contribute to the inter-individual variability in response to environmental factors (e.g., diet). In this context, we highlight recent findings regarding the diet-microbiome interactions and the large personalized data that it represents toward integration into nutritional recommendations affecting human health.

As we abovementioned, diet is a key determinant of personalized microbiome composition and function. Accordingly, dietary components such as carbohydrates, proteins, fatty acids, and some additives influence the human gut microbiome structure and function. Furthermore, the gut microbiome dynamically changes with immigration-related dietary shifts, seasons, and timing throughout a 24 h period, related to chrononutrition.

Different studies have elucidated how intake of dietary components modify gut microbiota in a person-specific fashion. For instance, a report showed that short-term intake of dietary fiber in healthy adults was associated with high proportions of *Prevotella* and *Coprococcus* species and high levels of caproate and valerate in a person-specific manner, with fewer microbiota shifts upon fiber intake. On the other hand, non-caloric artificial sweeteners (NAS) outline the gut microbiome structure and function in both mice and humans and impact postprandial glycemic responses in some, but not in all humans, indicating an effect in an individual-specific manner. In this context, human NAS responder and non-responder subsets are suggested to feature differential glycemic responses to food, and they might be recognized based on individualized microbiome patterns. Similarly, consumption of the probiotic *Lactobacillus paracasei* DG induced individual-specific alterations in fecal *Clostridiales* and butyrate production, depending on the initial intestinal microbial ecology, establishing a predictable fate by combining baseline host and microbiome features. The stable colonization of the probiotic *Bifidobacterium longum* AH1206 happened only in 30% of individuals, which was related to low pre-treatment resident *B. longum* levels and underrepresented microbiome-related carbohydrate utilization genes.

In individuals with obesity, the composition and function of the individual’s gut microbiota after weight-stabilization or weight-loss diet differed significantly from person to person, which was negatively correlated with their microbial diversity. Moreover, inter-individual microbiome responses to dietary interventions in obesity were also related to specific bacterial species at baseline, in both males and females. These personalized microbiome responses to dietary exposure may also be important in the context of disease. In obese men, the compositional and functional changes of the individual’s gut microbiota under a weight-stabilization or weight-loss diet varied significantly from person to person, which was negatively correlated with their microbial diversity, and relying on an individual’s baseline microbiome composition. Inter-individual microbiome responses to obese-related dietary interventions are also associated with specific bacterial species at baseline, in both males and females. Indeed, *Firmicutes* have been used as predictors of both host and microbiota responses to a weight-control diet in patients with obesity. In a large cohort containing 800 subjects with overweight/obesity in Israel, the high inter-individual variability in postprandial glycemic response was predicted by incorporating microbiome features and host characteristics, including anthropometrics and dietary habits, using machine-learning algorithms.

Overall, growing evidence suggests a contributing role of the gut microbiota in predicting the personalized host response to dietary interventions. However, still further studies are needed to decipher downstream mechanisms by which microbe's sense and react to specific food-derived compounds and their downstream impact on the host. Additionally, integration of multi-omics strategies not only limited to microbiome analyses but in combination with proteomics, metabolomics, transcriptomics, and epigenomics are required to identify potential clinical predictors of person-specific response, using advanced machine-learning algorithms and accurate validation methods (Kviatcovsky et al., 2021; Gibney et al., 2016).

## Conclusion

Future sequencing-based and culture-based gut microorganism surveys combined with mechanistic exploitations of the gut microbiome will exponentially expand our knowledge about the interactions within the global intestinal microbial community. Finally, yet importantly, exciting new knowledge about the multitude of chemicals that the global gut microbiome produces affecting host physiology and numerous pathologies may foster novel efficacious paths to stabilize metabolic health of the human host and prevent or combat common human metabolic disorders.

### Key points

- To describe the major microbes of the intestine
- To understand the main functions of the gut microbiota
- To know the new technologies for the detection of specific intestinal microbes
- To understand the dietary interactions between gut microbes and foods
- To mention some aspects in personalized nutrition using the gut microbiota

### Introduction

The microbiota can be described as “the full collection of microbes, i.e., bacteria, fungi, virus, etc., that naturally exists within a particular biological niche such as an organism, soil or a body of water, among others”. Actually, the “microbiota” word is also referred to as the metagenome of the microbiota. Indeed, the microbiome comprises all of the genetic material within a microbiota (the entire collection of microorganisms in a specific niche, such as the human gut). Gut microbes are key to many aspects of human health including metabolic, immune, and neurobehavioral traits (Valdes et al., 2018).

The microorganism's communities in the human digestive tract are an ecosystem that is both critical for health and also a possible pilot of several pathologies. The adult human intestine is colonized by more than 1000 microbial species including all domains of life: Archaea, Bacteria, and Eukarya (Plaza-Díaz et al., 2019; Plaza-Díaz and Gil, 2017). The microbiota properties in the human small intestine are fewer well described, primarily because of the complications in testing this segment of the digestive tract. Learning the small intestine ecosystem is predominantly important to digestive health because the duodenum and jejunum are tasked with facilitating the majority of nutrient assimilation and absorption. The intestinal epithelium is in constant and closed contact with luminal substances and the variable, dynamic enteric microbiota. The intestinal barrier is the main defense mechanism used to preserve epithelial integrity and to safeguard the organism from the environment. Defenses of the intestinal barrier consist of the antimicrobial peptides, secretory IgA, mucous layer, and the epithelial junction adhesion complex. After this barrier function is distorted, food and bacterial antigens can reach the submucosa and can provoke inflammatory responses, which may result in intestinal disorders, such as inflammatory bowel disease. In the present article, the objective is to describe the main microbes present in the intestine, to mention the new technologies for the detection of specific species, and to discuss the interactions between gut microbes and diet.

## Microbiota of the intestine

Specifically, there are more than 50 phyla of bacteria on Earth, but of these, the bacterial communities associated with humans are predominantly dominated by four, *Firmicutes*, *Bacteroidetes*, *Actinobacteria*, and *Proteobacteria*, and other phyla to a lesser extent, depending on the individual's characteristics and the distribution of microbes throughout the human body.

The relative abundance of these four phyla tends to be consistent across individuals, regardless of their place of origin, residence, or type of diet, e.g., in almost all humans studied so far, *Bacteroidetes* and *Firmicutes* predominate in the colon. In contrast, the composition of the vaginal microbiota is more variable; most women have a preponderance of *Firmicutes* with some other representatives, while a minority of women have a preponderance of *Actinobacteria* with some other representatives. It is estimated that 20–80% of the human phylum are directly associated with habitat (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

Fig. 1 shows that the greatest amount of bacterial load is found in the intestine and colon. The distribution of the microbiota in the human intestine is not homogeneous and the number of bacteria present ranges from  $10^4$  to  $10^{12}$  colony-forming units (CFU) in the stomach and duodenum, increasing from  $10^{11}$  to  $10^{12}$  CFU in the colon. There are also differences in longitudinal heterogeneity throughout the digestive tract and latitudinal variation because the intestinal epithelium is separated from the lumen by a thick and complex layer of mucus, generating a different type of habitat to that which may exist in the lumen or on the surface of the intestinal epithelium, causing a clear difference in the microbiota in each of these habitats.

The human intestine is the natural habitat for a large and dynamic bacterial community, but a substantial part of these populations remains as yet unknown. The dominant phyla of bacteria in the intestine are *Bacteroidetes*, *Firmicutes*, *Actinobacteria*, *Proteobacteria*, and *Verrucomicrobia*. In the small intestine, the *Enterobacteriaceae* and *Lactobacillaceae* families dominate, whereas in the colon there is a marked presence of species from the *Bacteroidaceae*, *Prevotellaceae*, *Rikenellaceae*, *Lachnospiraceae*, and *Ruminococcaceae* families (O'hara and Shanahan, 2006; Plaza-Díaz and Gil, 2017; Plaza-Díaz et al., 2019). Within the small intestine, in the duodenum, the composition of the microbiota is sparse and usually contains less than  $10^5$  CFU; *Haemophilus*, *Actinomyces*, and some anaerobes, and lactobacilli are found. In the jejunum and ileum, there is a continuous increase in the number ( $>10^8$  CFU) and variety of the microbiota with bifidobacteria, facultative anaerobes (*Bacteroides* and *Fusobacterium*), and strict anaerobes being present in increasing numbers from the ileocecal valve. The microbiota in the distal part of the small intestine is denser ( $>10^9$  CFU) and resembles that of the cecum, with large numbers of strictly anaerobic bacteria. In the large intestine,

Fig. 1 Variation in composition and number of the microbiota along the human gut. Abbreviations. UFC, unit forming-colony.

facultative anaerobic microorganisms (*Streptococcus* and *Enterococcus*) are commonly found. Finally, in the cecum, eubacteria, bifidobacteria, *Clostridium*, and Gram-positive bacteria are prominent (O'hara and Shanahan, 2006; Plaza-Díaz and Gil, 2017; Plaza-Díaz et al., 2019) (Fig. 1).

The gut microbiota in adults is estimated to consist of between 1000 and 1150 bacterial species, with some experts suggesting that only 160 of these species constitute the core microbiota that is present in most individuals. Although many of these species are found in most people, their relative abundance may vary, thus there is great individual variability. The complex bacterial community present in the human intestine does not remain constant over time but can vary due to several factors, among which we can find the environmental conditions of the digestive tract itself, the quantity and variety of bacteria in the different regions of the digestive tract, which is determined by a great diversity of complex intrinsic and extrinsic factors. There is also a reciprocal relationship between the host and the microbiota that inhabits it since the microbiota can have an important impact on the organism that hosts it and these effects can be beneficial or detrimental to the health of the individual. In recent years, great strides have been made in characterizing the composition of the microbiota and how such microbial numbers have functional interactions with the host. Such studies on function are becoming fundamental in understanding the role of the microbiota in the maintenance of human homeostasis and the pathogenesis of certain diseases (O'hara and Shanahan, 2006; Plaza-Díaz and Gil, 2017; Plaza-Díaz et al., 2019).

### High-throughput sequencing technologies

More than a decade ago, the majority of the knowledge and available information about the adult human gut microbiota came from culture-based methods. Nowadays, our faculty to understand the gut microbiota has significantly upgraded and developed due to high-throughput and low-cost sequencing methods targeting the bacterial 16S ribosomal RNA (rRNA) gene. Because this gene exists in all bacteria and Archaea with nine highly variable regions (V1–V9), which permits specific bacteria to be easily described (Poretsky et al., 2014; Thursby and Juge, 2017). More recently, the 16S rRNA sequencing focus has moved to analyze shorter sub-regions of the gene in greater depth. However, the employment of shorter read lengths could introduce some errors in the sequencing (Poretsky et al., 2014).

### Roles of intestinal microbiota

The influence of bacteria on intestinal physiology has been demonstrated in studies with germ-free animals through colonization. Thus, it has been observed that reconstitution of the microbiota in germ-free mice with an intestinal microbiota from other normal mice is sufficient to recover the immune function of the intestinal mucosa. Repopulation of the gut of germ-free mice with a single species, *Bacteroides thetaiotaomicron*, has been shown to affect the expression of several genes that control certain functions associated with nutrient absorption, metabolism, angiogenesis, mucosal barrier function, and enteric nervous system development (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

#### Protective and structural functions

Host defense against pathogenic microorganisms mediated by the intestinal microbiota requires a fine interpretation of the microenvironment present, as it must distinguish between commensal microorganisms and occasional pathogens and, in addition, differentiate subsequent responses for both cases (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

The mucosal epithelia and, in particular, the intestinal epithelium represent the first line of defense against action by pathogens; superficial enterocytes serve as afferent sensors of the luminal microenvironment by secreting antibacterial peptides, immunoglobulin A, and chemokines that alert and direct the immune response to the site of infection. M cells lining the lymphoid follicles transport luminal antigens to underlying dendritic cells and other antigen-presenting cells. Finally, intestinal dendritic cells play a role essentially as sensors of the immune system and can directly monitor intestinal contents, either by entry or extension of dendrites between superficial enterocytes without disrupting tight junctions. In addition, they can ingest and keep commensal bacteria alive, travel to mesenteric lymph nodes, where a local immune response against commensal bacteria is induced (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

The fine distinction between pathogenic and commensal bacteria is mediated by the antigenic pattern recognition receptor (PRR) system, the toll-like receptor (TLR) family, and NOD-like receptors (NLR). On the other hand, commensal bacterial fragments influence the normal development of the mucosal immune system and profoundly affect the development of the humoral components of this system, modulating the response of T and T helper cells type 1 and 2. The human microbiota controls the proliferation and differentiation of epithelial cells and is also responsible for modulating the maturation and activity of the innate and adaptive immune response (Fig. 2) (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

#### Metabolic functions

The microbiota has an adaptive yet renewable metabolic activity. Through the production of short-chain fatty acids (SCFA), resident bacteria positively influence intestinal epithelial cell differentiation and proliferation and may mediate other metabolic effects. All

**Fig. 2** Functions of the gut microbiota. Abbreviations. IgA, immunoglobulin A; SCFA, short-chain fatty acids.

this complex metabolic activity recovers valuable energy and absorbable substrates for the host and at the same time provides energy and nutrients for bacterial growth and proliferation. In addition, the commensal microbiota synthesizes some vitamins that are efficiently used by the host, such as vitamin K and several B vitamins, including biotin, folic acid, and vitamin B12 (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

It is important to note that each of the functions of the intestinal microbiota varies with age. Some factors as the diet may account for changes in host physiology associated with the development of immune system reactivity, but may also be caused by changes in the bacterial population of the large intestine. Some studies have indicated that bifidobacteria content decreases in older people, increasing those of clostridia and enterobacteria, favoring the progression of infections. Lactobacilli and bifidobacteria are some of the candidate microorganisms to be used in humans since there is evidence that some of these organisms can increase resistance to intestinal infections by inhibiting pathogens and improving the immune response of the host (Fig. 2) (Plaza-Díaz and Gil, 2017; O'hara and Shanahan, 2006).

## Microbiota and malnutrition

Child malnutrition accounts for almost half of all deaths in children under 5 years of age worldwide. At present, health efforts to restore nutritional intake remain inconclusive and have yielded modest results (Thursby and Juge, 2017). One of the new alternatives proposed is to modify the population of bacteria inhabiting the intestine which, as mentioned above, modulates intestinal metabolic activity. Childhood malnutrition has been associated with an altered microbiota (Thursby and Juge, 2017). New studies indicate that the composition of the microbiota is altered in chronically malnourished children. The time between conception and three years of age is crucial for human growth and development. Decades of research on the onset of health and disease have shown that environmental influences during this period can contribute to the onset of disease later in life. For example, suffering nutritional deficits or excess nutrients in early life can have metabolic and cardiovascular health consequences. Because of the symbiotic role of the gut microbiota in intestinal metabolism, it is thought that changes in its composition may contribute to these health problems (Plaza-Díaz and Gil, 2017).

The foods we eat influence the type of microbes that colonize the gut. Each microbial species has an optimal metabolic environment that is preferably compatible with its growth. As such, a diet rich in plant fiber promotes a gut microbiota considerably different from that promoted by a diet rich in animal fat. The microbiota converts non-digestible dietary components, such as fiber, into useful compounds to fuel the growth of intestinal cells that, in turn, promote the development of a healthy immune system (Myhrstad et al., 2020).

To investigate the stool microbiota of Malawian children with and without varying degrees of growth impairment, results from children who grew normally were compared with the idea of deriving a model of a healthy microbiota (Thursby and Juge, 2017). When such a model was applied to the entire cohort it was observed that children with weight-associated growth impairment had an immature microbiota compared to those of a healthy weight. Subsequently, it was investigated whether the difference in the gut

microbiota contributed to the observed impairment in growth (Gehrig et al., 2019). Bacteria were isolated from the fecal samples of the children to colonize the gut of germ-free mice. The mice were then fed a nutrient-poor diet that resembled a typical Malawian diet. After several weeks the mice harboring a microbiota-derived from growth-impaired donors gained significantly less weight than the control group that received the microbiota from healthy children. However, if both groups were housed in the same cage, the microbiota from the controls quickly transferred to the low-growing mice, regaining weight similar to the healthy animals. This effect was attributed to two bacterial species, *Ruminococcus gnavus*, and *Clostridium symbiosum*, which were introduced into germ-free mice along with the microbiota of stunted donors, and sustained weight gain followed. In addition, the levels of amino acid metabolism by-products were reduced in the livers of the mice that had regained weight compared to those of the growth-stunted mice (Gehrig et al., 2019).

In an animal study, the growth of normal young mice was compared with that of germ-free mice indicating that the presence of a previous microbiota promoted growth by increased production of Insulin-like Growth Factor-Binding Protein (IGFBP). If the mice had a nutrient-poor diet, microbial stimulation of this growth factor partially ameliorated the growth deficit. Not all strains of bacteria could promote growth in the manner detailed above. Different strains of a species had different effects on growth. These data obtained highlight the fact that each microbe interacts with its host in a heterogeneous manner, indicating that the beneficial growth-promoting effects of bacteria in mice cannot be applied to humans (Plaza-Díaz and Gil, 2017).

Growth and its relationship to breast milk were analyzed in malnourished children and the content of the breast milk they consumed. The breast milk of malnourished children had a lower amount of sugars, especially oligosaccharides. These sugars are of interest because they are abundant in human milk, but not in cow's milk. Strategies aimed at supplementing the infant's diet may include milk supplemented with oligosaccharides to promote healthy growth in infants who do not receive sugars through their mother's milk. However, the large-scale manufacture of these oligosaccharides is still difficult because of the technology required to achieve their use on an industrial scale.

The gut microbiota of children living in an urban slum in Bangladesh was investigated by collecting fecal samples from birth to the first two years of life. It was concluded that growth problems were associated with immature microbiota even in the early stages of malnutrition (Plaza-Díaz and Gil, 2017).

It is becoming increasingly clear that our diet, gut microbiota, and health are highly correlated. Therefore, we need to be aware that dietary interventions can affect the growth of billions of bacteria and those have an impact on the host in multiple domains (Plaza-Díaz and Gil, 2017).

### Gut microbiota: dietary interactions

Humans can only synthesize 11 of the 20 essential amino acids themselves; they trust food intake for the other nine along with all 13 essential vitamins. Most of these amino acids and vitamins came from meat, eggs, milk products, fruits, and vegetables, but a few essential compounds are produced by microbes, which are important producers of essential amino acids and vitamins themselves (Hirt, 2020).

Diet influences microbial colonization of the gastrointestinal tract, affecting health throughout the lifespan. The short-term consumption of diets composed entirely of animal or plant products alters microbial community structure and overwhelms inter-individual differences in microbial gene expression. An animal-based diet increases the abundance of bile-tolerant microorganisms (*Alistipes*, *Bilophila*, and *Bacteroides*) and decreases the levels of *Firmicutes* that metabolize dietary plant polysaccharides (*Roseburia*, *Eubacterium rectale*, and *Ruminococcus bromii*). Increases in the abundance and activity of *Bilophila* spp. on the animal-based diet support a link between dietary fat, bile acids, and the outgrowth of microorganisms capable of triggering inflammatory bowel disease (David et al., 2014).

A Western-type diet is related to metabolic disease incidence increased in developed nations. In contrast, diets high in fruits, vegetables, nuts, seeds, legumes, and whole grains and low in animal fats and sugary foods are protective against cardiovascular disease and metabolic disorders. These diets are supportive of health-promoting microbiota and metabolomic profiles, as evidenced by associations with the higher relative abundance of *Lachnospira*, *Prevotella*, and *Roseburia* and increased concentrations of fecal SCFAs (Hirt, 2020).

The gut microbiota has crucial capacities for non-digestible substrates fermentation as dietary fibers and endogenous intestinal mucus, and this fermentation generates the growth of the specific microbes that create SCFAs and gases. The main SCFAs formed are acetate, propionate, and butyrate (Valdes et al., 2018).

Butyrate is the key source of energy for human colonocytes, can stimulate colon cancer cells apoptosis, and can stimulate intestinal gluconeogenesis with positive effects on glucose and energy homeostasis. Butyrate is vital for epithelial cells to consume large amounts of oxygen through  $\beta$  oxidation, causing a state of hypoxia that preserves oxygen balance in the gut, avoiding dysbiosis in the gut microbiota. Propionate is transported to the liver, where it controls gluconeogenesis and signaling for satiety through interaction with the gut fatty acid receptors. Finally, acetate is the main abundant SCFA and is critical for bacterial growth, when acetate goes to peripheral tissues it is used in lipogenesis and cholesterol metabolism and could have some participation in central appetite regulation.

Some clinical evidence, especially from randomized controlled trials has shown that greater SCFAs production associates with lower diet-induced obesity and with decreased insulin resistance. Gut microbial enzymes contribute to bile acid metabolism, producing unconjugated and secondary bile acids that act as signaling molecules and metabolic regulators to impact central

host pathways. Also, some evidence has reported that higher diet quality prevails lower mortality and type 2 diabetes incidence. Besides, the positive influence of diet quality on body weight, body fat distribution, and inflammatory status, food components, and dietary patterns have been associated with the gut microbiota composition (Zhao et al., 2018). In addition, evidence has accumulated for a relation between gut microbial characteristics and type 2 diabetes.

A meta-analysis showed that data-derived patterns characterized by red/processed meat, refined grains, high-fat dairy, and fried products were related to a 44% higher diabetes risk, whereas a diet rich in vegetables, legumes, fruits, poultry, and fish predicted a 16% lower risk (Jannasch et al., 2017). Similar results were observed with a reduction in diabetes risk of 30% with the Mediterranean diet (Jannasch et al., 2017). The literature has important information showing that dietary components bioavailable to microbiota, such as dietary fats, proteins, carbohydrates, and polyphenols, impact the gut microbiota composition.

Some studies have added new information about the triangular relation of dietary patterns, the presence of prediabetes as an indicator of risk to develop diabetes, and gut microbiota composition. In participants who had completed a validated quantitative dietary questionnaire before stool collection, the dietary indices were positively related to alpha diversity indices, and decreased relative abundance of *Actinobacteria*. Some genera were associated negatively and positively with the diet quality, especially from *Roseburia* and *Lachnospiraceae* families (Liu et al., 2019). *Roseburia* and *Lachnospira* both metabolize fermentable carbohydrates, producing butyrate and that affects glucose metabolism and diabetes risk. In the case of *Lachnospira*, these bacteria use pectin from fruits and vegetables for the production of acetate. Also, *Roseburia* in the presence of these fermentable carbohydrates could condense two moles of acetate to form one mole of butyrate. A systematic review performed to analyze the dietary influences on fecal microbiota composition in healthy humans 1–20 years of age, indicates that a diet rich in indigestible plant polysaccharides is related to *Prevotella* species, i.e., *Prevotella copri*. In contrast, a diet with a content of a high-fat and -sugar diet is related to *Bacteroides* (Dinsmoor et al., 2021).

### Gut microbiota: microbial metabolites

Metabolomics is an important platform to distinguish the profile of metabolites by performing large-scale metabolic profiling after dietary interventions. In the nutrition field and health specifically, metabolic profiling may provide information about diet—that is, as food intake biomarkers, as well as the ongoing physiological responses triggered by the diet. Investigations of dietary responses, however, remain challenging due to the complex interplay between any bioactive compound with other nutritional components, and an immense variation between individuals, as previously reported.

Microbial metabolites do not seem to have a comparable behavior next to dietary interventions, which makes sense due to their great diversity. Secondary bile acids are conversion products of primary bile acids by the gut microbiota. Included in this group are deoxycholic and lithocholic acid, as well as their conjugates of taurine and glycine. They have been reported to increase following various interventions, including oral-glucose-tolerance test, yogurt, acidified milk, and wheat flour fortified with vitamin B and minerals, except for lower deoxycholate concentrations after the oral-glucose-tolerance test.

Propionate diminished after an oral-glucose-tolerance test. However, it augmented after the consumption of cranberry juice and green tea. Acetate, conversely, decreased following consumption of dark chocolate and black tea. Other specific gut microbiota products have been associated directly with human health outcomes. The trimethylamine production from meat and dairy differs on the gut microbiota and thus its amount in the blood varies between people. Trimethylamine is oxidized in the liver to trimethylamine N-oxide, which is positively related to an increased atherosclerosis risk and major adverse cardiovascular events. Indole propionic acid is highly related to the intake of dietary fiber and has strong radical scavenging activity in vitro, which looks to decrease the incidence of type 2 diabetes (Myhrstad et al., 2020). Indole propionic acid has been shown to grow following an optimized Nordic diet and acidified milk, but declines after an oral-glucose-tolerance test.

### Manipulating the gut microbiota through diet

Gut microbiota changes can occur within days of changing diet; remarkable differences have been found after African Americans and rural Africans switched diets for only two weeks (Zhao et al., 2018).

A subset of dietary fiber sources is fermentable, which means that they serve as growth substrates for microbes in the distal bowel. The consumption of resistant starches has been shown to facilitate the specific growth of bacterial groups (e.g., *Bifidobacterium adolescentis*, *Ruminococcus bromii*, and *Eubacterium rectale*) in some populations. Microbiota accessible carbohydrates offer a potential strategy to improve useful minority members of the microbiota. These changes only last as long as the carbohydrate is consumed, and they are highly individual, which provides a basis for personalized approaches. Many short-term feeding trials with purified dietary fibers or even whole plant-based diets either do not affect microbiota diversity or reduce it (Zhao et al., 2018), but can still have clinical benefits, potentially through metabolites such as SCFAs (Zhao et al., 2018; David et al., 2014).

Low fiber intake decreases SCFA production and shifts the gastrointestinal microbiota metabolism to use less favorable nutrients, leading to the production of potentially detrimental metabolites. Several meta-analyses have found clear links between dietary fiber and health benefits in a wide range of pathologies (Zhao et al., 2018), and dietary fibers significantly reduced insulin resistance in patients with type 2 diabetes, with clear links to the shifts in the microbiota and beneficial metabolites (such as butyrate).

Probiotics are living microorganisms that confer health benefits to the host when administered in adequate amounts. However, dead bacteria and their components can also exhibit probiotic properties. *Bifidobacterium* and strains of lactic acid bacteria are the most widely used bacteria that exhibit probiotic properties and are included in many functional foods and dietary supplements (Plaza-Díaz et al., 2019). Probiotics can affect health independently of the gut microbiota through direct effects on the host; for example, through immune modulation or the production of bioactive compounds. The therapeutic effect of probiotic supplementation has been studied in a broad range of diseases (Valdes et al., 2018). *Bifidobacterium longum* has been shown to depend on individualized features of the gut microbiota, providing a rationale for the personalization of probiotic applications.

In addition, gut microbiota changes in the composition and function, for example in the case of dysbiosis could be related to driving obesity-related pathogenesis and may be one of the most important drivers of mucosal barrier dysfunction. Several microbiota effects on the host are mediated by microbiota-derived metabolites (Wei et al., 2021). Also, novel products are tested for the food industry with anti-obesity activities (Shen et al., 2021; Su et al., 2021).

## Personalized nutrition through the microbiota

Blood glucose levels after a meal (postprandial response) are determined by an individual's daily food and nutrient intake. It has shown that the postprandial response to standardized meals is highly variable between individuals and depends on several factors that may include the gut microbiota. This is important because tracking individual responses to different foods can generate an integration of this information between health parameters and microbiota composition into a learning algorithm to develop individualized nutrition plans to improve the postprandial response (Plaza-Díaz and Gil, 2017). A study assessed glucose levels in a cohort of 800 people every 5 min for seven days during which participants followed their normal routine, except for the consumption of standardized meals. These data were used to calculate the postprandial response. A positive correlation between the abundance of *Proteobacteria*, *Enterobacteriaceae*, and *Actinobacteria* and elevated values in the postprandial response to some of the standardized meals was found, while the presence of *Clostridium* and *Prevotellaceae* correlated with lower responses (Zeevi et al., 2015). In that study, a computer learning algorithm based on clinical parameters and the microbiota was useful to predict individual postprandial responses. An initial analysis of individual postprandial responses from the algorithm showed that *Eubacterium rectale* growth is associated with low glycemic responses while *Parabacteroides distasonis* abundance was associated with higher values. The findings in this field indicate that the postprandial response is different and variable among individuals, even when they consume the same meal. The postprandial response has a multifactorial component with differences in the composition of the gut microbiota. Further studies should address in greater detail the possible mechanisms of action between the effect of diet and its relationship with the gut microbiota and metabolic diseases.

## Conclusion

Dietary patterns broadly agree on components of a healthy diet: primarily high intakes of fruits/vegetables, nuts, and whole-grain products and low intakes of red/processed meats and products high in sugar and certain fats. The beneficial health outcomes are likely a result, in part, of higher levels of SCFA derived from gut microbial fermentation of plant-based nutrients typical for a Mediterranean diet.

Dietary interventions and targeted nutritional therapies, such as medical foods, dietary supplements, living microorganisms, and nutraceutical food, could provide a great promise for the prevention and treatment of microbiota-related diseases.

Some specific genera from the gut microbiota are related to human health, and those are principally regulated through dietary interactions: However, more clinical trials, especially randomized clinical trials with an adequate number of subjects are needed to elucidate the specific changes in the gut microbiota related with the food intake.

### Key points

- To understand epigenetic modifications, chromatin structure and their impact on gene expression.
- To analyze the relationship between metabolic diseases and nutrieigenetics.
- To consider the hereditary transmission of epigenetic marks.
- To identify the ways in which chromatin can be modified by nutrients and dietary patterns and their functional importance.

### Glossary

**Precision nutrition** A concept that goes beyond personalized nutrition as it brings together knowledge based on the gene pool (gene sequence, epigenetics, transcriptomics), but also on phenotypic markers such as family history and previous illnesses, lifestyle, exercise, diet, microbiota, stress, culture, religion, aversions, preferences, allergies and intolerances, etc.

**Epigenetics** Science that studies modifications in gene expression that are not due to an alteration in the DNA sequence and are heritable

**DNA methylation** Epigenetic process by which a methyl group is added to the cytosine base at position 5 of the pyrimidine ring to form 5-methylcytosine. A high degree of methylation is associated with a closed conformation of chromatin and thus with gene silencing

**Covalent modifications of histones** Post-translational modifications of histone proteins (H1, H2A, H2B, H3 and H4), such as methylation, phosphorylation, acetylation, deamination, ubiquitination and proline isomerization, which can modify histone configuration and alter their interaction with DNA and other nuclear proteins, thus affecting chromatin compaction and gene expression

**Biomarker** Any molecule or chemical structure that can be used as an indicator of a biological state (normal or pathological), the response to a dietary, pharmacological or surgical intervention, the risk of suffering a certain pathology or the future evolution of a disease

**Non-coding RNA** RNA molecule that is not translated into a protein, such as transfer RNA (tRNA), ribosomal RNA (rRNA), and others such as snoRNAs, microRNAs (miRNAs), siRNAs, piRNAs and long non-coding RNAs (lncRNA). Many of the latter have regulatory functions on gene expression

**MicroRNAs** miRNAs are single-stranded non-coding RNAs, between 21 and 25 nucleotides in length, that have the ability to inhibit the expression of other genes through protein degradation during translation, inhibition of translation elongation, premature termination of translation (by ribosome misfolding), or inhibition of translation initiation

**Methyl donors** Molecules involved in the process of transferring a methyl group from S-adenosylmethionine to proteins or nucleic acids. For example, betaine, choline, some vitamins (folic acid, riboflavin, vitamins B6 and B12) and amino acids (methionine, cysteine, serine, glycine)

## Introduction

“Epigenetics” is defined as heritable modifications in gene expression that cannot be explained by changes in DNA sequence. Mechanisms involved cause heritable changes to cells without affecting DNA sequence (e.g., DNA methylation; histone modification; DNA replication timing; nucleosome positioning; and heterochromatinization, which result in selective gene expression or repression). Besides, “epigenomics” can be defined as the systematic study of the global gene expression changes due to epigenetic processes and not due to DNA base sequence changes.

The current scientific evidence shows that nutrients are capable of modulating metabolic, cellular and molecular processes by mediating transcriptional, translational and post-translational pathways and operations, including DNA organization and conservation and gene expression. Given the incontrovertible evidence of the involvement of environmental factors, such as dietary patterns, intake of specific nutrients and physical activity, in the incidence of certain diseases including metabolic syndrome, cardiovascular diseases and cancer, a new concept termed “nutriepigenomics,” has been established. Nutriepigenomics joins nutrigenomics (the study of the influence of nutrients on gene expression) and nutrigenetics (the way in which the genetic sequence conditions the individual response to nutrients) and makes it possible to explain some of the effects on human health nutrients, foods and their bioactive components, e.g., phytochemicals, through changes in epigenetic marks. Epigenetic changes are modulated by environmental exposure (including nutrition and physical activity), thus epigenetics is possibly involved in the development of aging-related and other non-communicable chronic diseases.

Epigenetic marks influence gene function and expression without modifying the primary nucleotide sequence of DNA. These include methylation and hydroxymethylation of certain nucleotides, chromatin compaction, various covalent modifications of histones, and the expression of miRNAs. This “overgenetic” signaling has made possible to show that, if there are nutritional alterations and metabolic imbalances in certain critical periods of development, the epigenetic modifications generated can induce stable changes in the differential expression of certain genes with effects on the structure or function of tissues and organs, thus predisposing to various pathophysiological disorders and diseases.

Epigenetic changes can be heritable and long-lasting. In addition, epigenetic processes are one of the ways by which environmental agents can influence gene expression and metabolic regulation throughout the life cycle, providing possible etiopathological explanations for chronic diseases typical of adulthood, whose origin may be based on physiological alterations in perinatal stages or on parental feeding behaviors during that period. Besides, epigenetic phenomena are potentially reversible, which allow us to think about possible therapeutic targets based on nutritional guidelines or personalized pharmacological therapies for their control, treatment and eventual modification. Early detection of changes in epigenetic signals (biomarkers) can also be used for the early diagnosis of diseases and precise individualized preventive action based on epigenetic biomarkers.

## Epigenetic modifications and chromatin structure

Among the epigenetic mechanisms that regulate gene function there are some “canonical” modifications, including histone acetylation, histone methylation and DNA methylation, and “emerging” modifications, including histone acylation, homocysteinylation, and serotonylation (Table 1). Others recently described include changes that affect chromatin folding (euchromatin vs. heterochromatin) or chromosome stability, and, in general, those processes that affect gene expression patterns without altering or being mediated by the DNA sequence (Fig. 1).

Histones are proteins responsible for DNA packaging as well as chromatin conformation and are subject to a wide variety of post-translational modifications including arginine and lysine methylation, lysine acetylation, serine and threonine phosphorylation, or lysine ubiquitination and sumoylation, among other molecular processes. These transformations occur mostly in the amino-terminal tails of histones on the nucleosome surface, as well as in the region of the nucleus. Histone alterations can affect chromosomal function by modifications in the electrostatic charge of the histone, resulting in a structural change or its binding to DNA and modifications in the binding sites for protein recognition modules such as bromodomains or chromodomains, which recognize acetylated or methylated lysine residues, respectively. These epigenetic mechanisms, which mediate chromatin rearrangement and heterochromatin formation, influence the regulation of gene expression. Acetylation is the most studied histone modification and the main enzymes involved in this process are histone acetyltransferases and histone deacetylases (HATs and HDACs, respectively).

DNA methylation occurs at cytosine bases which are converted to 5-methylcytosine by a DNA methyltransferase (DNMT). Cytosine residues with an added carbon ( $-\text{CH}_3$ ) are usually located next to a guanine (CpG dinucleotide), resulting in two diagonally arranged, side-by-side methylated cytosine residues opposing the complementary DNA strands. Different DNMT-type enzymes are

**Table 1** Types of epigenetics modifications.

<i>"Canonical" modifications</i>	
<i>Reaction substrates</i>	<i>Epigenetic modification</i>
SAM	DNA methylation
SAM	Histone methylation
Acetyl-CoA	Histone acetylation
<i>"Emerging" modifications</i>	
<i>Reaction substrates</i>	<i>Epigenetic modification</i>
Lactate	Histone lactylation
Succinyl-CoA	Histone succinylation
Benzoyl-CoA	Histone benzoylation
Crotonyl-CoA	Histone crotonylation
Butyrate	Histone butyrylation
$\beta$ -Hydroxybutyrate	Histone $\beta$ -hydroxybutyrylation
Homocysteine	Histone homocysteinylation
Serotonin	Histone serotonylation
Dopamine	Histone dopaminylation
UDP-GlcNAc	Histone O-GlcNAcylation
NAD <sup>+</sup>	Histone ADP-ribosylation
Methylglyoxal	Histone methylglyoxal adduction
<i>RNA modifications</i>	
<i>Reaction substrates</i>	<i>Epigenetic modification</i>
SAM	RNA methylation
Acetyl-CoA	RNA acetylation

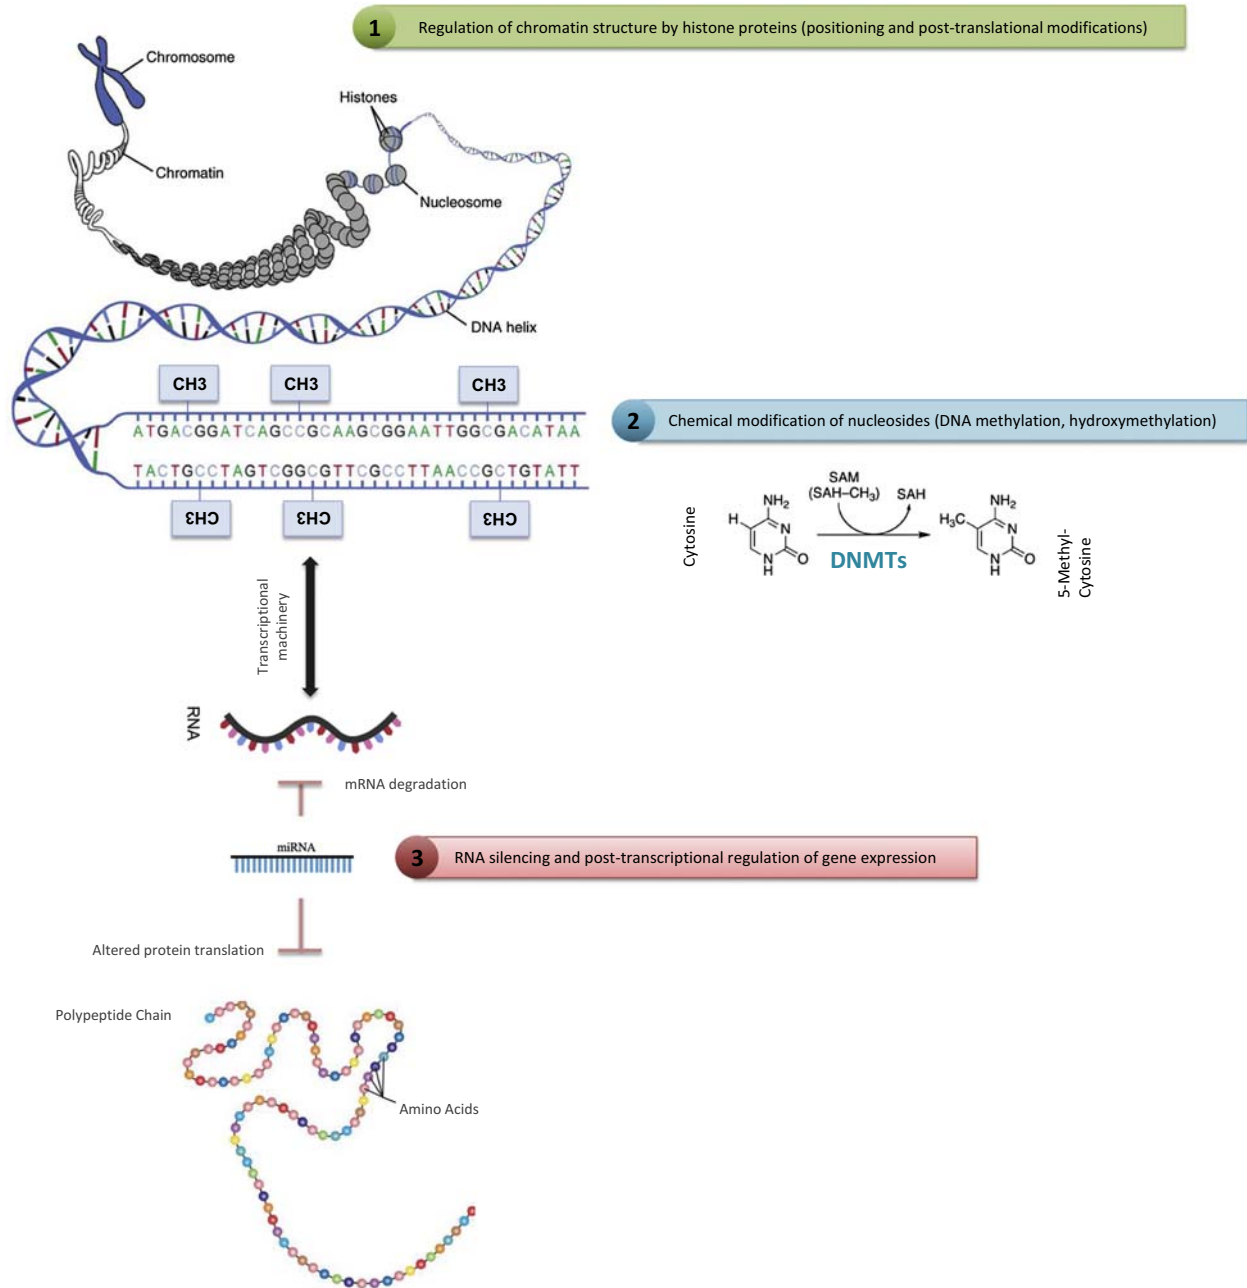

ADP, Adenine diphosphate; CoA, Coenzyme A; NAD, Nicotinamide adenine dinucleotide; SAM, S-adenosylmethionine; UDP-GlcNAc, Uridine diphosphate N-acetylglucosamine.

involved in these processes, either by de novo DNMTs, incorporating the initial pattern of methyl groups on a DNA sequence where there was no methylation before, or by maintenance DNMTs, copying the methylation pattern from a pre-existing DNA strand after cell replication. It has been proposed that the methyl group can intercept the DNA binding of certain transcription factors that control the transcriptional process. In some cases, genes that are more highly methylated (specifically in the promoter region) tend to be less accessible, often resulting in inhibition of their expression. DNA methylation in non-promoter regions may also be related to various functional tasks. For example, DNA methylation of intragenic regions may modulate gene expression by acting as alternative promoters. However, the correlation between DNA methylation of intragenic regions and gene expression is unclear, as controversial findings have been published in different cells and tissues. The evaluation of DNA methylation as a cause or biomarker of disease is consistent in some tumor types or obesity and diabetes.

The scientific literature also refers to several types of non-coding RNAs as epigenetics modifications, such as long non-coding RNAs (lncRNA), Piwi-associated RNAs (piRNA) or circular RNAs (circRNA). All these RNAs have in common that they do not code for proteins and appear to play roles in the control of gene expression, that's why they are recognized as epigenetic modification. The best known of which are microRNAs (miRNA), which are small non-coding RNA molecules (about 22 nucleotides) whose mission is usually the silencing of messenger RNA or the post-transcriptional regulation of protein synthesis. Several studies have shown that miRNAs are involved in the incidence of various diseases (from different types of tumors to obesity, diabetes and cardiovascular disease) and have high potential as biomarkers for both prognosis and diagnosis and also as possible therapeutic agents and targets, given that nutrients, hydration and physical activity can modulate the expression and actions of some of these RNAs.

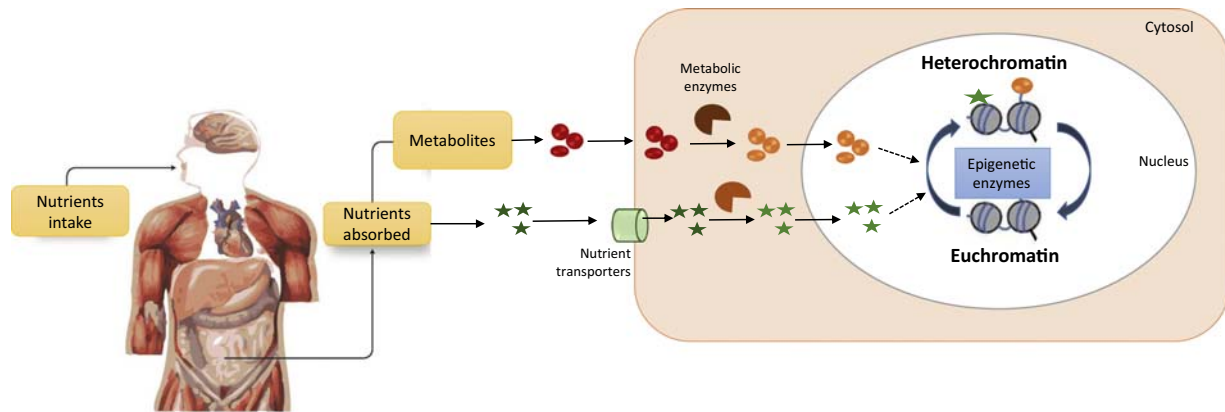

### Nutrient metabolic regulation by epigenetic mechanisms

Nutrients such as glucose, fatty acids, amino acids and vitamins are utilized by cellular metabolic pathways to produce metabolites that are used as substrates or activity modulators of chromatin-modifying enzymes (Fig. 2). These molecules are included in the regulation of a plethora of both "canonical" modifications, including histone acetylation, histone methylation and DNA methylation, and "emerging" modifications, including acylation, homocysteinylation, serotonylation and so forth (Dai et al., 2020). Pathways related to central-carbon, one-carbon and methionine metabolism, acetate metabolism, ketogenesis, and redox balance feed the pools of several of these metabolites and thus help to regulate the epigenomic landscape, in concert with chromatin modifiers, remodelers and transcription factors.

**Fig. 1** The main forms of epigenetic modifications. Modification of nucleosides in DNA such as by methylation and hydroxymethylation. Post-translational modification of histone proteins by methylation, acetylation, ubiquitylation, SUMOylation, citrullination and ADP-ribosylation. Changes in small non-coding RNA expression. Nucleoside and histone modifications regulate gene transcription by modulating the conformation of the chromatin and the access of DNA binding factors. Small non-coding RNAs (such as microRNAs) regulate gene expression by prompting mRNA degradation or modulating protein translation.

The ability of epigenetic modifications to respond to fluctuations in metabolic activities is a consequence of the intrinsic thermodynamic and kinetic parameters of different chromatin-modifying enzymes. The addition and removal of most of these modifications are catalyzed by enzymes (known as, “writers” and “erasers”) that utilize metabolites as substrates or cofactors (known as chromatin-modifying metabolites). The intracellular abundance of chromatin modifying metabolites is regulated by several mechanisms. Metabolites that are taken up by cells can passively or actively diffuse through the plasma and nuclear membrane to modify chromatin. Alternatively, metabolites can be processed internally by the activity of metabolic enzymes that convert them into substrates or cofactors for chromatin-remodeling enzymes. The metabolic enzymes can also translocate to the nucleus, where they can locally produce substrates for chromatin modification. The resulting consequences of metabolite abundance for the rate of chromatin modification are dependent on the kinetic and thermodynamic parameters of the particular enzyme. These

**Fig. 2** Metabolic regulation by epigenetic mechanisms. Nutrients are utilized to produce metabolites that are taken up by cells and can passively or actively diffuse through the plasma and nuclear membrane in order to modify chromatin. Alternatively, metabolites can be processed internally by the activity of metabolic enzymes that convert them into the substrates or cofactors for chromatin-remodeling enzymes.

enzymes include methyltransferases and acetyltransferases, among others. Finally, once the modifications have been deposited, effector proteins can recognize and bind to them using specific protein-binding modules, through which the markings determine a variety of intracellular fates, involving processes such as development, immune-system regulation or disease development.

A good example of metabolic enzymes involved in the synthesis of chromatin modifying metabolites, is acetyl-CoA and S-adenosylmethionine (SAM), which localize to the nucleus and interact with nucleosomes and chromatin-modifying enzymes. Levels of chromatin-modifying metabolites such as SAM are controlled by multiple mechanisms, including both environmental inputs such as nutrient availability and intracellular methyl group sinks that consume SAM. Methyl group sinks are mediated by enzymes that metabolize SAM, allowing them to divert methyl groups away from enzymes such as histone or DNA methyltransferases, thus affecting the activity of these enzymes. These mechanisms provide avenues for the control of metabolite levels and thus for chromatin to sense intracellular metabolic status.

## Epigenetics and dietary intervention

Due to the plasticity of epigenetic factors, environmental changes, such as dietary interventions, which alter food intake and composition or meal timing, have a significant impact on the epigenome. Dietary interventions, including caloric restriction, intermittent fasting or time-restricted feeding, have shown to induce promising improvements in patients' overall metabolic profiles (i.e., reduced body weight, improved glucose homeostasis), and an increasing number of studies have associated these beneficial effects with epigenetic alterations (Asif et al., 2020; ElGendy et al., 2018).

### Hypercaloric and high-fat diets

The response to high-fat diets (HFD) in animal models is associated with changes in the expression of hypothalamic neuropeptides, which regulate energy metabolism and appetite, as well as gene expression in hepatocytes and adipocytes where different epigenetic processes could participate in this adaptation. Additionally, in adult rodents, it has been shown that long-term HFD feeding has an effect on the methylation of obesity-related genes such as leptin (*LEP*) in adipose tissue, or melanocortin 4 receptor (*MC4R*) in the brain, probably contributing to changes in gene expression and appetite regulation. Moreover, while fasting decreases the amount of acetylated histone H3 and H4-positive cells in the ventrolateral subdivision of the ventromedial hypothalamus, dietary consumption of an HFD pattern for four weeks results in overexpression of histone deacetylases HDAC5 and HDAC8. These studies demonstrate that hypercaloric diets alter some epigenetic mechanisms related to the regulation of the expression of genes involved in the control of energy homeostasis.

As gestation and lactation are the periods of life most susceptible to epigenetic modifications, and with effects that persist into adulthood, a series of studies have been performed during the perinatal period, especially in rodents, which have proven that maternal overfeeding with HFD in rats induces overweight in the offspring independently of postnatal nutrition and also nonalcoholic steatohepatitis, explained by an alteration of mitochondrial metabolism and lipogenesis in the liver. The origin of other metabolic diseases in adults, such as hypertension, hyperlipidemia or insulin resistance and diabetes, may also be related to maternal overnutrition. These metabolic alterations in the offspring appear to be attributable, at least in part, to epigenetic modifications that persist into adulthood. Thus, neonatal overfeeding alters the DNA methylation patterns of the hypothalamic promoter region of the major anorexigenic neuropeptide, POMC. Maternal consumption of HFD can modify epigenetic marks in the offspring's brain and alter the expression of genes related to the mesocorticolimbic reward circuitry (dopamine and

opioids), inducing a preference for foods richer in sucrose and fat. Interestingly, these epigenetic modifications persist for at least two generations and may contribute to understanding part of the increased prevalence of obesity observed in most countries. However, not all studies reached the same conclusion, as there are examples in which an HFD intake during gestation and lactation at least partially protects the offspring from excessive weight gain through different hypothalamic mechanisms. Therefore, further studies are needed to elucidate the intrinsic mechanisms related to these effects, as well as complementary studies in humans (Cai et al., 2021). Within this context, unbalanced nutrition can lead to changes in epigenetic marks that may contribute to the development of metabolic complications. For example, an epigenome-wide screen identified 625 significant differentially methylated regions (DMRs) associated with diet-induced obesity phenotypes, of which 232 DMRs correlated with HFD alone, and 249 regions were conserved in adipose tissue from obese subjects. Another human study showed that acute intake of a HFD induced changes in the methylation of 6508 genes in skeletal muscle. In the same nutritional intervention, the observed changes did not reverse after 6–8 weeks of a normocaloric diet, suggesting that the recovery of epigenetic marks may be slow and that the set of modifications may influence gene expression levels over time. This finding could help to explain the “yo-yo” effect, which is characterized by an increasing difficulty to lose weight after each stage of treatment with low-calorie diets. However, a study in rats has demonstrated the reversibility of some epigenetic marks: the intake of a hypercaloric diet for 20 weeks altered the methylation of several CpG sites located in the promoter of the leptin gene in visceral adipose tissue. When the hypercaloric diet was replaced by a normocaloric diet, the original methylation levels for some of the CpG sites of the leptin promoter were recovered. This experiment confirms the possible reversibility of phenotypic and epigenetic changes induced by hypercaloric diet intake. However, more meticulous and longer-term follow-up would be needed to ensure that the initial pre-hypercaloric diet methylation levels can be reached for all genes.

### Caloric restriction and intermittent fasting

Numerous epidemiological and animal studies link suboptimal early nutrition and poor intrauterine growth with an increased risk of hypercholesterolemia, hypertension, type 2 diabetes and obesity in adulthood. In relation to the multiple mechanisms examined, it is clear that epigenetics plays a key role. Both energy restriction and low protein diets induce epigenetic modifications and metabolic alterations that persist into adulthood. Therefore, a moderate restriction of caloric intake during the periconceptional period is considered a stress factor and is accompanied not only by an increase in adrenal mass and an exacerbation of the cortisol stress response but also by epigenetic modifications such as decreased methylation in the *IGF2* and *H19* genes in the adrenal gland. As noted above, a present classic example of an association between periconceptional energy restriction and DNA methylation in humans comes from the analysis of people born during the Dutch Hunger Winter (between 1944 and 1945), which found persistent epigenetic differences associated with prenatal exposure to famine and increased risk of chronic disease in the 1970s by those individuals.

Furthermore, in adult mice and humans, it has been shown that weight loss, as a consequence of hypocaloric diets, may alter the DNA methylation pattern of different tissues, mainly adipose tissue, liver, pancreas or brain, among others. In adult mice, caloric restriction seems to reprogram orexigenic pathways and alter the reward circuitry in the brain by affecting epigenetic mechanisms. In these animals, caloric restriction promotes binge eating, and this result opens perspectives to study whether the yo-yo effect, which makes weight loss maintenance so complicated, maybe, at least in part, mediated by epigenetic mechanisms. However, it is difficult to determine whether these epigenetic effects are caused directly by caloric restriction or weight loss. Female obese patients subjected to bariatric surgery with significantly reduced body weight (27%) and food intake show reductions in global DNA methylation levels and differentially methylated genes associated with obesity and T2D in adipose tissues, thus providing context for weight loss and adipocyte reprogramming. These genes are associated with the regulation of body weight (*LEPR*, *FTO*), cholesterol homeostasis (*CETP*, *LCAT*), blood glucose (*IRS1*, *INSR*), adipose tissue function (*mTOR*, *RPTOR*), and epigenetic modifications (*FOXP2*, *HDAC4*, *DNMT3B*).

Modulation of lipid compartmentalization and efficient utilization of excess energy in adipose tissues are critical targets for the treatment of obesity and related metabolic dysfunctions. Dietary interventions, including intermittent fasting and caloric restrictions, markedly reduce adipocyte size and weight depots in rodent models of obesity, and confer improvements in adipose tissue inflammation and insulin sensitivity. Additionally, adipose tissue thermogenesis, via the induction of WAT “browning” (beige fat), and activation of BAT appear to be predominant pathways which elevate energy expenditure, mitochondrial biogenesis and energy dissipating capacity. However, studies investigating DNA methylation changes in adipose tissue upon dietary interventions are limited. In one study, obese women on a 6-months caloric restriction (1100–1800 kcal/day) who lost >3% of their body fat showed hypermethylation at three genomic loci in their subcutaneous adipose tissue. These loci were associated with lipid (e.g., *PLCL4*) and glucose (e.g., *ENC1*) homeostasis and epigenetic regulation (e.g., *PRDM8*). In another study, 36 h of fasting in young, healthy men increased DNA methylation at the promoter site of *LEP* in subcutaneous adipose tissue, leading to a 3-fold decrease in plasma leptin levels. In addition to DNA methylation, histone acetylation and deacetylation in adipose tissues are associated with the beneficial metabolic effects seen with dietary interventions. For example, 30% caloric restriction in HFD-fed mice led to a significant increase in histone 4 acetylation (H4ac) at the *Glut4* promoter, which is associated with increased *Glut4* mRNA expression in white adipose tissue and decreased plasma glucose levels. Additionally, several HATs and HDACs are involved in regulating adipose thermogenesis, which is one of the primary beneficial mechanisms of dietary interventions.

### Mediterranean diet

There is currently interest in knowing the influence of the different components of the Mediterranean diet on the beneficial effects of this dietary pattern for metabolic syndrome and cardiovascular disease and the epigenetic mechanisms potentially involved. In fact, some experiments have observed indications that some compounds frequently found in the Mediterranean dietary pattern, such as choline, but above all betaine, could be involved in the health effects through changes in DNA and histone methylation. Besides, the expression of some miRNAs also seems to be related to the beneficial effects of the Mediterranean diet. GWAS genomic studies have described an SNP of the *LPL* gene (rs13702) in the binding site for the miR-410 associated with circulating triglyceride concentrations and HDL cholesterol. In a nutritional intervention with a Mediterranean diet and a control (PREDIMED study), subjects carrying the C allele reduced their hypertriglyceridemia and their risk of cerebral infarction more when they followed a Mediterranean pattern especially rich in unsaturated fatty acids. With this initial knowledge, new findings are expected to associate the Mediterranean diet or some of its specific components with epigenetic “signatures” that contribute to explain at least partially the mechanisms of action by which this dietary pattern mediates its beneficial effect. In fact, in a very recent PREDIMED analysis (Arpón et al., 2017), specific components of the Mediterranean diet (MedDiet), particularly nuts and extra-virgin olive oil, were able to induce methylation changes in several peripheral white blood cell genes and modulate exosomal RNA content, with the former affecting a higher number of miRNAs (Mantilla-Escalante et al., 2021). These changes may have potential benefits in health, especially those changes in genes related to intermediate metabolism, diabetes, inflammation and signal transduction, which may contribute to explain the role of MedDiet and fat quality on health outcomes.

### Nutritional factors involved in epigenetic regulation

Given the responsiveness of epigenetic marks to dietary factors, research has attempted to relate the administration of compounds of plant origin with effects, i.e., phytochemicals, on epigenetic processes to apply them in the prevention and treatment of different diseases. In the future, it may be possible to speak of “epigenetic foods” as a group of functional foods containing bioactive compounds capable of modulating the expression of miRNAs and DNA methylation or inducing covalent modifications in histones. As in other epigenetics-related topics, this concept has been developed mainly about cancer prevention so that diverse plant components are being studied in relation to apoptosis, cell cycle regulation, differentiation, inflammation, angiogenesis, autophagy and metastasis, as well as in stress response (Kumari et al., 2020). Similarly, understanding the epigenetic effects of botanical compounds consumed with the diet may provide insights into prevention strategies to reduce the prevalence of metabolic diseases and prevent their comorbidities.

Among the components (nutrients and non-nutrients) of food that have been associated with epigenetic changes are methyl group donor molecules (methionine, choline, folic acid, betaine and vitamins B2, B6 and B12, which are involved in the methionine cycle), carbohydrates and proteins, short-chain fatty acids (butyrate, acetate and propionate) or omega-3/6 fatty acids, some minerals and antioxidant vitamins (vitamins A, E and C), as well as different bioactive compounds of plant origin, including various polyphenols, catechins, isoflavones and isothiocyanates.

### Methyl donor molecules

Dietary methyl groups are derived from foods containing methionine, serine, folic acid, biotin and choline, among other compounds, which are molecules that allow the transfer of a methyl group to DNA and histones via S-adenosylmethionine (SAM) (Mahmoud and Ali, 2019). The synthesis of methionine from homocysteine requires zinc, selenium and vitamins B6 and B12. Thus, methionine can be synthesized in the liver from homocysteine using methyl groups of betaine (derived from choline) or methyltetrahydrofolate. Therefore, when people have low levels of choline, dietary folate requirements increase and, conversely, when there is a folic acid deficiency, dietary choline requirements increase. However, not all individuals tend to develop similar health problems with methyl donor intake because other factors may be involved. In this sense, the presence of SNPs in genes involved in the regulation of choline and folic acid metabolism may increase or decrease the risk of functional methyl group deficiency and interfere with the proper methylation of macromolecules.

The importance of maternal methyl donor intake on germline epigenetic status was first published in 2006 for the *agouti* *Ay* mouse model. Another subsequent paper (2008) concluded that methyl donor supplementation induces DNA hypermethylation during development and prevents transgenerational amplification of obesity in *agouti* mice. Also, a methyl donor-deficient diet has been established as a good model for the induction of nonalcoholic steatosis in rodents, which is accompanied by numerous epigenetic and transcriptomic changes. Following these findings, many studies have analyzed the epigenetic effects of methyl donor-deficient or methyl donor-supplemented diets during pregnancy on different metabolic diseases, including possible alterations in offspring behavior (e.g., anxiety) through permanent changes in hippocampal DNA methylation. However, few studies have associated perinatal methyl donor administration with long-term changes in body weight and metabolism. In animal models, perinatal dietary methyl donor deficiency has been associated with increased adult adiposity, insulin resistance and hypertension in offspring, which is accompanied by alterations in global DNA methylation. Low maternal dietary choline content at the embryonic

stage in mice results in a significant reduction in the degree of genomic DNA methylation in the fetal hippocampal neuroepithelial layer, and the methylation level of protein kinase inhibitor (Cdkn3), the vicinity of the promoter of the vascular endothelial growth factor C and angiopoietin 2 genomic DNA also significantly decreases (Cai et al., 2021). However, few such studies have been carried out in humans. Therefore, further longer-term nutritional intervention trials are needed to understand the benefits and risks of methyl donor doses in relation to the development of obesity, even though nutrient supplementation during pregnancy is widespread in the fight against anemia and other micronutrient deficiencies.

The intake of methyl donors in adulthood also seems to be a determinant for the subsequent development of metabolic disorders. Thus, in adult mice, a diet deficient in methyl groups resulted in progressive fat accumulation and morphological changes in the liver similar to human nonalcoholic steatohepatitis, accompanied by important epigenetic alterations, such as aberrant histone modifications and loss of DNA methylation, especially in satellite regions. In patients with nonalcoholic fatty liver disease, a choline deficiency is often accompanied by increased fibrosis. Interestingly, it has been shown that fetal epigenetic programming is reversible in adult life by methyl donor supplementation. Thus, in rodents, maternal programming of the stress response is reversed by central infusion of methionine, whereas methyl donor supplementation prevents HFD-induced nonalcoholic fatty liver disease. Nevertheless, further studies both in animal models and human intervention are needed to precisely define the effect of supraphysiological intake of methyl donors on chronic diseases and be cautious in recommending these compounds during pregnancy. In this regard, some complementary studies have focused on the beneficial effects of betaine administration on adipose tissue dysfunction and insulin resistance and of folic acid supplementation in obese subjects with type 2 diabetes.

### Fatty acids and amino acids

In addition to methyl donors, other nutrients act as regulators of DNA methylation and histone covalent modifications, either by directly inhibiting enzymes that catalyze the processes or by altering the availability of substrates required for the corresponding reactions. The ability of different types of fatty acids to induce epigenetic modifications is less well known. Concerning the effects of *n*-3 polyunsaturated fatty acids (PUFA) on the DNA methylation status, a possible mechanism that has been proposed is that *n*-3 PUFA enhance the expression of DNMTs and consequently the DNA methylation. Furthermore, a potential interaction between *n*-3 PUFA and MeCP2 (methyl CpG binding protein 2) has been proposed, mainly in promoter regions, and consequently could be associated with the regulation of gene expression. Another possible mechanism by which *n*-3 PUFAs can affect methylation is that these FA are natural ligands of some transcriptional factors, such as PPAR $\gamma$ . In this context, it has been reported that interactions between PPAR $\gamma$  and fatty acids result in a decrease in cytokine expression, and in murine models, *Pparg* expression is modulated by DNA methylation in its promoter region. However, more studies are needed to elucidate the role of FA in the regulation of epigenetic mechanisms in the context of metabolic alterations and chronic diseases. Regarding the other types of FA, a specific mechanism in which they could alter epigenetic landmarks has not been described (González-Becerra et al., 2019).

A special case is that of butyric acid, a short-chain fatty acid produced during fermentation (mediated by gut microbiota) of dietary fiber sources. This molecule induces apoptosis in vitro and cell cycle arrest, presumably through inhibition of HDACs. It has been described how butyrate triggers histone H3K9ac to activate steroidogenesis through PPAR $\gamma$  and PGC1 $\alpha$  pathways in ovarian granulosa cells (Ye et al., 2021). As obesity is associated with major changes in the composition of the gut microbiota, butyrate-producing bacteria could be one of the factors linking both phenomena through epigenetic mechanisms. Other short-chain fatty acids produced by the gastrointestinal microbiota have also been associated with epigenetic changes. Thus, acetate, which enters the peripheral circulation to be metabolized by peripheral tissues, increases histone acetylation in nervous tissue and inhibits HDAC activity and expression in the brain, whereas propionate is involved in the propionylation of lysine 23 of histone H3 in different cell lines.

Moreover, the amino acid that seems to play the most determinant role in epigenetic mechanisms is methionine, an important source of methyl groups in biomethylation reactions and is key in regulating the monocarbon metabolism pathway. However, other amino acids (particularly serine, glycine and histidine), together with some vitamins, could also play an important role in providing methyl donors for DNA and histone methylation.

### Minerals and vitamins

A study of cord blood samples from the offspring of Gambian women has shown that periconceptional micronutrient supplementation, providing 14 minerals and vitamins, affects fetal methylation of some promoters in genes that, in some cases, persist in children until at least 9 months of age with clear differences between sexes. This strategy may not be adequate to prevent obesity and other chronic diseases since multivitamin supplementation in rats during gestation has been associated with increased food intake and the development of obesity in the offspring when fed HFD, which could be mediated by epigenetic mechanisms.

Specifically, some minerals have been associated with changes in epigenetic mechanisms that regulate gene expression. For example, selenium and zinc are involved in the regulation of DNMTs activity and play a key role in the one-carbon metabolism and in the activation of most HDACs. High intakes of various inorganic and organic forms of heavy metals, including chromium, arsenic, lead, cadmium, copper and nickel, have also been linked to epigenetic effects. Selenium, through selenoproteins, has been

related to some pathologies such as cancer, cardiovascular and autoimmune diseases. Although the importance of the interaction of selenium with the epigenome for human health is debated, epigenetic effects caused by selenium are not ruled out. Magnesium is another element that is capable of modifying epigenetic marks. Thus, magnesium deficiency in pregnant rats induces metabolic complications in the offspring by altering the methylation of specific cytosines in the hepatic 11 $\beta$ -hydroxysteroid dehydrogenase-type-2 (*HSD11B2*) promoter. Increased pre-conceptional and prenatal chromium exposure could lead to epigenetic control of endocrine imbalances and some metabolic functions.

Calcium is a mineral that appears to be related to weight regulation and other biochemical functions. However, this element has only been indirectly associated with epigenetic modifications and many more studies are needed to rule out that calcium could be a metabolic regulator through epigenetic mechanisms.

Some vitamins, including A, C and E, and carotenoids can decrease circulating concentrations of inflammatory and oxidative markers. Consequently, studies have been conducted with these molecules to assess whether they can induce epigenetic changes. On this regard, vitamin C promotes widespread DNA demethylation in human embryonic stem cells, while retinol alters histone phosphorylation levels in rat Sertoli cells. The epigenetic effects of vitamin E and lipoic acid require further analysis, although molecular modeling studies suggest that both may have a role as HDAC inhibitors. In recent years, the role of vitamin D on DNA methylation and other epigenetic mechanisms has gained special relevance (Ong et al., 2020). Observational and randomized controlled human trials have proven the vitamin D effects on DNA methylation. In this sense, different mechanisms have been proposed to account for these effects, mainly the altered expression of genes that directly or indirectly affect DNA methylation (*Bhmt1*, *DNMT1*, *DNMT3*, *TET2* and *TET3*). In summary, although further studies in animal models are still needed to understand the basic mechanisms of specific nutrients, current evidence suggests that dietary supplementation with certain vitamins and minerals could be useful as epigenetic therapy for metabolic disorders.

### Polyphenols and other plant compounds

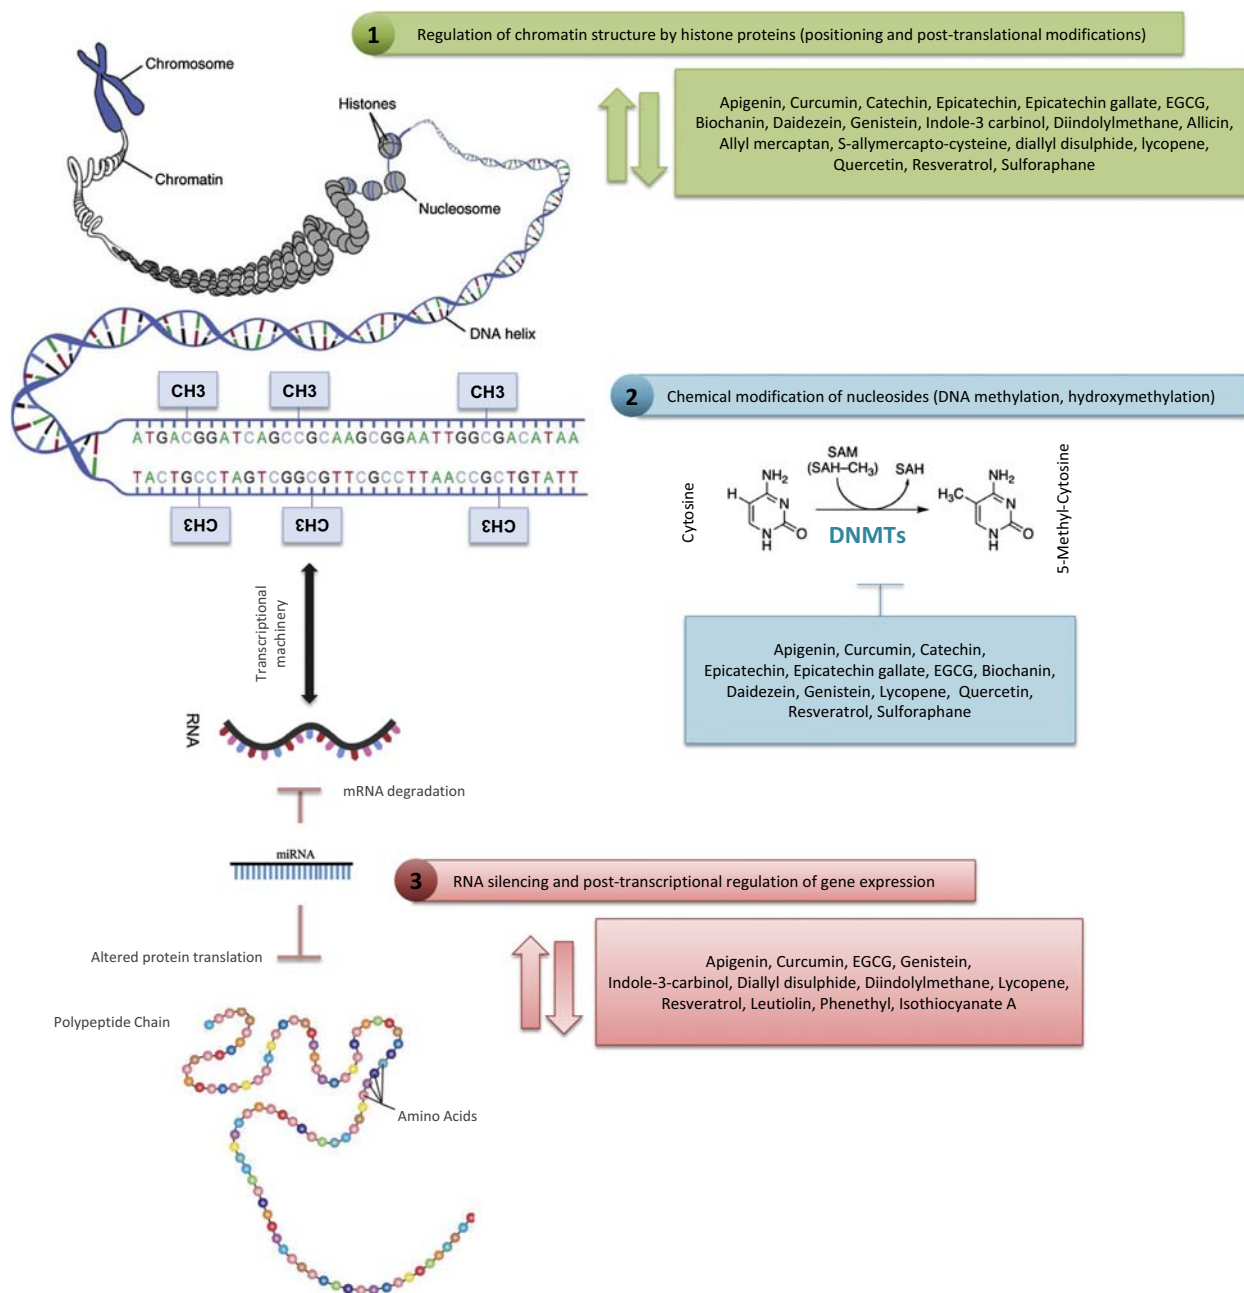

Polyphenols and other plant compounds are good candidates to show epigenetic properties for their potential applications as therapeutic agents that can be used to prevent or treat inflammation and oxidative stress, as well as health problems related to cancer and metabolic diseases such as type 2 diabetes, atherosclerosis, and hypertension. Among the plant-derived bioactive compounds that mediate epigenetic modifications are agents such as genistein (soybeans), resveratrol (grapes), curcumin (turmeric), catechins (green tea) and sulforaphane (cruciferous vegetables), which have been considered in cancer prevention and therapy because of their possible epigenetic interaction, by modulating DNMT, HAT and HDAC activities and endogenous miRNAs synthesis (Cione et al., 2019). Therefore, numerous compounds and plant extracts capable of modulating the activity of enzymes that regulate histone covalent modifications and DNA methylation have been studied in recent years. Some of these compounds about epigenetic modifications are shown in Fig. 3.

Tea catechins, the most abundant being epigallocatechin-3-gallate (EGCG), are a group of flavonoids considered as one of the most promising dietary treatments for metabolic syndrome. The administration of EGCG to mice significantly reduces body weight gain, blood glucose levels and insulin resistance, decreases liver damage and triglyceride levels in this organ and reduces plasma cholesterol and inflammatory cytokines. Some of these effects are undoubtedly mediated by epigenetic mechanisms such as the direct inhibition of DNMT by interacting not only with the catalytic site of the DNMT molecule but also by inhibiting acetyltransferase activity in histones.

Genistein is a flavonoid present in soybeans that can act as an endocrine disruptor. However, at certain doses and in a sex- and age-dependent manner, it may also inhibit adipogenesis in vitro in a manner similar to estrogens. A pioneering study demonstrated that supplementation of the maternal diet with genistein during early embryonic development can change the color of yellow *agouti* heterozygous (*Avy/a*) mice, which was significantly associated with increased methylation at a retrotransposon of the transcriptional start site of the *agouti* gene. In this same model, genistein decreased ectopic *agouti* gene expression and protected offspring from obesity in adulthood by altering the epigenome. Similarly, in non-human primates, consumption of soy protein and isoflavones improved body weight, insulin sensitivity and lipid profiles, accompanied by modifications in DNA methylation patterns in the liver and muscle.

Curcumin is a polyphenol with potent anti-inflammatory activity. It is also one of the natural compounds with the greatest potential as an anti-obesity treatment because, in vitro, it can suppress 3T3-L1 differentiation and induce apoptosis in adipocytes (Hassan et al., 2019). Curcumin is able to modulate histone deacetylases and acetyltransferases, DNA methyltransferase I activity and the expression of miRNAs, the involvement of curcumin-induced epigenetic mechanisms in animal models. It is an effective medicinal agent, including decreased HAT activity and HDAC2 activation, as it regulates several important molecular signaling pathways that modulate survival, govern anti-oxidative properties like nuclear factor E2-related factor 2 (Nrf2) and inflammation pathways, e.g., nuclear factor kappa B (NF- $\kappa$ B).

Resveratrol is a stilbenoid with potent free radical scavenger properties that show beneficial effects on type 2 diabetes and cardiovascular disease, sharing some healthful actions with caloric restriction. Among other consequences, this compound decreases the severity of hepatic steatosis in rats and exerts an inhibitory effect on insulin secretion. Apart from its potent anti-oxidant activity, resveratrol is an activator of SIRT1, an NAD(+)-dependent histone deacetylase that modulates gene expression in all tissues.

**Fig. 3** Dietary phytochemicals regulate gene expression through epigenetic mechanisms by altering DNA methylation patterns, histone modification, and changes in non-coding (micro) RNAs levels. Up and down arrows indicate abundance levels and  $\perp$  refers to inhibition.

Different organic sulfur compounds have shown certain anticancer effects, in part by acting through inhibition of HDAC activity. In this regard, the most interesting natural molecules are sulforaphane, an isothiocyanate present in cruciferous vegetables that exerts beneficial properties in colon, prostate and breast cancer cells, and diallyl disulfide, which metabolizes to allyl-mercaptan and induces histone acetylation in human colon cancer cells. Although there are no studies that have reliably demonstrated the protective effects of sulforaphane on obesity in animal models, this molecule is capable of inhibiting the differentiation of adipocytes in culture through cell cycle arrest and, in relation to diabetes, reducing the production of free radicals and the consequent inflammatory damage in diabetic neuropathy and nephropathy. Therefore, further studies are needed to investigate the role of sulfur compounds in the regulation of adipogenesis and body weight, as well as the involvement of epigenetic mechanisms in the process.

Other bioactive compounds (lycopene, garcinol, luteolin, buteine, apigenin, silymarin, rosmarinic acid, anacardic acid or baicalin, among others) could inhibit the activity of DNMTs or modify histone acetylation, and consequently they could be beneficial

for the treatment or prevention of some metabolic disorders. Many studies have recently demonstrated that olive oil, especially EVOO phenolic compounds, are bioactive molecules inducing epigenetics modifications such as miRNAs expression, DNA methylation and histone modifications with anti-cancer, anti-inflammatory, anti-aging and neuroprotective activities (Fabiani et al., 2021).

The low bioavailability of most polyphenolic compounds and the impossibility of accurately determining the amounts present in food makes it difficult to establish the actual doses and effects of polyphenols on DNA methylation in humans. Therefore, new long-term studies should be designed to test the effects of different amounts of pure compounds, both in animals (periconceptionally, growing or adult) and in humans. In addition, the design of new compounds that enhance the stability and bioavailability of natural molecules is an important objective in this field. On the other hand, it seems likely that synergies may exist between different phytochemicals and nutrients, so combinations should be investigated. Finally, the combination with an epigenetic perspective of plant-derived compounds and synthetic drugs could constitute a new therapeutic approach.

## Conclusions and future perspectives

To conclude, three core ideas could be highlighted: (1) epigenetic mechanisms are involved in the appearance and development of nutrition-related metabolic dysfunctions; (2) epigenetic marks could be useful for the prognosis and early diagnosis of nutritional diseases; and (3) nutritional or pharmacological agents could be used as new therapeutic strategies thanks to their capacity to induce epigenetic modifications. In the coming years, research on epigenetic mechanisms related to obesity, diabetes, and dyslipidemias could help prevent and control excessive fat deposition, glucose intolerance, and the development of cardiovascular disease through precision nutrition that takes into account personalized epigenetic aspects of nutritional homeostasis. Obviously, more in-depth studies suitably designed concerning the “epigenetic diet” are necessary to establish whether some nutrients or food components actually have a protective or adverse effect through the modulation of epigenetic processes.

In recent years, numerous omics techniques have been developed for the analysis of epigenetic modifications. With the rapid advancement of high-throughput sequencing technologies, epigenetic variations, especially variations in DNA methylation, have been extensively reported to be associated with a wide range of traits in humans, including not only phenotypes and diseases, but also behaviors and environmental exposures. Epigenome-Wide Association Studies (EWAS) have become a powerful approach to identify DNA methylation variations associated with biological traits. For genome-scale profiling of histone modifications, although chromatin immunoprecipitation followed by sequencing (ChIP-seq) is still the most widely used technique, alternatives have been developed to increase the coverage and resolution of epigenomic profiles in both bulk tissues and single cells. A new chromatin-profiling technology termed “cleavage under targets and release using nuclease” (CUT&RUN) is being used, in which DNA fragments bound to the modified histones are directly cleaved and released, instead of undergoing crosslinking, sonication and immunoprecipitation as they do in standard ChIP-seq. This new analysis has shown increased signal-to-noise ratio, efficiency and resolution and has enabled the profiling of chromatin modifications in very small numbers of cells. Based on CUT&RUN, techniques for chromatin profiling at the single-cell level recently have also been developed.

The coming years will undoubtedly offer remarkable advances in this field, although long-term experiments will probably be necessary to define new epigenetic paradigms. Selecting a multi-omics approach compared to a single-omic analysis offers some profound advantages on this line, allowing for the identification of associated factors from different biological processes, i.e., gene expression, protein synthesis and post-translational modifications, cellular metabolic processes, glycosylation, etc., maximizing the available information, and thus, increasing the possibility of identifying the root effect of the nutritional agent. For example, a single genetic variant or DNA methylation may be weakly associated with the pathophysiology of multifactorial disease. However, when a genetics finding is further supported with significant alterations in mRNA expression and in protein concentration, the possibility that the gene is an important factor in the pathogenesis of the disease increases. Similarly, individual changes in metabolites, lipids or glycans may have limited translational potential, but when combined, they may reveal important pathways associated with the etiology of a disease.

Genetic variants can introduce or delete methylation sites in CpG context, thereby induce changes in DNA methylation at the SNP site. Moreover, SNPs located in *cis* or *trans* of the CpG site can alter action of methylation enzymes. To further test for potential interactions between epigenetic profiles and genetic factors several studies have performed correlation analyses between DNA methylation and SNP genotypes. These methylation quantitative trait loci (meQTL) analyses are valuable tools to understand whether DNA methylation changes represent a mediator between genetic predisposition and clinical variables, a consequence of the interaction between genotype and phenotype or the effects genotype and methylation are independent from the genotype-phenotype associations. Blood circulating proteins as intermediate phenotypes can reveal the underlying disease-causing pathways. While changes in CpG methylation have been shown to induce changes in gene expression that can lead to changes in protein and metabolite levels, differences in transcript, protein, and metabolite levels, can in turn induce changes in CpG methylation. Therefore, mining the complex molecular networks from a multi-omics perspective, connecting genetic variants, CpG methylation, gene expression, protein, and metabolite levels to disease endpoints is necessary. In fact, the number of GWAS with deep molecular phenotypes, especially metabolomics and proteomics, is rapidly increasing. In the Website <http://www.metabolomix.com> it can be found tables of published GWAS with metabolomics (meQTLs), proteomics (pQTLs), and DNA methylation (mQTLs), as

well as EWAS with metabolomics (meCpGs) and with transcriptomics (eQTM). Such networks might eventually guide a more personalized nutrition of complex disorders. In addition, machine learning can be used to analyze large data sets, as the ones that derive from multi-omics measurements, and can lead to algorithms with predictive value.

### Key points

- To know the concept of nutrigenetics, its conceptual and methodological origin as well as its evolution over time.
- To know the main concepts behind gene-diet interactions and how they are assessed in nutrient-centered nutrigenetics.
- Estimate and interpret a gene-diet interaction in nutrigenetics both at the level of a single genetic variant and at the level of the combination of multiple genetic variants through the so-called “genetic risk scores” (GRS).
- To describe and interpret gene-diet interactions related to the main non-communicable chronic diseases.
- To assess the level of scientific evidence of the different types of epidemiological studies that analyze gene-food interactions at the individual or dietary level.

### Glossary

**Copy number variation** A phenomenon in which sections of the genome are repeated and the number of repeats in the genome varies between individuals

**Nutritional genomics** The joint study of nutrition and the genome including all other omics derived from genomics (transcriptomics, proteomics, metabolomics, epigenomics, etc.)

**Human genome** The complete set of nucleic acid sequences for humans, encoded as DNA and grouped by genes within the 23 chromosome pairs in cell nuclei and the small DNA molecule found within individual mitochondria

**Nutrigenetics** Study of gene variants within individuals and their impact on the metabolic utilization of nutrients

**Single nucleotide polymorphism (SNP)** A germline substitution of a single nucleotide at a specific position in the genome

## Introduction

Over the last 50 years, nutrient recommendations have been established for certain segments of the population according to sex, age and physiological condition. However, even when population-level nutrient intake recommendations exist, individuals respond differently to lifestyle and dietary interventions because their gene variants influence the absorption and metabolic utilization of nutrients.

One of the most important contributions of the discovery of the human genome has been the realization that there are millions of differences in the gene sequences of different individuals ([International HapMap Consortium, 2007](#)). The phenotypic differences that distinguish individuals in the human species are largely due to differences in the sequence of their genes, mainly centered on the existence of single-nucleotide polymorphisms (SNPs), copy number variants (CNVs) of some genes, and other variants such as inversions, insertions and deletions. About 88 million genetic variants (84.7 million SNPs, 3.6 million short insertion-deletions and 60,000 structural variants) are currently known ([The 1000 Genomes Project Consortium, 2015](#)). [Fig. 1](#) shows a summary of the main types of genetic variants. In addition, the methylation patterns of various genes that specify functional proteins and their promoter genes are an important source of individual diversity. This influences the expression of numerous genes and thus the types and concentrations of the encoded proteins, resulting in specific metabolic changes that ultimately lead to specific phenotypes.

**Fig. 1** Classes of human genetic variants. CNV: copy number variants; SNP: single nucleotide polymorphism.

Based on the data provided by the human genome project and knowledge of genetic polymorphisms or SNPs, as well as CNVs and other genetic variants, it has been found that there are certain variations in individuals that alter the interactions between nutrients, dietary components, foods and dietary patterns, and metabolic responses, affecting the susceptibility to the development of certain diseases. This inter-individual genetic variation questions the extent to which dietary recommendations, usually based on epidemiological studies, are valid for all racial and ethnic groups.

The study of gene variants within individuals and their impact on the metabolic utilization of nutrients is called “Nutrigenetics”. Currently, there is broad consensus in considering Nutrigenetics as the discipline that studies the different phenotypic responses to diet depending on the genotype of each individual, both for the treatment of a health problem and the prevention of disease. Therefore, Nutrigenetics studies the variable response of individuals to diet as a function of SNPs and CNVs and other functional variants in the genome including the identification and characterization of these genetic variants. Ultimately, Nutrigenetics aims to generate specific recommendations on the best dietary composition for the optimal benefit of each individual, i.e., to achieve “personalized nutrition” (Kohlmeier et al., 2016). Indeed, it is thought that the human genome and its inter-individual variations in key candidate genes may be very important in helping to decipher the molecular mechanisms that determine the interindividual response to diet and thus generate a series of response biomarkers that allow us to know in advance of dietary intervention, the success of the same or its best implications in the prevention and treatment of disease (Ferguson et al., 2016).

## Origin of the term and development of nutrigenetics

The term nutrigenetics as such was first used in 1975 by Dr. R.O. Brennan in his book entitled “Nutrigenetics: New Concepts for Relieving Hypoglycemia”. Although this term had not yet been coined, its concept and meaning had already been explained by several authors many decades earlier. Among them, Garrod (1902–1923), in his work on inborn errors of metabolism, was the first to suggest that the effect of genes on metabolism depended on the diet. Later, Beadle, 1945 and Wagner and Mitchell, 1955 outlined the concept of gene-diet interaction through their studies on insect eye pigments and went on to show that the phenotypic correction of a genetically determined disorder could be modified by an appropriate environment. Similar to these observations, the work of Beadle & Tatum in the 1940s experimenting on *Neurospora* also contributed to the concept of gene-diet interaction by observing that *Neurospora* species with lethal genetic mutations could or could not manifest that lethal phenotype by regulating the concentration of arginine in the medium, thus concluding that the nutritional environment could strongly modulate the effects of a genetic mutation even associated with death. Compiling these and other studies by contemporary authors, J.A. Roper of the Department of Genetics at the University of Glasgow published a review in 1960 entitled “Genetic determinants of nutritional requirements”, a review that was a pioneer of current Nutrigenetics and very advanced for the biotechnological limitations of the time. Interestingly, the conclusions of the review indicated that “nutritional-genetic” studies should be prioritized in future research and particularly in genetically complex diseases.

In parallel to these more basic researchers, Carl Rehnberg, best known for creating the first multivitamin in the 1930s, is also considered a pioneer of Nutrigenetics. While in China between 1917 and 1927, Carl observed that people living in agricultural areas in China were much healthier than people living in large cities. This led him to speculate on how nutrition can alter the expression of one’s genetic makeup.

The beginning of the Human Genome Project in the 1980s and the discovery in the early years of important genetic variants in candidate genes for different diseases, allowed us to make great progress in the identification of inter-individual variability through the analysis of the so-called SNPs.

Preceded by several animal studies on the influence of different nutrients in the diet on gene expression, the first studies on gene-diet interactions in humans were published in the late 1980s-early 1990s. It should be noted that the first studies of nutritional

intervention with different lipids were carried out with short-term nutritional interventions, fundamentally fat loads and measuring the effects in postprandial ways after a few hours. Among these studies, the one carried out by JL Breslow et al. at the Laboratory of Biochemical Genetics and Metabolism at Rockefeller University, New York, published in 1987, stands out for its pioneering nature. This study, in which 27 individuals were analyzed, showed different postprandial responses in chylomicron concentrations after administration of a fat overload with added vitamin A depending on the genotype of the common polymorphism in the apolipoprotein E (*APOE*) gene. This apolipoprotein, produced mainly in the liver, is a major component of triacylglycerol-rich lipoproteins and high-density lipoproteins. It is involved in the binding and subsequent clearance of these particles through specific cellular receptors. Given its role in lipoprotein metabolism, it is considered to be very relevant in the pathophysiology of atherosclerosis. Indeed, the discovery of several isoforms of this gene, as well as the genetic basis of the common polymorphism that determines them, made this polymorphism the main object of study of gene-diet interactions in the first nutrigenetic studies focused on the influence of the different types of fatty acids in the diet on lipid metabolism. Those studies found that the *APOE* gene, depending on the DNA base change in a common polymorphism in exon 4, results in an amino acid change affecting three common alleles, resulting in six genotypes: *e2/e2*, *e2/e3*, *e2/e4*, *e3/e3*, *e3/e4*, *e4/e4*. In general, it is observed that carriers of the *e2* allele have lower plasma concentrations of LDL-cholesterol (LDLc) than *e3/e3*; whereas the *e4* allele is associated with higher concentrations of LDLc and subsequently with a greater cardiovascular risk. The association of the *APOE* genotype with LDLc concentrations was replicated very consistently in various populations and aroused scientific interest in investigating whether genetic determinism existed or whether this association could be modulated by diet.

In 1990, Pietinen's group from the Department of Medicine at the University of Helsinki, Finland, published a gene-diet interaction study in 110 participants, with a longer duration of the intervention (up to 12 weeks), in which they analyzed the effect of a high-fat diet versus a low-fat and cholesterol diet on plasma lipid concentrations as a function of *APOE* genotype. They observed that the effect of *APOE* genotype on lipid changes was not deterministic and was diet-dependent, with the *e4* allele being associated with greater reductions for LDLc in those subjects with a low-fat diet and greater increases when changing diet.

Prompted by these results, several nutritional intervention studies analyzing the effect of genotype (*APOE* and other polymorphisms related to lipid metabolism: *APOA1*, etc.) were performed in different populations during the 1990s, but they were mainly studies performed on a small number of volunteers and with short-term interventions. Therefore, it was necessary to conduct larger studies including samples of thousands of individuals. A pioneering study in this regard was carried out by Fumeron et al. at INSERM-Faculté de Médecine Xavier Bichat in Paris, published in 1995. In this study, they analyzed 608 cases of myocardial infarction and 724 controls from the ECTIM study who were genotyped for the common polymorphism in intron 1 (named TaqIB after the restriction enzyme used to perform the genetic analysis based on restriction fragment length polymorphisms, RFLPs) in the cholesterol ester transfer protein encoded by the *CETP* gene. This polymorphism gave rise to two alleles, designated B1 and B2. It was known that people carrying the B2 allele had higher plasma concentrations of HDLc than B1B1, a finding frequently replicated in several studies. They also found that greater alcohol consumption was associated with a greater increase in HDLc concentrations in B2B2, as well as greater protection against myocardial infarction.

To consolidate a body of knowledge with solid evidence on gene-diet interactions in multiple populations, it was necessary to provide results in other cohorts. Dr. Ordovás' group at the JM-Human Nutrition Research Center on Aging in Boston pioneered the study of gene-diet interactions in the Framingham study, a cohort study focused on cardiovascular risk factors. In that study, despite observing a clear association of the *CETP*-TaqIB polymorphism with higher HDLc concentrations, the interaction with alcohol was not observed, and the effect of the B2 allele was to increase HDLc concentrations in both drinkers and non-drinkers. In contrast, in the Framingham study, Dr. Ordovás's group reported in 2001 an interaction between alcohol consumption and the *APOE* polymorphism in determining LDLc concentrations. These studies were replicated years later in the EPIC (European Prospective Investigation into Cancer and Nutrition Cohort)-Spain cohort that included 41,440 participants followed for up to 10 years (Ordovas and Corella, 2004).

Since the publication in 2001 of the first study showing a gene-diet interaction (*APOE*\*alcohol) in the Framingham cohort, the number of publications on gene-diet interactions in other relevant cohorts in nutritional epidemiology began to grow exponentially, thus contributing to the birth and consolidation of nutrigenetics as a new discipline (Corella and Ordovas, 2009).

The first nutrigenetic studies focused on polymorphisms in candidate genes because the technology for mass genome screening was not yet available. Moreover, they all started using the RFLP-based genotyping technique which was tedious for large samples of thousands of participants so that rarely more than one genetic variant was examined. Also, these early studies focused on examining the interaction with dietary nutrients (primarily macronutrients and, within these, the different types of fatty acids) as nutritional epidemiology at the time was focused on the analysis of nutrients rather than foods. The focus on dietary fatty acids was also because the first nutrigenetic studies were conducted in the field of cardiovascular disease, and, at that early time, the prevailing paradigm in the etiology of cardiovascular disease and its relationship to diet was the deleterious influence of diets high in fat, primarily saturated fatty acids.

As the cost of massive genotyping chips became cheaper and several genome-wide association studies (GWAS) were carried out, considering not only phenotypes related to cardiovascular disease but also many other pathologies, new genetic variants were discovered for which it was necessary to know whether their genetic effect was deterministic or could be modified by diet (Atanasiou et al., 2015). More diverse gene-diet interaction studies then began to be carried out, incorporating at the same time the determination of multiple genetic variants either employing chips or by allele-specific probes. To combine genetic variants, gene-diet interaction studies began to be performed using the concept of "genetic risk score" (GRS) (see below) instead of individual genetic variants to better capture the multigene influence on complex diseases.

Currently, the design of nutrigenetic studies is also being improved, integrating other omics to better understand the mechanisms and performing meta-analyses of several studies that analyze the same phenotypes, genetic variants and dietary components to determine the homogeneity or heterogeneity of the interactions found. All this contributes to increasing the level of evidence of gene-diet interactions so that they can be transferred to the recommendations of more personalized nutrition and allow better prevention or treatment of the disease. A current challenge is to perform gene-diet studies using the information obtained by direct sequencing that gives us the sequence of the whole genome of the participants, but it is still computationally complex and huge sample sizes are required.

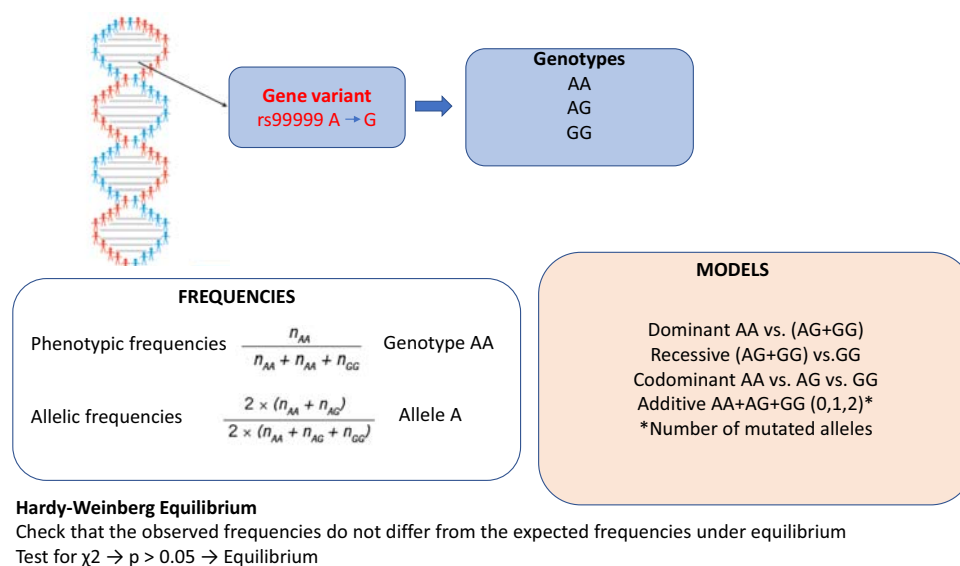

## Basic concepts of genetics applied to nutrigenetics

Some basic concepts are essential for understanding nutrigenetic studies. When we refer to the study of “candidate genes”, we are referring to genes that are known or hypothesized to be related to the phenotype of interest because they are directly involved in the metabolic pathways associated with it due to the functionality of the protein they encode. Whereas when we refer to new genes identified through GWAS, we focus on genes that have been discovered to be associated with the disease or phenotype of interest through statistical association analyses that have obtained very significant P-values, but whose function or the previous relationship with the phenotype of interest was unknown until then (Atanasovska et al., 2015).

As mentioned earlier, there are many types of genetic variants in DNA depending on their size, ranging from a base change to alterations in pieces of entire chromosomes. The most studied genetic variants are SNPs. In nutrigenetic studies, it is necessary to be familiar with the different models of inheritance that can be used to study how these polymorphisms influence phenotypes: dominant, recessive, codominant, and additive, since analyzing the data with one model or another has important implications. Fig. 2 shows how the genotypes are grouped in each of these models. Also in this figure, the concepts of genotypic frequencies and allele frequencies are presented, as well as the Hardy-Weinberg equilibrium. This equilibrium must always be checked when starting studies of gene-diet interactions to avoid misclassification biases (differential or non-differential), either due to errors in the genotyping technique or other types of errors in obtaining the samples, manipulation, etc.

Although the first nutrigenetic studies focused on one genetic variant, millions of SNPs have now been described in the genome, making essential to study several of them at the same time in the case of complex diseases. Some of these variants are inherited in clusters and constitute haplotypic blocks consisting of SNPs with high linkage disequilibrium. Other times, instead of analyzing several SNPs forming a haplotype, a single SNP chosen as a “tag” SNP, or indicator SNP of the whole haplotype, is analyzed, thus reducing the costs of determination. There are different strategies for the selection of these tag SNPs. The reduction in the cost of genotyping has led to an increasing number of SNP combinations being studied in the so-called “GRSs”.

The GRSs aggregates the effects of many genetic variants into a single number which predicts genetic predisposition for a phenotype. Normally the genetic variants most associated with a particular phenotype are chosen from the main GWAS that can be consulted through specific publications or also from the databases of GWAS (GWAS catalog of the National Human Genome Research Institute, NHGRI, in collaboration with the European Molecular Biology Laboratory (EMBL)). There exist several requirements for a genetic variant to be included in a GRS. These requirements will vary according to the study but basically, they are: to be strongly

**Fig. 2** Basic concepts of genetics for the interpretation of gene-nutrient interactions: genetic models, allele frequencies, genotypic frequencies and Hardy-Weinberg equilibrium.

associated with the phenotype of interest, to be in Hardy-Weinberg equilibrium, to have an allele frequency of the least frequent allele (MAF) exceeding a pre-established value, and not to have high linkage disequilibrium between them so that they are independent (**Fig. 3**). GRSs are typically composed of hundreds to millions of genetic variants which can be combined in several ways: unweighted and weighted. In weighted GRSs, we use a weighted sum of allele dosages multiplied by their corresponding effect sizes, as estimated from a relevant GWAS. In unweighted GRSs only the sum of the number of risk alleles contributed by each SNP included in the GRS is taken into account. However, the use of unweighted GRSs has the disadvantage that it does not take into account the magnitude of the association with the phenotype of interest for each of the SNPs included in the GRS, since the presence of each risk allele in the GRS scores the same regardless of whether it is an SNP highly associated with the risk phenotype or whether the association is 5 or 10 times smaller. Currently, there has become available a great resource from the EMBL, called PGS Catalog, that gathers all published GRSs consistently annotated with relevant metadata; including scoring files (variants, effect alleles/weights), annotations of how the PGS was developed and applied, and evaluations of their predictive performance. These GRS, both weighted and unweighted, are used as variables measuring genetic susceptibility in subsequent statistical analyses of gene-diet interactions.

### Genetic variants and susceptibility to disease

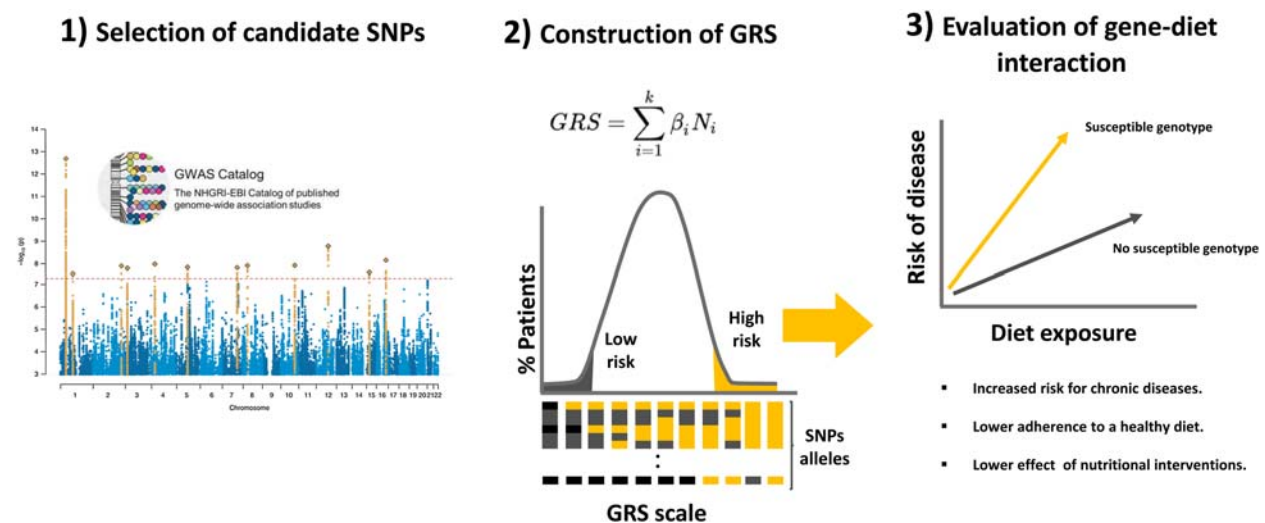

Thanks to genomic research, it is now known that the vast majority of human genetic information is shared by all individuals of our species. If any two subjects are considered, they share 99.9% of the DNA sequence, i.e., less than one variation every 100 base pairs. Many of these variations are SNPs and these, individually or as groups (haplotypes) alter the regulation of the expression of the affected genes, the processing of mRNA, and the activities of synthesized proteins and enzymes. Thus, each individual can trigger unique responses to environmental factors, including dietary components, based on a combination of SNPs in their genomic DNA.

Similarly, all racial and ethnic groups share most genetic variations. The small differences that do exist are responsible for human diversity, such as skin and hair colors, potential height and weight, etc. Some of these small differences are important variations from a medical point of view because they modify the susceptibility to the development of some pathologies.

Certain minority populations have a higher incidence of certain chronic diseases than majority populations, such as obesity, diabetes, asthma, cardiovascular disease (CVD), and certain types of cancer. For example, North Americans of African descent have a 60% higher risk of developing prostate cancer than those of European descent. Likewise, epidemiological studies such as NHANES III (The third National Health and Nutrition Examination Survey) have shown that African-American and Mexican-American women over the age of 50 and African-American men have a higher risk of CVD.

Currently, GWAS and GRS studies make it possible to analyze millions of polymorphisms in hundreds of thousands of subjects and to analyze risk haplotypes for certain diseases and their interaction with nutrients, foods and food patterns ([Atanasovska et al., 2015](#)). However, although much progress has been made in the last two decades, we are still far from knowing and understanding all the relevant interrelationships between genes, their variants and nutrients.

Among the potential benefits of understanding the genetic causes of complex diseases may include the following

**Fig. 3** The genetic risk scores (GRS) aggregates the effects of many genetic variants into a single number which predicts genetic predisposition for a phenotype.

1. The identification of individuals with a higher disease susceptibility will allow them to change their lifestyles to reduce the risk and will allow for increased medical surveillance to detect early signs of disease onset. Early diagnosis is almost always a determining factor in the success of treatment.
2. The identification of underlying genetic risk factors eliminates a variable in the study of genotype-environment interaction. Thus, the identification of environmental risk factors will be easier and more accurate.
3. Many diseases with similar clinical symptoms may be heterogeneous in their etiology. This ambiguity may affect the prognosis and result in a different response of patients to treatment.
4. If the different defects leading to the same disease can be developed, better treatments can be adopted.
5. The identification of the genes involved in the risk will allow the characterization of the proteins they encode and whose cellular functions are altered in the disease. This will facilitate a better understanding of the details of the normal and pathological state, respectively, and to develop of more rational therapies. In particular, the affected proteins can be used as a reference for designing and testing drugs that can modify their action.

### Influence of gene variants on the metabolic requirements and utilization of nutrients and foods

One of the classic examples of the relationship between genetic variants, disease and nutrients is phenylketonuria (PKU), caused by mutations in the gene coding for phenylalanine hydroxylase. Individuals with PKU have to eat a diet low in phenylalanine. Lactose intolerance is another example of genome-diet interactions. In this pathology, the consumption of milk and some dairy products such as evaporated milk, powdered milk and products made with these ingredients, leads to the appearance of digestive pain accompanied by nausea, gas and diarrhea. Epidemiological data indicate that the frequency of lactose intolerance varies widely depending on geographic area, age, race and ethnicity.

In humans, the ability to digest milk lactose is conferred by a  $\beta$ -galactosidase enzyme called lactase-phlorizin hydrolase (LPH). While in some humans, approximately two-thirds of humankind, the levels of this enzyme decline drastically after the weaning phase (a trait known as lactase non-persistence (LNP)), some other individuals are capable of maintaining high levels of LPH life-long (lactase persistence (LP)), thus being able to digest milk during adulthood (Anguita-Ruiz et al., 2020). The appearance of genetic polymorphisms associated with LP seems to have occurred in a relatively recent period, 10,000–12,000 years ago, coinciding with the domestication of animals. There are currently 11 known polymorphisms in the lactase gene grouped into four haplotypes called A, B, C, and U. Haplotype A, which confers lactose tolerance, has a frequency of 86% in the Northern European population, but only 36% in Southern European populations. Cultures that drink fresh milk usually have a higher frequency of this haplotype and the persistence of the polymorphism confers selective advantages such as better nutrition, prevention of dehydration, and improved calcium nutritional status. In particular, an SNP polymorphism (C/T13910) has been identified at a locus 14 kb upstream of the gene coding for lactase, at a locus on the long arm of chromosome 2 (2q21). This variant, initially identified in nine widespread Finnish families, is the most widely spread responsible for lactose tolerance among Europeans. In other words, members of these families can consume milk and dairy products without any complications. The polymorphism located in the lactase promoter gene alters the interactions of a regulatory protein that interacts with DNA. Interestingly, different polymorphisms affecting the same promoter region have been identified throughout the years in other populations (e.g., Middle East and Africa), although in a lower frequency, being responsible for milk tolerance (Anguita-Ruiz et al., 2020). The discovery of these variants makes it possible to individualize dietary interventions, specifically in infancy, by applying a genetic test for lactose intolerance.

Variants in genes required for lipid metabolism are valuable examples of Nutrigenetics. Indeed, gene variants encoding for *CETP*, lipoprotein lipase, low-density lipoprotein receptor and apolipoproteins B and E, may contribute to an increased risk of coronary heart disease. There is now sufficient evidence to indicate that variations in the *APOA1*, *APOA4*, *APOE*, and *APOB* genes contribute to the heterogeneity of lipid response after dietary intervention and that these genes are regulated directly or indirectly by PPARs and other nuclear receptors. On the other hand, in recent years the influence of different SNPs related to postprandial lipid metabolism has been studied. An example of this is the SR-BI gene, which belongs to the scavenger receptor family, because of its property to bind modified LDL particles and because it plays an important role as a receptor for high-density lipoprotein particles and in mediating the selective uptake of cholesterol esters. The presence of the minority allele 2 in exon 1 of the SR-BI gene has been associated with faster clearance of small triglyceride-rich lipoproteins (TRL), probably related to faster hepatic uptake. Also, the c.1119C > T polymorphism present in exon 8 of the gene has been shown to decrease the postprandial triacylglycerols response in LRTs in healthy males.

Although environmental factors such as diet, physical activity and alcohol play an important role in setting blood triacylglycerols concentrations, both triacylglycerols and cholesterol levels associated with LDL particles are strongly influenced by genetic variability. In the case of genes influencing LDL subclass patterns, diet-gene interactions contribute greatly to explaining the inter-individual differences in the effects of low-fat and high-carbohydrate diets on heart disease risk. Studies indicate that the response of plasma lipids to diet is highly complex and variable, and involves numerous SNPs involved in multiple metabolic pathways (Lange et al., 2015). Few observational studies have examined the interaction of SNPs present in potential candidate genes for the development of CVD and the consumption of diets with different fat compositions. However, in recent years some evidence has begun to emerge on the beneficial effects of some of them, such as the Mediterranean diet, concerning some genetic variations. This is the case of the Pro12Ala polymorphism in the PPAR gamma (*PPAR $\gamma$* ) gene locus. This polymorphism modifies the

peripheral insulin sensitivity response following high oleic acid intake. In addition, it has been shown that individuals carrying the Ala12 allele have a lower risk of developing diabetes mellitus. In line with these findings, it has been shown that monounsaturated fatty acid consumption is not associated with an increase in body mass index (BMI) or the risk of obesity in individuals with a specific variant at the *APOA5* gene locus, which encodes for apoprotein A V. Data from that study indicate that the interaction between the -1131T > C polymorphism of the *APOA5* gene and ingested fat influences BMI. This interaction is dose-dependent (Atanasovska, 2015; Ordoas and Corella, 2004).

Another interesting work was designed to study the interaction between the C677T polymorphism in the methylenetetrahydrofolate reductase (*MTHFR*) gene and the Mediterranean diet, concerning the response to LDL oxidation. This gene expresses the corresponding enzyme involved in the formation of methyl-tetrahydrofolate from the methylene form. The values of oxidized LDL (LDL-ox) were significantly higher in TT individuals compared to carriers of the C/T and C/C genotypes. An interesting finding of this study is that greater adherence to the Mediterranean diet correlated inversely with lower LDL-ox values. This effect was observed only in carriers of the T/T and C/T genotypes, but not in the C/C genotypes. The evidence derived from this study indicates a pathophysiological explanation by which the type of fat in the Mediterranean diet could modify coronary risk by lowering LDL-ox values.

Other studies have investigated genetic variants associated with obesity or resistance to weight loss in human populations, which has contributed to understanding some of the pathophysiological mechanisms of this disease. One of the most prominent examples is the fat mass and obesity-associated (*FTO*) gene; the minority (16%) of individuals carrying two copies of the rs9939609 SNP weigh around 3 kg more and have a 1.67 times higher risk of obesity than non-carriers. Variants in numerous other genes, such as those for peroxisome proliferator-activated receptors (*PPAR*), uncoupling proteins for oxidative phosphorylation (*UCP-1* and *UCP-3*), leptin receptor (*LEPR*), melanocortin receptor 4 (*MCR4*), 11 $\beta$ -hydroxysteroid dehydrogenase and several genes coding for antioxidant defense system proteins are also associated with obesity and may affect weight gain or loss in genetically predisposed individuals. Despite the need for further validation studies, valuable findings have been reported describing the interaction of macronutrient intake in carriers of various SNPs in genes that regulate processes such as thermogenesis, appetite and lipid or carbohydrate metabolism. Such is the case for carriers of *FTO*, *APOA5* and *PPARG* variants that generally increase their risk of obesity when they consume a certain type of fat, carbohydrate or protein (Albuquerque et al., 2015; Ruperez et al., 2014).

One of the best examples of diet-genotype interactions is type 2 diabetes, which occurs frequently in sedentary and obese individuals and certain minority groups such as Pima Indians (Bhori et al., 2022). Once diagnosed with diabetes, some individuals can control symptoms by increasing physical activity and reducing caloric intake, especially fat. In these cases, the expression of genetic information is changed by the environment. However, other individuals are refractory to such environmental changes and require treatment with medications.

Numerous chronic diseases do not show the metabolic flexibility observed in type 2 diabetes, i.e., symptoms do not reverse after the onset of the disease. Nevertheless, genotype and diet interactions contribute to the incidence and severity of many diseases such as obesity, cancer, atherosclerosis, asthma, etc. (Franzago et al., 2020).

Another example of the effects of gene polymorphisms on the metabolic utilization of nutrients is related to the perilipin (*PLIN*) gene, a key adipocyte protein involved in the action of hormone-sensitive lipase, and the discovery of new genetic variants associated with a lower risk of obesity in the Caucasian population. Thus, variants in this gene modulate the response to the hypocaloric diet in morbid obesity after 1 year of follow-up, so that carriers of the 11,482G > A allele have greater difficulties in losing weight (Ordoas, 2006).

Diet-genome interactions have also been studied with regard to inflammatory processes. Inflammation is an essential part of the body's response to infection, surgery and trauma, playing an important role in killing pathogens by creating a hostile tissue environment through the production of oxidative molecules and the activation of T and B lymphocytes. In addition, the body releases chemical mediators derived from the inflammatory process including three potent pro-inflammatory cytokines (interleukins 1 (IL-1) and 6 (IL-6)) and tumor necrosis factor. It has been observed that SNPs in genes responsible for producing molecules involved in inflammatory processes exert a modulatory effect on the intensity of inflammation. It has also been shown that both pro- and anti-inflammatory cytokines are influenced by differences in genotype.

Several oxidative molecules, especially oxygen free radicals, activate the production of the transcription factor nuclear factor kappa B (NFB), the most important mediator in the development of inflammation, and genetic variability influences the ability of some individuals to produce oxidative molecules that determine the activation of NFB which increases cytokine production and the expression of adhesion molecules, all of which increase the risk of host injury.

Natural Resistance Associated Macrophage Protein 1 (NRAMP1) has effects on TNF production and activation of nitric oxide-induced nitric oxide synthase (iNOS). There are four variants of the NRAMP1 gene, where alleles 1,2 and 4 are poor promoters and allele 3 causes elevated gene expression. Macrophage hyperactivity, associated with allele 3, is associated with susceptibility to autoimmune diseases and high resistance to infection, while allele 2 increases susceptibility to infection and protects against autoimmune diseases.

Some molecules suppress the production of proinflammatory cytokines and exert an anti-inflammatory influence; these include antioxidant defenses and interleukin-10 (IL-10). There are at least three polymorphic sites (-1082, -819 and -592) in the IL-10 promoter that influence its production and SNPs also occur in genes encoding enzymes involved in antioxidant defense, such as superoxide dismutase and glutathione peroxidase, which influence its activity.

Polymorphisms in cytokine genes may play a role in longevity by mediating individual responses to inflammatory stimuli. For example, possession of high IL-10-producing alleles decreases morbidity and mortality by having a protective effect against chronic inflammation.

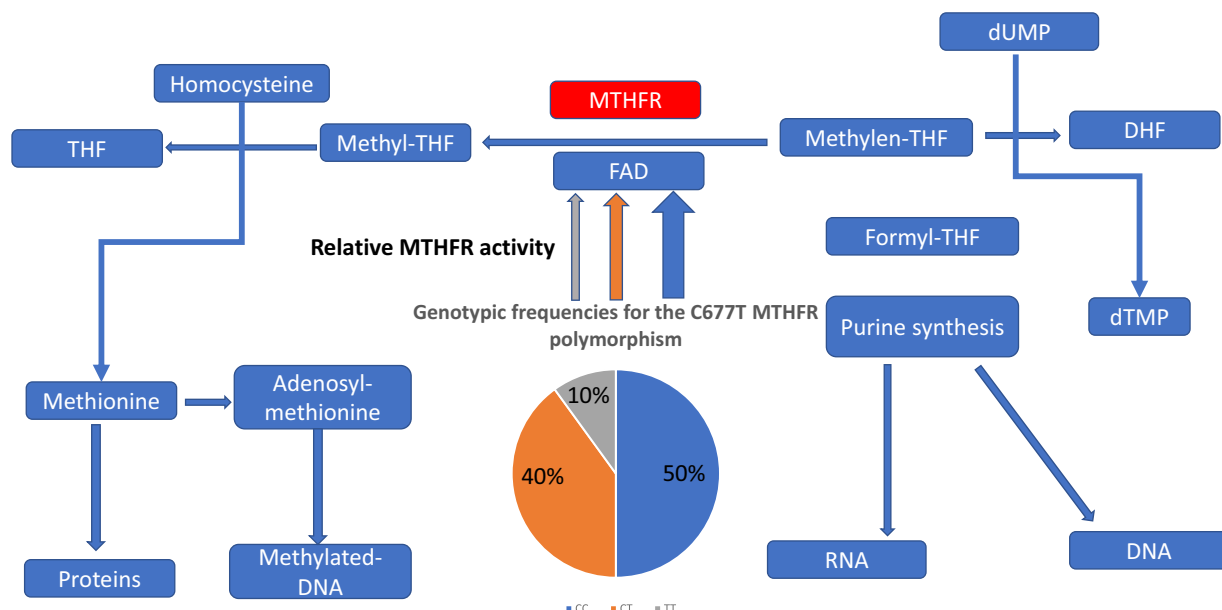

One method to reduce inflammatory stress is the consumption of foods that suppress the production of proinflammatory cytokines (fish oil) or act as antioxidants (vitamin E). The mechanism by which fish oil decreases the inflammatory response is multiple since at the metabolic level the polyunsaturated fatty acids of the n-3 series limit the production of eicosanoids derived from arachidonic acid, which are pro-inflammatory, but at the genetic level they intervene in the suppression of the production of TNF $\alpha$  and in the activation of some transcription factors such as PPAR. Vitamin E is an antioxidant that also modifies cytokine production. This vitamin suppresses the production of superoxide and other oxygen-free radicals.

Deficiencies of the approximately 40 micronutrients (vitamins and minerals) necessary for human development are associated with numerous diseases. Many micronutrient deficiencies are due to poor dietary intake, but approximately 50 genetic diseases can be attributed to enzyme polymorphisms. The latter can be remedied or ameliorated by administering high levels of the relevant vitamin or coenzyme. Changes in coenzyme concentrations may contribute to increased binding of the coenzyme to the affinity apoenzyme altered by a given polymorphism. One of the now classic examples of the influence of gene variants on nutrient metabolism is the C677T polymorphism in the MTHFR gene. This gene expresses the corresponding enzyme involved in the formation of methyl-tetrahydrofolate from the methylene form. The genotypic frequency of the population is about 50% for CC, 40% for CT and 10% for TT. The activity of the enzyme expressed by individuals homozygous for CC is higher than that of CT heterozygotes and that of CT heterozygotes higher than that of TT homozygotes. The lower activity of the enzyme in TT subjects results in the accumulation of homocysteine in plasma, due to lower levels of methyl-tetrahydrofolate, and consequently, a higher cardiovascular risk. This effect reverts to normal if individuals with the TT genotype ingest amounts higher than those recommended for the general population (Fig. 4).

Other examples of genetic polymorphisms associated with genes encoding enzymes whose cofactors are derived from micronutrients are FAD oxidase, for cardiovascular disease and migraines, NAD(P) quinone oxidoreductase 1 (C609T) and FAD, for cancer, glucose-6-phosphate dehydrogenase (C131G) and NADP concerning Fabism and hemolytic anemia, and aldehyde dehydrogenase E487K, present in half of Asians, and NAD about alcohol intolerance, Alzheimer's disease and cancer.

The focus on diet as a factor in determining genomic stability is more important than previously imagined because of the impact that food has on all relevant pathways, such as exposure, carcinogen activation and deactivation, DNA synthesis and repair, and apoptosis. For example, dietary deficiency of micronutrients required for DNA maintenance can produce effects similar to genetically inherited diseases that impair the activity of enzymes required for genomic stability and can alter DNA like exposure to carcinogens and radiation. Adjusting dietary intakes of micronutrients for some individuals with similar genotypes and ages may minimize the damage to chromosomal and mitochondrial DNA observed in numerous alterations related to micronutrient deficiencies, optimizing health, prolonging quality of life, and preventing the risk of early onset of certain cancers and other age-associated degenerative diseases.

There are numerous investigations of statistically significant gene-food interactions. One example is that related to the interaction between sugar-sweetened beverage consumption and genetic predisposition to obesity according to BMI (Qi et al., 2012). Two

**Fig. 4** Relative methylenetetrahydrofolate reductase (MTHFR) activity according to C677T polymorphism in the *MTHFR* gene. DHF: Dihydrofolate; dUMP: deoxyuridine monophosphate; dTMP: Deoxythymidine monophosphate; THF: Tetrahydrofolate.

cohorts of healthcare professionals in the United States, which included 6934 women participants in the US Nurses' Health Study (NHS, Nurses' Health Study) and 4423 men from the Health Professionals Follow-Up Study (HPFS) cohort were studied. In addition, the investigators included a replication cohort of 21,740 women participating in the Women's Genome Health Study (WGHS). For the study of genetic predisposition, they used a GRS that included 32 SNPs related to obesity. As for the diet, they focused on the consumption of sugary beverages. They found a statistically significant interaction between GRS and the consumption of these beverages by determining BMI prospectively. According to their results, the effect of consumption of sugar-sweetened beverages is associated with a higher risk of obesity in people with a greater genetic predisposition. These results have been replicated across the different cohorts analyzed, and constitute another important piece of evidence of gene-food interactions in phenotypes.

The genetic polymorphisms rs9939609 (C > A) in the FTO gene and rs17782313 (T > C) in the MC4R gene were determined in 7052 participants of the PREDIMED study. For both polymorphisms, the allele (A and C, respectively), has been associated with an increased risk of obesity. An unweighted GRS was constructed to capture in an additive manner the genetic risk of obesity associated with the combined presence of these two genetic variants so that in this GRS a score of 0 (equivalent to having no mutated allele), 1 (having one mutated allele, either FTO or MC4R), 2 (having two mutated alleles, one of each SNP or being homozygous for any of them), 3 (having three mutated alleles in any combination) or 4 (having four mutated alleles, which corresponds to the situation of being homozygous mutated for both SNPs). A higher GRS score was associated with a higher BMI.

Likewise, in more than 7000 participants of the PREDIMED study, important gene-diet modulations on the incidence of cardiovascular disease (total and separately for stroke and myocardial infarction) after a median follow-up of about 5 years, have been observed. Indeed, the polymorphism *TCF7L2*-rs7903146 is significantly associated with a higher incidence of stroke in homozygotes for the TT genotype in the control group. However, TT individuals, who were intervened with a Mediterranean diet, have a lower incidence (Corella et al., 2013).

Furthermore, the PREDIMED study described the statistically significant interaction between the rs7903146-*TCF7L2* (transcription factor 7 like 2) polymorphism and adherence to the Mediterranean diet by determining fasting plasma glucose concentrations at the start of the PREDIMED study (n > 7000). When adherence to the Mediterranean diet was low (score less than 9), the risk allele (T) was significantly associated with higher blood glucose, but with high adherence (equal to or greater than 9), the risk allele was not significantly associated with higher fasting blood glucose (Corella et al., 2013).

Despite the great advances achieved to date, nutrigenetics is an alive science branch in continuous evolution and progress. In the next years, thanks to the reduction in the cost of omics technologies and the availability of new and powerful analytics strategies such as GRSs and other machine learning approaches, we will experience a considerable boost in our ability to assess gene-diet interactions, not only restricting to the study of gene sequence variations but also focusing in epigenetics and other molecular alterations as responsible for the different responses of human to diet. Based on all these premises, it is fair to state that, through the elucidation of diet and gene interactions, nutrigenetics offer great opportunities to support patients with more personalized and effective dietary interventions helping in the management of chronic and serious metabolic diseases such as obesity, type 2 diabetes, CVD and several inflammatory diseases.

## Key points

- To understand the role of carbohydrates in the regulation of genes involved in their digestion and absorption.
- To know the role of glucose as a regulator of the insulin gene function and expression.
- To understand the action of glucose on glycolytic and lipogenic gene expression.
- To identify ChREBP as the main transcription factor responsible for the effects of glucose on gene expression.
- To understand the function and mode of action of the transcription factors PPARs, SREBP, LXRs, HNF-4 $\alpha$ , NF- $\kappa$ B, TLRs, and Nrf2 as regulators of gene expression in lipid metabolism.
- To identify the main genes regulated by amino acids and to unveil the mechanisms by which amino acids regulate gene expression.
- To understand the genomic actions of vitamins A and D.
- To know trace metals are involved in the regulation of gene expression.

## Introduction

During the second half of the 20th century, nutrition has developed rapidly based on basic sciences such as biochemistry and physiology and applied sciences such as epidemiology and public health. One of the most important aspects of research in human nutrition is to try to understand the functions of nutrients and non-nutrient components of food at the molecular level. This includes the actions of nutrients and bioactive compounds in foods and their metabolites on cellular transporters and receptors and the corresponding implications in cell signaling cascades and interactions with the genome. Likewise, another great challenge of nutrition is knowing how nutrients, bioactive compounds in food, and certain dietary patterns influence the human microbiome and how modifications in the intestinal microbial ecology influence the greater or lesser prevalence of chronic non-communicable diseases. The science of assessing the functions of nutrients and other food components using molecular techniques is called “Molecular Nutrition”.

“Nutritional genomics” is the science that attempts to provide a molecular-level explanation of how nutrients and other food components interact with an individual’s gene set and their impact on health status. The tools of the “omics” sciences (genomics, epigenomics, transcriptomics, proteomics and metabolomics) applied to nutrition enable the development of nutritional genomics (Ferguson et al., 2016; Kohlmeier et al., 2016). The term “nutrigenomics” is often used generically to refer to functional genomics. Still, actually, this term should only be used when referring to changes in gene expression due to certain nutrients or bioactive compounds in food.

Traditionally, it has been assumed that gene expression in eukaryotes was not directly influenced by nutrients but by the action of hormones, growth factors and cytokines. However, diet represents a powerful mechanism for modifying the cellular environment

of numerous tissues, organs and, consequently, the individual. Thus, during the last few years a large body of evidence has been found that environmental changes caused by nutrients and other food components in the cellular environment modify gene expression. This new science that studies the effects of nutrients and bioactive compounds in food on gene expression is strictly speaking called “nutrigenomics”, although, as mentioned above, this concept is often used in a broader context to refer to all interactions between genes and nutrients and food, i.e., functional genomics. This fact opens up the possibility of modifying gene expression in both healthy and diseased individuals through dietary manipulation.

It is now known that all nutrients (amino acids, glucose and other monosaccharides, fatty acids, vitamins, and minerals), beyond their classical metabolic actions, are also capable of modulating the gene expression of numerous genes, altering the phenotype of the individual. A common approach in nutrigenomics is to determine in an organ or tissue all the mRNAs present as a function of treatment with a particular nutrient or food. In addition, it is possible to determine all the proteins that appear or disappear in a specific organ or tissue due to the effects of nutrients or food consumption. It is also possible to perform a differential study of the metabolites present. In other words, while nutrigenetics would use gene sequencing as a fundamental tool, nutrigenomics would use transcriptomics, proteomics, and metabolomics, as fundamental elements to evaluate the actions of nutrients on gene expression and their metabolic repercussions on the phenotype of the individual.

## **Modulation of gene expression mediated by carbohydrates**

### **Expression of genes related to the digestion and absorption of carbohydrates in the small intestine**

In the small intestine, the expression of genes associated with digestion and absorption of nutrients is restricted to enterocytes. These come from undifferentiated crypt cells which, during their migration outward from the intestinal villi, show a sudden increase in the expression of genes related to digestion and absorption such as those of the digestive enzymes sucrase-isomaltase (SI) and lactase-florin hydrolase (LPH) and transporters such as the sodium-dependent glucose co-transporter (SGLT1), the glucose transporter GLUT2 and the fructose transporter GLUT5.

In general, a diet rich in carbohydrates will increase the expression of the disaccharidases and transporters involved in their metabolism, which in the long term will result in better utilization of these nutrients. This increase in the expression of disaccharidases and transporters will occur mainly at the level of their transcription, although, as indicated below, post-transcriptional regulation also occurs in some cases.

The enzymatic activity of disaccharidases, sucrase and lactase in the small intestine increases in response to dietary carbohydrates due to an increased synthesis of their respective mRNAs. The targets promoters of lactase and sucrase contain binding elements for transcription factors CE-LPH1 and SIF1 with a common consensus sequence, TTTTAT/C. To these elements binds Cdx-2, a transcription factor involved in the transcriptional regulation of intestinal epithelial genes and which is of great importance in a wide variety of phenomena from early cell differentiation to the maintenance of the intestinal epithelial lining. Cdx-2 is overexpressed by a carbohydrate-rich diet.

On the other hand, fructose absorption in the small intestine is carried out by GLUT5. In the presence of fructose, the regulation of this transporter is rapid and the observed increases in transport are paralleled by an increase in mRNA and protein amount. In contrast, other sugars, sugar analogs and metabolites do not alter the transcription rates of the gene. Regarding the regulation of GLUT2 expression in the small intestine, it has been described that both sucrose and fructose increase its expression and that after 30 days of a diet rich in fructose, GLUT2 is permanently localized in the apical membrane.

### **Regulation of insulin synthesis in pancreatic $\beta$ -cells by glucose**

Glucose homeostasis is maintained in the body by the action of the pancreas through the regulated release of glucagon and insulin, respectively. The pancreatic cell function coordinately regulates insulin gene expression, insulin biosynthesis, and insulin secretion.

Glucose controls all steps in gene expression, including transcription, pre-mRNA splicing and mRNA stability. Insulin gene expression is essentially restricted to pancreatic cells in adult mammals. The promoter has a highly conserved region 340 bp upstream of the start site on which both tissue-specific expression and metabolic regulation of the promoter occurs. A variety of transcription factors bind to this region, forming a transcriptional network that ensures precise regulation of the gene. Boxes A3, C1 and E1 constitute the *cis*-elements mainly involved in transcriptional activation. Glucose participates in insulin gene expression through the action of three transcription factors: PDX-1 (Pancreatic/duodenal homeobox-1), NeuroD1 (neurogenic differentiation 1) and MafA (mammalian homolog of avian MagA/L-Maf), which act by activating insulin gene expression in a coordinated and synergistic manner in response to increased glucose levels in a process that involves recruitment of transcription factors to regulatory elements, histone modifications and initiation of transcription (Fu et al., 2013).

### **Control of the expression of metabolic genes by glucose**

Dietary carbohydrates constitute one of the main nutrients leading to short- and long-term metabolism adaptations. These adaptations are mostly mediated by ChREBP (carbohydrate response element binding protein), a transcription factor belonging to the Mondo family of bHLH/LZ (basic helix-loop-helix leucine zipper proteins). Among the variety of dietary carbohydrates, glucose is not only a primary energy source for all organisms but has also been reported as the main regulator of the expression of genes

**Table 1** Genes regulated by carbohydrate response element binding protein (ChREBP).

<i>Ruta</i>	<i>Gene (gene symbol)</i>	<i>Activation/repression by glucose</i>
Glycolysis	Liver pyruvate kinase ( <i>Pklr</i> )	Activation
	Fructokinase ( <i>Fk</i> )	Activation
	GLUT2 ( <i>Glut2</i> )	Activation
	GLUT4 ( <i>Glut4</i> )	Activation
Gluconeogenesis	Catalytic subunit Glucose 6 Phosphatase ( <i>G6pc</i> )	Activation
	Phosphoenol pyruvate carboxykinase ( <i>Pepck</i> )	Repression
Lipogenesis	Fatty acid synthase ( <i>Fasn</i> )	Activation
	Acetyl CoA carboxylase 1 ( <i>Acc1</i> )	Activation
	Stearoyl CoA desaturase 1 ( <i>Scd1</i> )	Activation
	ELOVL <i>n</i> -6 fatty acid elongase ( <i>Elovl6</i> )	Activation
	Malic enzyme ( <i>Me</i> )	Activation
	Adiponutrin/patatin-like phospholipase domain-containing protein 3 ( <i>Pnpla3</i> )	Activation
Transcription	Krüppel like factor-10 ( <i>Klf10</i> )	Activation
	Differentially expressed in chondrocytes 1 ( <i>Dec1</i> )	Activation
	Pancreatic and duodenal homeobox 1 ( <i>Pdx 1</i> )	Repression
	Peroxisome proliferator activated receptor $\alpha$ ( <i>Ppara</i> )	Repression
	Hypoxia inducible factor ( <i>Hif1b</i> )	Repression
	Sirtuin 1 ( <i>Sirt1</i> )	Repression
Hormones and receptors	Insulin 1 ( <i>Ins1</i> )	Repression
	Insulin 2 ( <i>Ins2</i> )	Repression
	Glucagon receptor ( <i>Gcgr</i> )	Activation
	Regulator 16 of G protein signaling ( <i>Rsg16</i> )	Activation
Redox signals	Thioredoxin interacting protein ( <i>Txnip</i> )	Activation

involved in energy metabolism at the transcriptional level. Thus, glucose can activate the transcription of mainly glycolytic and lipogenic genes in which ChREBP participates as a central regulator. In addition, ChREBP plays a broader and no less crucial role in other processes ranging from glucolipotoxicity to apoptosis or proliferation of some cell types (Filhouland et al., 2013).

There is ample evidence demonstrating a direct and key role of glucose in regulating gene expression in adipose tissue and liver and in pancreatic cells. In these tissues, glucose stimulates the transcription of different genes coding for glycolytic and lipogenic enzymes: hepatic pyruvate kinase (*L-PK*), acetyl-CoA carboxylase (*ACC*), fatty acid synthase (*FAS*) and stearoyl-CoA desaturase (*SCD1*). Table 1 summarizes the genes regulated by ChREBP (Eissing et al., 2013).

For glucose to exert its effect on the expression of these enzymes, it must first be metabolized. Thus, in the liver, glucose metabolism by glucokinase (GK), the first enzyme of glycolysis, is necessary for the initiation of glucose-mediated signal transduction. Analysis of the promoters of these genes whose transcription is increased in response to glucose identified a carbohydrate response element (ChoRE) in their promoters and the transcription factor ChREBP that is able to recognize it. ChoRE has a conserved consensus sequence characterized by a tandem E box element separated by five nucleotides (5'-CACGTGnnnnnCACGTG-3'). Spot 14 (S14) was among the first genes in which a ChoRE element was detected in its promoter. It is expressed in the mammary gland and is responsible for lipid synthesis during lactation in response to carbohydrates.

There are several characteristics that make ChREBP compatible with a key role as a glucose-regulated transcription factor:

1. Its expression is most abundant in the liver and white and brown adipose tissue, where lipogenesis is very active and in the small intestine, kidney and pancreatic islets, whereas it is low in skeletal muscle.
2. Its expression in the liver is induced in response to a diet rich in carbohydrates but not in response to fasting or to diets rich in polyunsaturated fatty acids.
3. Gene silencing prevents glucose-dependent induction of *LPK*, *ACC* and *FAS* genes in adipocytes.

Following the identification of ChREBP, a second protein was discovered that interacts with ChREBP to form a heterodimer, Mlx (Max-like protein X). Thus, two ChREBP-Mlx heterodimers bind to the two E-boxes of ChoRE to provide a glucose-regulated transcriptional complex. Mlx is essential as a partner of ChREBP in the regulation of lipogenic enzyme genes in the liver since the use of dominant-negative forms of Mlx in hepatocytes, which are unable to bind DNA but do maintain their interaction with ChREBP, abrogates or decreases glucose-dependent transcription. MondoA also forms heterodimers with Mlx. Glucose signaling dependent on Mondo-Mlx interaction is evolutionarily conserved among worms, *Drosophila* and vertebrates.

#### Direct regulation of the transcription factor ChREBP activity by glucose and its metabolites

The amino-terminal domain of the ChREBP protein has several overlapping structural motifs. Of these, the GRACE and LID motifs stand out. While GRACE has a transcription-promoting effect in the absence of glucose or any of its metabolites, LID interacts with GRACE and blocks its activity. This interaction of LID with the GRACE domain extends to other regions of the amino-terminal end,

MCR I to MCR IV, regions in which signals that control trafficking to the nucleus of the transcription factor are also located and are therefore masked.

It is known that in the presence of high concentrations of glucose, the repression maintained by LID on the amino-terminal end of ChREBP is removed so that the import domains to the nucleus are exposed and the GRACE domain can bind to the target sequence, the ChoRE element. However, the mechanism by which glucose can induce this conformational change has not been confirmed. It has been proposed that glucose must be metabolized for its action to occur, so it is considered that it is a metabolite of glucose rather than glucose itself that can act as a ligand binding to ChREBP.

It is now considered likely that glucose-6-phosphate (G6P) is the metabolite responsible for this effect. The evidence supporting this assertion is that in the liver, glucokinase, the enzyme responsible for G6P synthesis, is essential for regulating ChREBP activity by glucose. Second, it has been shown that ChREBP-dependent transcriptional activity follows sigmoidal kinetics in response to variations in G6P concentration, which postulates this metabolite as an allosteric regulator of ChREBP. Structural models of the Mondo family members, MondoA and ChREBP, postulate a possible binding pocket to the MCR V domain, which would unlock the LID domain and allow it to pivot to expose the other domains present at the amino-terminal end. Although confirmatory work is required, the role of G6P in glucose regulation of ChREBP activity seems to be widely accepted (**Fig. 1**).

The response to G6P binding not only allows GRACE to bind to the target sequence but also exposes domains that control intracellular trafficking and at the same time allows other proteins to bind to domains that modulate transcriptional activity, as is the case for the 14-3-3 and CBP/p300 proteins.

Post-translational modifications, i.e., phosphorylation, O-Glucose-N-acylation, and acetylation modulate ChREBP function and regulate the state of ChREBP in response to glucose. ChREBP is the central protein of a complex network that regulates metabolic adaptations due to carbohydrate intake. In addition to the intrinsic mechanisms of ChREBP regulation, such as its transactivation by glucose metabolites, its translocation to the nucleus and its covalent modulation, ChREBP must be considered to be regulated by the signaling network of which it is a part. An example of this signaling is evident if we consider, for example, that insulin increases

**Fig. 1** Glucose regulation of glucose and lipid metabolism in the liver. Post-translational modifications by protein acetylation and O-GlcNAcylation activate ChREBP in response to glucose in liver cells. ACC, acetyl CoA carboxylase; CBP/p300, ChREBP coactivators; ChoRE, carbohydrate response element; ChREBP, carbohydrate response element-binding protein; Elov6, fatty acid elongase; FAS, fatty acid synthase; F2,6-BP, fructose 2,6-bisphosphate; G6P, Glucose-6-phosphate; GK, Glucokinase; HAT, Histone acetyltransferase; HBP, Hepatic pyruvate kinase; LPK, Hepatic pyruvate kinase; OGT, O-GlcNAc transferase; PEP, Phosphoenol pyruvate; SCD1, Stearoyl-CoA desaturase; X-5P, Xylulose-5-phosphate.

the synthesis of ChREBP $\alpha$ , which in turn will bind to the specific promoter of ChREBP $\beta$  and that increased transcription of the latter is responsible for many of the effects of carbohydrates in adipose tissue (Benhamed et al., 2015).

Although ChREBP responds to circulating levels of glucose, it was established early on that glucose metabolism was necessary for regulation to occur. In most tissues, glucose enters by diffusion mediated by specific transporters called GLUT and once inside the cell, it must be metabolized in order to exert its transcriptional regulatory activity. Since in liver the first stage of glucose metabolism produces glucose-6-phosphate (G6P), this was initially proposed as the molecule responsible for glucose-mediated signaling effects, particularly in lipogenesis-related genes. Among the proposed metabolites, xylulose-5-P (X5P), an intermediate of the pentose phosphate pathway, could be considered the transducer molecule since it has been described that treatment with xylitol, the precursor of X5P, activates protein phosphatase 2A, which is involved in the regulation of the activity of several transcription factors. In addition, another glucose metabolite, fructose 2,6-bisphosphate (F-2,6-BP) has been implicated in the activation of ChREBP in response to glucose in liver cells. F-2,6-BP is synthesized from fructose-6-phosphate by a bifunctional enzyme (6-phosphofructo-2-kinase-fructose-2,6-bisphosphatase, PF2K/F2,6BPase) that has different catalytic sites for its kinase and phosphatase activities. The hexosamine biosynthesis pathway may also be involved. Fig. 1 shows the regulation of some key genes involved in glycolysis and lipogenesis in the liver.

### Interaction of ChREBP with other transcription factors

The main transcription factor that acts synergistically with ChREBP is SREBP-1c (sterol regulatory element-binding protein-1c). Although SREBP was first described as a transcription factor involved in controlling the expression of genes related to cholesterol biosynthesis, the SREBP-1c isoform was later found to participate in the insulin-mediated activation of lipogenic genes. The promoter of the latter enzyme contains two SRE (sterol regulatory elements) to which SREBP-1c can bind for activation. In turn, GK synthesizes G6P, which, as mentioned above, is one of the metabolites capable of activating ChREBP. On the other hand, the promoters of several genes coding for lipogenic enzymes present binding sites for both SREBP-1c and ChREBP, so that the highest levels of expression of these enzymes are reached when both transcription factors bind to their respective binding sites in the promoters. Thus, lipogenesis is synergistically regulated in response to carbohydrates and lipids.

Another link between carbohydrate and lipid regulation of gene expression is the USFs (upstream stimulatory factors) family of transcription factors. These factors belong to the bHLH-LZ family and bind to E-boxes of the promoters of target genes to activate their transcription. USFs bind to the proximal promoter region of the gene coding for FAS and other lipogenic genes and are crucial for the recruitment of SREBP-1c and its binding to SRE for synergistic activation of lipogenic genes during feeding or insulin treatment. Coordinated activity with ChREBP in lipogenesis has been demonstrated using USF knockout animal models showing decreased lipogenic gene transcription in response to a carbohydrate-rich diet.

Another element that adds its effects to those of ChREBP is HNF4 $\alpha$  (hepatocyte nuclear factor 4). The promoter that regulates the expression of ChREBP $\alpha$  presents a binding site for this nuclear receptor, which therefore controls its expression in response to variation in glucose levels. In addition, HNF4 $\alpha$  has the ability to bind to the FAS and L-PK promoters, where it acts synergistically with ChREBP. This synergy is enhanced by high glucose levels and is also essential for reaching maximal enzyme expression levels.

### Regulation of lipogenesis by carbohydrates in the liver

The liver is the main organ responsible for *de novo* lipogenesis in response to high carbohydrate intake. The expression of enzymes involved in the synthesis of triacylglycerols in the liver is a process that is very well coordinated since a set of transcription factors activated by both hormonal and nutritional stimuli will participate in the induction/repression of genes involved in this process. Dysregulation of lipogenesis leads to the storage of triacylglycerols in the liver, steatosis, and other diseases, such as metabolic syndrome (Oosterveer and Schoonjans, 2014).

The effect of carbohydrates on gene expression in the liver occurs at several checkpoints ranging from membrane transporters to key enzymes of intermediary metabolism. Thus, one of the first checkpoints is constituted by the GLUT2 transporter. GLUT2 is the major glucose transporter in the liver. Its role is to introduce glucose during the post-absorptive state and release it into the blood during fasting. GLUT2 can be considered an early glucose sensor since part of the glucose generated from G6P in the endoplasmic reticulum by glucose-6-phosphatase will equilibrate with extracellular glucose through GLUT2. Alterations of this equilibrium lead to an increase of both glucose and G6P in the cytoplasm, which will increase the transcriptional activity of ChREBP in the nucleus and, therefore, to the induction of the gene coding for L-PK and lipogenic genes.

The second control point is constituted by the GK-ChREBP axis, which should be considered as the central glucose response system in the liver. The regulation of GK expression and activity is of vital importance in the sensitivity of the liver to glucose since it constitutes the first regulatory point of glycolysis and is the enzyme that catalyzes the conversion of glucose to G6P, a metabolite involved in the activation of ChREBP.

Insulin induces GK expression and although the molecular basis of this induction is not fully understood, several transcription factors have been described such as HFN-4, HIF-1 (hypoxia-inducible factor 1), SREBP-1c, LXR (liver X receptor), PPAR $\gamma$  (peroxisome proliferator activated receptor gamma), KLF-6 (Kruppel-like factor 6), TCFE3 (transcription factor E3) and LRH-1 (nuclear receptor liver receptor homolog 1) that control hepatic GK transcription.

The enzymes involved in the *de novo* lipogenesis are regulated rapidly by allosteric and phosphorylation/dephosphorylation mechanisms and in the long term at the transcriptional level in a well-coordinated manner involving different transcription factors in response to hormones (insulin) or nutrients (glucose). In the presence of insulin, which is necessary to activate glucose

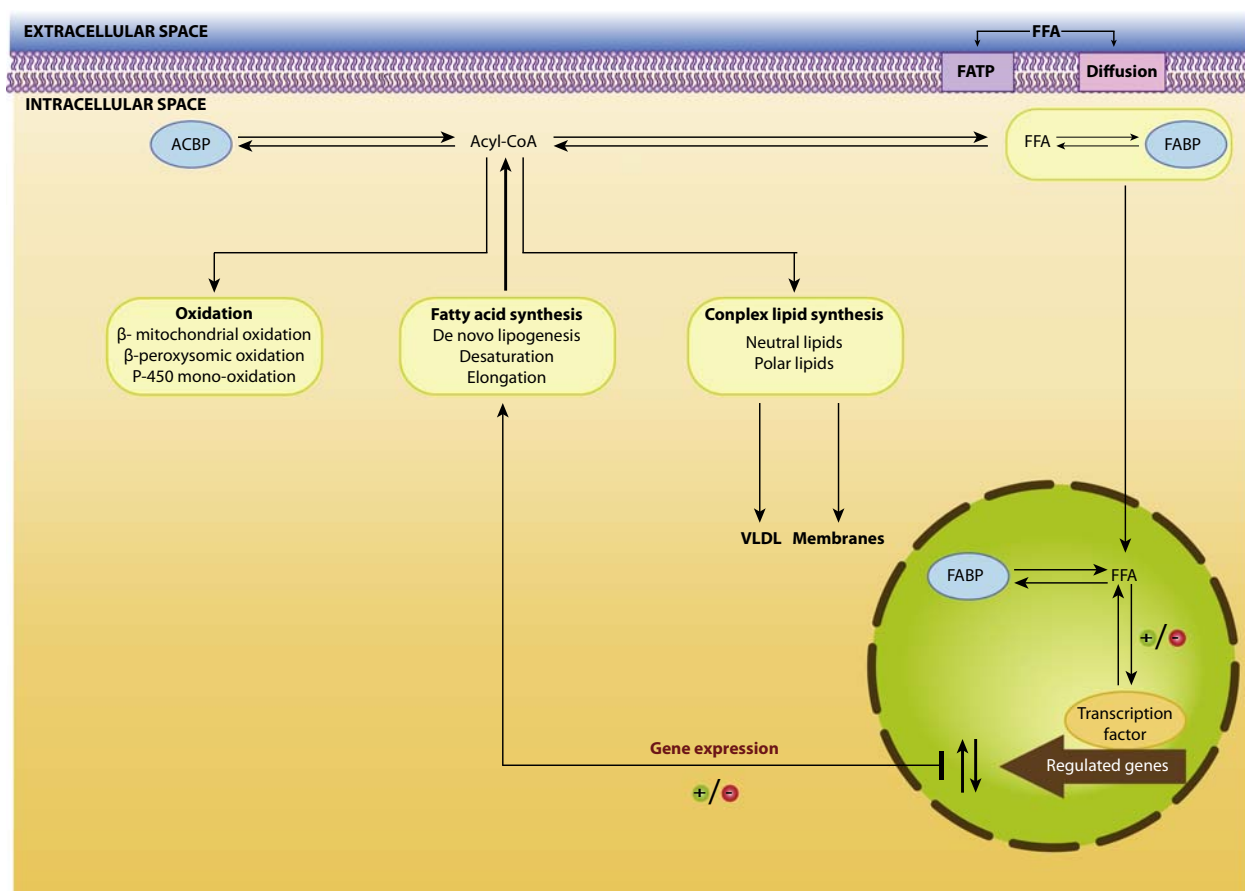

metabolism in hepatocytes, high concentrations of glucose induce the expression of genes coding for glucose transporters, glycolytic and lipogenic enzymes such as L-PK, ACC and FAS and decrease that of gluconeogenic genes, such as the phosphoenolpyruvate carboxykinase gene. These effects in the liver are mediated in a coordinated manner by SREBP-1c and ChREBP as indicated above. Likewise, other transcription factors such as USFs (upstream-stimulatory factors) and LXRs have also been implicated in the coordinated regulation of lipogenesis.

In a situation of insulin resistance, there is a situation of hyperglycemia and high glucose concentrations can induce glycolytic and lipogenic genes through the activation of ChREBP. ChREBP expression is positively related to hepatosteatosis. Thus, ChREBP-dependent expression of lipogenic genes when insulin-mediated signaling is inhibited may in part explain the active lipogenesis that occurs during insulin resistance.

### Modulation of gene expression mediated by lipids

Dietary lipids are macronutrients that are indispensable for mammalian growth and development. In addition to their energetic function and their role in membrane composition, fatty acids, both saturated and polyunsaturated, cholesterol and other sterols, as well as various eicosanoids or oxidized derivatives of the latter, modulate the expression of numerous genes involved in the oxidation of fatty acids themselves in the liver, muscle and adipose tissue, cholesterol and bile acid synthesis, adipocyte proliferation and differentiation, immune response, antioxidant defense and angiogenesis (Georgiadi and Kersten, 2012).

In mammalian cells, the signaling molecules are free fatty acids (FFA) and oxidized derivatives of polyunsaturated fatty, which are transported in and out of the cell with the help of a membrane protein, the fatty acid transporter (FAT). FFA is taken up by a specific fatty acid binding protein (FABP) and has various metabolic fates in the cytoplasm (Fig. 2).

**Fig. 2** Cellular transport of fatty acids and effects on the expression of genes related to lipid metabolism. ACS, acyl-CoA; ACBP, acyl-CoA-binding protein; FATP, fatty acid transport protein; FABP, fatty acid-binding protein; FFA, free fatty acids; TE, thioesterase; VLDL, lipoproteins; VLDL, lipoproteins; FATP, fatty acid transport protein; VLDL, very low density lipoproteins; TE, thioesterase; FATP, fatty acid transport protein.

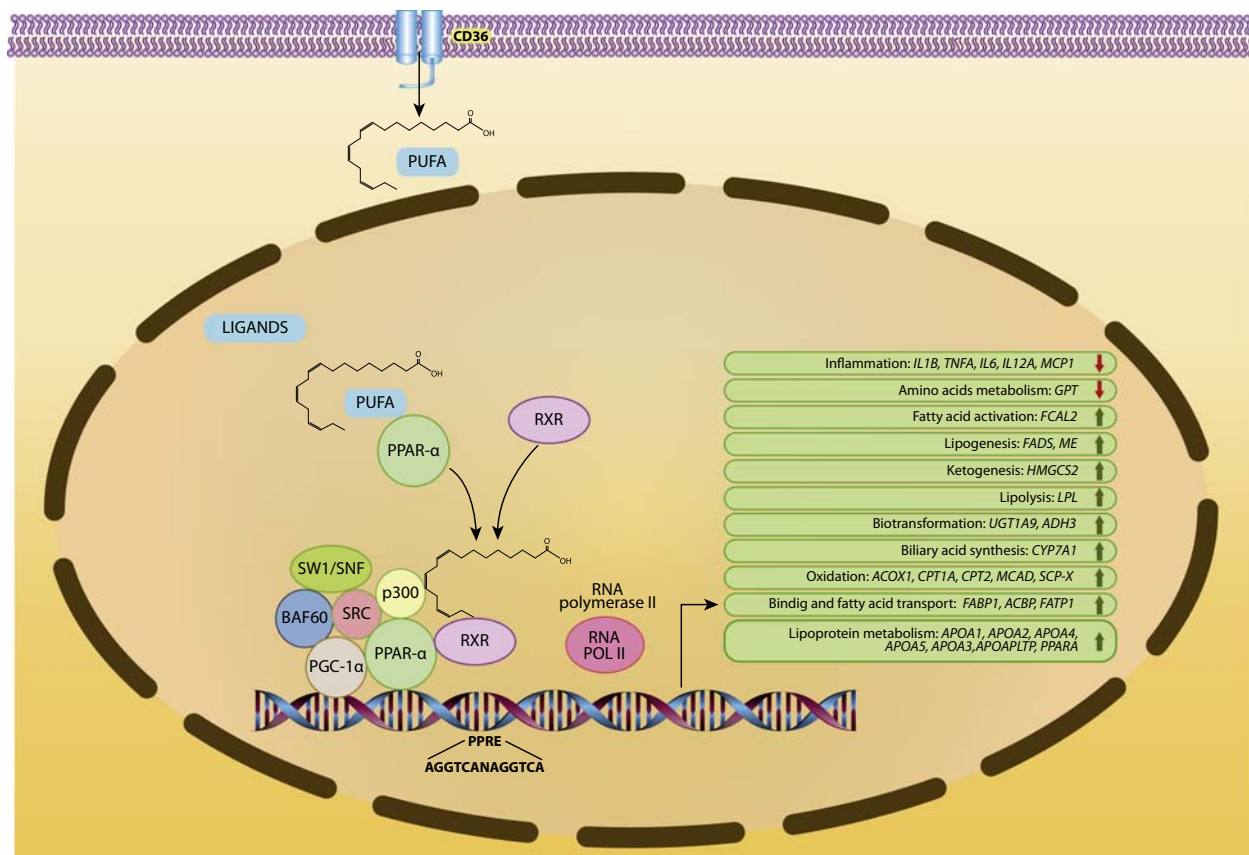

Free fatty acids bound to FABP, acyl-CoA or some fatty acid metabolites, such as eicosanoids, can:

- Induce a cascade of events leading to a covalent modification of a transcription factor, e.g., phosphorylation, altering its transactivation capacity.
- Directly bind and activate a transcription factor.
- Influence the transcription rate of a transcription factor and its synthesis.
- Modify the mRNA stability of both transcription factors and other target genes.

Specific transcription factors have been identified in mammals that respond to dietary lipids. These include at least seven major families of factors: PPAR (PPAR- $\alpha$ , PPAR- $\beta$ , PPAR- $\delta$  and PPAR- $\gamma$ ), three variants of SREBP (SREBP-1a, SREBP-1c and SREBP-2), HNF-4, LXR- $\alpha$  and LXR- $\beta$ , ChREBP, nuclear factor enhancer of activated B-cell kappa light chains (NF- $\kappa$ B) and Toll-like receptors (TLRs) (Contreras et al., 2013).

The effects of fatty acids are mediated either directly by their specific binding to various nuclear receptors (PPAR, LXR, HNF-4 $\alpha$ ), producing changes in the *trans* activation of these transcription factors, or indirectly by changes in the abundance of transcription regulatory factors (SREBP-1c, ChREBP). On the other hand, fatty acid-responsive transcription factors bind to a fatty acid recognition sequence or response element in the promoter of a target gene region, as monomers, as homodimers or as heterodimers with other transcription factors, e.g., retinoid receptors (RXR). Fig. 3 shows the main effects on gene expression of polyunsaturated fatty acids (PUFA), indicating the transcription factors involved.

At the cellular level, the physiological response to fatty acids depends on the amount and chemical structure of the fat ingested, the specific fatty acid metabolism of particular cell types (oxidative pathways, kinetics and competitive reactions), the cellular abundance of membrane and nuclear receptors and the involvement of specific transcription factors. The mechanisms of fatty acid-mediated regulation of gene expression are involved in the control of carbohydrate and lipid metabolism, in cell growth and

**Fig. 3** Mechanism of action of polyunsaturated fatty acids (PUFA) on peroxisome proliferator-activated receptor- $\alpha$  (PPAR- $\alpha$ ) and its effects on gene expression. PPAR- $\alpha$  can be activated by various ligands such as PUFA, fibrates and pyrinixic acid (WY14643) that modulate the transcription of certain genes. RXR is able to interact with PPARs, originating basal transcription with RNA polymerase II and transcribing certain genes such as CYP3A4, HMGCS2, SREBP1-c, APOA1, APOA2, APOA5, CPT-1, FGF21. APO: apolipoprotein; BAF60: Brahma 1 gene/Brahman-associated factor 60; CD36: differentiation cluster/cluster 36; CPT1: carnitine palmitoyltransferase 1; CYP: cytochrome P-450; FGF21: growth factor 21; HMGCS2: hydroxymethylglutaryl CoA synthase; p300: histone p300 acetyltransferase; PGC1 $\alpha$ : peroxisome proliferator-activated receptor (PPAR) co-activator 1 $\alpha$ ; PPRE: peroxisome proliferator response element; RXR: retinoid receptor; SRC: steroid receptor coactivator; SREBP1-c: sterol response element binding protein 1c.

differentiation, and in the production of cytokines, adhesion molecules, and eicosanoids that regulate numerous physiological and pathophysiological processes, including immune response and inflammation.

### Modulation of gene expression mediated by amino acids

Amino acids (AAs) are the building blocks of proteins and are essential substrates for the synthesis of low molecular weight compounds such as glutathione and other active peptides, nitric oxide (NO) and polyamines, which are of great biological importance. But in addition, AAs in mammals are able to regulate gene expression by control of translation initiation and post-translational modifications, by regulation of miRNAs at the transcriptional level, by mRNA stabilization, as well as by modulation of chromatin through epigenetic processes. Although the control mechanisms of gene expression mediated by AA availability have been intensively studied in bacteria and lower eukaryotes, such as yeasts, the control of transcriptional events, including cell signaling processes, transcription factors and the corresponding cis-elements of DNA, modulated by AAs, have been studied very little in mammals and, in particular, in humans.

Mammals have evolved a wide range of adaptive mechanisms to detect and respond to nutrient fluctuations. A deprivation of AA activates the Amino Acid Response (AAR), which comprises multiple signal transduction pathways. AAR activation regulates gene expression at different levels, both at the level of chromatin structure and at the initiation of transcription. The heterogeneity of the factors involved suggests the existence of multiple AARs that depend on the particular AA, the cell type considered and the configuration of the promoter gene (Kilberg et al., 2012). The complexity of AA-mediated regulation of gene expression is increased by the fact that many of the target genes encode transcription factors that, in turn, act by directing the transcription of several subordinate genes. Studies with the asparagine synthase (ASNS) and C/EBP homologous protein (CHOP) genes, which encodes a nuclear protein related to the C/EBP family of transcription factors, -CCAAT/Enhancer Binding Protein (CCAAT/Enhancer Binding Protein), which forms dimers with other members of its family and is involved in cell apoptosis, have allowed the characterization of AA-specific response sequences in its promoters, termed AA response elements (AARE) and nutrient responsive response elements (NSRE), especially glucose. Although considerable progress has been made in understanding the mechanisms controlling AA-dependent gene expression, numerous questions remain to be resolved.

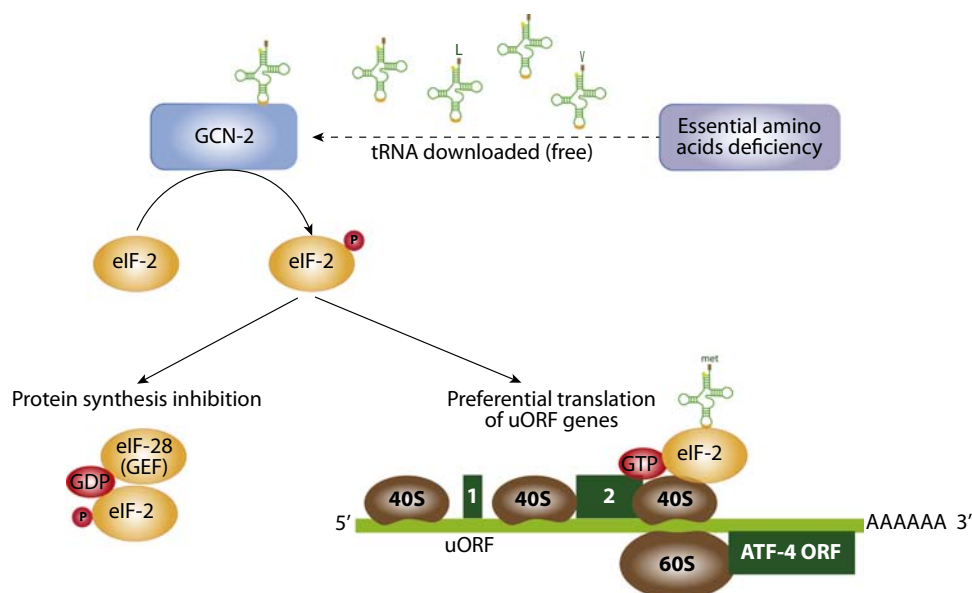

Generally, a state of malnutrition or poor AA assimilation is associated with a wide range of diseases, in which modulation of gene expression has been recognized as a component. For example, in individuals with a protein deficiency, decreased expression of insulin-like growth factor 1 (IGF-1) has been described, which together with other genes may contribute to morbidity in adults and may decrease growth in malnourished children. In healthy adults, consumption of a low-protein diet decreases IGF-1 expression and increases insulin-like growth factor binding protein 1 (IGFBP1) expression. A protein-deficient diet not only has immediate effects on the expression of certain genes, but also has long-term effects through epigenetic mechanisms. In fact, protein or AA restriction during fetal (in utero) development causes fetal hepatic DNA methylation changes and changes in gene regulation, possibly leading to the development of metabolic syndrome during adulthood. Furthermore, in rats fed wheat gluten, which is deficient in lysine and threonine, there is an induction of genes involved in cholesterol biosynthesis. Similarly, studies in animals fed a diet deficient in methionine or leucine resulted in rapid weight loss, adiposity and impaired health. These results indicate that AA are capable of regulating different metabolic pathways.

In mammary cells, at least three molecules capable of determining AA availability have been described to date:

- (1) general non-derepressor control kinase 2 (GCN2), which regulates transcription initiation in cells in the absence or deprived of AA by sensing uncharged tRNAs.
- (2) activation of c-JUN by JUN kinase, this pathway is important in pathologies such as cancer and in the development of diabetes.
- (3) the mammalian target protein kinase of rapamycin (mTOR), which functions to confirm the existence of an adequate level of AA to support protein synthesis and cell growth.

GCN2 and mTOR kinases are highly conserved, having a major role in controlling transcription and translation, as well as regulating the adaptive response during amino acid deprivation. GCN2 has the ability to sense the levels of each of the AA, it is activated in response to protein fasting, cellular purine limitation or DNA damage. AA limitation activates this kinase through a mechanism involving the accumulation of uncharged tRNA. GCN2 phosphorylates eukaryotic translation initiation factor 2 (eIF2)  $\alpha$  at serine 51, leading to a decrease in protein synthesis (Fig. 4). Paradoxically, although phosphorylation of eIF2 $\alpha$  leads to inhibition of protein synthesis, it leads to an increase in the translation of specific mRNAs, most notably ATF4. Therefore, ATF4 protein synthesis is selectively increased in response to AA deficiency. Among the genes that are activated by ATF4 are those of the transcription factors ATF3, C/EBP $\beta$  and CHOP, and the ASNS gene. Some genes regulated by ATF4 require transcriptional upregulation of ATF2, which encodes a histone acetyltransferase. In response to a reduction of AA, and in particular leucine, ATF-2 phosphorylation is induced in human cells, leading to cellular apoptosis.

Cells use translational control to modulate gene expression throughout their life cycle in all tissues and its dysregulation can contribute to numerous diseases, including cancer. Like any biosynthetic process, translation consumes substantial amounts of energy and AA. When either is limited, protein synthesis needs to be inhibited. Therefore, mammals have evolved translation control mechanisms, most of them sensitive to the availability of nutrients, cellular energy, stress situations, hormones and growth factors.

**Fig. 4** Mechanism of action of general control nonderepressible 2 kinase (GCN-2) upon essential amino acid deficiency. Phosphorylation of eukaryotic translation initiation factor 2 $\alpha$  (eIF-2 $\alpha$ ) by GCN-2 results in a coordinated response that limits the ribosomal transcription of most messenger RNAs while activating the transcription of specific genes containing upstream open reading frames (uORF), such as activating transcription factor 4 (ATF-4). GEF: guanosine nucleotide exchange factor.

The limiting step of protein synthesis is translation initiation during which the small unit of ribosomes is recruited to the 5' end of the mRNA to scan the initiation codon. Therefore, control mechanisms often relate to the control of the initiation factors of this process (protein synthesis, degradation and turnover). One of the mechanisms of control of translation initiation requires the assembly of translation initiation factor 4F (eIF-4F) with the cap at the 5' end mRNA. The eIF-4F consists of three factors (eIF-4E, eIF-4G and eIF-4A) and for assembly eIF-4E binds to the cap at 5', recruiting eIF-4G and eIF-4A. The eIF-4E factor binding protein (4EBP-1) exerts an inhibitory action on the binding of eIF-4G to eIF-4E and phosphorylation of 4EBP-1 allows the recruitment of eIF-4G and eIF-4A and thereby initiation of protein synthesis.

A key pathway of translation regulation that integrates and responds to environmental causes, such as the availability of AA and energy, and the presence of insulin, is the so-called mTOR pathway, through phosphorylation and inhibition of the 4EBP-1, together with activation of ribosome kinase S6 (S6K), which are described below (Haissaguerre et al., 2014). However, this pathway controls other important metabolic and cellular functions, such as autophagy. Fig. 5 summarizes the control of amino acid-mediated protein biosynthesis and other signals through the mTOR pathway.

The presence of amino acids, especially leucine, activates the mTOR pathway by phosphorylating 4EBP-1 and allowing the assembly of the eIF-4F complex and, therefore, the initiation of translation. Likewise, mTORC1 phosphorylates eIF-4G at several sites allowing its scaffold function for eIF-4F formation. Another important target of mTORC1 is the S6Ks, especially S6K-1, which coordinate ribosome biogenesis. It is now known that both the mTORC1 complex and S6K-1 associate with the translation initiation complex eIF-3. Thus, immediately after its activation, the mTORC1 complex is recruited by the eIF-3 complex, resulting in the phosphorylation of S6K-1, which is thus activated, as well as of factor 4EBP, which is separated from eIF-4E. On the other hand, the recruitment of active S6K-1 by newly synthesized mRNA is made possible by the scaffolding protein called SKAR, which in turn, in order to be active, needs to be phosphorylated by S6K-1 itself.

## Regulation of gene expression by vitamins A and D

Vitamin A and vitamin D present a clearly transcriptional mechanism, while sharing the fact that they are both vitamins and hormones/prohormones (Al Tanoury et al., 2013; Christakos et al., 2016). Their biological actions predominantly involve interaction with specific nuclear receptors, made possible by their lipophilic structure, which allows access through the plasma membranes. Nuclear receptors are located inside the cell, in the cytoplasm or in the nucleus itself, and respond to typically lipid-soluble ligands (which otherwise would not have access) by modulating gene transcription. Class 2 of these receptors include the thyroid hormone receptor (TR), vitamin D receptor (VDR), retinoic acid receptors (RAR and RXR) and PPAR. These receptors generally act as heterodimers in which the retinoid X receptor associates with the VDR, RE, RAR or PPAR. In general, proteins belonging to the nuclear receptor superfamily are single-chain polypeptides with 3 main domains: an amino-terminal variable domain, a highly conserved DNA-binding domain, and a carboxyl-terminal ligand-binding domain. Between the DNA-binding

**Fig. 5** Control of amino acid-mediated protein biosynthesis and other signals through the mTOR (mammalian target protein kinase of rapamycin) pathway. 4EBP-1: eIF-4E factor-binding protein; AMPK: AMP (adenosine monophosphate) activated protein kinase; ATP:adenosine triphosphate; eEF-2K: eukaryotic elongation factor 2K; eIF-4E: eukaryotic translation initiation factor 4E; ERK: extracellularly regulated kinase; FYRK: eukaryotic translation initiation factor 4E,extracellularly regulated; FYVE (Fab1p, YOTB, Vac1p, and EEA1): proteins containing Fab1p, YOTB, Vac1p, and EEA1 domains; GβL: G protein subunit-like, also known as LST-8 (leukocyte specific transcript); GSK-3β: glycogen synthase kinase 3β; GDP: guanosindiphosphate; GEF:guanine nucleotide exchange factors; GTP: guanosine triphosphate; HIF-1α, HIF 1b: hypoxia-inducible factors 1a and 1b; IR: insulin receptor; IRS-1: insulin receptor substrate 1; LKB-1: tumor suppressor; PDK-1: phosphoinositide-dependent protein kinase; PI3K: phosphatidylinositol-3-kinase; PIP<sub>2</sub>: phosphatidylinositol-bisphosphate; PIP<sub>3</sub>: phosphatidylinositol-3-phosphate; PKB: protein kinase B; PRAS40: proline-rich protein; PX: protein kinase B; PRAS40: proline-rich protein; PX: proline-rich protein; PX (Phox homology): proteins containing PX domains; Rag (Ras-related small GTPases): family of small GTPases; Raptor (regulatory associated protein of mTOR): regulatory protein associated with mTOR; Redd1/2 (protein regulated in development and DNA damage response): DNA damage-induced transcripts; Rheb: small GTP-bound G protein; Rictor: rapamycin-independent partner of mTOR; RSK: ribosomal S6 kinase; S6K: ribosomal S6 kinases; 5'-UTR: 5'-untranslatable region of mRNA; TSC: tuberous sclerosis complex; TSC-1: hamartin; TSC-2: tuberin.

domain and the ligand-binding domain is a hinge region. Modulation of the transcriptional activity of these receptors is critically dependent on interaction with various cofactors.

The active form of vitamin A (except for visual function) is retinoic acid (transretinoic acid), which acts as an activating ligand for RAR receptors, of which there are 3 types with different isoforms. The active form of the RAR receptors is as a heterodimer, forming a pair with RXR receptors, giving rise to multiple possible combinations. Several possible RXR receptor ligands have been identified, including 9-cisretinoic acid, but it is not clear which of these is relevant *in vivo*, nor indeed whether the presence of such a ligand is necessary. Other potentially relevant vitamin A receptors have been identified, most notably the PPAR/receptor. In addition, RAR receptors appear to be involved in non-transcriptional modulatory mechanisms (Al Tanoury et al., 2013).

The active form of vitamin D is calcitriol, which acts as an activating ligand of the VDR receptor. Unlike vitamin A, there is a single form of VDR, although multiple polymorphic variants have been identified, some of which appear to be clinically relevant (Christakos et al., 2016). The biologically active form of VDR is as a heterodimer, pairing with RXR receptors. As in the case of vitamin A, there are non-transductional modulation mechanisms, which depend on two types of receptors: the VDR itself, located in the

caveolae of the plasma membrane, and an independent receptor called MARRS (membrane-associated rapid steroid response protein). This type of mechanism produces faster responses than the classical transcriptional actions, but its biological significance is not clear at present.

## Regulation of gene expression by trace metals

Trace metals play a fundamental role in human nutrition as most of them are considered essential for a proper cellular functioning. However, excessive intake or exposure can be highly harmful to health. This is why organisms have developed homeostatic mechanisms to control the correct concentrations of these metals (Ng et al., 2015).

Intracellular regulation of iron in man is performed by a post-transcriptional regulatory mechanism, mediated by iron regulatory proteins (IRPs) and iron responsive elements (IREs) and copper actively participates in the function of transcription factors, such as Ace-1, Mac-1 and Amt-1, which are key factors in human metabolism. Intracellular iron concentration modulates the expression of most of the proteins related to iron metabolism, including the transferrin receptor (RTf), the outbound transporter ferroportin, the iron storage protein ferritin, and the inbound iron transporter DMT1.

Iron regulatory proteins IRP1 and IRP2 are cytosolic proteins that bind to hairpin mRNA structures, called iron response elements (IRE), which are located in the 5' (ferritin and ferroportin mRNA) or 3' (RTf and DMT1 mRNA) untranslated regions of the mRNA (5' or 3' UTRs) that encodes it. In their structure, IRP proteins contain a cube-shaped core between domain 1 and domains 2–4, which allows them to detect the intracellular iron content. When the content of the labile iron pool is low, the core is in a 3Fe-4S (3-iron-4-sulfur) conformational state, i.e., open state. Under these conditions, proteins can bind to the IRE elements of mRNAs and thus regulate their expression. When IRP proteins bind to the 5' non-coding end of the mRNA, translation is inhibited, as the entry of the major subunit of the translational complex is blocked. When they bind to the 3' non-coding end, the mRNA is stabilized as the action of RNAases is prevented. Therefore, when the iron content in the labile iron pool is low, the IRPs bind to the IRE elements and prevent the translation of ferritin and ferroportin, resulting in decreased iron storage and reduced iron efflux from the intracellular medium, respectively, and in addition, stabilization of the RTf and DMT1 messengers occurs, resulting in increased iron uptake. When intracellular iron increases, the core IRP proteins change conformational state to 4Fe-4S, i.e., closed state, losing their ability to bind mRNAs.

Transcriptional regulation plays a key role in the control of trace metal homeostatic gene expression, in particular, cadmium, selenium and nickel directly impact transcriptional regulatory mechanisms (Ng et al., 2015). The metallothionein gene has more than one response element in its promoter, including the metal responsive element (MRE). The synthesis of metallothionein augments in response to increased levels of most of the trace metals. The transcription factor MTF-1 allows to connect the transcriptional response mediated by trace metals with the purpose of increasing the intracellular amount of metallothioneins whose function is to contain the intracellular excess of metals avoiding their toxicity. This property gives the system the ability to integrate and coordinate gene expression in order to maintain cellular homeostasis. Indeed, trace metal nutrigenomics and nutrigenetics research has enabled significant progress in understanding the genetic potential to respond to changes in trace metal availability.

## Conclusions

A diet rich in carbohydrates increases the expression of the disaccharidases and transporters that are involved in their metabolism, so that in the long term there is a better utilization of the contribution of these nutrients from the diet. This increase in the expression of disaccharidases and transporters will occur mainly at the level of their transcription, although in some cases post-transcriptional regulation also occurs. Glucose participates in the coordinated regulation of insulin gene expression, insulin biosynthesis and insulin secretion. Also, glucose stimulates the transcription of genes coding for glycolytic and lipogenic enzymes: L-PK, ACC, FAS and SCD-1. ChREBP is the key element mediating glucose sensitivity in different cell types.

In addition to their energetic function and their role in membrane composition, fatty acids, both saturated and polyunsaturated, cholesterol and other sterols, as well as various eicosanoids or oxidized derivatives of the latter, modulate the expression of numerous genes involved in the oxidation of fatty acids themselves in liver, muscle and adipose tissue, cholesterol and bile acid synthesis, adipocyte proliferation and differentiation, immune response, antioxidant defense and angiogenesis. The effects of fatty acids are mediated either directly by their specific binding to various nuclear receptors (PPAR, LXR, HNF-4 $\alpha$ ) producing changes in the trans activation of these transcription factors, or indirectly by changes in the abundance or stability of transcription regulatory factors (SREBP-1c, ChREBP, Nrf2 etc.). On the other hand, fatty acid-responsive transcription factors bind to a fatty acid recognition sequence or response element in the promoter of a region of a target gene, as monomers, as homodimers or as heterodimers with other transcription factors, e.g., retinoid receptors (RXR).

Amino acids regulate gene expression through multiple mechanisms, including both transcriptional and mechanisms, including modulation of transcription, translation and epigenetic mechanisms. Three molecules capable of determining amino acid availability have been described, GCN2, which regulates the initiation of transcription in cells in the absence or deprived of amino acids; activation of c-jun by Jun kinase, an important pathway in diseases such as cancer and in the development of diabetes, and mTOR,

which is capable of determining the existence of an adequate level of amino acids and, among other mechanisms, activates protein synthesis. The amino acid leucine has been identified as the main modulator of the mTORC-1 complex.

Vitamin A and vitamin D present a clearly transcriptional mechanism, while sharing the fact that they are both vitamins and hormones/prohormones. Their biological actions predominantly involve interaction with specific nuclear receptors, made possible by their lipophilic structure, which allows access across plasma membranes. These receptors generally function as heterodimers in which RXR is associated with the VDR, RAR or PPAR.

Intracellular regulation of iron in man follows a post-transcriptional mechanism, mediated by mechanism, mediated by IRPs and IREs. Copper is actively involved in the function of transcription factors such as Ace-1, Mac-1 and Amt-1, which are essential in human metabolism. Metallothionein has more than one response element in its promoter, including the MRE. Transcriptional regulation plays a key role in controlling the expression of trace element homeostatic genes; in particular, cadmium, selenium and nickel directly impact transcriptional regulatory mechanisms.

## Key points

- To describe the biochemical mechanisms involved in the resolution of inflammation.
- To know the chemical structures of resolvins, protectins and maresins, and the major pathways involved in their synthesis.
- To understand the variety of receptors that mediate the effects of resolvins, protectins and maresins.
- To know the role of resolvins, protectins and maresins in the resolution of inflammation and other biological effects.

## Introduction

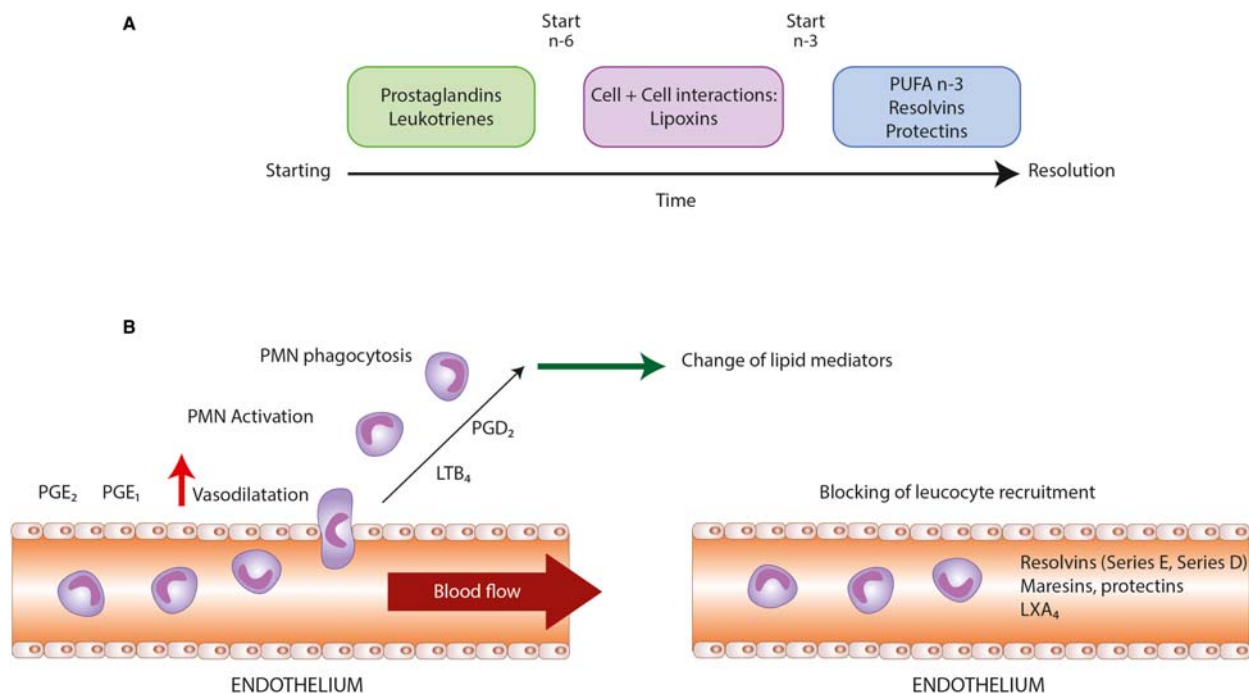

The acute inflammatory response can be divided into two phases, an initial onset phase and a resolution phase (Fig. 1A). The onset phase is accompanied by the so-called cardinal signs or pillars of inflammation, i.e., flushing (redness), heat (fever), pain, tumor (swelling and edema) and loss of function (*functio laesa*), and is regulated by numerous chemical mediators. Among these compounds are proteins, peptides, and lipid mediators, including eicosanoids, which give rise to chemical gradients capable of regulating leukocyte trafficking or diapedesis to the affected area. Neutrophil infiltration and accumulation of macrophages as well as monocytes result from the initiation phase of the acute inflammatory response (Fig. 1B). Therefore, an inappropriate elimination of these cells after their action can lead to a chronic process (Panigraphy et al., 2021).

The resolution phase is also based on five pillars: (a) elimination of microorganisms, dead cells, cellular debris and antigens; (b) restoration of vascular integrity and perfusion; (c) tissue regeneration; (d) remission of fever; and (e) elimination of pain. During the resolution phase of the inflammatory process, there is a decrease in the presence of proinflammatory mediators, as well as the synthesis of other mediators aimed at restoring homeostasis. The synthesis of these “pre-resolution” mediators has helped to demonstrate that this process is biochemically active (Fig. 1B) (Panigraphy et al., 2021; Serhan, 2014).

At the tissue level, restoration of homeostasis is defined as the cessation of leukocyte infiltration in response to chemotactic signals, apoptosis of polymorphonuclear cells and active clearance by macrophages of apoptotic cells. Analysis of exudates following the inflammatory process has identified several specialized pro-resolving mediators (SPMs) (Serhan, 2014; Serhan et al., 2015a). This name encompasses different chemical families of lipid mediators with different functions, including lipoxins, resolvins, protectins and maresins, which mitigate the infiltration of polymorphonuclear leukocytes, decrease the production of proinflammatory mediators and stimulate the uptake of apoptotic polymorphonuclear-dependent macrophages (Fig. 2) (Serhan and Petasis, 2011; Serhan et al., 2015b). These mediators are synthesized from n-3 polyunsaturated fatty acids, such as eicosapentaenoic acid (EPA, 20:5 n-3), docosapentaenoic acid (DPA, 22:5 n-3), and docosahexaenoic acid (DHA, 22:6 n-3), except for lipoxins (LX), which are synthesized from arachidonic acid (AA), 20:4 n-6. From EPA derive the E-series resolvins, and DHA is the precursor of the D-series resolvins, protectins and maresins. DHA derivatives are generally referred to as “docosanoids” (Dyall et al., 2022; Ishihara et al., 2019). Like DHA, DPA is a precursor of docosanoids whose physiological effects are however still poorly known (Drouin et al., 2019; Hansen et al., 2017).

Fig. 3 represents a general scheme of the synthesis of resolvins, protectins and maresins and their role in inflammation resolution and homeostasis.

In addition, Fig. 4 shows, as an example, the chemical structures of arachidonic acid-derived lipoxins LXA4 and LXB4, EPA-derived resolvins E1 and E2, and DHA-derived resolvin D1, protectin D1 (also called neuroprotectin (NPD-1)) and maresin 1, all derived from DHA, as well as the interaction with currently known receptors.

**Fig. 1** Role of lipoxins, resolvins, protectins and maresins in the resolution of the inflammatory reaction. (A) Hypothetical sequence of lipid-derived mediators that moderate acute inflammation from onset to resolution and return to homeostasis. (B) Lipid mediators controlling influx to the site of inflammation, with succession from the proinflammatory leukotriene B<sub>4</sub> (LTB<sub>4</sub>) to the resolving factor lipoxin A<sub>4</sub> (LXA<sub>4</sub>). PUFA: polyunsaturated fatty acids; PG: Prostaglandin; PMN: Polymorphonuclears.

In addition to their participation in the resolution of inflammation, some of these compounds play a protective role on the nervous system, retina, liver and lungs (Bazan, 2009; Levy and Serhan, 2014). As their name indicates, this protection is mainly exerted by protectins. Although the mechanism is not sufficiently elucidated, these findings underline the importance of DHA in these tissues. As is schematized in Fig. 5, one of the possible mechanisms is related to cell survival, since protectins inhibit apoptosis (Serhan et al., 2015b).

### Biological functions of pro-resolving mediators derived from n-3 polyunsaturated fatty acids

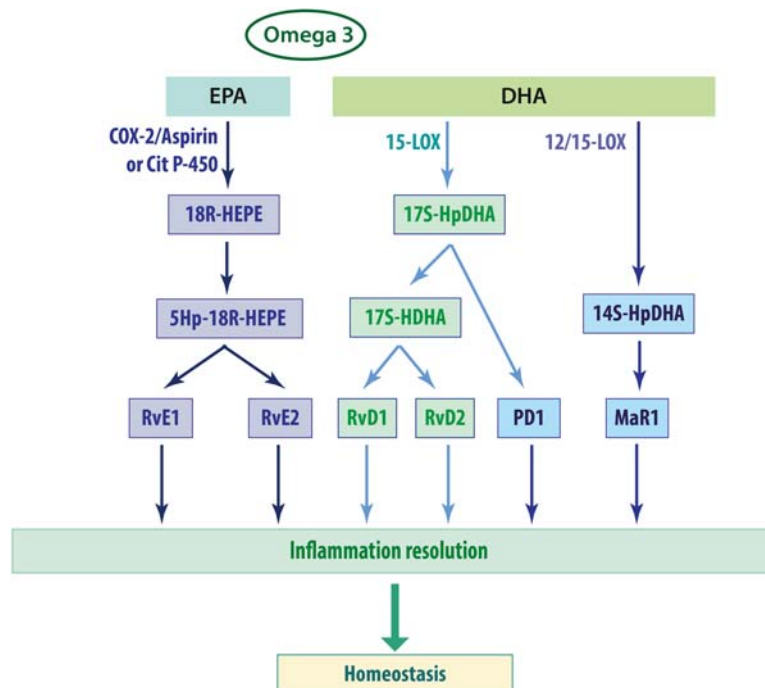

SPMs induce an anti-inflammatory response by inhibiting granulocyte migration and activation, as well as sensory neuronal activation, and limiting cytokine production by a variety of structural cells, including epithelial cells, endothelial cells and fibroblasts. In addition, SPMs have multiple actions by regulating the sentinel cells of the innate immune system and by decreasing the production of cytokines and amphiregulins. They also promote resolution by inducing the production of regulatory T cells and stimulating natural killer (NK) cells to trigger granulocyte apoptosis, engage macrophages to phagocytose bacteria and other noxious stimuli, and eliminate apoptotic cells via efferocytosis (Serhan, 2014; Serhan et al., 2015a,b).

#### Resolvins

The E series resolvins (RvE1, RvE2 and RvE3) are produced by the vascular endothelium with the intervention of aspirin-modified cyclooxygenase 2 (COX-2), which transforms EPA to 18R-hydroperoxyeicosapentanoic acid and 18S-hydroperoxyeicosapentanoic acid. These intermediates are rapidly metabolized by 5 lipoxygenase (5-LOX) to give rise to resolvins E1 and E2 (Serhan and Petasis, 2011; Spite et al., 2014). The production of resolvins E1 is increased in the plasma of individuals ingesting EPA in the diet, resulting in the amelioration of clinical signs of inflammation (Ishihara et al., 2019). Similarly, DHA-derived resolvins, the D-series resolvins, have been shown to be effective in decreasing inflammation by decreasing platelet-leukocyte adhesion and converting DHA into molecules with dual anti-inflammatory and pro-inflammatory functions (Serhan and Petasis, 2011; Spite et al., 2014). Notably, both RvE1 and RvE2 are resolvins that are antagonists for the endogenous LTB<sub>4</sub> receptor, the BLT-1 receptor, which explains their strong ability to control leukocyte trafficking to the inflammatory focus (Fig. 6).

**Fig. 2** Roles of lipoxins, resolvins, protectins and maresins in the resolution of acute inflammation. 5-LOX: 5-lipoxygenase; 12-LOX: 12-lipoxygenase; AMD: Age-related macular degeneration; IBD: Inflammatory bowel disease; LTA4, LTB4 and LTC4: Leukotrienes; LXA4: and LXB4: Lipoxins A4; MaR1: Maresin 1; PD1: Protectin D1; PGD2 and PGE2: Prostaglandins; RvE1 a RvE2: Resolvins derived from eicosapentaenoic acid; RvD1 and RvD2: Resolvins derived from docosahexaenoic acid.

### Protectins

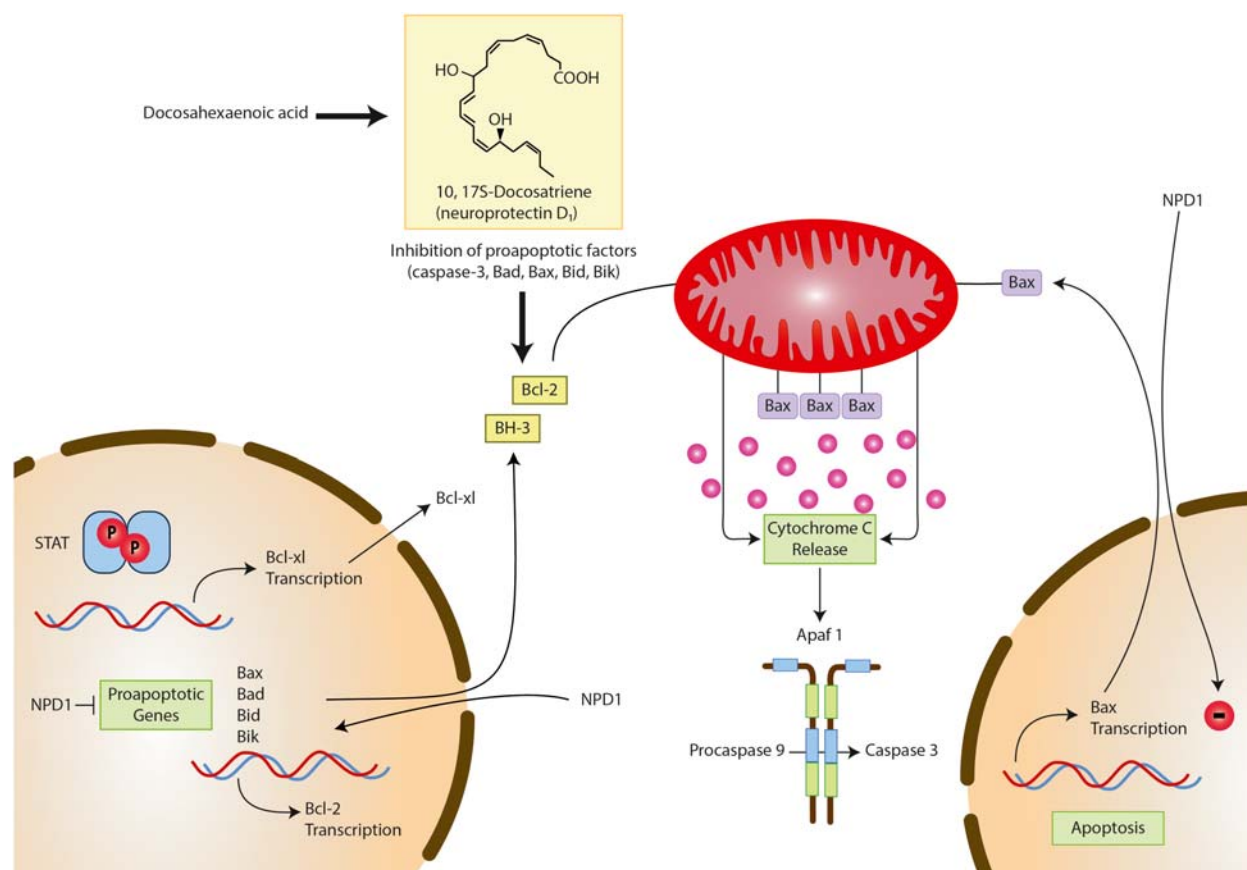

Independently of the neuroprotective action of protectin D1 mentioned above (Fig. 5), protectins decrease the secretion of interferon-gamma (IFN- $\gamma$ ), as well as tumor necrosis factor-alpha (TNF- $\alpha$ ), by blocking T-cell migration. Several studies have found a new pathway of protectin synthesis, known as protectin D1, mediated by aspirin (Serhan et al., 2015b; Hamidzadeh et al., 2022). In this new pathway, the synthesis of protectins is produced from DHA by the action of COX; this compound presents positive interactions with receptors of the peroxisome proliferative receptor-gamma (PPAR- $\gamma$ ) family. Both protectins, regardless of the synthesis pathway by which they are obtained, decrease neutrophil transmigration through endothelial cells and enhance the efferocytosis process (from the Latin *effere*, "to bring to the grave") performed by macrophages for the elimination of apoptotic neutrophils. Although protectin D1 can decrease leukocyte recruitment, leukocyte influx is not completely blocked. However, this fact does not compromise the host defense.

### Maresins

In recent years, a new family of mediators of the resolution of acute inflammation, also derived from DHA and produced by macrophages, has been discovered and termed maresins. Members of this family have potent direct actions on phagocytes, including inhibition of neutrophil recruitment or stimulation of efferocytosis, a process very similar to macropinocytosis, whereby phagocytic cells eliminate apoptotic and necrotic cells (Serhan et al., 2015b).

Maresin biosynthesis is initiated in macrophages by the action of 14-LOX from DHA. Maresin 1 (MaR1) is the first identified member of the macrophage-derived proresolving mediator family and is known to exert direct actions on leukocytes. MaR1 is a more potent mediator than RvD1 in the case of efferocytosis stimulation and exerts a pivotal effect in regulating the resolution

**Fig. 5** Role of docosahexaenoic acid and docosanoids in neuroprotection. APAF1: Apoptosis protease-activating factor; NPD-1: Neuroprotectin D1.

phase of the inflammatory process, tissue regeneration and damage resolution. MaR2 has also been discovered, which exerts an important action *in vivo* by limiting polymorphonuclear trafficking (Dyall et al., 2022).

The presence of MaR1 in the inflammatory response occurs at late stages with the entry into play of macrophages. Macrophages are key regulators of the inflammatory response, with different subtypes linked to the spread or resolution of inflammation. Within this context, there are two broad categories of macrophages: classical or M1 macrophages, with proinflammatory properties, and M2 macrophages, linked to the resolution phase of the inflammatory response and the restoration of homeostasis. Several studies have shown that both DHA and DHA-derived mediators of resolution, including RvD1, can stimulate the macrophage phenotype from the proinflammatory profile toward the resolution phase phenotype, M2. It has also been found that macrophages with M2 phenotype are associated with high levels of MaR1, a finding that allows linking it to their regenerative and homeostatic actions. In addition to its actions on leukocytes, this mediator exerts direct actions on tissues, inducing regeneration, probably by a mechanism of stem cell regulation, promoting their differentiation, a fact similar to that recently discovered for another mediator, protectin D1. The activation of MaR1 may influence the resolution of inflammation through the selective reduction of LTB4 by direct inhibition of its synthesis.

## Conclusions

SPMs include several chemical families of lipid mediators with different functions, including lipoxins, resolvins, protectins and maresins, which block the chemotaxis of polymorphonuclear leukocytes, decrease the production of cytokines and other proinflammatory mediators and stimulate the phagocytosis within inflamed tissues, leading to inflammation resolution and homeostasis.

**Key points**

- Chemical and biological features for fat- and water-soluble vitamins are described with a primary focus on their mechanisms of action. In addition, the mechanism of action for selected vitamin-like conditional nutrients are briefly reviewed.
- Descriptions for the primary functions of fat-soluble and water-soluble vitamins, including the selected conditional nutrients, are provided. Factors (e.g., dietary deficiencies, genetic polymorphisms, dietary interactions) are identified that result in perturbations of essential functions. Other perspectives include why certain vitamins are well-suited to serve as catalysts for transfer, redox, or single carbon reactions.
- Key features of the whole-body regulation of vitamins include descriptions for their digestion, absorption, transport, and cellular metabolism. It is emphasized that the dietary requirements for vitamins are allometric and most related to energy needs and metabolic rate.

**Glossary**

**ABC transporters** (ATP-binding cassette transporters) are one of the most prominent ATP-requiring transporter families

**Autosomal recessive** An autosomal recessive disorder has two copies of an abnormal gene (also cf., Recessive gene)

**Biocatalyst** A substance, especially an enzyme, that initiates or modifies the rate of a chemical reaction

**Biofactors** Any material that has a significant biochemical function

**Carbonium and Carbanions** Carbonium ion and carbanion are charged chemical species containing carbon atoms with different valences, i.e., a carbonium is a trivalent ( $C^{\sigma+}$ ), and a carbanion is pentavalent ( $C^{\sigma-}$ )

**Corrin ring** A corrin features four pyrrole-like subunits organized into a conjugated structure

**Crohn's disease** A type of inflammatory bowel disease associated with abdominal pain, severe diarrhea, fatigue, weight loss, and malnutrition

**Cytochromes P450 (CYPs)** Are enzymes containing heme as a cofactor and function as monooxygenases oxidizing steroids, fatty acids, and xenobiotics. In addition, they are essential for the clearance and catabolism of various compounds

**Energy components (Thermodynamic and Nutritional)** The three principle thermodynamic energy components are entropy (system thermal energy unavailability for conversion into mechanical work), enthalpy (the total heat content of a system), and free energy (a thermodynamic quantity equivalent to the capacity of a system to do work). In nutritional terms, enthalpy most represents heat of combustion (e.g., of individual foods). Free energy broadly represents basal metabolism plus work. Finally, entropy may be viewed as a force for catalysis and heat production

**Dietary Reference Intakes (DRI)** Set of four reference values Estimated Average Requirements (EAR), Recommended Dietary Allowances (RDA), Adequate Intakes (AI), and Tolerable Upper Intake Levels (UL)

**GPCR** (G-protein-coupled receptors) are common signaling receptors in cells. Their activity is regulated by factors that control their ability to bind to and hydrolyze guanosine triphosphate

**JAK-STAT signaling factors (Janus Kinase and Signal Transducer and Activator of Transcription signaling)** Can interconnect with other cell-signaling pathways involved in processes such as immunity, cell division, cell death, and tumor formation

**Leaving groups** Moieties in compounds that have the characteristics of a weak base. The weaker the base, the better the leaving group

**NF- $\kappa$ B** Proteins are structurally-related transcription factors that control numerous cellular and organismal processes related to immune and inflammatory responses, developmental strategies, and cellular growth

**Polymorphism** The inheritance of a trait controlled by a single genetic locus with two alleles, in which the least common allele has a frequency of about 1% or greater. Genetic polymorphism is a difference in DNA sequence among individuals, groups, or populations

**RARs (Retinoic acid receptors) and RXR (retinoid X receptors)** Are ligand-controlled transcription factors that function as heterodimers to facilitate regulation of cell growth, differentiation, survival

**Recessive genes** Genes whose effects are masked in the presence of a dominant gene. Chromosomal DNA has two alleles one inherited from the mother and the other from the father. A recessive gene is only expressed when an organism has two recessive alleles (known as homozygous recessive). If an organism has one dominant and one recessive allele, it will show the dominant trait

**REE** (Resting energy expenditure) represents the energy as calories or joules required by the body at rest

**ROS** (Reactive oxidant species) are unstable molecules (free radicals) that contain oxygen and react with other molecules in a cell, causing a wide variety of cellular damage

**TRPV6** (Transient receptor potential cation channels) mediate calcium movement in cells

**Xenobiotics** Are chemical substances that include plant constituents, drugs, pesticides, cosmetics, flavorings, fragrances, food additives, industrial chemicals, and environmental pollutants, i.e., not endogenous to animal organisms

**Xerophthalmia** Is an abnormal dryness and inflammation of the conjunctiva and cornea of the eye, most often associated with vitamin A deficiency

## Introduction

Relationships linking food components to health were first described in texts from Greek philosophers in the fourth and fifth centuries BC, the Egyptian medical text, the *Papyrus Ebers* (written 1550–1570 BC), and the *Qianjin Fang*. The *Qianjin Fang* (Precious Prescriptions for Emergencies) was edited by the Chinese physician Sun Simiao in 652 BC and is thought to be the first nutrition-related guide used in traditional Chinese medicine. It comprises 30 volumes and addresses more than 200 topics, many of which are related to diet and nutrition. An example taken from the *Papyrus Ebers* suggests that liver consumption is a treatment to improve vision, including night blindness.

By the mid-1700s, a large number of documents focused on the treatment of specific diseases. Perhaps the best known is Dr. James Lynn's treatise (*Treatise on the Scurvy*), noting that fresh fruits and vegetables seemed effective in treating scurvy. In the late 1800s, relationships associated with the consumption of monotonous diets became appreciated, i.e., diets based on a limited selection of similar ingredients. For example, the occurrence of pellagra was associated with consuming diets based almost exclusively on corn (niacin deficiency), and the occurrence of polyneuritis was related to consumption of polished rice (Beriberi, thiamin deficiency).

By the 1920s, considerable information regarding potential micronutrient deficiencies was known, developed concurrently with the isolation of so-called underlying curative factors. However, structural elucidation methods and the ability to thoroughly assess functional mechanisms were not as available. Thus, early progress was largely inferential. For example, in an autobiographical article (Szent-Gyorgyi, 1963), Albert Szent-Gyorgyi, who in 1937 was the Nobel Prize recipient for his work in part related to vitamin C, describes attempts to publish features of a new 6-carbon sugar with strong reducing potential. The crystalline form of the new sugar was obtained from oranges, lemons, cabbage, and adrenal glands. Because he did not have good structural information, he first called the unknown carbohydrate "ignose." When the *Biochemical Journal* rejected this name, he humorously suggested naming it "godnose," as in "only God knows." Eventually, the "new 6-carbon sugar" became designated as factor C and eventually vitamin C. Table 1 summarizes specific functions of the 13 established vitamins starting with the first to be recognized, fat-soluble factor A (in 1913) to the last, vitamin B12 (isolated in 1947).

From the 1950s, the search for additional vitamin and vitamin-like factors continued, along with studies focused on a better understanding of vitamin requirements and mechanisms. In the 1980s, many of the current platforms for structural and mechanistic determinations became routinely available (e.g., computing applications, high-resolution spectroscopic methods, nuclear magnetic resonance, X-ray diffraction methodologies).

## General principles

When serving as biocatalysts, vitamins facilitate transition states that lower the activation energy of given reactions. Biocatalysts increase reaction rates or enable reactions at lower temperatures. They also affect the reaction environment or bind substrates to change physical and chemical properties, making them more susceptible to chemical alteration. Moreover, biocatalysts facilitate the coupling of the spontaneous processes of catabolism to the less spontaneous processes of anabolism. Another essential function is the transfer of specific functional groups from which substances are produced, maintained, or destroyed, and energy is made available to produce heat or work. Such transfer reactions range from redox reactions to chemically complex bond formation and cleavage steps that result in the transfer of functional groups and changes in cellular energy or chemical potentials. In addition, it is now clear that vitamins and vitamin-like compounds influence many processes essential to cell signaling or gene regulation.

### Physiology: perspectives on the digestion, absorption, transport, and the metabolism of vitamins

#### Digestion and absorption

The following provides perspectives critical to understanding key features pertinent to the cellular, organ, or whole-body regulation of vitamins. The body handles the digestion of food-based vitamins and cofactors through specific and nonspecific pathways similar to other exogenous compounds (xenobiotics) undergoing absorption, digestion, metabolism, and excretion processes.

The fat-soluble vitamins (A, D, E, and K) are absorbed from the intestinal lumen by mechanisms similar to those used to absorb other dietary lipids. In the small intestine, lipid substances are first incorporated into luminal lipid-derived micelles containing bile acids. Such lipid micelles initially form as large fat droplets rich in dietary triglycerides and other lipids esters and ethers. However, lipases secreted from the pancreas and intestinal cells along with bile acids facilitate the formation of amphipathic micelles. Micelles are colloidal, i.e., heterogeneous mixtures of dispersed particles smaller than lipid enriched suspensions (e.g., 4–8 nm in diameter). Accordingly, micelles have a high probability of contact with small intestinal enterocytes capable of absorbing lipids. The lipids enter such enterocytes primarily by facilitated diffusion processes. Overall, the process is very efficient for dietary lipids; for example, over 90% of dietary triglycerides are absorbed via small intestinal enterocytes. For most fat-soluble vitamins, 40–80% are absorbed when sufficient dietary lipid is present. Next, within the enterocyte, lipid components of the micelle, including fat-soluble vitamins, are further processed, and eventually incorporated into chylomicrons and exported via exocytosis into the lymphatic system and the bloodstream. As it relates to the nutritional status of each of the fat-soluble vitamins, intestinal, biliary, and pancreatic diseases that cause decreased dietary lipid absorption may also cause a decrease in the absorption of fat-soluble vitamins and result in compromised vitamin status.

Analogous to the strategies for fat-soluble vitamins, a strategic step in enhancing water-soluble vitamin bioavailability is solubilization. Water-soluble vitamins exist in foods in their various cofactor, coenzyme, and co-substrate forms. Accordingly, the first step in their liberation by gastrointestinal enzymes (proteinases, hydrolases, phosphatases, nucleosidases, etc.) followed their association with specific carriers to increase solubility or protect from deleterious factors in the intestinal luminal environment.

**Table 1** Vitamins – active forms, primary functions, and requirements.

Xerophthalmia (nutrition-related night blindness, nyctalopia); impaired reproductive, neonatal growth development.
<b>Vitamin D</b> (D <sub>2</sub> -ergocalciferol and D <sub>3</sub> -cholecalciferol) <b>7-dehydrocholesterol:</b> 7-DC + UV light → D <sub>2</sub> (plants) or D <sub>3</sub> (animals)	<b>M &amp; W:</b> 15–20 μg (~600–800 IU) <b>UL:</b> 100 μg (4000 IU)	1α,25-diOH-vitamin D <sub>2</sub> or 1α,25-diOH-vitamin D <sub>3</sub> .	Bone mineralization; CA and P homeostasis; non-skeletal effects: immune, endocrine (e.g., insulin regulation); cardiovascular and neurotrophic functions.	Transcriptional activation through vitamin D receptor (VDR) and retinoid X receptor interactions; regulation of cell proliferation and differentiation.	Osteomalacia, rickets
<b>Vitamin E</b> (tocopherols, includes 8 isoforms: α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol).	<b>M &amp; W:</b> 15 mg (~22 IU) <b>UL:</b> 100 mg (1500 IU)	α-tocopherol is considered the most active ROS scavenger and γ-tocopherol is the best scavenger of peroxy radicals and reactive nitrogen species.	ROS scavenging; alterations in the activities of protein kinases, phospholipases, cyclooxygenases, various phosphatases; γ-tocopherol is capable of trapping electrophilic mutagens.	To a varying degree, tocopherol isomers act as antioxidants. In addition, the unsubstituted C-5 position of γ-tocopherol can also trap lipophilic electrophiles such as reactive nitrogen oxide species.	Increased potential for nerve and muscle damage; a weakened immune system; hemolytic anemias
<b>Vitamin K</b> (K <sub>1</sub> -Phylloquinone and K <sub>2</sub> -menaquinone).	<b>M:</b> 120 μg <b>W:</b> 90 μg <b>UL:</b> NA	Both K <sub>1</sub> and K <sub>2</sub> can act as vitamin K-dependent carboxylases.	Vitamin K serves as a cofactor for the γ-glutamyl carboxylases involved in activating six clotting factors involved in the control of coagulation. In addition, vitamin K is also a cofactor for the matrix Gla-proteins and osteocalcin essential in the regulation of matrix and bone calcification.	As a cofactor for γ-glutamyl carboxylases, the mechanism involves first the generation of a strong base by oxygenation of vitamin K. Vitamin K is converted to vitamin K epoxide, the intermediate of which is a highly basic alkoxide. This intermediate is thought to abstract hydrogen from targeted glutamyl γ-carbons to facilitate CO <sub>2</sub> addition to form glutamyl residues.	Vitamin K—dependent hemorrhagic disease.
<i>Water-soluble vitamins</i>					
<i>Vitamin (other designations) and precursors</i>	<i>Adult daily maintenance requirements</i>	<i>Active forms cofactor, co-substrate, co-enzyme forms</i>	<i>Physiological functions</i>	<i>Biochemical functions</i>	<i>Associated deficiency disease</i>
<b>Ascorbic acid</b> (Vitamin C)	<b>F:</b> 75 mg <b>M:</b> 90 mg <b>UL:</b> 2000 mg	Ascorbic acid	Ascorbic acid acts as an antioxidant and as a cofactor/co-substrate for hydroxylases essential for growth, wound healing, and collagen formation.	Ascorbic acid is an electron donor for hydroxylase enzymes. Ascorbic acid functions to maintain iron in the Fe <sup>2+</sup> state to facilitate its interaction with O <sub>2</sub> . Peptidylglycine α-amidating monooxygenase (PGAMox) also requires ascorbate. PGAMox amidates peptide hormones to increase stability and activity. At a chemical level, ascorbate maintains vitamin E in a reduced state and contributes to glutathione reduction-related pathways.	Scurvy

<i>Vitamin (other designations) and precursors</i>	<i>Adult daily maintenance requirements</i>	<i>Active forms cofactor, co-substrate, co-enzyme forms</i>	<i>Physiological functions</i>	<i>Biochemical functions</i>	<i>Associated deficiency disease</i>
<b>Niacin</b> (nicotinamide, nicotinic acid, vitamin B <sub>3</sub> , nicotinamide riboside) <b>Tryptophan:</b> Tryptophane → → → NAD → → → nicotinamide	<b>M:</b> 16 mg <b>W:</b> 14 mg <b>UL:</b> 35 mg	Niacinamide is a component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) and their derivatives.	Niacin via NAD, NADP, or their derivatives aids in converting carbohydrates into glucose and the metabolism of fats and proteins. Deficiency signs result in thick, light-sensitive scaly pigmented skin lesions, diarrhea, fatigue, depression, disorientation, memory loss.	Nicotinamide adenine dinucleotide (NAD <sup>+</sup> ) is essential to ATP generation. In addition, NAD serves as a substrate for mono and poly (ADP-ribose) polymerase pathways necessary for DNA repair. NAD <sup>+</sup> serves as a substrate for sirtuin-related reactions. NAD <sup>+</sup> /NADH catalyzes two-electron transfers. First, a hydride is transferred from a substrate to NAD <sup>+</sup> , with the electrons flowing to the positively charged nitrogen of NAD <sup>+</sup> .	Pellagra
<b>Riboflavin</b> (Vitamin B <sub>2</sub> )	<b>M:</b> 1.3 mg <b>W:</b> 1.1 mg <b>UL:</b> Not known	Riboflavin is a component of flavin mononucleotide (FMN, or riboflavin-5'-phosphate) and flavin adenine dinucleotide (FAD).	Important to neonatal growth and development, the function of redox-respiratory enzymes, and maintenance of epithelial tissues, reproduction	One-electron and one proton transfers in redox reactions	Ariboflavinosis
<b>Pantothenic acid</b> (Vitamin B <sub>5</sub> )	<b>AI:</b> 5 mg	Pantothenic acid is a component of coenzyme A (CoASH) and acyl carrier protein (ACP).	CoASH is essential in numerous oxidative and biosynthetic reactions in intermediary metabolism. ACP is a part of the fatty acid biosynthesis cycle.	Thioesters are obligatory intermediates in key processes in which ATP is used or regenerated. Thioesters are involved in the synthesis of all esters, including those found in complex lipids. Thioesters often act as "high-energy" components for their associated reactions.	Pantothenic acid deficiency. A nutritional deficiency is rare. When observed, it is likely the result of a CoASH-related polymorphisms.
<b>Pyridoxine</b> (Vitamin B <sub>6</sub> )	<b>M:</b> 1.3–1.7 mg <b>W:</b> 1.3–1.5 mg <b>UL:</b> 100 mg	Pyridoxal 5' phosphate (PLP) and pyridoxamine 5' phosphate (PMP).	Pyridoxal 5'-phosphate is a coenzyme used in more than 140 enzyme reactions essential in amino acid, glucose, and lipid metabolism. PLP also aids in the synthesis of hemoglobin as a coenzyme for aminolevulinic acid synthase.	PLP catalyzes transaminase reactions and is a required coenzyme for glycogen phosphorylase (GP). Transamination occurs in two steps: (1) the transfer of an amino group to PLP to form pyridoxamine phosphate (PMP) and (2) oxidative deamination of PMP and amination of the keto-acid. For GP (catalyzes the sequential phosphorylase of glycogen to release glucose-1-phosphate), the phosphate group of PLP acts as an acid catalyst for the reaction. In addition to essential roles in carbohydrate, protein, and amino acid metabolism, PLP is an essential cofactor for the biosynthesis of sphingolipids.	Vitamin B6 deficiency

<i>Water- soluble vitamins</i>					
<b><i>Vitamin (other designations) and precursors</i></b>	<b><i>Adult daily maintenance requirements</i></b>	<b><i>Active forms</i></b> <i>cofactor, co-substrate, co-enzyme forms</i>	<b><i>Physiological functions</i></b>	<b><i>Biochemical functions</i></b>	<b><i>Associated deficiency disease</i></b>
<b>Biotin</b> (Vitamin H or B7)	<b>AI:</b> ~30 µg	Peptidyl biocytin	Biotin acts as a cofactor for biotin-dependent carboxylases that play critical roles in the intermediate metabolism of gluconeogenesis, fatty acid synthesis, and amino acid catabolism.	Biotin catalyzes the transfer of CO <sub>2</sub> groups to various target macromolecules. Biotin comprises a ureido ring, a tetrahydrothiophene ring, and a valeric acid side chain. It is the ureido ring that functions as the CO <sub>2</sub> carrier. The overall reaction of biotin consists of two steps. In the first step, carboxy-phosphate is generated from bicarbonate with MgATP as an energy source. In the second step, carboxy-biotin results from the nucleophilic attack of the carboxy-phosphate intermediate's carboxyl group. The enzyme-biotin CO <sub>2</sub> is then transferred to an appropriate receptor.	Biotinidase deficiency, a rare inherited disorder, is the most common cause of biotin deficiency. Biotinidase catalyzes the conversion of biocytin to biotin.
<b>Folic acid, Folacin</b> (Vitamin M. Pteroylglutamic acid; Vitamin B9)	<b>M&amp;W:</b> 400 µg <b>UL:</b> 1000 µg	Folic acid is a collective term for pteroylglutamic acids and its oligo-glutamic acid conjugates.	Reduced folic acid (THFA) catalyzes one-carbon transfer reactions essential in amino acid metabolism and in purine and pyrimidine modifications critical to DNA and RNA production. Folate derivatives participate inosine phosphate biosynthesis. Methyl-THFA catalyzes vitamin B12 to methyl-B12 via the methionine cycle and regulates the methylation of homocysteine to methionine. THFA is also essential for S-adenosylmethionine generation.	THFA serves as a one-carbon carrier bound at positions N5, N10, or both on the folate pteridine ring. The one-carbon units come from ser, gly, his, or trp. The one-carbon units can exist in one of three oxidation states, equivalent to methanol, formaldehyde, or formate. The folate pteridine ring is also capable of redox reactions. For example, in thymidylate synthase, the folate pteridine ring undergoes a two-electron oxidation. Reduction is required to recycle dihydrofolate back to THF.	Macrocytic-megaloblastic anemia. Folate—related reproductive failure

<i>Water- soluble vitamins</i>					
<i>Vitamin (other designations) and precursors</i>	<i>Adult daily maintenance requirements</i>	<i>Active forms cofactor, co-substrate, co-enzyme forms</i>	<i>Physiological functions</i>	<i>Biochemical functions</i>	<i>Associated deficiency disease</i>
<b>Cobalamin</b> (Vitamin B12)	<b>M&amp;W:</b> 2.5 µg <b>UL:</b> Not established	Methylcobalamin and 5-deoxyadenosylcobalamin; Hydroxycobalamin and cyanocobalamin become active after conversion to methylcobalamin or 5-deoxyadenosylcobalamin.	Enzymes that require B12 are methyltransferases (use methylcobalamin as the cofactor) and isomerases (use deoxyadenosylcobalamin as the cofactor). Methylmalonyl coenzyme A mutase (MUT) is an isomerase that aids in the conversion of L-methylmalonyl-CoA to succinyl-CoA. Methylmalonyl-CoA results from the metabolism of odd-chain fatty acids or cholesterol sidechains. MUT is also necessary for myelin synthesis and the catabolic degradation of isoleucine, methionine, threonine, and valine.	The cobalt center in the corrin ring of cobalamin can catalyze both one- and two-electron reductive processes. The ability to shuttle between the +1, +2, and +3 oxidation states is responsible for the versatile chemistry of vitamin B12. Such versatility allows cobalamin to serve as an electron donor for the deoxyadenosyl radical form of the vitamin. Four of the six coordination sites are provided by the corrin ring and a fifth by adimethyl-benzimidazole group. The remaining coordination site allows for additions, such as a cyano group (utilized for commercial forms of the vitamin), a hydroxyl group, a methyl group, or the 5'-deoxyadenosyl group. Cyanocobalamin and hydroxocobalamin are converted to bioactive forms by enzymatically replacing the cyano or hydroxyl groups. The cobaltic ion is a strong Lewis acid. Vitamin B12 reactions resemble Grignard reactions. The reactions proceed through carbanion intermediates stabilized by the cobaltic ion.	Cobalamin deficiency; hypo-cobalaminemia, B <sub>12</sub> deficiency anemia

Moreover, each water-soluble vitamin uses specific carriers associated with enterocytes for their initial absorption. Sodium-dependent multivitamin transporters have been identified (Said, 2013). Water-soluble vitamins, such as folic acid, vitamin B12, riboflavin, biotin, pantothenic acid, and thiamin, utilize specific transport systems (Fig. 1). From a disease or nutritional status perspective, it is important to know regions of the intestine in which a given set of vitamin carriers resides, along with biochemical and physiological features of given receptors. Regional inflammation in the intestine may promote specific vitamin deficiencies. For example, B12 receptors are found in the ileum and are compromised by Crohn's disease, which affects the ileal region. Excessive alcohol exposure is also associated with perturbations in thiamin and folic acid status. Alcohol exposure promotes lesions in the jejunum and upper ileal regions, primary sites for thiamin and folic acid absorption.

Concerning the biochemical and physiological features of given receptors, transport efficiencies may also vary due to polymorphisms or the presence of vitamin antagonists that reduce transport efficiencies. Moreover, it is now appreciated that the microbiome can be an important source of indispensable vitamins. Recent studies demonstrate that microbiota-generated water-soluble vitamins are of nutritional value and their uptake by the colon is by receptor-related mechanisms. Although the microbiota was considered insignificant because of the belief that microbiota absorptive epithelia could not carry out effective vitamin transport, it is now appreciated that human colonocytes engage in carrier-mediated transport for many, if not all, of the water-soluble vitamins.

### **Whole-body, organ, and cellular transport**

A typical strategy for delivering fat-soluble vitamins to targeted organs and cells is transport by lymphatic chylomicrons. The lipid bilayer structure allows uncharged hydrophobic molecules, such as lipids, to pass through cell membranes by diffusion driven by differences in the concentration gradient. In addition, it is now apparent that for specific lipids, such as cholesterol and fat-soluble vitamins, various transport systems are involved. For example, cholesterol membrane transporters (e.g., scavenger receptor class B

**Fig. 1** Water-soluble vitamin absorption. Vitamins are first released from associated proteins, peptides, and cofactor-related moieties by the action of intestinal and pancreatic enzymes. Vitamin absorption occurs when sufficiently solubilized to interact with specific enterocyte carriers and transporters. In addition, a facilitated mechanism mediates the transport of dehydroascorbic acid via glucose transporters. Other water-soluble vitamins utilize specific receptors and transporters. Abbreviations: SVCT1 (sodium-ascorbate co-transporters); RFVT3 (riboflavin transporters, e.g., RFVT/SLC52A); SMCT1 (sodium-coupled monocarboxylate transporter 1); SMVTs (sodium dependent multivitamin transporter); ABC (ATP-binding cassette transporters); PCFT (proton-coupled folate transporter); RFC (reduced-folate transporter); THTR1 and 2 (high-affinity/low-capacity thiamine transporters); R-TCCbl (Transcobalamin Receptor).

type I) and members of the ATP-binding cassette transporter family (e.g., ABCA1 and ABCG1) are involved in vitamin E and K transport. Next, cells accumulate lipid substances and package them into small lipid droplets. A current view is such lipid droplets within lipid-processing cells have multiple cellular functions, such as distributing lipids to various membrane-bound organelles within the cell for further processing.

The transport of water-soluble vitamins in blood to the liver and other organs can involve albumin or globular fractions due to nonspecific ionic or hydrophobic interactions. Entry onto cells, however, requires specific cellular membrane transporters. Without membrane transporters, polar substances do not diffuse efficiently across cell membranes. The liver is a principal organ responsible for converting vitamins to active forms. The complexity of the process is illustrated in Fig. 2, depicting the relationships between tryptophan and niacin and their conversion to niacin's various cofactor and co-substrate-related derivatives.

Moreover, once activated, each of the water-soluble vitamins is used directly or shuttled to highly regulated pathways that exist for transport to other cells or subsequent modifications to facilitate disposal or turnover. Much of the cellular vitamin-derived cofactor pool is also bound to transporters designed for cellular efflux and eventual delivery to other cells. For the fat-soluble vitamins, liver-derived lipoprotein particles might be used (e.g., for carotenoid pigments and retinyl esters) or specific protein carriers (e.g.,  $\alpha$ -tocopherol transfer protein). In addition, if sufficiently polar (e.g., retinoic acid derivatives), more direct transfer into blood may occur.

### Turnover

All processes related to the whole body and cellular vitamin turnover occur with a high degree of metabolic control. When vitamins are in excess, they are either excreted or sequestered and compartmentalized to protect cells from toxicities associated with nonspecific reactions. Excess water-soluble vitamins are excreted usually in urine, either in their cofactor forms or as derived metabolites. Their rates of excretion often reflect intake. Although recycling via enterohepatic circulation may occur, fat-soluble vitamins and vitamin B12 are excreted in bile into the intestine.

### Vitamin requirements

As catalysts and signaling molecules for energy-related processes, the dietary requirements for most vitamins are related to energy needs and metabolic rate. Consequently, vitamin requirements are similar in most animals when expressed relative to metabolic body size or per unit of food energy consumed. A common denominator for many aspects of biological research is that diet

**Fig. 2** Niacin metabolism. Niacin is derived from dietary sources and the cellular catabolism of tryptophan. As nicotinamide, niacin is the catalytic moiety for nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which serve in multiple cellular functions. In addition, oxidized NAD (NAD<sup>+</sup>) is utilized as a co-substrate in polyriboylation and sirtuin-related protein deacetylase reactions. Both types of reactions are important in regulating a range of cellular functions. Moreover, NAD<sup>+</sup> can be converted to cyclic ADP ribose (cADPR) or adenosine diphosphate ribose (ADPR). ADPR and cADPR also act as cellular signaling molecules.

composition and nutrition needs are similar even for dissimilar species. For example, animals have evolved using many of the same genetic strategies. Mice and humans each have about 30,000 genes, yet only about one in a hundred are unique to either organism. As a result, animals have similar vitamin requirements when expressed relative to the food energy consumed.

Moreover, the magnitude of such requirements may be estimated based on metabolic size or the resting or basal metabolic rate for given species using concepts that evolved from the early work of Kleiber and others (Kleiber, 1961; Rucker and Steinberg, 2002). Kleiber's law, now considered one of the few quantitative laws in biology, states that an animal's basal metabolic rate scales to the  $3/4$  power of the animal's mass. Simply stated, the relationship can be indicated as  $q_0 \sim kM^{3/4}$ , where  $q_0$  represents the animal's resting or basal metabolic rate,  $M$ , the animal's mass in Kg, and  $k$ , a constant if needed. It is a concept that has been validated in numerous empirical and theoretical studies.

Given that vitamin requirements are energy-related and universal, an appreciation for biological quarter-power relationships opens the door to a broader range of information translatable to human health and a better understanding of nutritional risks. For example, as it relates to nutritional requirements, one may ask - how is it possible to extrapolate from a mouse of  $\sim 30$  g to a human with a mass of  $\sim 70$  Kg. A comparison or extrapolation based directly on body mass suggests that human requirements may be 2300-fold greater than those for mice. The use of Kleiber's law, however, indicates estimations of basal metabolic requirements only differ by  $\sim 350$ -fold metabolic body size (e.g.,  $q_{\text{Human}} \sim k(70 \text{ Kg})^{3/4}$  compared to  $q_{\text{Mouse}} \sim k(0.03 \text{ Kg})^{3/4}$ ). This ratio is similar to empirical values for basal metabolism or resting energy expenditure (REE). For example, a small adult mouse's daily REE is  $\sim 3.5$ – $4.5$  Kcals (14–18 KJs). For a 70 Kg human, the values for REE are  $\sim 1400$  Kcals (women) to  $\sim 1600$  (men) Kcals or 5600–6400 KJs per day. The division of a  $\text{REE}_{\text{Human}}$  of  $6000 \pm 400$  KJ by  $16 \pm 2$  KJs is also  $\sim 350$ -fold.

The same relationships also hold for drug and toxicological assessments. For example, if a substance causes harm in a 30-g mouse at 1 mg/kg of body weight, one cannot assume that harm in a human may require 2000 times or greater that amount. Instead, concerns for humans are more likely to be encountered at dosages of 350 mg, approximately seven times less than those estimated on a per Kg body weight basis. As a final point, the Kleiber relationships also have applications for nutrients that can be synthesized in some animals but are essential to others (Rucker and Steinberg, 2002). For example, in animals that produce ascorbic acid, the daily rates for its production are about the same in mice and rats as the daily dietary ascorbic acid requirements for animals that cannot produce it, such as humans and guinea pigs (Rucker and Steinberg, 2002).

The factors most important in dictating the relative need for specific vitamins include:

- Chemical stability.
- The number and types of catalytic events involving the vitamin.
- Its interactions with associated enzymes or regulatory proteins.
- The presence or absence of pathways for its synthesis.

In this regard, vitamins required daily in millimolar amounts are usually less chemically stable, function in oxidative environments, or are involved in numerous reactions. In addition, such vitamins often exist in tissues as dissociable cofactors. In contrast, vitamins required daily in micromolar amounts are usually engaged in fewer reactions. They are also more likely to be bonded covalently to the proteins they serve as cofactors or signaling molecules. Moreover, if their function is cell signaling, as few as 1000 molecules or less may initiate an event (Rucker and Steinberg, 2002).

Primary deficiencies often occur when monotonous diets or limited combinations of foods are consumed. Examples include:

- Vitamin C deficiency (Scurvy) is due to a diet absent of fruits and certain vegetables.
- Thiamin deficiency (Beriberi) is due to diets based mainly on polished or refined rice.
- Niacin deficiency (Pellagra) is due to the consumption of a corn-based diet with low levels of niacin and tryptophan, the cellular precursor for the niacin (cf., Niacin).

Vitamin deficiencies can also arise through various mechanisms, including compromised stability due to unfavorable chemical conditions (pH, heat, presence of oxidants), poor availability or bioavailability, interactions with other competing substances, and genetic influences (e.g., polymorphisms). For example, thiamin is one most unstable of the B vitamins. Baking, pasteurization, or boiling food can reduce the thiamin content by 50%. Vitamin C is also temperature-sensitive and easily degraded during cooking.

Polymorphisms of genes for proteins involved in vitamin absorption and metabolism can also influence requirements (He et al., 2017). A polymorphism is the occurrence of two or more different morphs or forms of a gene (i.e., alternative phenotypes that allow two or more possibilities of a genetic trait). Genetic polymorphisms can affect the metabolism of vitamins (e.g., transport, conversion to active forms, turnover), which in turn may affect the expression of genes or activity of proteins that require the vitamin. Knowledge of specific polymorphisms may often explain why some individuals have different vitamin requirements. Some typical examples are offered in the next section.

Lastly, there are physiological factors and competitive interactions that influence requirements. Among these are potentially higher needs during growth, pregnancy, and lactation. In addition, inflammation and fever associated with various disease states can impact global metabolism and the need for given vitamins. Vitamin absorption may also be compromised with aging. For example, Vitamin B12 deficiency is more common among the elderly because of a higher prevalence of atrophic gastritis. Atrophic gastritis is an autoimmune disorder, which, if severe, can destroy stomach parietal cells, which produce factors essential to the absorption of vitamin B12. Examples of competitive interactions include:

1. Warfarin (coumadin) interferes with vitamin K regeneration.
2. Phenothiazines (e.g., chlorpromazine) interfere with riboflavin absorption and renal reabsorption.
3. Medications (e.g., colchicine, metformin, various antibiotics) may decrease the absorption of vitamin B12.
4. Methotrexate and sulfacetamide interfere with the absorption of folic acid and its cellular transport.

In addition, food preservatives, such as sulfites, can oxidatively destroy thiamin and ascorbic acid. In addition, plant thiamin antagonists, such as caffeic acid, chlorogenic acid, and tannic acid or agents that promote intestinal inflammation (e.g., alcohol), may interfere with thiamin absorption.

## Functions and mechanisms: fat-soluble vitamins

### Vitamin A

Vitamin A (retinol, retinal, and retinoic acid) is essential to vision, cell division, growth, reproduction, and immunity. Relationships between vitamin A and its dietary and metabolic precursors are shown in Fig. 3 (e.g.,  $\beta$ -carotenoids, tetraterpenoids produced from eight isoprene moieties). Carotenoids are yellow, orange, and red pigments found in plants, algae, bacteria, and fungi. In plants and algae, carotenoids absorb light and facilitate the transformation of light into chemical energy for photosynthesis. Carotenoids also serve as primary plant antioxidants under a severe excess of radiant energy and as chloroplast antioxidants in drought and heat stress.

Many of the biochemical mechanisms that serve as underpinnings for such processes are also used in animals, particularly mechanisms essential to vision, cell signaling, and antioxidant defense. The mechanisms in part involve the isomerization of isoprene moieties in response to light energy. The resulting conformational energy is then transferred to cell-related energy or regulatory processes.

One of the earliest symptoms of vitamin A deficiency is night blindness (nyctalopia, an inability to see well in poor light). Nyctalopia can occur when the retinal form of vitamin A is insufficient. Retinal is the photosensitive cofactor for the protein opsin. When retinal and opsin are combined, rhodopsin, the active holo-form, is produced. Rhodopsin (found in retinal rod cells) mediates the ability to sense light.

In tissues, including the eye, retinal is formed from the direct oxidation of retinol or  $\beta$ -carotene by the irreversible oxidative cleavage (e.g.,  $\beta$ -carotene +  $O_2 \rightarrow 2$  retinals). The latter is catalyzed by the action of ocular  $\beta$ -carotene 15,15'-monooxygenase or dioxygenase. In the eye, the active metabolite, 11-cis-retinal, is produced from retinol by the successive action of retinol isomerase and 11-cis-retinol dehydrogenase. 11-cis-retinal next combines with the protein opsin to form rhodopsin, the active visual pigment.

Terpenoids, such as 11-cis-retinal, interact with photons of light and isomerizes to all-trans-retinal. The resulting conformation change triggers a chemical signaling cascade linked to the eye's neural system. For example, upon absorption of a photon of light,

**Fig. 3** Vitamin A. Relationships between vitamin A and its dietary and metabolic precursors are illustrated. The active forms of retinol (retinal and retinoic acid) are formed from the direct oxidation of retinol or β-carotene by the irreversible oxidative cleavage (e.g., β-carotene + O<sub>2</sub> → 2 retinals). Vitamin A is sequestered in cells as retinyl esters. Because of differences in structure, carotenoids, such as α- or β-carotene, result in one molecule of retinal following oxidative cleavage.

the covalently bound 11-cis-retinal isomerizes to the all-trans form of retinal, which results in an apo-opsin/rhodopsin-related conformational energy. This conformational energy is transferred to ocular transducin, a guanine nucleotide-binding protein or G-protein (Fig. 4).

G-proteins act as molecular switches inside cells and regulate enzymes, ion channels, and transporter proteins. For example, activation of G-protein coupled pathways leads to hydrolysis of cGMP to GMP. The decrease in intracellular cGMP induces the closure of sodium and calcium channels, leading to hyperpolarization of the rod cells and a change in the neural transmission perceived as vision. Thus, the process allows the transformation of a physical event (photo perception) into a chemical event (ionic

**Fig. 4** Vitamin A and vision. Retinoids, such as 11-cis-retinal, interact with apo-opsins in the rod cell of the eye. 11-cis-retinal can capture photons of light, which results in its isomerization to all-trans-retinal. The resulting conformational change transforms apo-opsin into rhodopsin. Next, a chemical signaling cascade is initiated from the generated conformational energy. The cascade activates ocular transducin, a guanine nucleotide-binding protein or G-protein, which modulates ion channels to allow the signal to interact with the eye's neural network.

electrochemical transmission). Moreover, different retinal-opsin complexes, found predominately in the cones of the eye, can absorb photons of different wavelengths of light, allowing the perception of color.

Following photon activation, 11-cis retinal isomerizes to all-trans-retinal and is released from rhodopsin. The all-trans-retinal is immediately reduced to all-trans-retinol and transported back to the retinal pigment epithelium. Although complex, this process prevents inhibitions due to potentially reversible reactions; thus, it allows sensing light energy at high efficiency, even as low as a few photons of visible light.

Vitamin A deficiency also may result in dryness, conjunctivitis of the cornea, and a condition called xerophthalmia. Xerophthalmia is the primary cause of nutrition-related blindness globally, owing to the eye's sensitivity to vitamin A deficiency. For xerophthalmia, the form of vitamin A that is most important is retinoic acid and products derived from it. The following section describes the retinoic acid receptor (RAR) and retinoid X receptor (RXR) cell signaling. RAR/RXR signaling plays essential regulatory roles in inflammation, cell differentiation, and the immune system (Kiss et al., 2013).

The retinoic acid receptor (RAR) and retinoid X receptor (RXR) families belong to the large group of ligand-activated transcription factors (Fig. 5). Each has 3 isotypes designated RAR $\alpha$ , - $\beta$ , - $\gamma$  or NR1B1–3 and RXR $\alpha$ , - $\beta$ , - $\gamma$  or NR2B1–3. As a cell-signaling molecule, retinoic acid can affect transcription through its interactions with retinoic acid receptors. In their native states without retinoic acid, the RARs recruit corepressor proteins to promoter regions, which leads to inhibition of selected gene transcription (Kiss et al., 2013).

The action of RXR isoforms is complex. RXR can heterodimerize with RAR and other nuclear receptors (e.g., constitutive androstane, farnesoid X, liver X, peroxisome proliferator-activated, pregnane X, thyroxine, and vitamin D receptors). When an RXR heterodimerizes with one of the nuclear receptors, nuclear response elements specific for one of the associated nuclear receptors are the target. The heterodimer is active (promotes transcription) when the associated nuclear receptor is bound to its ligand. The binding of agonist ligands results in dissociation of or less interaction with corepressors that inhibit transcription. Concerning the RAR-RXR heterodimer, the RAR ligands are all-trans retinoic acid or 9-cis retinoic acid. The 9-cis retinoic acid, however, is more potent than all-trans retinoic acid and binds with higher affinity. Without all-trans retinoic acid or 9-cis retinoic acid, transcription is inhibited. Accordingly, changes in the 9-cis retinoic acid concentration can switch genes containing response elements specific for RAR-RXR from a transcriptionally silent state to an active state. More than 500 genes are regulated by RAR/RXR signaling; however, far less is directly activated via classical RAR response element pathways. There is also the issue of retinoid derivative turnover or affinity for given RARs. For example, all-trans derivatives of retinol turnover more rapidly than derivatives of 11-cis-retinol.

**Fig. 5** The retinoic acid receptor (RAR) and retinoid X receptor (RXR) transcription factors. The RXR can heterodimerize with RAR or other nuclear receptors (e.g., the vitamin D receptor). There is transcription when the nuclear receptor (e.g., RAR) is bound to its ligand (9-cis or all-trans retinoic acid) as a heterodimer.

RAR/RXR signaling becomes increasingly important in aging due in part to vitamin-related regulatory functions related to inflammation, immunity, and protection of the neural system. Based on studies in knockout mice, vitamin A-related developmental pathologies are compounded when more than one of the RAR genes is inactivated. Although few congenital structural disabilities have been reported due to vitamin A deficiency, RAR genes are nevertheless essential for organogenesis and early mammalian development. As a final comment, in addition to transcriptional regulation, RARs and RXRs have nongenomic functions. RARs interact with several protein kinases systems whose signaling cascades are initiated by receptors at the cell surface.

Acute hypervitaminosis A has been reported to cause congenital malformations in the central nervous system, heart, thymus, and craniofacial structures. For example, congenital disabilities have been found in babies born to mothers who have been exposed to isotretinoin, a synthetic 13-*cis*-retinoic acid compound prescribed for severe acne and other medical conditions. Noteworthy, hypervitaminosis A is linked more to animal sources than plant carotenoid enriched sources for food-derived vitamin A sources.

## Vitamin K

Vitamin K most often refers to one of two structures containing isoprene chains, phyloquinone (vitamin K<sub>1</sub>) and menaquinone (vitamin K<sub>2</sub>). Phyloquinone is abundant in green leafy vegetables, whereas menaquinone can be produced by bacteria or within animal tissues if there is a source of 1,4-naphthoquinone with a methyl group in the 2-position as a precursor. For example, menaquinone (vitamin K<sub>2</sub>) may be formed after alkylation of menadione with isoprene units derived from the cholesterol synthesis pathway. Although not used as a supplement for humans due to safety concerns, menadione is commonly used in poultry, pig feed, and commercial pet foods as a source of vitamin K.

Scheme 1

## Functions and mechanisms

Vitamin K serves as a cofactor for  $\gamma$ -carboxylases (designated vitamin K-dependent carboxylases) essential to coagulation, bone formation, and control of matrix calcification. Vitamin K-dependent carboxylases (4.1.1.90, peptidyl-glutamate 4-carboxylases) catalyze the addition of carboxyl groups to the Glu- or  $\gamma$ -glutamyl domains of given proteins. The mechanism involves the generation of a strong base by oxygenation of vitamin K. The carboxylase is a bifunctional enzyme that converts vitamin KH<sub>2</sub> to vitamin K epoxide. The intermediate in the process, a vitamin K alkoxide, is highly basic. This intermediate is thought to abstract hydrogen from targeted glutamyl  $\gamma$ -carbons to form glutamyl residues with carbanion at its  $\gamma$ -carbon. Carbanions are carbon atoms containing a negative charge. The negative charge provides nucleophilic properties that facilitate the formation of new carbon-carbon bonds. CO<sub>2</sub> has a positive or carbonium ion character. Consequently, CO<sub>2</sub> reacts easily with the  $\gamma$ -carbanion, which converts the original glutamyl residues to a  $\gamma$ -carboxyglutamyl residue. The reaction does not require ATP but utilizes the energy of vitamin KH<sub>2</sub> oxidation to perform the chemical work required in Gla synthesis.

Scheme 2

## Blood coagulation, osteocalcin, and Gla-matrix proteins

Vitamin K serves as a cofactor for the  $\gamma$ -glutamyl carboxylases involved in the activation of six clotting factors: prothrombin, also designated as factor II, factor VII, an extrinsic factor, factors IX and X in the intrinsic pathway and proteins C and S. Proteins C and S aid in preventing inadvertent blood clots and in the control of coagulation.

In each of the factors, there are N-terminal  $\gamma$ -glutamyl domains. Such domains engage in calcium-binding in a cooperative manner. The addition of calcium facilitates interaction with cellular phospholipid membranes at the injury site and activated platelets. For example, for calcium-bound prothrombin, the membrane-bound proteinase, prothrombinase, cleaves the calcium-enriched

N-terminal  $\gamma$ -glutamyl domain to yield thrombin as an active proteinase. Thrombin, in turn, serves as the proteinase catalyzing the cleavage of fibrinogen to fibrin, a near-terminal step in the coagulation cascade.

Vitamin K is also a cofactor for the so-called matrix Gla-proteins and osteocalcin, both members of another family of vitamin K<sub>2</sub>-dependent, Gla-containing proteins. The matrix Gla-proteins have a high binding affinity for calcium and can inhibit or control the mineralization in various extracellular matrices (e.g., the matrix of blood vessels).

In bone, matrix Gla-proteins and osteocalcin work together. Moreover, it is noteworthy that although osteocalcin is secreted by osteoblasts and concentrates in bone, it is now recognized as an endocrine-like peptide hormone with multiple functions. These functions extend beyond the control of bone mineral formation in the skeletal system and include glucose homeostasis, exercise capacity, and brain development.

### Vitamin K antagonists

Diet-related hemorrhagic disease was first described 100 years ago. Cattle in the Northern USA and Canada were afflicted by unusual, sometimes fatal, bleeding that resulted from minor injuries. Moldy silage made from clover was often implicated. Over the next 20 years, the active agent in clover was identified as coumadin. Coumadin (also marketed as Warfarin) inhibits the action of blood clotting factors by inhibiting the quinone and epoxide reductases essential in the regeneration of reduced vitamin K. The net result is a failure of  $\gamma$ -carboxylation of the Gla-domain-containing coagulation factors.

### Vitamin E

Vitamin E comprises a chromanol ring with a phytyl sidechain located at the C2 position of the chromanol ring (Fig. 6). Vitamin E, as a designation, is a group of eight compounds that include four tocopherols and four tocotrienols. Vitamin E is now accepted as a free radical scavenging antioxidant found primarily in cellular and cellular organelle membranes. The  $\alpha$ -tocopherol forms of vitamin E function within the glutathione peroxidase pathway and protect cell membranes from oxidation by reacting with lipid radicals produced in lipid peroxidation chain reactions. The oxidized tocopheroxyl products that result are recycled back to their reduced forms through reduction by other antioxidants, such as ascorbate and ubiquinol, the reduced form of CoQ10.

Vitamin E also influences cell signaling. Reactive oxygen species are known to trigger various cell signaling pathways (Lushchak, 2014). Different analogs of vitamin E can induce other cellular events, suggesting that vitamin E's impact goes beyond reactive oxygen scavenging. Some examples of enzymes identified as being modulated by Vitamin E status include the activities of protein kinase B, protein kinase C, protein tyrosine kinases, phospholipases, cyclooxygenases, and various phosphatases. Whether insufficient Vitamin E leads to imbalanced oxidative states that activate ROS-sensitive genes or alter interactions of cellular enzymes that control cell signaling and other independent strategies needs clarification.

All forms of vitamin E can act as ROS scavengers (Fig. 6). The different forms of vitamin E, however, have differing antioxidant potentials. The degree of methylation of the chromanol ring of  $\alpha$ -tocopherol influences chromanol resonance and the location and stabilization of radical derivatives. Note that the chromanol rings of  $\beta$ - and  $\gamma$ -tocopherols contain two methyl groups;  $\delta$ -tocopherol chromanol is methylated in only one position.

Tocopherols and tocotrienols quench electrons by donating a hydrogen ion from their chromanol hydroxyl group. Other reductants (e.g., vitamin C) can subsequently replace the donated hydrogen ion on Vitamin E to restore vitamin E's antioxidant capacity. Because vitamin E regeneration is dependent on a sufficient balance of hydrophilic chemical reductants within cells, the transfers occur at the interface of cell membranes.

Although the need for ROS control for the optimal health of cells is apparent, its role in specific cellular signaling events remains unclear. Moreover, the  $\gamma$ -tocotrienols have anti-inflammatory properties superior to those of  $\alpha$ -tocopherol when examined in experimental models to assess inflammatory disease; also, tocotrienols have hydrophobic side chains with three carbon-carbon double

**Fig. 6** Vitamin E isomers. The isomeric forms of vitamin E (tocopherol). Tocopherols and tocotrienols quench electrons by donating a hydrogen ion from the chromanol phenolic group, which reacts with and resolves peroxy and alkoxyl radicals generated during lipid peroxidation.

bonds. This feature allows a more efficient penetration into tissue membranes than all-trans saturated phytyl chains. Furthermore, the presence of  $\gamma$ -tocotrienols in cells is associated with reduced cyclooxygenase- and 5-lipoxygenase catalysis of eicosanoids and suppression of NF- $\kappa$ B and STAT-related pro-inflammatory signaling. In addition, the  $\gamma$ -forms of vitamin E have functions in addition to acting as primarily H ion donors. For example,  $\gamma$ -tocopherol (the form not methylated at position 5) can act as a nucleophile capable of trapping electrophilic mutagens. This is important because nitric oxide (NO), an essential physiological regulator, is easily modified by rapid reaction with superoxide radical ( $O_2^{\cdot-}$ ) to yield peroxynitrite. Nitric oxide regulates the dilatation of blood vessels, raising the blood supply and lowering blood pressure. As a neurotransmitter, nitric oxide acts in the nitrergic neurons active on smooth muscle. In contrast, peroxynitrite acts as an oxidant and nitrating agent that can damage molecules, such as DNA and proteins (7).

**Scheme 3**

The importance of vitamin E's role as an antioxidant and to aspects of cell signaling is amplified by observations that for most animals, the apparent daily requirements for vitamin E are related to the amounts of polyunsaturated fatty acids in foods. One gram of diene-fatty-acid equivalents requires the intake of  $\sim 0.5$  mg *RRR*- $\alpha$ -TOH or its equivalent. The bioavailability of vitamin E is influenced by the amount of dietary lipid, medical conditions, such as Crohn's disease, and lipid-related genetic polymorphisms.

Regarding turnover, the initial step is  $\beta$ -oxidation of vitamin E's phytyl sidechain leading to the water-soluble end-product carboxyethyl-hydroxychroman (CEHC). CEHC is excreted in the urine; bile is another route of excretion. Fecal stools contain numerous vitamin E metabolites in various states of oxidation and phytyl chain-links. An essential protein in intracellular transport of Vitamin E is  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP). Patients with mutations in the  $\alpha$ -TTP gene may have low circulating vitamin E in blood and tissues due to an inability to transfer Vitamin E to lipoproteins. Moreover, many tissues (placenta, uterus, central nervous system) express  $\alpha$ -TTP.

## Vitamin D

Vitamin D is a secosteroid (a steroid with a "broken" B ring). The most important forms of vitamin D are vitamin D<sub>3</sub> (cholecalciferol) and vitamin D<sub>2</sub> (ergocalciferol). Each form differs only in its side chain structure. Both forms function as prohormones.

**Scheme 4**

Vitamin D<sub>3</sub> as cholecalciferol is found in foods, such as oily fish, red meat, liver, and egg yolks. It can also be synthesized in skin from 7-dehydrocholesterol, a reaction that requires exposure to UVB radiation. Vitamin D<sub>2</sub> is also found in fish oils and fungi such as mushrooms. Analogous to vitamin D<sub>3</sub>, mushrooms convert the vitamin D<sub>2</sub> precursor, ergosterol, into vitamin D<sub>2</sub> when exposed to UV light. Vitamin D<sub>3</sub> does not occur, however, in other plants.

As prohormones, the most active forms of vitamin D<sub>2</sub> or D<sub>3</sub> are their respective 1,25-hydroxy (1,25-OH-) derivatives (1,25-OH-D<sub>2</sub> or D<sub>3</sub>). Vitamin D<sub>2</sub> and D<sub>3</sub> are first converted to a 25-OH-derivative, mainly in the liver. Next, the kidney converts the 25-OH-derivative of cholecalciferol to 1,25-dihydroxycholecalciferol and 25-hydroxyergocalciferol to 1,25-hydroxyergocalciferol (Fig. 7).

Vitamin D controls calcium absorption, immune and neural functions, protecting bone and muscle, apoptotic events, and insulin regulation. The interaction between activated Vitamin D (either as 1,25-OH-D<sub>3</sub> or 1,25-OH-D<sub>2</sub>) and its receptors resemble steroid hormone signaling events. The vitamin D receptors (VDR) bind to specific vitamin D response elements (VDREs) to stimulate gene transcription of genes containing VDREs (cf., the previous section related to RAR/RXR signaling). Moreover, some VDREs have been located within introns or between genes, which indicates that there may be multiple ways in which vitamin D and VDR can influence transcription or regulate gene activity.

Regarding calcium absorption and transport, genes specific to these processes are activated by 1,25-OH-D to promote calcium absorption. Some examples of induced genes are transient receptor potential cation channel 6 (TRPV6) and transient receptor potential cation channel 5 (TRPV5). TRPV6 mediates calcium absorption from the intestinal lumen, whereas TRPV5 is involved in the reabsorption of calcium from the renal tubule back into the blood. For example, mutations in these receptors may cause

**Fig. 7** Precursor and active forms of vitamin D. The active forms of vitamin D act as a steroid hormone to control functions that range from calcium absorption to insulin regulation.

hypocalcemic rickets. Mutations in TRPV6 have been found in infants with transient neonatal hyperparathyroidism. In contrast, mutations that amplify TRPV6 expression are linked to increased kidney stone formation.

Moreover, many genes with VDREs have functions beyond calcium or skeletal metabolism. Some are important in immunity and are upregulated in response to infections. In addition, several of the gene products associated with immunity, such as protein tyrosine phosphatase nonreceptor type 22 (PTPN22) and the cluster of differentiation 226 (CD226), are implicated in autoimmune diseases such as Type 1 diabetes, Crohn's disease, systemic lupus erythematosus, and rheumatoid arthritis. Other genes associated with certain cancers (e.g., colorectal cancer and chronic lymphocytic leukemia) have VDREs and respond to vitamin D exposure. Indeed, the discovery of binding sites for activated VDR has spurred significant interest in identifying roles for Vitamin D beyond bone and calcium metabolism (Fig. 7).

Following absorption, the various forms of Vitamin D are transported to targeted sites utilizing a vitamin D binding protein (VDBP). In this regard, several autoimmune diseases (e.g., multiple sclerosis, rheumatoid arthritis, and systemic lupus erythematosus) are influenced by vitamin D deficiency or polymorphisms in proteins related to vitamin D transport. Vitamin D regulates the immunomodulation of macrophages, dendritic cells, T and B lymphocytes, all of which express vitamin D receptors. Polymorphisms and defects in VDBP and vitamin D receptors account for more than one-half of the vitamin D serum variance associated with the expression of autoimmune and skeletal-related disorders.

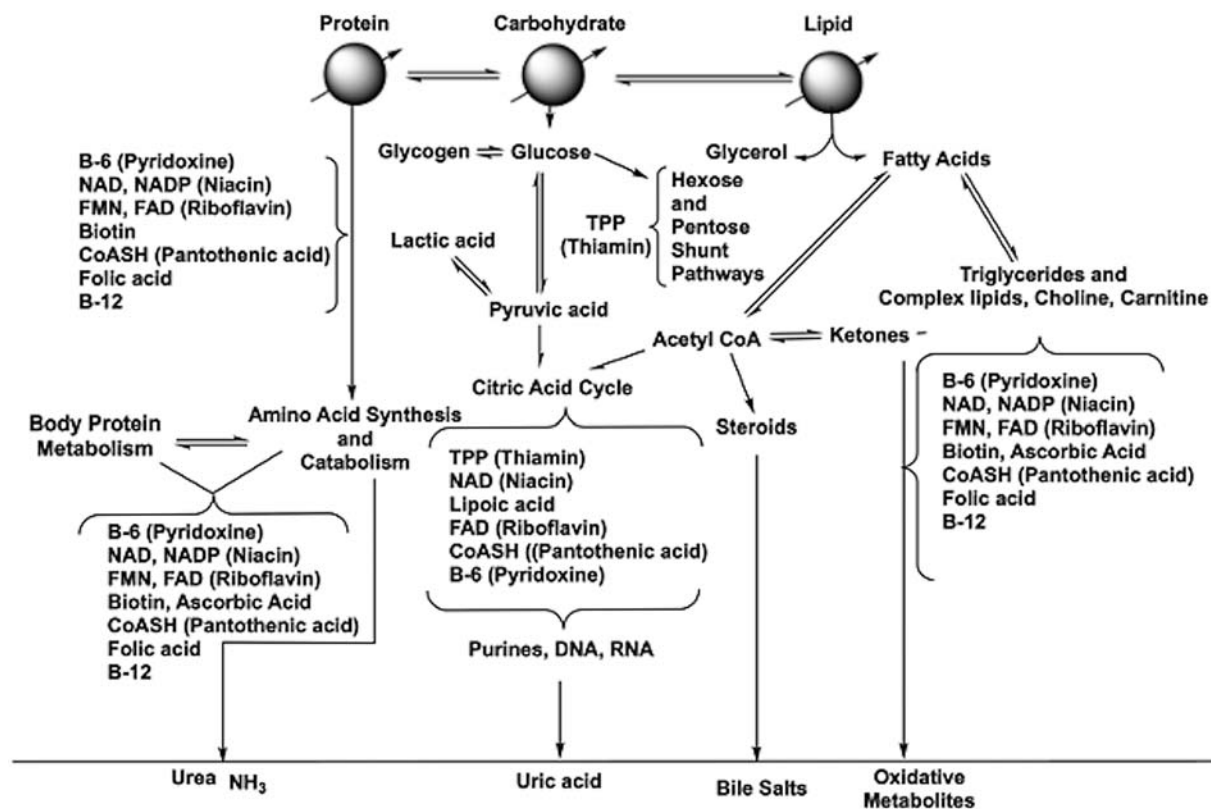

In cells, vitamin D is converted to its various hydroxylated forms by enzymes in the cytochromes P450 superfamily of monooxygenases (hydroxylases). These proteins oxidize steroids, fatty acids, and xenobiotics (e.g., hormone synthesis and disposal). In the liver, cytochrome P450 2R1 is the vitamin D 25-hydroxylase responsible for converting vitamin D to 25-OH-D in the liver, followed by 25-OH-D hydroxylation to 1,25-OH-D in the kidney. For humans, the half-life of 25-hydroxy-Vitamin D is 15–25 days, whereas the half-life of 1,25-hydroxy-Vitamin D is only about 15 h. Accordingly, for assessing vitamin D status, the measurement of 25-hydroxy-Vitamin D is normally used.

## Functions and mechanisms: water-soluble vitamins

### Cofactor, coenzyme, and cell signaling functions

Fig. 8 depicts processes in which water-soluble vitamins play essential roles as co-enzymes and cofactors. For example, ascorbic acid, riboflavin, and niacin serve primarily as redox cofactors, although niacin's functions extend to serving as substrates for compounds

**Fig. 8** Metabolic functions of water-soluble vitamins. The water-soluble vitamins in their active forms as cofactors, coenzymes, or cosubstrate are involved in all aspects of energy regulation and the metabolism and interconversions of the macronutrients protein, carbohydrates, and lipids.

important to cell-signaling and DNA repair. Thiamin, pyridoxine (vitamin B6), and pantothenic acid, as a component of coenzyme A, are distinguished because of their importance to carbohydrate and amino acid transport and acyl and acetyl transport. As cofactors, thiamin, pyridoxine, and coenzyme A facilitate the formation of good leaving groups in reactions that are often used in catabolic processes. Good leaving groups are relatively stable weak bases. As nucleophiles, in subsequent transfer steps, good leaving groups give up their pair of electrons to form bonds with molecules that have electrophilic character. Another type of transfer reaction involves those essential to the transfer of single carbons. Single or one-carbon (1C) transfers are found in a series of interlinking metabolic pathways, for which 1C units are generated for the synthetic processes (e.g., DNA, polyamines, amino acids, creatine, and phospholipid synthesis). Vitamins essential for the transfer of single carbons include biotin, folic acid, and vitamin B12 (cobalamin).

### Oxidation-reductions: ascorbic acid, riboflavin, and niacin

Redox or reduction-oxidation reactions describe chemical reactions in which atoms or intermediates have their oxidation states changed, although the actual transfer of electrons may not always be obvious, particularly those involving covalent bonds. Redox reactions utilize mechanisms that range from ion hydride transfers, radical hydrogen ion transfers, or one electron plus one proton transfers. As components of coenzymes, riboflavin (as flavin mononucleotide [FMN] and flavin adenine dinucleotide [FAD]), niacin (as nicotinamide adenine dinucleotide [NAD] and nicotinamide adenine dinucleotide phosphate [NADP]), and ascorbic acid have chemical features that make them ideal as intermediate carriers of electrons. Each also acts over a wide range of chemical potentials.

### Ascorbic acid

Ascorbic acid (vitamin C) is one of the most important redox cofactors in animal systems. Although most animals make sufficient ascorbic acid, for others, ascorbic acid is essential because the complete pathways for ascorbic acid synthesis are absent (e.g., higher primates, guinea pigs, bats, and some species of birds and fish).

### Functions

In mono- and dioxygenases, ascorbic acid maintains metals (specifically Fe and Cu) in their reduced states (Fig. 9, Table 1). Important reactions and processes that require ascorbic acid include: (1) norepinephrine synthesis by functioning in dopamine- $\beta$ -hydroxylase, (2) hormone activation by functioning in peptidyl glycine-amidating monooxygenase, (3) carnitine biosynthesis by serving as a cofactor for two of the hydroxylation steps in the pathway of carnitine biosynthesis. Ascorbic acid is also essential for

**Fig. 9** Hydrogen peroxide and Fenton-related reactions catalyzed by ascorbic acid. Ascorbic acid reacts with hydrogen peroxide and its derivatives resulting in dehydroascorbic acid. Although the response eventually can lead to ROS, the initial reaction with aqueous peroxy radicals retards their formation. Ascorbic acid also acts by restoring the antioxidant properties of fat-soluble vitamins, such as vitamin E and other antioxidants. Reduced iron and copper can serve as highly destructive Fenton catalysts. As a reductant, it can retard ROS formation; however, in the presence of iron and copper, ascorbic acid can promote their ability to act as a Fenton catalyst in the generation of ROS.

hydroxylations that optimize collagen, elastin, C1q complement, and acetylcholine esterase synthesis and function. The hydroxylations occur in two stages. First, a highly reactive high-valent iron-dioxygen complex is formed. Next, nucleophilic attack at the C2 position of proline generates an intermediate that is converted to hydroxyproline using energy supplied from the cleavage of  $\text{CO}_2$  from  $\alpha$ -keto-glutarate.

**Scheme 5**

Ascorbic acid is also associated with protecting lipid, DNA, and proteins from oxidants. For example, when peroxy radicals are generated in plasma, ascorbic acid is consumed faster than other antioxidants, such as uric acid, bilirubin, and vitamin E. Ascorbic acid is 100 times more reactive than polyunsaturated fatty acids in reacting with peroxy radicals. Moreover, ascorbic acid can form relatively stable free radical intermediates. This ability significantly delays or prevents free radical-initiated oxidations.

### Metabolism

The bioavailability of dietary ascorbic acid is dose-dependent, but absorption (mainly in ileum and jejunum) can be as high as 70–80% at physiological intakes (10–100 mg per day). L-ascorbic acid enters cells via  $\text{Na}^{+}$ -dependent transport. Dehydroascorbic acid can also enter by facilitated diffusion utilizing the glucose transporters (GLUT 1, 3, and 4), although under physiological conditions, these transporters may play minor roles due to competition from glucose. Some tissues can accumulate as much as 100 times the level of ascorbic acid in blood (e.g., adrenal glands, pituitary, thymus, corpus luteum, and retina). The accumulation of ascorbic acid occurs because of cellular dehydroascorbate reduction systems capable of rapidly generating reduced ascorbic acid. Dehydroascorbic acid is easily destroyed by oxidation. In addition, the chemical reduction of ascorbate minimizes the potential for ascorbic acid radical generation. It is also important to appreciate that ascorbic acid acts as a pro-oxidant under aerobic conditions when metals capable of redox ( $\text{Fe}^{2+} \leftrightarrow \text{Fe}^{3+}$ ;  $\text{Cu}^{+1} \leftrightarrow \text{Cu}^{+2}$ ) are present. Reduced iron and copper can serve as highly destructive Fenton catalysts (Fig. 9).

During postnatal development, going from a relatively hypoxic to a hyperoxic environment results in rapid adaptive changes. From a quantitative point of view, glutathione (GSH) and ascorbic acid are the most abundant reducing agents in cells. However, glutathione levels are low in the prenatal stages of growth. Furthermore, when GSH levels are decreased, ascorbate levels are also reduced because of the degradation of dehydroascorbic acid. Therefore, in newborns, dietary sources of ascorbate are essential because they spare glutathione owing to its low rate of synthesis.

Biosynthesis of GSH occurs in the cytosol in a tightly regulated manner. Critical determinants of GSH synthesis are the availability of the sulfur amino acid precursor, cysteine, glycine, and glutamate. These amino acids, however, may be limited because of their use in growth and extracellular matrix production processes. The nutritional disease associated with ascorbic acid deficiency is scurvy. The features of scurvy (poor wound healing, osteopenic abnormalities, impaired lipid metabolism, behavioral changes) are easily linked to perturbations resulting from the inability to facilitate hydroxylations and lack of ROS protection.

When cellular levels of ascorbic acid are abnormally elevated, there is increased expression of ascorbic acid decarboxylase activity, which catalyzes the oxidation of ascorbate to  $\text{CO}_2$  and C-4 or C-5 fragments. Moreover, ascorbic acid may be converted to 2-O-methyl or 2-sulfate derivatives and excreted. Because mechanisms are in place to homeostatically regulate ascorbic acid, evidence of toxicity, other than gastric upset, is seldom observed. However, decreased histamine production can occur when ascorbic acid is consumed in near gram quantities per 1000 kcal. High dietary amounts can also facilitate gastric nitrosamine reductions.

### Riboflavin (vitamin B2)

Originally called vitamin G, riboflavin was renamed vitamin B2 when it was recognized to be part of the yeast B complex. The cofactor forms for riboflavin are flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). Riboflavin is associated with enzymes designated flavoproteins. Riboflavin's planar isoalloxazine ring facilitates the redox transfer reactions catalyzed by FMN and FAD.

#### Functions

FMN is usually associated with membrane proteins involved in the mitochondrial electron system, whereas FAD is found in membrane-bound and soluble enzymes. Flavins can exist in four redox states: the flavin-N(5) oxide, quinone, semi-quinone, and hydroquinone (Fig. 10A and B). FAD and FMN are cofactors usually used in aerobic processes, functioning as cofactors for oxidases. However, FAD also can function in anaerobic environments as cofactor dehydrogenase reactions. Flavins are particularly useful for reactions involving oxygen and sulfur, which usually proceed one electron and one proton at a time. For example, enzymes containing flavin moieties are distinguished because they can transfer hydrogen directly to molecular oxygen (Fig. 10C).

FAD exists as an equilibrium mixture of open and folded conformers in aqueous solutions. The planar isoalloxazine ring self-associates with the adenosine the adenine nucleotide. The planar isoalloxazine structure also promotes the resonance and localization of electrons in isoalloxazine ring nitrogens. However, the reduced form of FAD has a boat-like configuration (Fig. 10B).

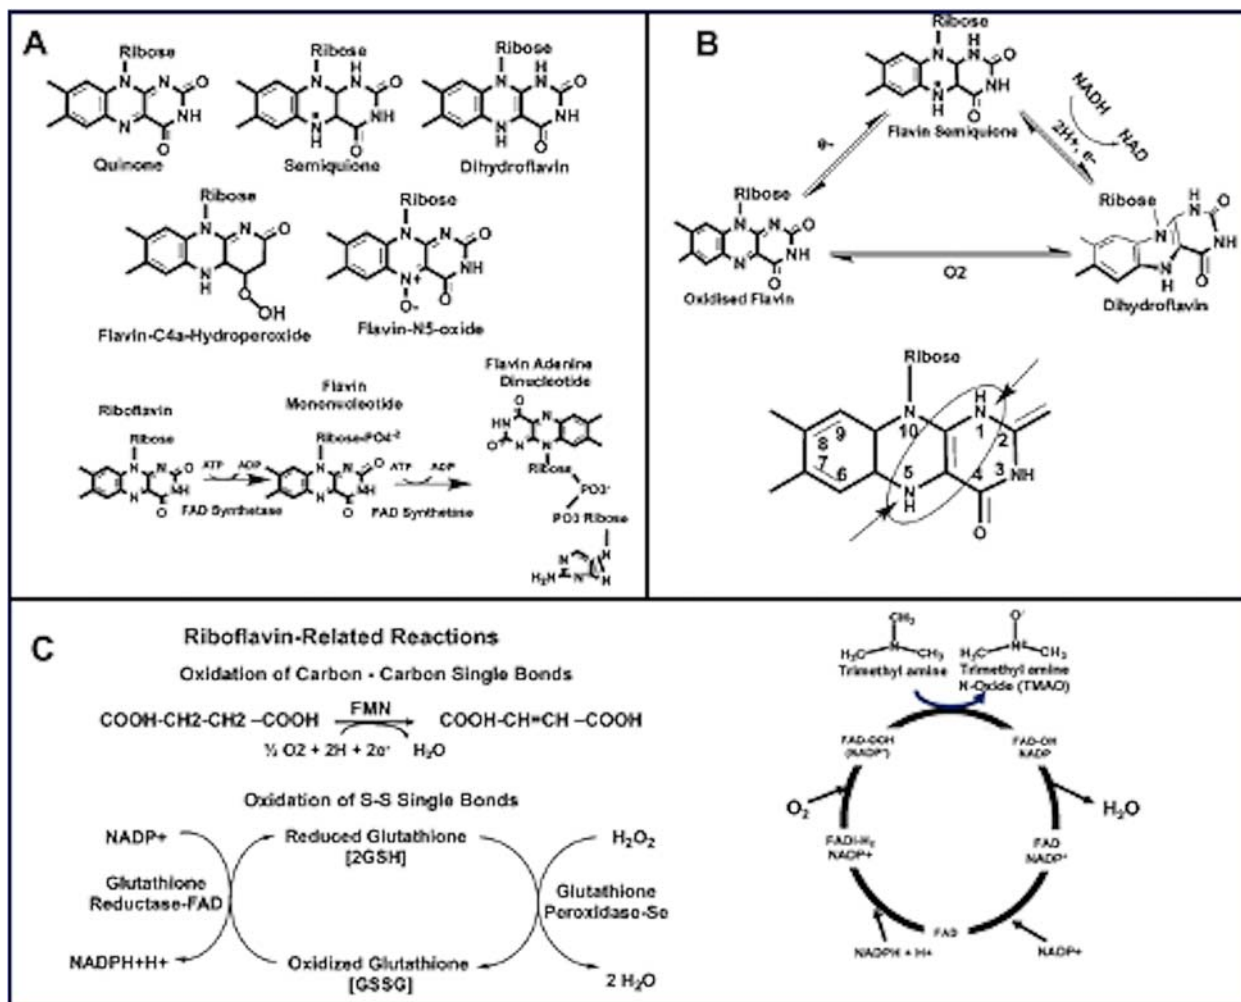

#### Metabolism

Riboflavin is absorbed by active processes and is transported in blood by a riboflavin transporter. Many flavin-containing proteins are found in the smooth endoplasmic reticulum of cells associated with microsomal phase 1 and 2 enzymes and processes and xenobiotic metabolism. FMN and FAD are tightly bound in given flavoproteins. Consequently, riboflavin turnover is a function of the turnover of enzymes that it serves in cofactor form. In this regard, riboflavin deficiency is more often a function of protein inadequacy than riboflavin deprivation. Riboflavin deficiency is rarely found in isolation but may occur with other water-soluble vitamins and protein deficiencies.

Riboflavin deficiency is classically associated with the so-called oral-ocular-genital syndrome. Signs of riboflavin deficiency include lesions of the oral cavity (cheilitis), inflammation of the tongue (glossitis), and accompanying seborrhea and dermatitis in the genital area. Drugs with chemical structures similar to riboflavin (e.g., chlorpromazine, imipramine, amitriptyline, penicillin, and theophylline) can displace riboflavin from binding proteins that are important to riboflavin and FMN transport. In addition, many flavoproteins and riboflavin transporters are also targets for polymorphic alterations, which can result in the need for higher levels of systemic riboflavin for activation. Further, toxicity is seldom a concern, in part because riboflavin is not very soluble due to isoalloxazine ring self-association and its association with other planar aromatic compounds.

### Niacin

Niacin (vitamin B3) is the generic name for nicotinic acid (pyridine-3-carboxylic acid), nicotinamide (pyridine-3-carboxamide), and related derivatives, such as nicotinamide riboside. As nicotinamide, niacin is the catalytic moiety for nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which serve in multiple functions (e.g., as cofactors, co-substrates, or signaling molecules) in numerous catabolic and anabolic reactions (cf. Fig. 2). For example, as enzymatic cofactors, NAD and NADP catalyze the transfer of hydrogen and electrons from one molecule to another. In addition, oxidized NAD ( $\text{NAD}^+$ ) is utilized as a co-substrate in polyribosylation and sirtuin-related protein deacetylase reactions. Moreover,  $\text{NAD}^+$ , when converted to cyclic ADP ribose (cADPR) or adenosine diphosphate ribose (ADPR), acts as signaling molecules (Fig. 11).

**Fig. 10** Riboflavin. Riboflavin's planar isoalloxazine ring facilitates the redox transfer reactions. FMN is usually associated with membrane proteins involved in the mitochondrial electron system, whereas FAD is found in membrane-bound and soluble enzymes. Flavins can exist in various redox states, e.g., quinone, semi-quinone, hydroquinone, and flavin-N(5) oxide. Flavins are particularly useful for reactions involving oxygen and sulfur, which usually proceed one electron and one proton at a time.

### Functions

With few exceptions, the redox-related reactions of NAD and NADP involve dehydrogenase (oxidoreductase) enzymes. As a family, NAD and NADP-linked dehydrogenases constitute almost 20% of all classified enzymes and utilize about half of the cellular niacin for their activation. The relative abundance of oxidized NAD(P)<sup>+</sup> and the redox balance of NAD<sup>+</sup> to NADH and NADP<sup>+</sup> to NADPH mediate the cell's fate in a wide range of metabolic conditions. For example, decreasing the levels of NAD<sup>+</sup> can influence the rate of cellular apoptosis and, in the whole organism, the rate of malignancies, diabetes, and neurodegeneration. Thus, the ratio of NAD<sup>+</sup>/NADH and NADP<sup>+</sup>/NADPH may be viewed as redox couples that are significant determinants of the cellular redox state. NAD participates primarily in energy-yielding catabolic reactions. NADP<sup>+</sup> performs less of a catabolic role, but in its reduced form, NADPH is a reductant in anabolic reactions, especially the biosynthesis of fatty acids and other lipids.

NAD and NADP arise by phosphorylation and condensation of niacin with ATP (Fig. 2). NADP also contains a phosphate group on the 3' position of the pentose nearest to the adenine derived from ATP (catalyzed by NAD kinase). Regarding chemical features, the functional site of NAD<sup>+</sup> and NADP<sup>+</sup> is the nicotinamide ring. The oxidized nicotinamide has a quaternary nitrogen with a positive charge. The oxidized ring accepts two electrons and one proton from a substrate reducing the ring and abolishing the positive charge on the nitrogen. A unique feature of the reactions catalyzed by NAD and NADP is hydrogen transfers are in the form of hydride ions, the anion form of hydrogen (H<sup>-</sup>).

Moreover, there is stereospecificity associated with the reactions. The two hydrogen atoms of niacin at the 4-position are prochiral. The transfer of an H<sup>-</sup> ion to NAD or NADP can be either from the front (A-side, pro-R) or the back (B-side, pro-S) of the niacin moiety, depending on how NAD or NADP fits into its binding domain on the enzyme. There are about the same number of pro-R versus pro-S favoring dehydrogenases that require NAD and NADP in cells. The binding of NAD to dehydrogenases or

**Fig. 11** Cyclic ADP ribose and Adenosine diphosphate ribose. Cyclic ADP-ribose is one of several molecules involved in the lipopolysaccharide-stimulated proliferation of human peripheral blood mononuclear cells. The adenosine diphosphate ribose activates the TRPM2 ion channel (a non-selective calcium-permeable cation channel) and part of the Transient Receptor Potential ion channel superfamily.

reductases is such that hydride transfer involves only one side of the nicotinamide moiety. Consequently, the binding of the non-preferred form is weaker, and the maximum velocity is slower. Examples of dehydrogenase and reductases that prefer the R form are alcohol, lactate, and isocitrate dehydrogenases, including dihydrofolate reductase, whereas glyceraldehyde-3-phosphate, 3-phosphoglycerate, glutamic acid, glucose-6-phosphate dehydrogenases, and glutathione reductase prefer the S form.

**Scheme 6**

As a substrate, the NAD<sup>+</sup> form of niacin participates in mono- and polyribosylation reactions and reactions broadly classified as deacetylations and deacetylations. Both types of reactions are important in regulating a range of cellular functions. For example, in the nuclei of cells, polyribosylation of specific histones and transcription factors precedes the normal process of DNA repair. NAD serves to generate groups of ADP-ribose moieties that are transferred to proteins to form long branched chains in reactions designated as poly-ADP-ribosylations. Mono-ADP-ribosylations also occur. As a protein modification, mono-ADP-ribosylations can switch on and off enzymatic activities ranging from glycolysis to oxidative stress.

In addition to mono- and polyribosylation reactions, NAD<sup>+</sup> also serves as a substrate in deacetylase, desuccinylase, demalonylase, demyristoylase, and depalmitoylase reactions. A family of enzymes designated sirtuins carries out these reactions. A depiction of the deacetylation mechanism is given in Fig. 2. Sirtuins are implicated in cellular processes, such as aging, responses to inflammation and stress, DNA repair, and energy efficiency. Reversible acetylation is a regulatory mechanism in that accessibility to an active site can be controlled by acetylation. Acetylation can also alter protein conformation in ways that influence catalytic parameters. For example, histone acetylation is a critical modification that changes chromatin architecture and regulates gene expression by opening or closing the chromatin structure. Mammals have seven sirtuins (SIRT, silencing information regulator transferases) in the deacyl- and deacetylation of proteins such as histones and metabolic enzymes that involve cellular energy metabolism.

As a component of cADPR, niacin signals the mobilization of Ca<sup>2+</sup> from the endoplasmic reticulum by activating ryanodine receptors (Fig. 11). In cardiac and skeletal muscle, ryanodine receptors release Ca<sup>2+</sup> from intracellular compartments during excitation-contraction coupling. cADPR also activates transient receptor potential melastatin 2 (TRPM2), another calcium ion channel, which responds during inflammation and cellular temperature fluctuations. Ryanodine receptors and TRPM2 also act synergistically during muscle contraction.

### Metabolism

A part of the daily need for niacin is produced from tryptophan degradation. Because of a potential internal source, niacin is often designated a “conditional” vitamin. Niacin is needed in amounts corresponding to 3–5 mg per 1000 kcal or 4.2 MJ. The niacin requirements are often expressed as equivalents, where one equivalent corresponds to 1 mg of niacin. For example, the degradation of 50–60 mg of tryptophan to niacin produces about one equivalent or 1 mg.

Factors that lead to niacin deficiency (pellagra) are diets low in tryptophan (most often corn-based) or conditions that reduce the body's ability to convert tryptophan to niacin, such as Hartnup disease or carcinoid syndrome. Pellagra is characterized by dermatitis, diarrhea, and mental disturbance. Pellagra was relatively common throughout the 1800s, mainly where corn was consumed as the primary food energy source and not nixtamalized. Nixtamalization is a process for preparing corn (maize) and other grains, in which the grain is soaked and cooked in an alkaline solution. This type of processing improves the digestion of corn and substantially increases niacin availability.

In pharmacologic doses (gram quantities), niacin-derived compounds are used therapeutically. For example, nicotinic acid is used when increased blood flow or vasodilatation is desirable. In gram quantities per day, nicotinic acid is also an effective lipid-lowering agent (increases HDL). Niacin, as a supplement, also reduces the synthesis of the low-density lipoprotein (LDL)-C precursor and very-low-density lipoprotein (VLDL). In addition, the mobilization of free fatty acids from adipose tissue is decreased. Niacin (as a supplement) can inhibit hormone-sensitive lipase in adipose tissue, reducing triglycerides catabolism to free fatty acids and the transport of free fatty acids to the liver.

There are, however, important caveats to the exposure to high levels of niacin derivatives. Niacin is excreted predominantly as methylated pyridines (e.g., methylation of niacin to 1-methylnicotinamide), requiring methionine as a methyl donor. Hyperhomocysteinemia may occur. The response is also accompanied by decreased plasma concentrations of vitamins B6 and B12.

### Generation of leaving groups: thiamine, vitamin B6, pantothenic acid

As noted, cofactors function in part by allowing the possibility of different transition states that lower the activation energy of given reactions. With regard to the generation of leaving groups, this usually implies enriching the nucleophilic or electrophilic character of transition state intermediates to better engage in nucleophilic or electrophilic substitutions. The vitamin-derived cofactors, thiamin pyrophosphate (TPP) and pyridoxal-5'-phosphate (PLP), and pantothenic acid as a component of coenzyme A serve as excellent examples of such functions:

#### Thiamin

##### Functions

Thiamin comprises a pyrimidine and thiazole moiety linked by a methylene bridge. There are three phosphorylated forms: thiamin monophosphate (TMP), thiamin diphosphate (TDP), and thiamin triphosphate (TTP).

Scheme 7

The thiazole moiety acts as a ylid (a neutral dipolar molecule containing a negatively charged atom attached to a heteroatom with a formal positive charge). The carbanion character of TPP's thiazole ring is retained in transition state intermediates. Examples of enzymes in which TPP is used for this purpose are pyruvate,  $\alpha$ -ketoglutarate, or branched-chain amino acid dehydrogenase complexes and 2-hydroxyphytanoyl-CoA lyases. The relationship of the subunits essential for converting pyruvate to acetyl-CoA is shown in Fig. 12 (Patel et al., 2014). TPP catalyzes the reversible cleavage of the carbon-carbon bond connecting a carbonyl group to an adjacent reactive group (usually a carboxylic acid or an alcohol). The TPP-substrate bond is broken in reverse reactions, reforming the thiamin ylid and substrate carbonyl.

TPP is also a cofactor for transketolases, enzymes associated with the pentose phosphate pathway and photosynthesis. In transketolases, TPP accepts a 2-carbon fragment from a 5-carbon ketose (e.g., D-xylulose-5-P) and then transfers the fragment to a 5-carbon aldose (e.g., D-ribose-5-P) to form a 7-carbon ketose (e.g., sedoheptulose-7-P). The second reaction catalyzed by transketolase in the pentose phosphate pathway involves the transfer of a 2-carbon fragment from D-xylulose-5-P to erythrose-4-phosphate, which results in fructose 6-phosphate and glyceraldehyde-3-P. This reaction connects the pentose phosphate pathway to glycolysis (Fig. 13).

**Fig. 12** Pyruvate dehydrogenase complex. The pyruvate dehydrogenase complex (PDHC) comprises three subunits essential for converting pyruvate to acetyl-CoA, CO<sub>2</sub>, and NADH. The conversion is irreversible. The control of PDHC activity is complex and involves allosteric interactions with its substrates and products, as well as covalent modification by (de)phosphorylation. For example, PDH is inhibited by its products and can be inactivated by phosphorylation by PDH kinases.

### Metabolism

The majority of thiamin present in cells is TDP. It has been proposed that TPP has a specific role in nerve excitability, but this is not confirmed. Recent reports, however, suggest that TPP may play a role in cell energy metabolism. The requirement for thiamin is 0.5–1.0 mg per 1000 kcal or 4.2 MJ of diet. Factors that most influence the need for thiamin are exposure to antagonists and thiaminases (enriched in fermented foods). Antagonists used in experimental settings are pyriethamine and oxythiamine, which inhibit the

**Fig. 13** The Hexose monophosphate shunt and transketolase pathway. The hexose monophosphate shunt (also known as the pentose phosphate pathway) consists of two parts. First, an oxidative pathway component converts glucose-6-phosphate to ribulose-5-phosphate and a non-oxidative component that further generates three, four, and five carbon units. The pathway plays an essential role in generating NADPH reducing equivalents, nucleic acid synthesis, and connecting the pentose phosphate pathway to glycolysis. The role of thiamin diphosphate (TPP) is to serve as a cofactor for two transketolases. In the first reaction, TPP accepts a 2-carbon fragment from D-xylulose-5-P and transfers it to ribulose-5-phosphate to generate sedoheptulose-7-P and glyceraldehyde-3-phosphate. The second reaction involves the transfer of a 2-carbon fragment from D-xylulose-5-phosphate to erythrose-4-phosphate, generating fructose 6-phosphate and glyceraldehyde-3-phosphate.

phosphorylation of thiamin. In addition, the coccidiostat, amprolium, can inhibit thiamin absorption. Alkaline conditions, heat, and oxidants can reduce or chemically modify active forms of thiamin. For example, milling whole grains to remove the bran reduces the thiamin content. Moreover, foods rich in tannins can bind and facilitate the oxidation of thiamin, which leads to reduced availability. Thiamin deficiency is characterized by peripheral neuropathy, including abnormal reflexes, diminished sensations, and cardiac failure due to impaired oxidative metabolism.

## Vitamin B6

### Functions

The main biological functions of vitamin B6 as a cofactor include aminotransferase, decarboxylase, and deaminations reactions. Amino transferases (i.e., transaminases) are essential in the interconversion of amino acids to corresponding  $\alpha$ -keto acids to set the stage for eventual oxidative metabolism. Decarboxylations and aldol reactions (electron withdrawal from the  $\alpha,\beta$ -carbons of amino acids) are essential in the generation of amino acid-derived neurotransmitters (e.g., histidine to histamine, tryptophan to serotonin, glutamate to  $\gamma$ -aminobutyric acid, or dihydroxyphenylalanine to dopamine).

**Scheme 8**

The cofactor form of vitamin B6 (pyridoxal-5'-phosphate, PLP) is also a cofactor for glycogen phosphorylase ([Migocka-Patrzałek and Elias, 2021](#)), which catalyzes the hydrolysis of ether bonds in glycogen to form 6-phosphoglucose. In addition, the formation of heme is vitamin B6 dependent. The synthesis of  $\delta$ -aminolevulinic acid initiates the heme pathway from glycine and succinyl-CoA, the rate-limiting enzyme responsible for this reaction. Vitamin B6 is also an essential component of enzymes that catalyze sphingolipids' formation, particularly the synthesis of ceramides.

**Scheme 9**

In transamidase, decarboxylase, and deaminase reactions, the 4-formyl (aldehyde) substituent of PLP condenses with the  $\alpha$ -amino group of amino acid substrates to form an azomethine (Schiff-base) linkage. The Schiff-base linkage allows the conjugated double-bond system to extend into PLP's pyridinium nitrogen, which weakens bonding around the  $\alpha$ -carbon of the amino acid substrate. Then, depending on the enzyme, transaminations, decarboxylations, or subsequent substitutions at the carbon adjacent to the  $\alpha$ -carbon are facilitated. Stated differently, PLP helps stabilize a carbanion at the  $\alpha$ -carbon of the targeted amino acid. Moreover, in PLP-dependent enzymes, PLP is attached to the  $\epsilon$ -amino group of the lysyl group at the active site within the enzyme. This can set the stage for an initial "transimination" with an amino acid, which occurs faster than an aldehyde with an amino acid, i.e., transaminations.

In glycogen phosphorylase reactions, the organic ring of PLP functions as a reversible electron sink with the phosphate group of PLP acting as an acid-base catalyst to prime free phosphate ion for an attack on the terminal glycosidic bond of the glycogen substrate. Glycosidic bonds are ethers, which prefer cleavage by acids. For their cleavage, the 5'-phosphate moiety of PLP acts as the acid catalyst to yield as a product, glucose -6- phosphate (9).

### Metabolism

The vitamin B6 requirement is 1.6 mg–2.0 mg per day for adults, increasing during pregnancy and lactation periods. The richest sources of vitamin B6 are meats and whole grains. Vitamin B6 is absorbed in the upper gastrointestinal tract. The cofactor forms of vitamin B6 present in foods are first dephosphorylated by intestinal alkaline phosphatases and then absorbed. The B6 vitamers are transported to target cells by albumin. In cells, rephosphorylation of the B6 vitamers (pyridoxal, pyridoxamine, and pyridoxine) to corresponding 5'-phosphates is catalyzed by cellular pyridoxal kinases. The pyridoxine and pyridoxamine forms may then be oxidized, if needed, to pyridoxal phosphate. The B6 vitamers are most abundant in muscle, kidney, and liver (the primary sites for amino acid metabolism).

The products of vitamin B6 metabolism are excreted in the urine. The primary product is 4-pyridoxic acid. Other urine products may include additional pyridoxine derivatives. Drug-induced vitamin B6 deficiency can also occur following the administration of tuberculostatic drugs, such as isoniazid (isonicotinic acid hydrazide). This drug forms hydrazone derivatives with the pyridoxal forms of B6. Penicillamine ( $\beta$ -dimethylcysteine), a copper chelator, may also interfere with normal B6 metabolism due to the formation of thiazole derivatives. A naturally occurring antagonist to vitamin B6 is linatine (1-amino-D-proline). The signs of Vitamin B6 deficiency are energy-related and neurological due to the inability to produce  $\alpha$ -ketoacids and vital biogenic amines from amino acid precursors. Microcytic anemia may also occur from decreased heme synthesis.

### Pantothenic acid

#### Functions

Pantothenic acid (composed of pantoic acid linked to  $\beta$ -alanine) is required for coenzyme A (CoA) biosynthesis (Fig. 14) and as the cofactor for acyl carrier protein (ACP). CoA is an essential cofactor for the transfer of acetyl and acyl groups (Naquet et al., 2020). For CoA synthesis, pantothenic acid is phosphorylated to 4'-phosphopantothenate by pantothenate kinase, which also serves as the principal regulatory enzyme for the process. Next, cysteine is added by the enzyme phospho-pantothenoylcysteine synthetase to form 4'-phospho-N-pantothenoylcysteine, followed by decarboxylation and adenosyl-monophosphate addition to form dephospho-CoA. In a final step, dephospho-CoA is phosphorylated to coenzyme A by dephospho-coenzyme A kinase. In addition, a 4'-phosphopantetheine moiety is essential to the function of acyl carrier protein (ACP), which aids in the transfer of acyl groups in fatty acid and polyketide biosynthesis complexes. ACP is sometimes called a "macro-cofactor" because, as a small polypeptide chain (M.W. ~8500–8700 Da), it may be isolated and separated from the fatty acid synthase enzyme complex. Although few reports are specifically related to the regulation of the holo-ACP peptide or the fatty acid synthase ACP-domain, it is reasonable to assume overall production of ACP activity is linked closely to CoA production.

Scheme 10

**Fig. 14** Pantothenic acid and Coenzyme A (CoA) synthesis. For CoA synthesis, pantothenic acid is first phosphorylated to 4'-phosphopantothenate by pantothenate kinase (PK). PK is the central control and rate-limiting step for the CoA synthesis pathway. Feedback-inhibition by acetyl and acyl-CoA controls PK activity. The intracellular concentration of ATP is also involved in the overall regulation of PK and CoA synthesis. In addition, carnitine is a non-competitive inhibitor for PK in part due to its role as a lipid membrane transporter for medium/long-chain fatty acids facilitating their oxidation, resulting in subsequent energy production.

An essential feature of the intermediates arising from the transfer reactions catalyzed by CoA or 4'-phosphopantotheine enzymes is they are "high energy" compounds. CoA and ACP react with acetyl or acyl groups to form thioesters. Thioesters ( $-S-C(=O)-R$ ) are thermodynamically less stable than typical esters ( $-O-C(=O)-R$ ) or amides ( $-N-C(=O)-R$ ). The double bond character of the  $C=O$  bond in thioesters does not extend significantly into the  $C-S$  bond. Consequently,  $S-C(=O)-R$  is not stabilized by resonance. Thioester bonds have a greater negative standard free energy of hydrolysis and are more reactive than oxygen esters in nucleophilic displacement reactions involving acyl groups. For most reactions involving CoA or ACP, additional energy from an energy source (e.g., ATP) is not required to transfer acetyl or acyl groups. For reference, the  $-\Delta G$  of hydrolysis is  $\sim -7.5$  kcal/mol for acetyl-CoA compared to 7–8 kcal/mol for the hydrolysis of ATP to AMP or pyrophosphate or ADP and phosphate.

**Scheme 11**

CoA is involved in processes that range from energy and fatty acid metabolism to protein acetylations, prenylations, and acetylations (Naquet et al., 2020). CoA is essential as a cofactor in amino acid metabolic pathways. As a  $\beta$ -Hydroxy  $\beta$ -methylglutaryl (HMG) derivative, CoA-HMG is an intermediate in mevalonate and ketogenesis pathways essential in cholesterol and steroid hormone synthesis. Moreover, CoA has also been identified as a cofactor in redox regulation, acting as a reactive oxygen species (ROS) inhibitor. The attachment of CoA to certain proteins that require  $-[S-S]-$  bonding for activity occurs during oxidative and metabolic stress. CoA addition (S-thiolation or CoA-thiolation) prevents irreversible sulfhydryl ( $-SH$ ) oxidation. Proteins that require exposed cysteine residues for activity are often targets for ROS (e.g., free radicals, peroxides in various forms, or heavy metals).
