Growth and development refers to the growth of an organism in size as assessed by anthropometric measurements of body weight, length, and circumferences (head and body), as well as changes in body composition, primarily cell number and size, organ size, and the relative amounts of fat mass and lean mass (muscle, bone, organs). Most of the relevant concepts about growth and development apply to the fetal period of development, the focus of this review. This period encompasses the greatest changes in growth rate, body proportions, and body composition during the life of an organism. In the first third of gestation (first trimester), during the embryonic period, growth occurs primarily by increased cell number (hyperplasia). In the middle third of gestation (second trimester), cell size also increases (hypertrophy) while the rate of cell division stabilizes. In the last third of gestation (third trimester), the rate of cell division declines while cell size continues to increase.

Many terms are used to describe variations in growth. For example, human newborns are classified as having normal birth weight (greater than 2500 g), low birth weight (less than 2500 g), very low birth weight (less than 1500 g), or extremely low birth weight (less than 1000 g). Obviously, classification by weight alone says little about growth rate, as most infants with less than normal birth weights are the result of a shorter than normal gestation, i.e., they are born preterm (<37 weeks of gestational age). Furthermore, it is inappropriate to label newborns as abnormally grown when their birth weight is less than some arbitrarily determined “normal” birth weight, but their mother was quite small to begin with; such newborns are considered constitutionally small but not abnormal. Classifying newborns according to duration of gestation (e.g., preterm, term, or post term) on the basis of birth weight also is erroneous, because infants with intrauterine growth restriction (IUGR) are smaller and macrosomic infants of diabetic mothers are larger than normal at any gestational age.

## Growth of fetal size

Under usual conditions, the fetus grows at its genetic potential. Small fetuses of small parents or large fetuses of large parents do not reflect fetal growth restriction or fetal overgrowth, respectively; in fact, their rates of growth are normal for their genome. The smaller (generally, shorter) the mother, the more she limits fetal growth by “maternal constraint,” which represents a limitation of uterine size (Gluckman and Hanson, 2004). Uterine size is directly related to maternal height; thus, a shorter mother will have a smaller uterus with reduced endometrial surface area and the capacity for placental growth (Rochow et al., 2018). Placental size is the primary determinant of its capacity to supply oxygen and nutrients to the fetus. A clear example of maternal constraint is shown in Fig. 1, depicting the reduced rate of fetal growth of multiple fetuses in a monotocous species—human—that optimally supports only one fetus.

Fetal size tends to increase exponentially in the first third or trimester of gestation. It increases relatively linearly in the middle third or second trimester of gestation, and into the third part or third trimester of gestation, the period of largest increase in fetal mass. Fetal size then slows during the latter part of the third trimester, producing the typical S-shaped curve of fetal size vs. gestational age that is derived from cross-sectional measurements of birth weights at different gestational ages (Fig. 2). The length of gestation is more strongly related to the growth of neural tissue mass (range 0.015–0.033 g<sup>1/3</sup>/day—a 2.2-fold range) than to the growth of the fetal body (range 0.033–0.25 g<sup>1/3</sup>/day—a 7.6-fold range). The physiological significance of this relationship is not known, but intrauterine development of the relatively large brain in human fetuses is made possible by their relatively slower rate of somatic growth compared with other mammals.

## Developmental change of fetal body composition

Fetal growth during the last third of gestation requires large increases in oxygen and nutrient supplies and appropriate utilization of oxygen and nutrients to produce net synthesis of complex molecules (e.g., protein) and cell replication and

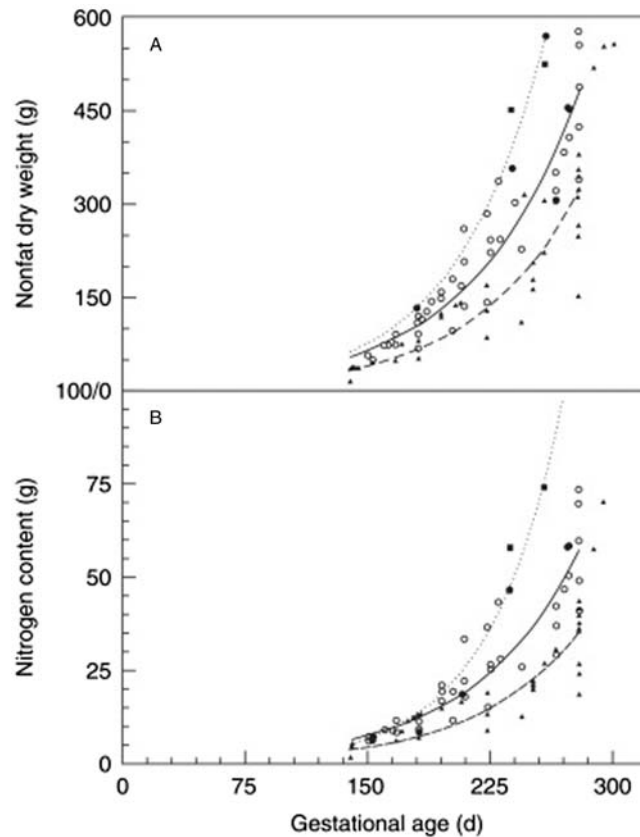

**Fig. 1** Mean birth weight of single and multiple fetuses related to duration of gestation. Adapted from [McKeown and Record \(1952\)](#); Reproduced with permission from [Ounsted and Ounsted \(1973\)](#).

**Fig. 2** Birth-weight percentiles for gestational age. Solid lines represent California total singleton live births, 1970–1976; dotted lines represent Colorado General Hospital (Denver, Colorado) live births, 1948–1960. Reproduced with permission from [Creasy and Resnik \(1999\)](#).

hypertrophy. Nutrient substrate supply is coupled with increased development of anabolic hormones and growth factors in fetal tissues and fetal plasma to produce increased nitrogen and carbon deposition in protein, carbohydrate deposition in glycogen, and fatty acid, glycerol, and triglyceride deposition as fat in adipose tissue. Growth of these tissues gradually replaces water in the fetal extracellular space.

Chemical composition studies of normal human infants are limited. Based on data from 15 studies that included 207 infants, nonfat dry weight and nitrogen content (predictors of protein content) show a linear relationship with fetal size and an exponential relationship with gestational age ([Fig. 3](#)) ([Sparks, 1984](#)). As gestation proceeds, larger fetuses grow faster than smaller fetuses, as do

**Fig. 3** Non-fat dry weight (A) and nitrogen content (B) are plotted against gestational age for LGA (■, ·····), AGA (○, ———), and SGA (◆, ———) infants. Reproduced with permission from Sparks (1984).

net protein accretion and tissue and organ mass. At each gestational age, however, fetal size (and thus birth weights) varies considerably, as do nonfat dry weight and nitrogen content; protein accretion and therefore protein nutritional requirements follow accordingly as gestational age advances and fetal size increases.

### Water

Fetal water content increases directly with but not proportionally to body weight, as fetal body water, expressed as a fraction of body weight, decreases with advancing gestation. The relatively larger growth of adipose tissue in the human fetus compared with all other species of land mammals further dilutes the body concentration of water. Extracellular water as a fraction of fetal body weight also decreases more than intracellular water as gestation advances; this is mainly due to increasing cell number and increasing cell size rather than the intracellular concentrations of osmotic substances.

### Non-fat dry weight

Comparative aspects of chemical and physical growth in fetuses of six different species are summarized in Table 1. Despite growth rate variations of up to 20-fold and weight-specific fat content variances at term of up to 16-fold among these species, nonfat dry weight and protein weight-specific contents as fractions of total weight at term are constant. Protein concentration is about 12% in all species at term and fetal protein content is linearly related to fetal weight; thus, protein accretion in the fetal rat occurs about 23 times faster than it does in the human. These species-related differences in growth rate are remarkable and require marked differences in the capacity of the placenta to transport nutrients to the fetus.

### Nitrogen balance, protein turnover, protein synthesis, and lean body mass

According to animal data, only about 80% of the nitrogen content of the fetus is found in protein; the remainder is found in urea, ammonia, and free amino acids. Additional nitrogen requirements for urea excretion and for other possible nitrogen excretion products are not known for human fetuses. Protein accretion accounts for the largest fraction, up to 90%, of fetal growth, contributing to the replication (hyperplasia) and growth (hypertrophy) of all cells and all tissues and organs. Fetal protein

From McCance and Widdowson (1985).

synthesis, breakdown, and accretion rates have been measured in animal models, principally the fetal sheep, with isotopic tracers of selected amino acids, especially essential amino acids such as leucine and lysine. The tracers allow calculation of the fractional protein synthetic rate ( $K_S$ , or the fraction of body proteins that are synthesized/unit time), which can be compared with fractional growth rate ( $K_G$ ).  $K_S$  and  $K_G$  have been calculated and compared in fetal sheep using two tracers,  $^{14}\text{C}$ -leucine and  $^{14}\text{C}$ -lysine, at different gestational ages (Kennaugh et al., 1987). As shown in Fig. 4,  $K_S$  and  $K_G$  decrease with gestational age, but the decline in  $K_S$  is greater. The 3–4 fold greater protein synthetic rate and 50% greater net protein accretion rate in the fetus at mid-gestation compared to near term are proportional to the greater amino acid nitrogen uptake rates, metabolic rates, and glucose uptake and utilization rates at this earlier stage of gestation. Estimates of amino acid requirements in mid-gestation fetal sheep range from 3.5 to 4.5 g/kg/day; when scaled to the ~55% slower human fetal growth rates at 20–28 weeks gestation, these amino acid requirements compare favorably with that of 4 g/kg/day in human fetuses as determined by the factorial method (Ziegler, 2007). The decreasing  $K_S$  and  $K_G$  with gestation also indicate that nutritional requirements, particularly for protein, decline at the same time. Thus, at 28–34 weeks, protein requirements decrease to 3.0–3.5 g/kg/day, and by term gestation to 1.5–2.0 g/kg/day, a rate that is provided by mature maternal milk with full breastfeeding.

Hindquarters	14.5	15.1	22.0

<sup>a</sup>From Bell et al. (1987).

The decline in  $K_S$  and  $K_G$  with gestational age also indicate that the reduced rate of fetal growth in later gestation is an intrinsic quality of fetal development and not the result of insufficient nutrient supply. Even at term gestation, however, the fetus has higher protein synthetic rates than protein breakdown rates, reflecting an anabolic state with considerable net amino acid uptake and accretion (van den Akker et al., 2009). Mechanisms underlying the decrease in protein synthetic rate over gestation are not well understood, but a partial explanation for the continued anabolism can be derived from the changing proportion of body mass contributed by the major organs (Table 2). The mass of bone, skin, gastrointestinal tract, and skeletal muscle, for example, increase markedly during later gestation, but these organs have relatively lower fractional protein synthetic rates. Thus, whole body fractional protein synthetic rate should decrease despite the continued anabolism. It also is clear that a direct, causal relationship between continued anabolism but declining fractional protein synthetic rates cannot be made to anabolic endocrine-paracrine factors acting as principal regulators of fetal protein synthesis rate and thus fetal growth rate, (e.g., insulin, pituitary and placental growth hormone, placental lactogen, IGFs, epidermal growth factors), because the secretion and plasma concentrations of these growth hormones increase with advancing gestation.

### Glycogen

Many tissues in the fetus, including brain, liver, lung, heart, and skeletal muscle, produce glycogen over the second half of gestation. Liver glycogen content, which increases with gestation, is the most important store of carbohydrate for systemic glucose needs immediately after birth, because only the liver contains sufficient glucose-6-phosphatase for release of glucose into the circulation. Skeletal muscle glycogen content increases during late gestation and forms a ready source of glucose for glycolysis within the myocytes. Lung glycogen content decreases in late gestation with loss of glycogen-containing alveolar epithelial cells, development of type II pneumocytes, and onset of surfactant production. Cardiac glycogen concentration decreases with gestation as cellular hypertrophy develops, but cardiac glycogen appears essential for postnatal cardiac energy metabolism and function. At term, fetal liver glycogen concentration in most species is about 80–120 mg/gm, at least twice the adult concentration. In the relatively slowly growing human fetus, glycogen synthesis rates are low (about 2 mg/day/gm), representing less than 2% of estimated whole body glucose utilization rates (Hay et al., 2016b).

Macrosomic fetuses of diabetic mothers have very high body and organ contents of glycogen. In IUGR fetuses, placental insufficiency and decreased placental glucose supply to the fetus would tend to decrease fetal organ glycogen content. This could be augmented by acute hypoxic stress, especially right before birth, that would increase catecholamine and glucagon secretion, both of which would increase glycogen breakdown. More recent studies have shown, however, that the tendency to reduced glycogen content in IUGR fetuses is balanced or even exceeded by increased glycogen formation in peripheral (non-hepatic) tissues and organs produced by increased insulin sensitivity and cellular glucose uptake capacity. These increases represent compensatory adaptations in IUGR fetuses to the chronically low glucose concentrations.

### Fat

Fetal fat content as a fraction of fetal weight varies several fold among species (Fig. 5). The fat content of newborns at term of almost all land mammals is 1–3% and is considerably less than that of the human, 10–20%. Differences in body fat content among species are due primarily to the capacity of the placenta to transfer lipids, principally fatty acids, to the fetus and to the capacity of the fetus to synthesize triglycerides, produce fat, and store fat in adipose tissue cells that human fetuses develop in relatively large abundance by late gestation. Even in the species such as the human that take up fatty acids from the placenta and deposit fat in fetal tissues, the rate of fetal fatty acid oxidation is presumed to be low, because plasma concentrations of fatty acids are low and the carnitine palmitoyl transferase enzyme system is not sufficiently developed to transfer long chain fatty acids to the respiration pathway inside the mitochondria. Fetal fatty acid oxidation also is limited by the ready supply of glucose, lactate, and amino acids that are preferentially metabolized to oxidation in the tricarboxylic acid cycle. In the human fetus, calories produced by the complete oxidation of glucose, lactate, and amino acids can fully meet the amount of energy required for maintenance metabolism. In the human fetus between 26 and 30 weeks gestation, nonfat and fat components contribute equally to the carbon content of the fetal body. After that period, fat accumulation considerably exceeds that of

**Fig. 5** Fetal fat content at term as a percent of fetal body weight among species. Reproduced with permission from Hay (2003).

the nonfat components. At 36 weeks gestation, 1.9 g of fat accumulates for each gram of nonfat daily weight gain, and by term, the deposition of fat accounts for over 90% of the carbon accumulated by the fetus. The rate of fat accretion is approximately linear between 36 and 40 weeks gestation, and by the end of gestation, fat accretion ranges from 1.6 to 3.4 g/day/kg. By term, the fat content of the human fetus is 15–20% of body weight, ranging from less than 10% in IUGR fetuses to 25% or more in macrosomic infants of diabetic mothers (Hay et al., 2016b).

### Caloric accretion in the fetus

Fat has a high energy content, ~9.5 kcal/g, and a very high carbon content, approximately 78%. Thus, differences in fetal fat concentration among species lead to large differences in calculated caloric accretion rates and carbon requirements of the fetal tissues for growth. The caloric concentration of nonfat dry weight is fairly consistent across species and also within species at different developmental stages, indicating that the ratio of protein to non-protein substrates in the tissues is relatively constant. Thus, caloric accretion rate of any fetus can be estimated from the growth curve of that fetus and its change in whole body fat and water concentrations over time.

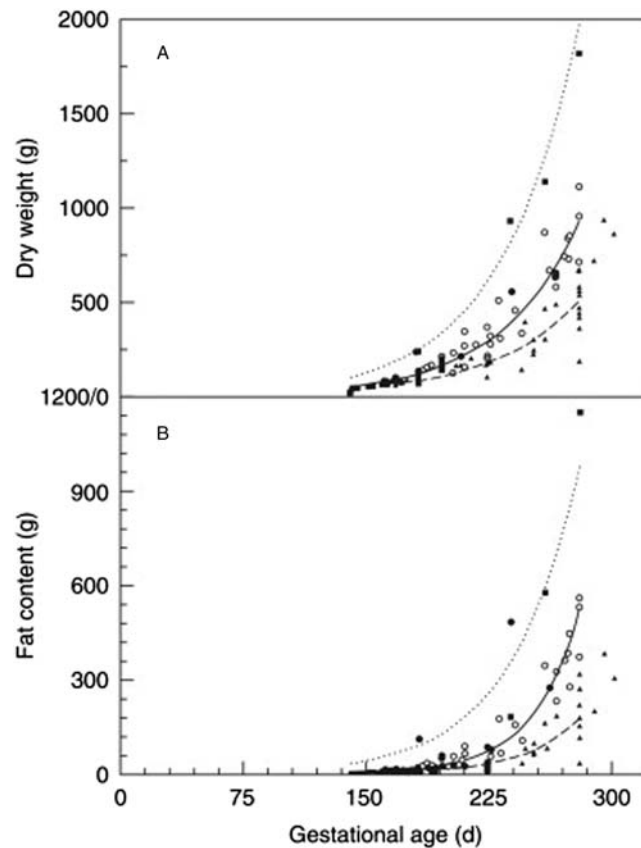

Data for caloric accretion and caloric distribution in the human fetus are shown in Table 3 (Sparks et al., 1980). Because growth of fat and non-fat (protein plus other) tissues are metabolically linked through energy supply that is used for protein synthesis and the production of anabolic hormones that promote positive protein, fat, and carbohydrate growth, restriction of nutrient supply is likely to produce growth deficits of all tissues, not just fat, i.e., growth restriction involves limitation of neuronal and myocyte replication and brain and muscle growth as well as fat and glycogen deposition. Indeed, chronic experimental selective caloric (glucose) restriction in the fetal sheep leads to increased protein breakdown as well as to lower rates of fetal growth and lipid content. In contrast, as shown by the growth curves in Fig. 6 from human infants born preterm at different times over the last third of gestation, there is a bias toward thinner infants with less fat content, indicating that in a species such as the human that does lay down considerable fetal fat during late gestation, differences in the caloric requirements for intrauterine growth later in gestation reflect fat deposition more than the growth of non-fat tissues. IUGR fetuses of all species, however, show reduced growth of skeletal muscle, and preterm infants tend to have less muscle mass with a slight excess in body fat mass, the latter likely the result of excess nutritional energy intakes. Importantly, the reduced skeletal muscle mass in normal preterm infants persists, but the excess fat mass does not (Hamatschek et al., 2020). An important long term adverse consequence of reduced muscle growth might involve diminished whole body insulin action and a tendency to hyperglycemia and type 2 diabetes, as skeletal muscle is the principal insulin-sensitive tissue in the body in older children and adults.

**Table 3** Calculation of the caloric distribution in the term human infant.<sup>a</sup>

Wet weight	Wet weight	Fat	Nonfat wet weight	Nonfat dry weight
Weight (g)	3450	386	3064	511
Total calories (kcal)	5950	3650	2300	2300
Caloric concentration (kcal/g)	1.73	9.45	0.75	4.5

<sup>a</sup>The values in this table are from Ziegler et al. (1979).

### Mineral accretion in the fetus

Fetal calcium content is best correlated with fetal body length; this is true for both AGA and SGA infants. Using this index, fetal calcium content increases exponentially with a linear increase in length. Using this estimate, the human fetal rate of calcium accretion is about 85 mg/day/kg. Accretion of other minerals varies more directly with body weight, and according to the distribution of the minerals into extracellular (e.g., sodium) or intracellular (e.g., potassium) spaces.

### Regulation of fetal growth

Regulation of fetal growth represents a mix of genetic mechanisms and environmental influences through which the genetic factors are expressed and modulated. The single most important environmental influence that affects fetal growth is the nutrition of the fetus, including oxygen as well as the principal nutrient substrates, amino acids, glucose, and lipids. Oxygen and nutrient substrate supply to the fetus and the resulting increases in fetal tissue and plasma concentrations of anabolic hormones and growth factors are regulated by maternal health, maternal nutrition, uterine growth (including uterine blood flow and endometrial surface area), and placental growth and function.

### Genetic factors

Maternal genotype is more important than fetal genotype in the overall genetic regulation of fetal growth. Table 4 presents estimates of the quantitative contribution of fetal and parental factors to fetal growth and birth weight at term. The more modest regulation by the paternal genotype acts through its contribution to trophoblast development and thus placental-to-fetal nutrient transport capacity. More specific gene targeting studies have shown the importance of genomic imprinting on fetal growth. For example, in mice normal fetal and placental growth require that the IGF-II gene be paternal and the IGF-II receptor gene be maternal, and paternal disomy producing IGF-II gene over-expression results in fetal overgrowth while maternal disomy producing IGF-II under-expression results in fetal dwarfism. In humans, isopaternal inheritance of IGF-II alleles is associated with the Beckwith-Wiedemann syndrome that includes hyperinsulinism and fetal macrosomia.

Derived from [Penrose \(1954\)](#), [Milner and Gluckman \(1996\)](#).

### Non-genetic maternal factors

There is a high correlation between birth weights of siblings that extends to cousins. The non-genetic, maternal nature of this effect is demonstrated by embryo transfer and cross-breeding experiments. For example, a small-breed embryo transplanted into a large-breed uterus will grow larger than a small-breed embryo remaining in a small-breed uterus ([Ounsted and Ounsted, 1973](#)). Furthermore, partial reduction in fetal number in a polytocous species such as the rat produces greater than normal birth weights in the remaining offspring. Conversely, transfer of a large-breed embryo into a small-breed uterus will result in a newborn that is smaller than in its natural large-breed environment. Such evidence demonstrates that fetal growth is normally constrained, and that this constraint comes from the maternal environment. This is a physiological process and includes the maternal-specific capacity of uterine size, placental implantation surface area of the uterus, and uterine circulation, which together support the growth of the placenta and its capacity to transport oxygen and nutrients to the fetus to support fetal growth.

### Maternal nutrition

Normal variations in maternal nutrition have relatively little effect on fetal growth, because they do not markedly alter maternal plasma concentrations of nutrient substrates or the rate of uterine blood flow, the principal determinants of nutrient substrate delivery to and transport by the placenta. Human epidemiological data from conditions of prolonged starvation, as well as nutritional deprivation in experimental animals, indicate that even severe limitations in maternal nutrition limit fetal growth by 10%–20%, although muscle mass is preferentially reduced under such maternal dietary restrictions ([Gauvin et al., 2020](#)). Restriction of caloric and protein intakes to less than 50% of normal for a considerable portion of gestation are needed before marked reductions in fetal growth are observed; such severe conditions often result in fetal loss before the impact on late gestation fetal growth rate and fetal size at birth are manifested.

Fetal macrosomia is common in pregnancies complicated by maternal diets excessively rich in sugars and fats ([Armitage et al., 2005](#)). Fetal macrosomia also is common in pregnancies complicated by gestational diabetes mellitus in which maternal and fetal plasma hyperglycemia and hypertriglyceridemia plus fetal hyperinsulinemia combine to produce excessive fetal adiposity. More recent observations of increasing fetal birth weight and macrosomia in relation to increased maternal obesity, a potentially serious adverse impact of the world wide obesity epidemic, remain mechanistically unexplained, although there is some evidence that obese pregnant women also tend to be hypertriglyceridemic as well as slightly hyperglycemic, both of which would contribute to increased lipid and glucose supply to the fetus, increased fetal insulin secretion, and fetal fat production. The placentas in diabetic and obese pregnant mothers also have greater amounts of lipoprotein lipase, which hydrolyzes maternal plasma triglycerides into free fatty acids that are then transported to the fetus and contribute to fetal fat mass production ([Heerwagen et al., 2018](#)). Maternal diets lower in simple sugars, higher in complex carbohydrates, and limited in total lipid can contribute to less fetal fat mass gain and the potential to prevent later life obesity in these offspring ([Hernandez et al., 2016](#)).

### The placenta

The placenta exerts strong control over fetal growth by providing nutrients directly or in metabolically altered form and amount. The size of the fetus is directly related to the size of the placenta ([Molteni et al., 1978](#)). Naturally and experimentally, placental growth precedes fetal growth, and failure of placental growth is directly associated with decreased fetal growth. There is considerable variation in this control, however. For example, experiments in sheep that limited placental growth did not result in proportionately reduced fetal weight, indicating that the capacity of the smaller placenta to transport nutrients to the fetus adaptively increased or that the fetus developed increased capacity to extract nutrients from the placenta and direct those nutrients to growth. More

characteristically, though, limitation in placental function to transfer nutrients to the fetus directly limits fetal growth. In fact, fetal growth restriction is seen as a natural and reproductively successful (though not perfect) compensatory adaptation to nutrient limitation. There is a direct relationship between fetal weight and placental weight in humans, although functional interactions between placenta and fetus also are important to fetal growth and development.

### Growth of the placenta and its transport capacity

Placental nutrient transfer capacity increases over gestation by increased placental growth, primarily of membrane surface area and vascular development in the fetal villi, allowing for the increase in nutrient supply required for the growing fetus. Placental size, morphology, vascular surface area, and membrane transporter abundance are regulated by imprinted paternally-derived genes, such as the placental-specific Igf2-H19 gene complex (Reik and Walter, 2001). A larger paternal vs. maternal Igf2 gene allele supply leads to a larger placenta and the potential for a larger fetus. Activity of the imprinted genes also can be affected by epigenetic modification, which allows for considerable environmental influence over gene expression. Thus, DNA methylation can limit placental-specific Igf-2 gene activity, leading to intrauterine growth restriction (IUGR) of the placenta and, in turn, the fetus.

### Maternal endocrine influences on fetal growth

Changes in maternal circulating growth hormone and growth hormone-like peptides such as placental lactogen, which increase during pregnancy, have combined effects that induce maternal insulin resistance and lead to higher circulating concentrations of glucose and lipids. These in turn are transported in increased amounts to the fetus where, combined with their stimulatory effects on fetal insulin and IGF-I and II, promote fetal adiposity (or macrosomia, as in the infant of the diabetic mother) and limit fetal protein breakdown, both of which promote fetal growth.

### Fetal endocrine and autocrine/paracrine-acting growth factor influences on fetal growth

**Pituitary Growth Hormone:** Growth hormone, which classically acts as the major regulator of postnatal growth, has no demonstrable influence on fetal growth.

**Insulin and IGFs:** Both insulin and IGF-1 regulate protein synthesis through well-recognized intermediates in their signal transduction pathways, including the mammalian target of rapamycin (mTOR) and the eukaryotic initiation factors, which are active in all cells throughout their lifespan, even in the fetal period (Shen et al., 2002). mTOR is an evolutionarily-conserved protein that functions as a sensor for growth factors, nutrients, energy, and stress, and coordinates these signals to regulate cell growth and proliferation.

**Insulin:** Fetal insulin does regulate fetal growth, although the complete absence of insulin does not abolish fetal growth. In sheep, for example, fetal pancreatectomy in late gestation limits fetal growth rate only by 20%–30%, and pancreatic agenesis in humans produces IUGR fetuses that are 30%–50% less than normal weight near term. Insulin infusions into the fetus and excessive fetal insulin secretion enhance fetal glucose utilization and produce increased adiposity. Such hyperinsulinemic conditions also limit protein breakdown, which supports increased protein accretion, but overall there is little impact of excess insulin to promote excess growth of non-fat lean body mass in the fetus. The primary action of fetal insulin is to promote glucose utilization and, in turn, enhance protein accretion by providing more energy substrate to fuel protein synthesis and to substitute glucose carbon for amino acids to fuel oxidative metabolism. For example, reducing fetal glucose supply lowers fetal weight and oxygen consumption to the same extent, indicating that oxidative metabolism of glucose was responsible for the growth. Similarly, removal of insulin from the fetus increases fetal glucose concentration and the transfer of glucose from mother to fetus via the placenta, which reduces fetal glucose oxidative metabolism and results in reduced net fetal carbon accretion and reduced fetal growth.

Insulin also acts in the fetus to increase amino acid uptake by cells in insulin sensitive tissues, promoting direct amino acid synthesis into protein via both the mTOR pathway and the MAP-kinase pathway, and, when energy is deficient, into oxidative metabolism and energy production (Brown et al., 2021). In the fetus and the preterm newborn, the anabolic effects of insulin on protein kinetics depend on the adequacy of circulating amino acids and glucose. Insulin is anabolic and induces a net gain in protein balance in the fetus and preterm infant when euglycemia, maintained by glucose infusion, is complemented by a mixed amino acid infusion producing aminoacidemia (Thureen et al., 2000).

Amino acids, and particularly leucine, also function as direct-acting nutrient signals that activate protein synthesis, which is true in normal and growth restricted fetuses (Brown et al., 2012). Leucine in particular can stimulate mTOR, the key regulator of the protein synthetic pathway, independently of insulin or IGF-1. However, amino acids alone do not activate the phosphorylation of any of the proteins in the protein synthetic pathway. Thus, insulin appears to be a more effective regulator of the mTOR signaling pathway in the fetus, at least when administered acutely (Brown et al., 2009). These observations indicate that amino acids can independently up-regulate particular signal transduction proteins during late gestation fetal growth and emphasize, as does the data showing insulin activation of the MAP-kinase pathway, that nutrient-hormonal interaction is central for regulation of growth.

Insulin-like Growth Factors, IGF-I and IGF-II: Mice lacking the IGF-I gene have markedly reduced rates of fetal growth in late gestation (Woods et al., 1996). IGF-II knockouts also have delayed fetal growth that is more pronounced in early to mid-gestation. IGF-I receptor knockout mice are more growth restricted than either IGF-I or IGF-II knockouts alone. These IGF-I receptor knockouts are growth restricted to the same extent as mice in which both IGF-I and IGF-II genes are deleted, confirming that receptor activation is the principal growth-regulating step in IGF-I and IGF-II action. IGFs also regulate fetal growth by regulating placental growth. IGF-II gene knockout mice have smaller placentas and, in turn, lower IGF-I and IGF-II binding proteins. IGF binding proteins modulate the effects of IGF-I and IGF-II on fetal growth. (Abuzzahab et al., 2003).

IGF-I also has been shown to have anabolic effects on protein metabolism in the fetus. A series of studies in late gestation fetal sheep have shown that fetal IGF-1 infusion suppresses whole fetal protein breakdown and amino acid oxidation, and increases organ growth without promoting amino acid transfer from the placenta, together resulting in net fetal protein accretion (Stremming et al., 2021). The effect of IGF-1 on the suppression of proteolysis was dose-dependent, and when combined with an insulin infusion, both hormones resulted in increased fetal protein synthesis.

## Interpretation of growth curves

Cross-sectional growth curves have been developed from anthropometric measurements in populations of infants born at different gestational ages. Such curves have been used to estimate whether growth of an individual fetus or preterm newborn is within or outside of the normal range of fetal growth, which has been most commonly but arbitrarily defined as between the 10th and 90th percentiles for the population of fetuses included in the growth curve analysis. Fetuses and newborn infants who are within the 10th and 90th percentiles for weight vs. gestational age are considered appropriate for gestational age (AGA), those who are less than the 10th percentile are considered small for gestational age (SGA), and those who are greater than the 90th percentile are considered large for gestational age (LGA). Importantly, fetuses and newborn infants who are <10th percentile or >90th percentile for anthropometric measurements can be perfectly normal, as their size is determined by parental stature and genetic background; they should not be assumed to have had fetal or intrauterine growth restriction or overgrowth simply based on their size.

Fetal and preterm neonatal growth curves represent the late second and the third trimester in humans. Each curve is based on defined, usually local populations with variable composition of maternal age, parity, socio-economic status, race, ethnic background, body size, degree of obesity or thinness, health, pregnancy-related problems, and nutrition, as well as the number of fetuses per mother, the number of infants included in the study, and how and how well measurements of body size and gestational age were made, all of which contribute to the wide range of anthropometric measurements at any gestation age. Variability also occurs because estimates of gestational age of newborn infants often are imprecise due to variations in maternal post-implantation bleeding and irregular menses, onset and appearance of physical features of maturation in the infant, and inter-observer assessments of an infant's developmental stage. The best of the many growth curve studies have excluded obviously abnormal infants, and have involved defined, relatively homogeneous populations. Even with such precautions, there has been no complete assurance that all of the infants included in the cross sectional measurements who were born preterm had grown normally in utero; therefore, it is not known for certain whether their anthropometric measurements at birth represent those of normally growing fetuses. It is likely, however, that inclusion of a relatively small number of slowly growing fetuses is balanced by an approximately equal number of more rapidly growing fetuses. Furthermore, anthropometric measurements have their own inherent range of accuracy, and cross-sectional, static size-for-gestational-age groupings of neonates may not accurately reflect the dynamics of fetal growth (Demerath and Fields, 2014). In addition, means of fetal growth rates from different populations do not necessarily reflect growth of a given fetus or the changes in body composition with growth that occur with advancing gestational age.

A large variety of fetal growth curves developed from cross sectional measurement of weight at birth are shown in Fig. 7, representing infants born in North America and Europe and from low and high socioeconomic backgrounds, multiple races and ethnic origins, "normally" short and tall mothers as well as the majority of normal sized mothers, and low (sea level) and moderately high (~1 mile, or ~1500 m) altitudes. The average fractional growth rate or growth velocity among this diverse population is 17 g/day/kg, ranging from 15 to 20 g/day/kg for average sized infants, slower for smaller infants and faster for larger infants. The Fenton growth curves are the most robust, with ~4 million infant measurements <37 weeks gestational age from several international populations screened for normal pregnancies and excluding abnormal infants (Fenton and Kim, 2013). The Olsen (~250,000 singleton "normal" preterm infants, 57.2% male, who survived to discharge), NICHD Fetal Growth Studies (~1700 infants, serial ultrasound and birth weight combinations, including data for race and ethnicity), and Mihatsch et al. (~1.8 million "normal" preterm infants in Germany) growth curves are similar, representing data from North America and Europe (Olsen et al., 2010; Buck Louis et al., 2015; Mihatsch et al., 2004). Given the commonality of growth rates from these diverse studies representing almost 8 million infants, it is unlikely that concerns regarding inclusion of abnormally growing infants are significant.

The Intergrowth 21st curves are projections into the fetal period from serially measured growth, primarily after birth through 2 years of age, of "healthy" infants of "healthy" mothers from pooled international populations that included smaller mothers and mothers from different racial and ethnic backgrounds (Kiserud et al., 2017). In marked contrast to the approximately 8 million infants in the fetal curves from Fenton, Olsen, NICHD, and Mihatsch, the actual fetal data used for the Intergrowth 21st curves

**Fig. 7** Regardless of the growth curve, birth weight by gestational age is relatively constant from ~26 to 38 weeks gestation at an *average* growth rate of ~15–20 g/kg/day (mean of 17 g/kg/day). Adapted from Naeye and Dixon (1978), Fenton and Kim (2003), Olsen et al. (2010), Mihatsch et al. (2004), Buck Louis et al. (2015).

included only 201 infants <37 weeks, only 12 infants (9 males and 3 female) <32 weeks, and no female infants <30 weeks; the fetal data are not normally distributed, as the curves are projected from postnatal growth. Thus, the Intergrowth 21st fetal growth curves do not represent actual fetal growth as well as the very large and robust cross sectional growth curves noted in Fig. 7.

The two recent growth curves that have been derived in part from serial fetal ultrasound measurements during gestation, the NICHD Fetal Growth study and the Intergrowth-21st Project, provide continuous rather than cross-sectional growth patterns when combined with neonatal birth weight data at the completion of a pregnancy (Buck Louis et al., 2015; Kiserud et al., 2017). Curiously, there is an apparent conflict between such ultrasound-derived fetal growth curves that show a rate of fetal growth in late gestation that is continuous with postnatal growth rather than the actual slowing of fetal growth rate in late gestation (after 36 weeks in human gestation) that has been shown with actual measurements in humans and animal models (see Fig. 2).

There are, however, several advantages of serial ultrasound measurement of fetal growth. Serial ultrasounds theoretically permit examination of the change in fetal growth with time in normal pregnancies rather than establishing growth curves based only on birth weights of pregnancies that are by definition pathological because they ended prematurely. Ultrasound-derived fetal growth curves also may allow the early detection of fetuses who are not SGA, but who are experiencing growth faltering or IUGR, or those who are growing faster than normal in terms of circumferences, whether LGA or not, such as in infants of diabetic and/or obese mothers. Serial ultrasound measurements of fetal growth also can help determine how environmental factors can inhibit (for example, maternal under nutrition globally, or hypoglycemia specifically) or enhance (for example, maternal over nutrition globally or hyperglycemia and hypertriglyceridemia specifically) the rates of fetal growth.

There are several nutritional implications of fetal and preterm neonatal growth curves. Growth should proceed symmetrically following normal fetal growth for weight, length, head circumference, and body lean and fat mass components. Failure to provide sufficient protein and energy nutrition, from either maternal or neonatal under nutrition, leads to growth faltering that universally has been shown to produce later life shorter stature and abnormal neurodevelopment. Excess maternal protein intake does not increase fetal growth and actually may worsen growth restriction and lead to fetal death, especially when the fetus already is growth restricted (Rush et al., 1980). Excess energy, even when length and head circumference of the fetus or preterm infant are growing appropriately, leads to excess fat mass production. When this occurs in fetal life, it appears to predispose to later life obesity, whereas modest amounts of excess fat in the preterm infant do not appear to last. Mechanisms for this discrepancy are uncertain, but might relate to the development of excess adipocytes in the fetus, perhaps from mesenchymal stem cells that populate and then proliferate in peripheral adipose tissue, that does not occur after birth (Baker et al., 2017). When fetal IUGR is the result of placental insufficiency, the fetus also is deprived of oxygen and is relatively hypoxic, a condition that also might lead to later life excess adiposity. This would not likely occur in preterm infants after birth when oxygenation is normal.

### Extremes of growth and development: intrauterine growth restriction and macrosomia

Extremes of fetal growth and body composition are important, as both IUGR and macrosomia may predispose the fetus to the same later life disorders of obesity, insulin resistance, and type 2 diabetes, despite their very different patterns of intrauterine growth (Godfrey et al., 2011).

**Intrauterine growth restriction (IUGR)**

In developed countries, three to seven percent of newborns are classified as IUGR. The percentages vary depending on arbitrary definitions, such as <10th percentile or >2 standard deviations below the mean for a population based on weight at birth at a given gestational age. Any definition of IUGR likely is an underestimate, however, as it is commonly based on infants who are SGA (e.g., <10th percentile weight for gestational age), whereas fetal growth restriction can occur within normal percentiles of weight, length, and circumferences. For example, an infant at the 50th percentile at 20 weeks gestation but falls to the 25th percentile by 30 weeks has experienced growth faltering or IUGR, but still is within normal weight for gestational age ranges. Attempts also have been made to improve the diagnosis of fetal growth faltering or IUGR by the use of standards that incorporate maternal and paternal size, which aim to distinguish fetuses that grow more slowly than normal and are smaller at any gestation because the parents are small from those with growth faltering resulting from a disease process (Robinson et al., 2000).

Most cases of fetal growth faltering occur when the fetus experiences deficits in oxygen and nutrient supplies from a less than optimally functioning placenta; these cases are identified as Placental Insufficiency IUGR (PI-IUGR). Most of the oxygen and nutrient deficits can be attributed initially to maldevelopment of the placenta, which not only is reduced in size but also has structural abnormalities in its vasculature and reductions in transport capacity. These changes in the placenta, with the additional factor of chronic hypoxia, can lead to circulatory changes in many fetal vascular beds and altered metabolism that produce a wide range in clinical severity of PI-IUGR. Animal based studies and human observational studies indicate, however, that the placenta is not always dysfunctional in IUGR pregnancies. Instead, adverse changes in placental transport observed in the fetal growth restriction placenta also represent adaptations to reduced fetal anabolic metabolism and growth in response to an inability of the mother to allocate resources to the fetus.

Recent studies in fetal sheep with placental insufficiency have clarified the mechanisms by which fetal hypoxemia leads to fetal growth faltering. Fetal hypoxemia increases blood flow to the fetal adrenal glands and increases adrenal norepinephrine output. The increased norepinephrine inhibits pancreatic insulin secretion, which in turn decreases fetal growth rate (Leos et al., 2010). Fetal oxygenation therefore plays a central role in the pathogenesis of all placentally mediated fetal IUGR. The reduced oxygen delivery in IUGR fetuses indicates impaired placental oxygen transport, whereas reduced fetal oxygen consumption presumably reflects metabolic adaptation to diminished substrate delivery that results in slower fetal growth.

Postnatal complications of the unique IUGR fetal metabolism are common and can be quantitatively significant. IUGR fetuses have up-regulated peripheral glucose and insulin sensitivity in response to low glucose and insulin concentrations, with maintained or even increased glucose transporter concentrations in insulin independent (brain—Glut 1) and insulin sensitive (skeletal muscle, heart—Glut 4) tissues. These changes maintain glucose utilization rate (GUR) and insulin sensitivity, i.e., GUR/kg is normal at less than normal glucose and insulin concentrations. Also, although glucose stimulated insulin secretion (GSIS) is reduced in IUGR fetuses, they also have increased in vitro fractional islet insulin secretion. In vivo, IUGR fetuses are relatively hypoxic and have increased plasma catecholamine concentrations. Fetal insulin concentrations increase with an adrenergic receptor blockade, proof that they suppress insulin secretion in IUGR fetuses. Increased peripheral glucose uptake capacity from increased or at least maintained glucose transporters persists well after birth. Increased fractional insulin secretion also persists, as does increased insulin secretion after reduction of catecholamine suppression of insulin secretion. When added to the greater brain to body (or liver) ratio and thus greater body weight-specific GUR in asymmetrically grown IUGR infants, persistent hypoglycemia clearly is a natural complication of normal adaptive mechanisms in the fetus that maintain glucose utilization at the expense of growth, thereby ensuring survival. After birth, persistence of this condition can lead to maladaptive hypoglycemia (Hay et al., 2016a).

Generally, chronically IUGR fetuses have less subcutaneous fat and skeletal muscle, with low weight/length ratios or low Ponderal Index values ( $\text{Ponderal Index} = \text{weight (grams)} / [\text{length (cm)}]^3$ ) that are the result of reduced skeletal muscle mass as much as or more than reduced fat mass. IUGR fetuses, in fact, uniquely have reduced muscle mass from reduced insulin and amino acid activation of net protein synthesis and myocyte proliferation (Brown and Hay, 2016). IUGR imposes increased risks of specific types of fetal and neonatal morbidity and mortality (Table 5). The earlier fetal growth restriction develops the longer it lasts, and the more severe it becomes the more likely the infant will have persistent short stature after birth (Villar et al., 2021), even into adulthood. Muscle mass also is permanently limited, as myocyte proliferation stops with birth; this is true for both skeletal and cardiac myocytes, the former contributing to risk for diabetes and the latter to heart failure (Sayer et al., 2008; Louey et al., 2007). Brain growth also is diminished, including permanent deficits in neuronal number, dendritic formation and arborization, and synapse development, leading to permanent neurodevelopmental, cognitive, and behavioral deficits later in life (Smart, 1986).

**Possible adult disorders resulting from intrauterine growth restriction**

Interest in IUGR has been enhanced recently by retrospective epidemiological, clinical follow-up, and animal studies that indicate long-term consequences in adult life of chronically IUGR offspring, including higher incidences of obesity, insulin resistance, impaired glucose tolerance, enhanced hepatic glucose production, pancreatic insulin secretion deficiency, type 2 diabetes mellitus, hypertriglyceridemia, and cardiovascular disease, particularly hypertension (Bloomfield et al., 2006). These conditions, often called the Metabolic Syndrome, may represent an example of “programming,” in which an insult, when applied at a critical or sensitive stage in development, produces lasting, even lifelong, effects on the structure or function

**Table 5** Risks of specific types of fetal and neonatal morbidity and mortality in IUGR infants.

<i>Problem</i>	<i>Pathogenesis/pathophysiology</i>
Intrauterine death	Chronic hypoxia Placental insufficiency Growth failure Malformation Infection Infarction/abruption
Asphyxia	Preeclampsia Acute hypoxia/abruption Chronic hypoxia Placental insufficiency/preeclampsia Acidosis Glycogen depletion
Meconium aspiration	Hypoxia
Hypothermia	Cold stress Hypoxia Hypoglycemia Decreased fat stores Decreased subcutaneous insulation Increased surface area Catecholamine depletion
Persistent pulmonary hypertension	Chronic hypoxia
Hypoglycemia	Decreased hepatic/muscle glycogen Decreased alternative energy sources Heat loss Hypoxia Decreased gluconeogenesis Decreased counterregulatory hormones Increased insulin sensitivity
Hyperglycemia	Low insulin secretion rate Excessive glucose delivery Increased catecholamine and Glucagon effects
Polycythemia/hyperviscosity	Chronic hypoxia Maternal–fetal transfusion Increased erythropoiesis
Gastrointestinal perforation	Focal ischemia Hypoperistalsis
Acute renal failure	Hypoxia/ischemia
Immunodeficiency	Malnutrition Congenital infection

of the organism. Mechanisms responsible for these later-life morbidities are not fully established. There is relatively consistent evidence in human IUGR infants and those produced experimentally in animal models of diminished pancreatic growth and development, which might present later in life as pancreatic insufficiency when the adult starts and then continues eating a diet rich in simple carbohydrates and lipids. IUGR fetuses also tend to have increased peripheral insulin and glucose sensitivity, which would augment fat production and obesity with such a diet (Thorn et al., 2011). The fetal liver in response to lower plasma glucose concentrations and perhaps hypoxia develops net glucose production from hepatic insulin resistance, the opposite of the increased peripheral insulin sensitivity, with increased development and activation of the key regulatory gluconeogenic enzymes, particularly PEPCK (Wesolowski and Hay, 2016). In part, these changes in IUGR fetal metabolism represent a compensation to maintain glucose supply to the brain and heart as glucose concentrations decline. Over time, however, these changes in fetal metabolism are overcome by peripheral insulin resistance, presumed to be the result of developing obesity with reduction in the insulin signal transduction pathways in both adipocytes and myocytes that result from specific products of intracellular fat metabolism, leading to glucose intolerance. When coupled with pancreatic insufficiency, this would lead to type 2 diabetes. A common theme among these observations is that excessive weight gain of adipose tissue starting at any weight percentile and continuing or even starting after birth is the strongest predictor of the Metabolic Syndrome disorders. The greatest risk for obesity is excess fat mass gain after 6 months to one year after birth. Hypertension in adulthood in individuals who experienced IUGR, also part of the Metabolic Syndrome, may be the result of restricted renal and adrenal development.

## Macrosomia

At the other end of the birth weight spectrum are macrosomic, large for gestational age (LGA) infants. These infants were exposed to excess nutrient supply in utero, principally of carbohydrates and lipids. Macrosomic newborns have increased specific morbidities primarily associated with metabolic complications of maternal diabetes mellitus during pregnancy and associated birth complications and birth injuries as a result of excessive fetal size.

Macrosomia is defined in a newborn as a birth weight more than two standard deviations above the mean percentile for gestational age, >90th percentile weight for gestational age, or a birth weight greater than 4000 g at term. Neonatal macrosomia has a strong ethnic predisposition affecting up to 50% of Latino and Native American pregnant women versus 19% of African-American pregnant women. Macrosomia is characteristic of infants of diabetic mothers (IDMs) who were hyperglycemic during pregnancy. The diabetes can be long standing, but the most common group producing macrosomic infants are women with gestational diabetes mellitus (GDM), most of whom also are obese, and obesity itself predisposes to fetal macrosomia (Heerwagen et al., 2010). The percentage of pregnant women who have some form of GDM has been increasing worldwide and now is well above the historical range of 3–5 % of all pregnancies, perhaps as high as 20–50%. The risk of macrosomia is not consistent across all classes of diabetes; it primarily reflects the degree and duration of maternal hyperglycemia and hypertriglyceridemia and particularly high spikes of these conditions following meals that are more common in gestational diabetes. Maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia; maternal and fetal hypertriglyceridemia contribute to the effect of the excess glucose and insulin to produce excess fat deposition in the fetus.

## Development of type II diabetes in later life in macrosomic offspring

IDMs, particularly those with macrosomia, have increased risk of developing Type II diabetes earlier in life. Mechanisms responsible for this sequence of events include insulin resistance and insufficient insulin secretion ( $\beta$ -cell dysfunction) in response to hyperglycemia. Typically, glucose intolerance from obesity and increased insulin resistance progress to fasting hyperglycemia and the inability of pancreatic  $\beta$ -cells to compensate by increasing their rate of insulin secretion. This form of  $\beta$ -cell failure appears to be reversible over short periods by improved glycemic control, but long-term exposure to hyperglycemia can lead to  $\beta$ -cell exhaustion and specific inhibition of insulin secretion. The insulin resistance also extends to the liver where glucose production increases. This triad of insulin resistance, reduced  $\beta$ -cell insulin secretion, and increased hepatic glucose production produces Type II diabetes.

## Conclusion/summary/outlook

The fetal period of growth and development encompasses the greatest changes in growth rate and body proportions and composition during the life of an organism. Total body cell number and the cellular structure of all organs takes place during this period. Such growth and development require adequate supplies of oxygen, amino acids (both essential and non-essential), carbohydrates (principally glucose), lipids (principally essential fatty acids), water, and minerals. Such supplies are regulated by the size and function of the placenta. Growth of the placenta is dependent on paternal genes and the size of the uterus, which is directly related to maternal height. Restriction of fetal growth (IUGR, or a slower than normal rate of fetal growth) most commonly occurs due to a smaller, dysfunctional placenta, and in under developed areas, from maternal under nutrition. Maternal over nutrition, principally of sugar and fat, leads to fetal macrosomia (excess body fat), which is the most common outcome in pregnancies complicated by maternal diabetes and obesity. Both fetal growth restriction and fetal macrosomia are associated with later life metabolic disorders, including obesity, insulin resistance, and diabetes.

### Key points

- List the main objectives and activities linked to growth monitoring and promotion.
- Summarize the proper measurement of weight, length, and height.
- Explain the use and interpretation of growth measurements using a standard or reference population, an appropriate anthropometric index, and a correct cutoff point to define an anthropometric indicator.
- Summarize some challenges with growth monitoring and promotion.
- Describe the evidence for effectiveness of growth monitoring and promotion.

### Glossary

**Growth monitoring** The serial weighing and measuring of the length/height (and head circumference if  $\leq 2$  years old) of a child and graphing these measurements on a growth chart

**Growth promotion** The process of assessing growth using repeated weight, length/height, or head circumference measurements and providing counseling and motivation for actions to improve patterns of growth, nutrition, and health

**Growth surveillance** Monitoring the growth status of a population. Usually, measurements of height and weight are taken periodically on a representative sample of children to monitor trends in growth status in the population over time

**Growth standard** Defines a recommended pattern of growth that has been associated empirically with specified health outcomes and minimization of long-term risks of disease. It represents “healthy” growth of a population and suggests a model or target pattern of growth for all children to achieve. A standard describes “what should be”

**Growth reference** Describes the expected growth pattern of a defined population, without making any claims about associated health outcomes. A reference describes “what is”

**Growth velocity** The average change in a specific anthropometric measure over a specific age interval. Growth velocity varies depending on the child’s age and is a more sensitive measure of small changes in growth status than attained growth

**Length/height** The length or height of children is measured from the top of the child’s head to the bottom of their heel. In children under 24 months of age, recumbent length is used; in children 24 months and above, standing height is used

**Malnutrition** Deficiencies, excesses, or imbalances in intake of energy, protein and/or other nutrients. The term malnutrition includes both undernutrition and overnutrition

**Z-scores** Z-scores are a statistical unit used to describe how far a measurement is from the standard or reference population average (i.e., mean or median). Percentiles are commonly used in the clinical setting. Use of z-scores is almost universal for population-based applications and research reporting. For comparison purposes, the 50th percentile is equal to a z-score of 0, the 15th and 85th percentiles approximate z-scores of  $-1$  and  $+1$  respectively, the 2.5th and 97.5th percentiles approximate z-scores of  $-2$  and  $+2$  respectively, and the 1st and 99th percentiles approximate z-scores of  $-3$  and  $+3$ , respectively

<i>Z-score</i>	<i>Exact percentile</i>	<i>Rounded percentile</i>	<i>Z-score</i>	<i>Exact percentile</i>	<i>Rounded percentile</i>
0	50th	50th			
−1	15.9	15th	+1	84.1	85th
−2	2.3	3rd	+2	97.7	97th
−3	0.1	1st	+3	99.9	99th

## Introduction

Growth monitoring and promotion is regarded as an essential component of primary health care for infants and children. Serial measurements of weight and height for all children, and head circumference for infants and toddlers, are compared with the growth of a large sample population of children depicted on an appropriate growth chart and are used to confirm a child's healthy growth and development. The objective of growth monitoring and promotion is to screen for potential nutritional or health problems which subsequently prompts action before a child's health is seriously compromised.

The consequences of undernutrition during the early years include compromised immunity, cognitive problems, and stunted growth. Excess energy intake may predispose to conditions such as obesity, diabetes, and metabolic syndrome later in life. When potential problems are identified early, health professionals, and parents can work together to initiate action before the child's nutritional status or health are significantly affected.

Despite the ubiquitous use of growth monitoring and promotion globally, how effective it is and the conditions that would make it effective are not known.

## Objectives and activities

The main objectives of growth monitoring and promotion are to:

- Screen children at risk of poor nutrition and health.
- Initiate effective action in response to abnormal patterns of growth.
- Teach parents how nutrition, physical activity, genetics, and illness can affect growth and, in doing so, motivate and facilitate individual initiative and improved child-care practices.
- Provide regular contact with and facilitate use of primary health care services.

Activities linked to growth monitoring and promotion at the individual level include:

- Accurately measuring weight, length or height, and head circumference.
- Precisely plotting measurements on the appropriate growth chart.
- Correctly interpreting the child's pattern of growth.
- Discussing the child's growth pattern with the parent(s) or caregiver and agreeing on subsequent action when required.
- Assessing the child's response to the actions.

Adapting the objectives and activities of interventions to the environment in which they are used is important. In practice, growth monitoring is different in low-income and high-income settings due to differences in the burden of disease, resources, and training. In low- and middle-income countries, undernutrition and infectious diseases such as diarrhea and respiratory infections are believed to primarily affect growth outcomes in the first 5 years of life. In contrast, in high-income countries, such conditions are less common and milder, and the focus is more on growth disorders such as growth hormone deficiency or Turner's syndrome. This different focus affects the target age range when children are monitored. Whereas in low- and middle-income countries growth monitoring targets children under 5 years of age, in high-income countries it covers all of childhood up to and including puberty.

In addition to detecting disease and raising parental awareness at the individual level, growth monitoring theoretically can create community mobilization. With caregivers being more aware and concerned about their child's health, they may influence community leaders and collective action to improve the underlying social and economic determinants of poor health.

Growth surveillance (i.e., monitoring the growth of populations) provides information about average child growth and prevalence of growth faltering that is useful for comparison, policy, and planning. For example, monitoring the growth status of populations from different regions is useful for identifying areas where the prevalence of malnutrition is highest, which in turn allows resources and support staff to be effectively targeted.

## Measurement of growth

During infancy, the measurement of weight is simple to do, requires reasonably inexpensive equipment, and provides a convenient global summary of the infant's size. Birth weight is a useful proxy for fetal growth. An advantage of weight is that it relates closely to the caregivers' own perception of her child's size. Although weight is the easiest anthropometric measure to obtain, weight lacks the biological specificity necessary to differentiate variation due to height from variation due to body mass at a given height.

The routine collection of length or height measurements (recumbent length before 24 months of age and standing height for older children) is important to enable the assessment of length or height itself and weight relative to length or height. Body mass index (BMI) (i.e., ratio of weight in kilograms to the square of height in meters) is valuable for monitoring both undernutrition and overweight and obesity in childhood. During infancy, length is difficult to measure for several reasons. The optimal equipment is a length board with a sliding footboard, which is expensive and needs regular calibration. Simpler equipment such as a tape measure increases the measurement error dramatically. Furthermore, proper length measurement requires two trained observers, one to hold the infant's head against the headboard and the other to position the footboard and take the measurement. Keeping an infant still long enough to take the measurement is challenging. For these reasons, infant length is often measured either poorly or not at all. Standing height is best measured with a stadiometer or a tape measure that has been carefully attached to a wall and a measuring block for the head.

Head circumference is another important measure in neonates and toddlers to detect abnormal patterns of growth due to conditions such as inadequate nutrition or hydrocephalus. Other available anthropometric measures that are used to describe growth status during childhood include mid-upper arm circumference, which is most commonly used in resource-poor settings to detect acute malnutrition. Other measurements such as triceps and subscapular skinfolds are useful proximate measures of body fat but are not widely used due, in part, to technical difficulties and the required skill of individuals to perform the measurements accurately and precisely.

The process of anthropometry requires attention to detail; suitable equipment that is regularly maintained and calibrated; observers who are trained in correct measurement technique; regular quality control sessions in which observers are checked against both themselves, each other, and an expert, for intra-rater and inter-rater reliability, measurement precision, and accuracy; correct recording and graphing of the results; and correct interpretation. Only in this way can valid conclusions be made.

Variability in infant and child measurements can result from several influences: the setting in which the measurements are taken (e.g., home or clinic), the degree of filling of the stomach or bladder (for weight), the behavior and cooperation of the child being measured, accuracy and precision of instruments, the technical ability (i.e., training, experience, and reliability) of the anthropometrist, and the methods for recording data. Adequate training on the use of appropriate measurement techniques, continual standardization, adherence to specified methods and procedures, and monitoring of data quality are essential for reducing measurement error and minimizing bias. A comprehensive description of the techniques used in the development of the WHO Child Growth Standards can be found under the Further Reading section.

## Use and interpretation of growth measurements

The proper use of growth measurements requires the selection of (1) an appropriate standard or reference population with which to compare the child or community, (2) an appropriate anthropometric index, and (3) correct cutoff points to interpret anthropometric measurements and classify children according to the extent of malnutrition.

## Growth standards and references

In the context of growth assessments, the distinction between a standard and a reference is important from theoretical and practical perspectives. A standard defines a recommended pattern of growth that has been associated empirically with specified good health outcomes and minimization of long-term risks of disease. A standard embodies the concept of a norm or target and thus leads to a value judgment about what should be. In contrast, a reference describes the expected growth pattern of a defined population without making any claims about associated health outcomes. A reference provides a means of grouping and analyzing data and making comparisons but does not involve a value judgment.

There is now broad international consensus about the utility of the World Health Organization (WHO) Child Growth Standards ([www.who.int/childgrowth/en](http://www.who.int/childgrowth/en)) for assessing the growth of preschool children. Based on an international sample of breastfed infants and young children, the WHO standards depict human growth of children up to 60 months of age under optimal environmental conditions and can be used to assess children everywhere, regardless of ethnicity, socioeconomic status, and type of feeding. A salient outcome of the WHO growth standards project is the striking similarity in length or height of the child populations from the six countries (Brazil, Ghana, India, Norway, Oman, and the USA) that participated in the study (Fig. 1). The WHO standards have been adopted by more than 120 countries worldwide. Figs. 2, 3 and 4 present examples of generic WHO growth charts for weight, height, and head circumference in the age group 0–60 months. Useful software to monitor the growth of individual children and populations can be found at [www.who.int/tools/child-growth-standards/software](http://www.who.int/tools/child-growth-standards/software).

After 5 years of age, the WHO reference for school-age children and adolescents is recommended by the WHO for both clinical and epidemiological use in the 5–19 years age group. The full set of tables and charts is available at [www.who.int/toolkits/growth-reference-data-for-5to19-years](http://www.who.int/toolkits/growth-reference-data-for-5to19-years), including application tools such as software for clinicians and public health specialists.

## Anthropometric indices

Anthropometric indices are combinations of measures and are essential for interpretation and comparison. In children the three most used indices to assess growth status are weight-for-age, height-for-age, and weight-for-height. Weight-for-age is the most used and, in many low-income countries, the sole anthropometric index used. These anthropometric indices can be expressed as Z-scores or percentiles relative to a standard or reference population. A Z-score (i.e., standard deviation score) is the difference between an individual measurement and the sex-specific median value of the standard or reference population, divided by the sex-specific standard deviation of the standard or reference population. A Z-score of zero corresponds to the measurement being at the median of the standard or reference population. Z-scores of +1 and –1 correspond to values one standard deviation above or below the median, respectively. Z-scores of +2 and –2 correspond to analogous values. Z-scores are comparable across ages, sexes, and other traits. For example, a Z-score of +2 always designates the same relative position within a normal distribution. This consistency has enormous advantages whenever comparisons are made.

## Indicators, cutoff points, and interpretation of anthropometric measurements

Indicators are intended to provide guidance for assessment, referral, or intervention by selecting a cutoff point for a continuous anthropometric measure or index. Cutoffs can be based on the mathematical estimation of presumed risk depending strictly on the cutoff's distance from a given measurement's average (i.e., mean or median) or on a demonstrable link between the cutoff and a designated health outcome (e.g., illness or death).

Indicators are commonly expressed in terms of cutoffs in percentiles or multiples of a standard deviation (i.e., Z-score) of the targeted measure's distribution. The recommended cutoffs (percentiles and Z-scores) by the WHO for classification of undernutrition and overnutrition are presented in [Table 1](#).

**Fig. 4** Head circumference-for-age for boys from birth to 5 years (z-scores). Reproduced from WHO Child Growth Standards at <https://www.who.int/tools/child-growth-standards/standards>.

**Table 1** Recommended cutoffs by the WHO for classification of undernutrition and overweight/obesity.

Indicator	WHO child growth standards (birth to 5 years)	WHO reference 2007 (5–19 years)
Underweight (i.e., low weight-for-age)	<–2 Z-scores or <3rd centile	<–2 Z-scores or <3rd centile
Stunted (i.e., low length-for-age or height-for-age)	<–2 Z-scores or <3rd centile	<–2 Z-scores or <3rd centile
Wasted (i.e., low weight-for-length/height or BMI-for-age)	<–2 Z-scores or <3rd centile	<–2 Z-scores or <3rd centile
Overweight (i.e., high weight-for-length/height or BMI-for-age)	>+2 Z-scores or >97th centile	>+1 Z-scores or >85th centile
Obese (i.e., very high weight-for-length/height or BMI-for-age)	>+3 Z-scores or >99.9th centile	>+2 Z-scores or >97th centile

An important concept in the use of anthropometric measurements for interpreting growth is the need for serial measurements. One-time measurements, taken and plotted accurately on a growth chart, reflect a child's size at one time and may be used to screen children for nutritional risk using the cutoffs indicated in [Table 1](#). One-time measurements do not provide adequate information to assess a child's growth and are not sufficient to be considered growth monitoring ([Mangasaryan et al., 2011](#)). A series of weight and length or height measurements over time are more informative and reflect a child's growth pattern.

The interpretation of the commonly used anthropometric indicators (based on one-time measurements) is as follows:

**Low weight-for-age:** Weight-for-age reflects body mass relative to chronological age. It is influenced by both the child's height and his or her weight. Its composite nature makes interpretation uncertain. For example, weight-for-age fails to distinguish between short children of adequate body weight and tall, thin children. In the absence of significant acute malnutrition in a community, similar information is provided by weight-for-age and height-for-age in that both reflect an individual's or population's long-term health and nutritional experiences. Short-term changes, especially reductions in weight-for-age, reveal changes in weight relative to height. In general terms, the worldwide variation of low weight-for-age and its age distribution are like those of low height-for-age.

*Low height-for-age:* Stunted growth reflects a process of failure to reach linear growth potential because of suboptimal health or nutritional conditions. On a population basis, high levels of stunting are associated with poor socioeconomic conditions and increased risk of frequent and early exposure to adverse conditions such as illness or inappropriate feeding practices. Similarly, a decrease in the national stunting rate is usually indicative of improvements in overall socioeconomic conditions of a country. The worldwide variation of the prevalence of low height-for-age is considerable, ranging from 5% to 65% among low-income countries.

In populations without significant undernutrition, low height-for-age in individual children likely signals deprivation due to conditions not necessarily related to poverty. Thus, for example in high-income countries, it is necessary to also consider the possible metabolic or genetic mechanisms that may result in growth failure.

*Low weight-for-height:* Wasting or thinness results in most cases from a recent and severe process of weight loss, which is often associated with acute starvation or severe disease, but wasting also may be the result of chronic unfavorable conditions. Provided there is no severe food shortage, the prevalence of wasting is usually below 2.5%, even in poor countries.

*High weight-for-height:* Overweight is the preferred term for describing high weight-for-height. Even though there is a strong association between high weight-for-height and obesity as measured by adiposity, greater lean body mass can also contribute to high weight-for-height. On an individual basis, therefore, fatness or obesity should not be used to describe high weight-for-height.

*High BMI-for-age:* Another measure of body mass relative to height, BMI, provides a widely used indicator for classifying overweight and obesity for individual and population use. Although there is some reluctance to describe children as obese based on BMI alone, i.e., without considering more direct measures of body fat, recognition of the difficulties inherent in obtaining more proximate measures of body fat and lack of references to interpret them has resulted in BMI-for-age alone being used to define overweight and obesity. In its favor, high BMI-for-age in childhood and adolescence is associated with high percentages of body fat and known risk factors for cardiovascular disease.

## Challenges in conducting growth monitoring and promotion

Conducting growth monitoring and promotion is challenging in practice. Some challenges are limited agreement about what growth monitoring and promotion actually means and what are its objectives (Mangasaryan et al., 2011), poor quality measurements and other implementation constraints (Mangasaryan et al., 2011; Roberfroid et al., 2005a; Scherdel et al., 2016), problems of low coverage (Mangasaryan et al., 2011; Roberfroid et al., 2005a), lack of guidance on serial measurements, and the absence of internationally agreed and validated algorithms to define abnormal growth (Scherdel et al., 2016; Roberfroid et al., 2005a).

The lack of agreement on a definition of growth monitoring and promotion and confusion around its objectives has resulted in discordant expectations and minimal evidence of its impact (Mangasaryan et al., 2011). For instance, there are no set agreed-upon activities that constitute growth promotion. Furthermore, other interventions are often built into growth monitoring and promotion activities, without distinguishing them as separate inputs with potentially separate objectives.

Quality of implementation of growth monitoring and promotion activities depends largely on the context. Experiences from large-scale programs in low- and middle-income settings have demonstrated important deficits in the technical abilities of staff to measure and chart growth but also in interpreting growth charts and initiating appropriate action. These deficits are particularly striking in situations where resources for the latter activities are lacking, making growth monitoring a futile exercise. Training of health workers on effective counseling and communication skills is essential to the quality of implementation. When conveying messages and recommendations to parents, health workers need to ensure this information leads to benefits rather than harm due to the potential for misinterpretation of information. For instance, growth monitoring may not be beneficial if parents who are assured that they do not have a stunted child then interpret this message as no longer needing to give as much attention to their child's nutrition and subsequently reduce the support provided to that child.

Coverage of growth monitoring and promotion on a large-scale, to reach all target children in a setting, has proved to be challenging. Attendance is low, particularly in older children and in families with the most at-risk children. Low attendance could be due to parents' lack of interest after completing the vaccination schedule, weakness of awareness campaigns to motivate caregivers, and barriers to using the information received during the monitoring sessions because of illiteracy and low food access (Roberfroid et al., 2005b).

Although growth monitoring entails periodic frequent anthropometric measurements, guidance is lacking on how to conduct and interpret the repeated measurements. For instance, no consensus exists on the recommended frequency for growth monitoring. UNICEF recommends monthly growth monitoring in the first year of life (with no recommendation thereafter), whereas WHO has no recommended schedule but indicates to follow country-specific guidance if available (WHO, 2008).

A review of 69 studies reporting algorithms for growth monitoring in children found seven algorithms used to define abnormal growth, but all suffered from lack of validation and poor sensitivity and specificity (Scherdel et al., 2016). The lack of validated algorithms is especially marked in high-income countries where the emphasis is on detecting primary growth disorders such as Turner syndrome, Celiac disease, cystic fibrosis, growth hormone deficiency, renal tubular acidosis, and small-for-gestational age with failure to catch up.

## Evidence of effectiveness

Growth monitoring and promotion, along with other activities, is often seen as a catch-all for nutritional problems and an effective means of improving the nutritional status of children. No rigorous evidence exists, however, on the effectiveness of growth monitoring and promotion that justifies its use. A 2000 Cochrane Review attempted to answer the question “Does growth monitoring work?” The authors defined growth monitoring as “the regular recording of a child’s weight, coupled with some specified remedial actions if the weight is abnormal in some way” (Panpanich and Garner, 2000). Only two randomized clinical trials testing the effectiveness of growth monitoring were identified. In India, there was no difference in mean weight or height gain between children whose growth was monitored for 30 months and control children (George et al., 1993). A study in Lesotho showed that mothers trained to use a growth chart were more knowledgeable about growth patterns after 4 months (Ruel et al., 1990). A recently conducted cluster-randomized trial in Zambia assessed the effectiveness of two growth monitoring models: home-based growth monitoring using a growth chart installed against a wall at home and community-based growth monitoring combined with a micronutrient-fortified soy and maize flour for children with stunted linear growth (Fink et al., 2017). No differences were found in child length or height growth between the two models. Compared to their peers in the control group who received no intervention, those who received community-based growth monitoring with nutrition supplementation performed worse on developmental tests.

## Conclusion

Growth monitoring and promotion activities are meaningful if they empower parents to provide adequate nutrition, care, and support for their child. Despite the limited evidence on the effectiveness of growth monitoring and promotion, enormous resources are devoted to it each year in low-, middle-, and high-income countries. The near-universal implementation appears to be mostly motivated by the belief that growth monitoring is intrinsically beneficial for children and their parents.

## Key points

- Nutrient needs during lactation are elevated secondary to the mobilization of tissue stores and transfer of nutrition through the milk
- The development of these recommendations and guidelines were created based on fundamental nutrient needs from the World Health Organization (WHO) and the Institution of Medicine
- Without adequate nutritional intake during lactation, nutrient depletion may occur due to the excessive mobilization of nutrient stores

## Introduction

Human lactation causes a significant increase in the requirement for most nutrients. Lactation is primarily supported by mobilization of tissue stores, which affects weight and nutritional status. Without adequate nutritional intake during lactation, nutrient depletion may occur due to this excessive mobilization of nutrient stores (Allen, 2006). Nutritional status during lactation can affect milk quantity and composition. Recommended intakes of most nutrients for lactation are 10–90% higher (Institute of Medicine, 1991). The dietary recommendations for lactation are those of the Food and Agriculture Organization/World Health Organization Reports on fats (2008) and micronutrients (2001), and the dietary reference intakes (DRIs) of the Institute of Medicine (USA and Canada) for micronutrients (1997, 1998, 2000, 2001), and macronutrients (2002), with an update on calcium and vitamin D in 2011. The rationales for the recommended nutrient intakes, and requirements and dietary recommendations for energy, fats, protein, calcium, zinc, folate, and vitamin A are addressed specifically. Given calls from LGBTQ+ organizations and statement from the Academy of Breastfeeding Medicine, this chapter will use non-gendered language to support and affirm non-cisgender or gender diverse lactating parents (Bartick et al., 2021). While using the anatomical term "breast" or "breast milk" in this chapter, please note that the term may be triggering and therefore recommended to discuss preferred terms with each client/patient.

## Rationale for recommended nutrient intakes

Recommendations on dietary nutrient intakes for lactation by different scientific authorities are typically based on the estimated total amount of each nutrient secreted daily into breast milk, the efficiency of milk synthesis, and the bioavailability of the nutrient. This estimate for each nutrient is then added to the recommended nutrient intake for nonpregnant, non-lactating assigned female at birth individuals (FAO/WHO, 2008). The onset of lactation after parturition is brought about by the major hormonal changes that occur in this period. During the first 2–7 days postpartum a thick yellow fluid (colostrum) is secreted. With the progress of lactation,

the volume of milk secreted increases and its nutrient composition changes. After approximately 21 days, the milk is considered mature milk (Darragh and Lönnerdal, 2011). The volume of breast milk secreted daily increases rapidly in the first postpartum days, from ~500 mL on day 5, ~650 mL at 1 month, and ~750 mL at 3 months, thereafter remaining relatively stable until decreasing during weaning. In industrialized countries, the average volume of breast milk produced is 750–800 mL day<sup>-1</sup> in the first 4–5 months postpartum and decreases to 600 mL day<sup>-1</sup> during 6–12 months after delivery (Neville et al., 1988). In this period, the volume of milk produced may be even lower and is quite variable, depending on the weaning practices for the infant. The FAO/WHO and DRI committees (2008) considered 750 and 780 mL, respectively, as the average milk volume produced during full lactation and the basis for recommendations. For most nutrients, average concentration in mature milk multiplied by the average milk volume was used to estimate the total amount of nutrient secreted daily into breast milk. A correction factor was then applied when the bioavailability of a nutrient in the diet is less than 100%, and where known, for the anabolic cost of milk synthesis. The final value was added to the recommended intake for nonpregnant, nonlactating assigned female at birth individuals. The stage of lactation was considered to be a factor for some nutrients and, where applicable, separate values were given according to the period of time postpartum (Medicine, 2002).

The volume of milk secreted during lactation is not influenced by nutritional status, unless undernutrition is severe. The composition of breast milk for most nutrients is also adequate to support infant growth and development regardless of nutritional status of the lactating individual. However, diet and nutritional status do have an influence on the concentration of some micronutrients such as vitamins A, D, thiamin, riboflavin, vitamins B<sub>6</sub> and B<sub>12</sub>, choline, iodine, and selenium. Also, the fatty acid composition of breast milk can be affected by diet (Daniels et al., 2019).

When setting recommendations, the DRI committees take gestational parent age into account, so there are separate values for adolescent (≤18 years) and adult (19–50 years) lactating individuals. For some nutrients, adolescents may have greater requirements than adults because they are still growing and they need to cover their own nutrient demands. Recommended intakes of vitamins A and C, calcium, phosphorus, magnesium, iron, and zinc are also higher for adolescents than for adults during lactation (Institute of Medicine, 2011).

In general, there is considerable uncertainty about dietary nutrient recommendations for lactation due to high intra- and inter-individual variability in breast milk volume output, specific nutrient concentrations in milk, and the temporal changes in milk volume and nutrient concentrations during a day and across the period of lactation. The composition of human milk is affected by several factors depending on the nutrient, such as stage of lactation, changes during a feeding, diurnal rhythm, diet, gestational age of the infant at birth, and parity. Moreover, the total amount of nutrients secreted into breast milk depends on the extent and duration of breast feeding. In addition, physiological adaptations to the high nutrient demands for lactation may include increased nutrient absorption and conservation, and use of nutrient stores. These adaptations are quite specific for each nutrient and not easily quantified, which contributes to the degree of uncertainty. Gestational parental age and nutritional status during pregnancy and lactation may also influence the homeostatic adaptations during lactation including the efficiency of nutrient absorption and the degree of mobilization of maternal nutrient stores.

## Requirements and dietary recommendations

### Macronutrients

#### Energy

The dietary energy intake recommended for healthy adults is that required to maintain energy balance, considering gender, age, weight, height, and level of physical activity. The energy requirements during lactation include the additional energy that is necessary for milk production, which differ by the stage and extent of breastfeeding.

The energy density of human milk is mainly determined by its fat content, which represents 50–60% of the total energy in mature milk and is the most variable energy-yielding component. Protein and lactose contribute to approximately 5% and 38% of energy, respectively. The mean energy density of representative 24 h pooled mature milk samples from well-nourished individuals ranges from 0.64 to 0.74 kcal g<sup>-1</sup> (2.7–3.1 kJ g<sup>-1</sup>) (USDA, 2020).

The estimated energy requirements (EER) for lactation are set by the DRI committee and based mainly on studies done in the 1990s, using the doubly labeled water method. The main findings in individuals who were fully breastfeeding their infants up to 6 months of age were: total energy expenditure of 2109–2580 kcal day<sup>-1</sup> (8860–10,840 kJ day<sup>-1</sup>) or 35.8–41.0 kcal kg day<sup>-1</sup> (150–172 kJ kg<sup>-1</sup> day<sup>-1</sup>), milk energy output of 483–538 kcal day<sup>-1</sup> (2030–2260 kJ day<sup>-1</sup>), and energy mobilization from tissue stores of 72–287 kcal day<sup>-1</sup> (300–1200 kJ day<sup>-1</sup>) (DRI, 2005). It was concluded that the energy requirements of lactating, well-nourished individuals are met primarily from the diet and partially by mobilization of tissue stores, without evidence for adaptations in basal metabolism and physical activities. The EER for lactation during the first 6 months is calculated as the sum of the EER obtained from the equation for nonlactating adults (using current age, weight, and physical activity level), the energy secreted in milk energy (500 kcal day<sup>-1</sup> or 2100 kJ day<sup>-1</sup>), and subtracting the energy derived from tissue mobilization during the weight loss that normally occurs during lactation (170 kcal day<sup>-1</sup> or 714 kJ day<sup>-1</sup>). The committee assumed a milk production rate of 0.78 L day<sup>-1</sup> from birth through 6 months of age, a milk energy density of 0.67 kcal g<sup>-1</sup> (2.8 kJ day<sup>-1</sup>), and an average gestational weight loss of 0.8 kg month<sup>-1</sup>. For the second 6 months of lactation, the incremental EER is calculated assuming a milk energy output of 400 kcal day<sup>-1</sup> or 1680 kJ day<sup>-1</sup> (a milk production rate of 0.6 L day<sup>-1</sup>) and no weight loss. The EER for lactating

adolescents (14–18 years) is calculated in the same manner as for lactating adults, but the increment for lactation is added to the appropriate equation for estimating the EER of nonlactating adolescents.

The acceptable macronutrient intake distribution ranges, expressed as percentage of total dietary energy, are the same as for the general adult population: 10–35% protein, 20–35% fat, and 45–65% carbohydrates (DRI, 2005). Natural simple sugars, such as those present in fruit, and complex carbohydrates (polysaccharides), such as in cereals (rice, wheat), cereal products (flour, pasta) and starchy roots, should be the preferred sources of carbohydrates in the diet. Added sugars, usually sucrose, should not be higher than 25% of dietary energy. Many of the energy-yielding carbohydrate food sources are also sources of dietary fiber which is beneficial for reducing the risk of coronary heart disease, ameliorating constipation, and other health outcomes. A total fiber intake of 29 g day<sup>-1</sup> is recommended for lactating women. Whole grain cereals, nuts, legumes, and fruit are good fiber and energy sources, and are also nutrient-rich foods. Restriction of energy intake during lactation to values below 1800 kcal (7500 kJ) per day may lead to low intakes of other nutrients including vitamins and minerals.

### Fat

Total fat content of human milk is affected by several factors, including stage of lactation, stage of feeding, and parity, while dietary intake of energy, fat, or fatty acids and overall nutritional status have little influence, except when there is long-term or severe maternal undernutrition (Jensen, 1989). Milk fat content is highly variable, averaging 35–40 g L<sup>-1</sup> in mature milk from well-nourished individuals delivering at term gestation. The content of individual fatty acids in milk is also highly variable, especially for the long-chain polyunsaturated fatty acids (LCPUFA, especially docosahexenoic acid, DHA), and more dependent on diet than total fat. The concentration of DHA can vary from 0.2 to 1% of total fatty acids and is proportional to the usual dietary intake. Fatty acid intake and relative contribution of carbohydrate and fat to total energy intake, as well as the body stores and endogenous synthesis of the lactating individual, influence the fatty acid composition of human milk. In well-nourished persons, the polyunsaturated EFA linoleic acid (18: 2n-6) and  $\alpha$ -linolenic acid (18: 3n-3) represent approximately 11 and 1% (wt/wt), respectively, of the total fatty acids in milk. LCPUFA of the n-6 and n-3 series account for 1.2 and 0.6% of the fatty acids, respectively (Delgado-Noguera, 2015).

The adequate transfer of polyunsaturated fatty acids from circulation of the lactating individual to the milk and the synthesis of LCPUFA, especially arachidonic acid (20: 4n-6), dihomo- $\gamma$ -linolenic acid (20: 3n-6), eicosapentenoic acid (EPA, 20: 5n-3), and DHA (22: 6n-3), from their respective EFA precursors, are important for infant growth, neurodevelopment, and visual function. These polyunsaturated fatty acids are structural components of all cell membrane phospholipids. Arachidonic acid and DHA are the two quantitatively most important LCPUFA in the brain and retina, and the LCPUFA with 20 carbon atoms are precursors for the synthesis of eicosanoids, a group of signaling molecules. The major part of the polyunsaturated fatty acids in human milk (70–85% in an omnivorous diet) is derived from body stores which reflect dietary intake over the long term, and not from direct dietary transfer (Delgado-Noguera, 2015).

The metabolic fate of individual fatty acids depends on dietary energy intake and energy balance. Therefore, the intake and requirements for fat, EFA, and LCPUFA are usually expressed as a percentage of the total energy in the diet, rather than total intake. The fat intake recommended for lactating persons is in the range of 20–35% which is the same range as recommended for the adult population. Concerning the fatty acid intake, FAO/WHO (2008) recommends an additional intake of 1–2% as EFA (3–4 g day<sup>-1</sup>) during the first 3 months of lactation, and up to 4% (about 5 g day<sup>-1</sup>) thereafter due to depletion of fat stores. Based on the median linoleic and  $\alpha$ -linolenic acid intakes of lactating individuals in the US, the DRI committee recommends an intake of 5–10% (average 13 g day<sup>-1</sup>) of n-6 (as linoleic acid) and of 0.6–1.2% (average 1.3 g day<sup>-1</sup>) of n-3 (as  $\alpha$ -linolenic acid) polyunsaturated fatty acids throughout lactation, with a 10% contribution from LCPUFA in the n-6 and n-3 series to these ranges. The ratio of n-6: n-3 unsaturated fatty acids in the diet is important because these fatty acids are desaturated and elongated, and incorporated into membranes, using the same series of enzymes. Increased intake of linoleic acid reduces the conversion of  $\alpha$ -linolenic acid to EPA and DHA, whereas the conversion of linoleic acid to arachidonic acid is inhibited by EPA and DHA, as well as by arachidonic acid,  $\alpha$ -linolenic acid, and linoleic acid itself. The n-6:n-3 ratio recommended for adults by both DRI and FAO/WHO committees is 5:1 to 10:1. Vegetable oils are the main dietary source of n-6 fatty acids, and also of n-3 fatty acids although in lower amounts. Fish such as herring, mackerel, and salmon are good sources of n-3 fatty acids.

The intake of trans fatty acids (trans isomers of oleic and linoleic acid) present in hydrogenated food fats and oils, deep-fried foods, and meats are of special concern during lactation when intake is excessively high, or when EFA intake is low during pregnancy and lactation. An inverse correlation of arachidonic acid and DHA with trans fatty acids in plasma lipids has been reported in infants, suggesting impaired LCPUFA synthesis and metabolism.

### Protein

The average protein content in colostrum is 15–20 g L<sup>-1</sup> decreasing to approximately 8–10 g L<sup>-1</sup> in mature human milk during the first 6 months of lactation. The protein concentration in human milk is not affected by diet, body composition, or undernutrition.

The recommended dietary allowance (RDA) of protein for adolescent and adults who are lactating set by the DRI committee is 1.1 g kg<sup>-1</sup> of body weight per day. This corresponds to an increment of 25 g day<sup>-1</sup> above the RDA for nonlactating persons assigned female at birth, and is the same as for pregnancy. Recent data have shown that protein intakes of 1 g/kg/day are able to maintain good milk production, and promote conservation of skeletal muscle apparently by down-regulating protein metabolism. The recommended range of percentage of energy from dietary protein is the same as for the general adult population (10–35%).

The factorial approach was used to estimate the protein RDA for lactation, assuming that the maintenance protein requirement of the lactating individual is not different from that of nonlactating individual assigned female at birth, and that the additional protein and/or amino acid requirements are proportional to milk production. The additional protein requirement for lactation is defined as the output of total protein and nonprotein nitrogen (the latter converted to protein by multiplying by 6.25) in milk. Nonprotein nitrogen represents 20–25% of total milk nitrogen, mainly as urea. It is taken into account because it is assumed that the nitrogen needed to cover the total nitrogen loss in milk should be derived from dietary protein. The total protein output, approximately  $10 \text{ g day}^{-1}$ , is divided by the incremental efficiency of nitrogen utilization (0.47), which is assumed to be the same in lactating adults and adolescents. The additional estimated average requirement due to milk production is therefore  $21.2 \text{ g day}^{-1}$ . After correction by the coefficient of variation and rounding off, the RDA for lactation is  $+25 \text{ g day}^{-1}$ , which corresponds to  $+0.46 \text{ g protein kg day}^{-1}$  (based on a reference of  $57 \text{ kg individual}$ ) above the RDA for nonlactating individuals assigned female at birth.

Recommendations for individual indispensable amino acids for lactation by the DRI committee assume that the incremental needs correspond to the amino acids secreted in milk, because there are no specific data on the amino acid requirements of lactating individuals. Therefore, the RDA for amino acids in lactation is calculated by adding the average amounts of amino acids in human milk in the first 6 months of lactation (expressed as  $\text{mg kg}^{-1} \text{ day}^{-1}$ ) to the respective RDA for nonlactating adults assigned female at birth. Overall, recommendations for indispensable amino acids are 36% (histidine) to 80% (tryptophan) higher during lactation. High-quality protein from sources such as eggs, milk, meat, and fish provide the requirements for all indispensable amino acids. Individuals who restrict their diets to plant proteins (cereals, legumes, nuts, starchy roots, vegetables, and fruits) may be at risk of inadequate intakes of certain indispensable amino acids. However, adequate complementary mixtures of plant proteins, with increased digestibility through processing and preparation, can provide high-quality protein.

## Minerals and vitamins

Daily requirements for several micronutrients (riboflavin, vitamins B<sub>12</sub>, C, A, and E, copper, iodine, manganese, selenium, and zinc) are higher during lactation than during pregnancy, indicating that lactation is a very demanding process. The only micronutrients needed in lower amounts during lactation are iron, due to the small amount of iron secreted into human milk and to the usual amenorrhea, and folate. However, iron requirements may be high postpartum for those who need to replace major blood losses during delivery.

The recommended intakes for micronutrients during lactation established by FAO/WHO and DRI committees are summarized in [Table 1](#). The percentages of change from the recommendations for nonpregnant nonlactating adults are also shown. To meet these intakes, those lactating should be guided to consume daily a large variety of foods rich in micronutrients, because food diversification contributes to improve the intake of limiting nutrients. Micronutrients most commonly at risk of inadequate intakes by lactating women are calcium, zinc, folate, and vitamin A.

## Calcium

It is estimated that an average of  $200 \text{ mg}$  of calcium per day is secreted into mature human milk although this amount is variable, usually ranging from  $150$  to  $300 \text{ mg day}^{-1}$ . The diet does not affect human milk calcium concentration except when calcium intake is very low ( $<300 \text{ mg day}^{-1}$ ). The primary source of calcium for milk production is the increased mobilization of calcium from bone due to the increased bone resorption that occurs during lactation, favored by the low estrogen concentration. This results in a net loss of bone mass during lactation that is regained after weaning upon return of ovarian function. The decreased urinary calcium excretion during lactation also contributes to the calcium economy for milk secretion. The efficiency of intestinal calcium absorption is not increased during lactation and does not contribute to the extra calcium needed for milk production.

Calcium homeostasis is maintained during lactation and has been found to be independent of dietary calcium intake. It has been demonstrated that the loss of bone mass during lactation is not affected by calcium supplementation with habitual adequate dietary calcium intakes ([Prentice, 2000](#); [Polatti et al., 1999](#)). Because the loss of bone calcium that occurs during lactation is not prevented by increased dietary calcium, and the calcium lost appears to be regained after weaning, the recommended intake of calcium during lactation is the same as that for nonpregnant nonlactating adults assigned female at birth of the same age, being  $1000$  and  $1300 \text{ mg day}^{-1}$  for adults and adolescents, respectively. Even if not increased during lactation, the recommended calcium intake may be difficult to obtain for those with a low habitual intake of dairy products. Therefore, those who are lactating should be guided to consume dairy products such as milk, yogurt, cheese, and other calcium-rich foods such as fish with edible bones, broccoli, and kale.

Lactating adolescents are a group of special concern regarding calcium intake due to the already high calcium requirements of non-pregnant nonlactating adolescents. They are still increasing their own bone density as well as needing the increased calcium requirement to support lactation. Studies are needed to investigate if they are able to regain bone after weaning to the same level as when they were nonpregnant and nonlactating, and if they would benefit from increased calcium intake.

**Table 1** Daily recommended mineral and vitamin intakes for lactating adults.

Nutrient	FAO/WHO <sup>a</sup>		IOM <sup>b</sup>	
	Recommended value	% change <sup>c</sup>	Recommended value	% change <sup>c</sup>

<sup>e</sup>0–3 months postpartum, assuming moderate bioavailability.

<sup>f</sup>4–6 months postpartum, assuming moderate bioavailability.

## Zinc

Zinc concentrations in human milk are highest in colostrum, decrease rapidly during the first 3 months postpartum, and continue to fall but more gradually at later stages of lactation. Typical milk zinc concentrations are 4 mg L<sup>-1</sup> at 2 weeks, 3 mg L<sup>-1</sup> at 4 weeks, 2 mg L<sup>-1</sup> at 8 weeks and 1.2 mg L<sup>-1</sup> at 24 weeks. These concentrations are not influenced by either dietary intake or zinc supplementation, at least in well-nourished individuals (Krebs, 1998). Less is known about the effect of low dietary zinc intakes on milk zinc concentrations, but some reports indicate that concentrations in developing countries may be slightly lower than those in developed countries at comparable times postpartum (Krebs, 1998).

Average daily losses of zinc in human milk range from 2.2 mg during the first month postpartum to 1 mg at 6 months (Dror and Allen, 2018). The average estimate of daily output of zinc in milk during the first 3 months of lactation is 1.6 mg, which would theoretically double the minimum endogenous zinc losses during lactation. However, homeostatic mechanisms such as enhanced zinc absorption and reduced urinary zinc excretion compensate for the secretion of zinc into human milk, independent of zinc intake. Intestinal conservation of endogenous fecal zinc appears to contribute to zinc homeostasis during lactation at low zinc intakes (<8 mg day<sup>-1</sup>). Involution of the uterus, decreased blood volume, and increased resorption of trabecular bone in the postpartum period also contribute to mobilizable zinc pools to compensate for the increased needs. These sources appear to provide up to 0.5 mg day<sup>-1</sup> of zinc during the first 3 months of lactation (Krebs, 1998). Taking all these adaptive mechanisms into account, the average estimate for the increased requirement for absorbed zinc during the first 6 months of lactation is 1.35 mg day<sup>-1</sup>. Therefore, dietary zinc requirements during lactation are substantially increased, both for adults and adolescents.

Bioavailability is an important factor in setting dietary zinc recommendations because the efficiency of dietary zinc utilization may vary up to fivefold depending on the overall composition of the diet, and particularly on the negative effect of dietary phytate. The efficiency of absorption is inversely related to the level of dietary zinc, except when phytate intake is high. Dietary zinc recommendations during lactation are set at 12 mg day<sup>-1</sup> for those consuming a mixed diet, but requirements will be higher for those

whose diet is high in phytate because it is based mainly on unrefined cereals and legumes. Red meat, milk, poultry, eggs, and seafood provide highly available zinc, and their consumption should be encouraged during lactation.

### **Vitamin A**

Vitamin A is present in human milk as retinyl esters (95%) and free retinol. Vitamin A activity is also provided as carotenoid precursors, mainly as  $\beta$ -carotene, which accounts for up to 30% of total carotenoids in human milk. The concentration of vitamin A is high in early lactation ( $600\text{--}2000\ \mu\text{g L}^{-1}$ ) and declines thereafter to  $200\text{--}1100\ \mu\text{g L}^{-1}$  (Dror and Allen, 2018; Haskell and Brown, 1999). It is responsive to dietary intake, particularly in those with poor vitamin A status.

Dietary recommendations for vitamin A during lactation are based on replacing the amount of the vitamin secreted into breast milk during the first 6 months of lactation, while preserving vitamin A stores. Because the bioconversion of carotenoids in human milk is still uncertain, the contribution of carotenoids in breast milk to meeting the vitamin A lactation is not considered.

Based on the average milk vitamin A concentration of  $485\ \mu\text{g L}^{-1}$ , an additional intake of 400  $\mu\text{g}$  retinol activity equivalents (RAE) per day is recommended during lactation, which represents an increase of over 70% compared to the recommendations for non-pregnant nonlactating adolescents and adults. A RAE is defined as 1  $\mu\text{g}$  all-trans-retinol, 12  $\mu\text{g}$   $\beta$ -carotene, or 24  $\mu\text{g}$   $\alpha$ -carotene or  $\beta$ -cryptoxanthin. The amount of carotenoids equivalent to 1 RAE is double the equivalent to 1 RE (retinol equivalent).

The vitamin A intake recommended during lactation can be obtained as the preformed vitamin from foods of animal origin (primarily milk products, eggs, and liver) and as carotenoid precursors in green leafy vegetables and ripe, colored fruits. However, meeting the recommended intake by consumption of plant sources alone, as is the case in many developing countries, may be difficult unless the diet contains some carotenoid-rich foods such as sweet potatoes.

### **Folate**

The concentration of folate in human milk increases during the lactation period, with lower values for colostrum ( $10\text{--}40\ \mu\text{g L}^{-1}$ ) than for mature milk ( $79\text{--}133\ \mu\text{g L}^{-1}$ ) (Dror and Allen, 2018). These concentrations are several-fold higher than in plasma, independent of folate status, indicating that the mammary gland actively transports and regulates the secretion of this vitamin into milk. Folate concentration in breast milk is maintained with the concomitant depletion of folate when dietary intake is low. Supplementation during lactation has little effect on milk folate but it benefits the folate status of the lactating individual (O'Connor, 1994). Dietary folate requirements during lactation are based on the average milk folate concentration of  $85\ \mu\text{g L}^{-1}$  and assume 50% absorption from a mixed diet. The average extra amount of dietary folate needed to cover lactation is thus estimated as  $133\ \mu\text{g day}^{-1}$ , an increase of approximately 40% above the nonpregnant nonlactating average folate requirements. Dietary folate recommendations during lactation are set at 500  $\mu\text{g}$  dietary folate equivalents (DFEs) daily. A DFE is defined as 1  $\mu\text{g}$  of food folate, or 0.6  $\mu\text{g}$  of folic acid from fortified food or as a supplement taken with meals, or 0.5  $\mu\text{g}$  of folic acid as a supplement taken on an empty stomach. Thus, in order to meet lactation requirements, less of this vitamin is needed when given as pure folic acid than as natural food folate.

Although folate is found in a variety of foods, such as fresh green vegetables, oranges, legumes and nuts, several servings per day of these foods are needed to meet recommended intake. Moreover, considerable losses of folate can occur during food harvesting, storage, and cooking. Fortification of wheat flour with folic acid has become mandatory or encouraged in many countries in order to reduce the risk of neural tube defects in those at risk of this condition.

### **Other B vitamins**

Deficiency of thiamin, riboflavin, vitamin B<sub>6</sub>, vitamin B<sub>12</sub>, and choline can result in low concentrations in breast milk and subsequent infant deficiency. It has been estimated that intakes of infants exclusively breastfed by a deficient mother may be in the range of 16% (vitamin B<sub>12</sub>) to 80% (vitamin B<sub>6</sub>) of their recommended Adequate Intakes (Allen, 2012). Further information is needed about the status of these vitamins in lactation and their infants because intakes of most B vitamins are inadequate where animal source food consumption is low—a common situation in resource limited populations. Increasing dietary intake through supplementation increases the milk content of these vitamins and improves the status of the parent and infant.

## **Conclusions**

Human lactation causes a significant increase in the requirement for most nutrients given the need to provide adequate nutrition to infant and to support the mass mobilization of tissue. Without adequate nutritional intake during this time, those lactating are at risk for nutrient depletion which can affect milk production and composition. The recommended dietary intakes of both macro- and micronutrients during lactation developed by the World Health Organization and Institute of Medicine account for the amount not only to maintain nutrient stores of the individual lactating but also to ensure optimal composition of human milk for the infant.

## Glossary

**Arborizing ductal network** The system of ducts composed of epithelial cells that connect lobuloalveolar units to the nipple.

**Junctional complex** Tight junctions branching networks of transmembrane protein strands that seal adjacent epithelial cells, preventing passage of ions and other substances from blood to milk.

**Lobuloalveolar unit** The portion of the mammary gland specialized for producing and secreting milk. The lobuloalveolar unit is composed of a single layer of secretory epithelial cells that synthesize and secrete milk. Secretory epithelial cells are surrounded by a network of myoepithelial cells that contract in response to oxytocin stimulation to stimulate milk ejection.

**Paracellular transport** The passage of substances between epithelial cells. Paracellular transport is regulated by tight junctions and is closed during lactation.

**Secretory activation** The hormone regulated process of maturation of gene expression, secretory mechanisms and transport pathways that occurs after parturition, and that is required for copious milk secretion. Secretory activation is also called lactogenesis II.

**Transcytosis** The endocytic uptake of substances at the basal membrane and their transport to the apical membrane for secretion.

Lactation is a uniquely mammalian physiological process in which the caloric and nutrient reserves of the mother are transformed into a complex fluid capable of supporting the nutritional demands of newborns for sustained periods. Milk, the product of lactation, is a mixture of solutes whose composition reflects the activities of distinct secretion and transport processes of the mammary gland and mirrors the differing nutritional requirements of mammalian neonates. In humans, this fluid is capable of providing the full-term infant with all the nutrients required for the first 4–6 months of life as well as offering significant protection against infectious disease. Although artificial formulas are widely utilized for human infant nutrition in developed countries, many components of human milk, including critical growth factors, long-chain polyunsaturated fatty acids (PUFA), antiinfectious oligosaccharides and glycoconjugates, and the protein lactoferrin, are not duplicated in formula. Although it is likely that such substances are beneficial even to healthy infants in well-protected environments, they are particularly important for infants living under conditions of inadequate sanitation, as well as for preterm infants and infants with feeding problems. Despite the obvious importance of milk to neonatal nutrition and the selective advantage of lactation in mammalian evolution, the physiological mechanisms underlying milk secretion and utilization are not well understood and the molecular mechanisms involved in the production of individual milk components are still poorly characterized. In this article, the functional anatomy of the mammary gland is described, followed by a brief description of human milk composition and a review of the transport mechanisms involved in the secretion of individual

milk components. The authors then summarize the functional differentiation of the mammary gland and the initiation of lactation – a process that involves a series of carefully programmed functional changes that transform a prepared, but nonsecretory, gland into a fully functioning organ during the first week postpartum in humans.

### Functional Anatomy of Lactation

The lactating mammary gland consists of an arborizing ductal network that extends from the nipple and terminates in grape-like lobular clusters of alveoli forming the lobuloalveolar unit, which is the site of milk secretion. A stylized diagram of these structures is shown in **Figure 1**. Alveoli are composed of a single layer of polarized secretory epithelial cells that possess specialized features indicative of highly developed biosynthetic and secretory capacities, including numerous mitochondria, an extensive rough endoplasmic reticulum network, and a well-developed Golgi apparatus. Secretory components including lipid droplets and casein-containing secretory vesicles are found juxtaposed to the apical membrane of these cells. The epithelial cells are connected to each other through a junctional complex composed of adherens and tight junctional elements that function to inhibit the transfer of extracellular substances between the vascular system and milk compartments during lactation (**Figure 2**). The basal portion of alveolar epithelial cells is surrounded by a meshwork of myoepithelial cell processes that contract to bring about milk ejection and by a connective tissue stroma that supports and separates the lobules. The stromal component also contains lymphatics and becomes extensively vascularized during lactation to sustain the biosynthetic demands of alveolar epithelial cells. In nonpregnant, nonlactating animals, the stroma contains a large adipose component.

The nipple, which is the termination point of the mammary ductal network, is innervated by the fourth intercostal nerve. Afferent sensory stimuli from suckling are transmitted to the spinal cord and the brain, resulting in the release of prolactin and oxytocin from the pituitary. Prolactin, secreted from the anterior pituitary, acts directly on alveolar epithelial cells to foster the synthesis and secretion of milk components. Oxytocin, secreted from the posterior pituitary, stimulates contraction of the myoepithelial cells that surround the alveoli and ducts. This process, called the 'letdown reflex,' forces the milk from the alveoli through ductules into ducts draining several clusters of alveoli. In humans, the small ducts converge into 15–25 main ducts that drain sectors of the gland and open directly on the nipple. The secretory product is stored in the alveolar space until myoepithelial cell contractions force it through the ducts toward the nipple, where it is available to the suckling infant.

**Figure 1** Camera lucida drawing of a section of the breast of a woman who died 2 days after last suckling her infant (a). The drawing clearly shows collecting ducts and the grape-like lobuloalveolar units, which are engorged with milk. (b) Cross-sectional diagram showing the relationships of the lobuloalveolar unit composed of milk-secreting alveoli and ducts with the other cellular compartments of the mammary gland. ## Milk Composition

The major macronutrients in milk are lactose (a disaccharide unique to milk); lipids; proteins, including casein,  $\alpha$ -lactalbumin, lactoferrin, secretory immunoglobulin A (sIgA), and many others present at much lower concentrations; and minerals such as sodium, chloride, calcium, and magnesium. Other nutritionally important substances in milk are enzymes, vitamins, trace elements, and growth factors. The lipid content of milk varies considerably between species. In human and cow's milk, the fat accounts for approximately 4% of milk volume, whereas in whales and seals it can account for as much as 60% of milk volume. Milk fat is primarily composed of triglycerides, a major source of neonatal calories, and it also contains cholesterol and phospholipids, essential for early neonatal development. Casein micelles form a separate phase that can be pelleted by high-speed centrifugation or acidification. These micelles have a high calcium and phosphate content. The aqueous fraction of milk, often called whey, is a true solution that contains all the milk sugar as well as the major milk proteins lactoferrin,  $\alpha$ -lactalbumin, and sIgA and nonprotein nitrogen compounds (mostly urea); the monovalent ions sodium, potassium, and chloride; citrate; calcium; free phosphate; and most of the water-soluble minor components of milk. The casein fraction from cow's milk, usually obtained by rennin precipitation, is used in cheese making, whereas the whey has a multiplicity of uses, most notably as the base for infant formula. Urea and other nonprotein nitrogen components of milk are a source of nitrogen for amino acid and protein synthesis. Isotope utilization studies indicate that on average 10–20% of urea nitrogen is converted into protein by breast-fed infants. Significantly higher utilization rates, however, have been measured in children recovering from infection, suggesting that alterations in urea nitrogen utilization may be a homeostatic response. Human and bovine milk differ primarily in their concentrations of lactose, mono- and divalent ions, and casein levels and the existence of antiinfectious agents in human milk (Table 1). These differences are related to the specific needs of these species. Human milk, for example, possesses higher concentrations of lactose and lower divalent ion concentrations than cow's milk. The high lactose concentration provides a large amount of 'free water,' *via* osmotic regulation, that serves as a reserve for temperature regulation *via* sweating in human infants. Human milk also contains a number of agents that protect against gastrointestinal and respiratory infections, including oligosaccharides that interact specifically with pathogen receptors, lactoferrin, and sIgA. Bovine milk, however, contains high concentrations of casein, which provides protein and associated calcium and phosphate needed to support the rapid growth of young calves.

## Synthesis and Secretion of Milk Components

Solutes enter milk through five general pathways (Figure 2). Endogenously generated substances, including the major milk proteins, oligosaccharides, and nutrients such as lactose, citrate, phosphate, and calcium, are secreted through an exocytotic pathway (pathway I). Lipids and lipid-associated proteins are secreted by a process that is unique to mammary epithelial cells (pathway II). The transcytosis pathway (pathway III) transports a wide range of macromolecular substances derived from serum or stromal cells, including serum proteins such as immunoglobulins, albumin, and transferrin; endocrine hormones such as insulin, prolactin, and insulin-like growth factor-1; and stromal-derived agents such as immunoglobulin A (IgA) cytokines, and lipoprotein lipase. In addition, various membrane transport pathways (pathway IV) exist for the transfer of ions and small molecules, such as

glucose, amino acids, and water across basal and apical plasma membranes. Finally, there is a paracellular pathway (pathway V) that provides a direct route for entry of serum and interstitial substances into milk. This pathway, however, closes during the first few days of lactation in humans. Transport through these pathways is affected by the functional state of the mammary gland and regulated by direct and indirect actions of hormones and growth factors. The general cellular and physiological properties of these pathways are summarized next.

### Exocytotic Pathway (I)

Like exocytotic secretion mechanisms found in other cells, proteins, oligosaccharides, and nutrients such as lactose and citrate are packaged into secretory vesicles within the Golgi that are then transported to the apical region of the cell, where they fuse with the apical plasma membrane, discharging their contents into the extracellular space. A unique feature of this pathway in the mammary gland is the presence of high concentrations of lactose, phosphate, citrate, and calcium within the vesicles. Lactose is synthesized in the Golgi from UDP-galactose and glucose, which have entered from the cytoplasm using specific transporters, by the enzyme β-galactosidase, with α-lactalbumin acting as a cofactor. The high concentration of lactose present in the Golgi during lactation osmotically stimulates the influx of water that contributes to the fluidity of milk. Casein micelle formation begins in the terminal Golgi with condensation, and simultaneous phosphorylation, of casein molecules. The addition of calcium, possibly in the secretory vesicle, leads to maturation of casein micelles into particles sufficiently dense to be seen in the electron microscope. This complex thus delivers an efficient package of protein, calcium, and phosphate that provides the nutrients necessary for bone growth, among other things. Calcium enters the cytoplasm from the plasma by a poorly defined transport process. Cytoplasmic calcium is then transported into secretory vesicles by an ATP-dependent Ca<sup>2+</sup> pump localized on Golgi and secretory membranes. The phosphate in secretory vesicles is derived from the hydrolysis of UDP-galactose during the synthesis of lactose. Citrate is generated endogenously within the cytoplasm of alveolar epithelial cells and transported into the Golgi lumen by an undefined process.

### Lipid Secretion Pathway (II)

Estimates of the quantity of milk lipid secretion during lactation in humans and rodents indicate that in many species, the lactating mammary gland may be one of the most lipogenic organs in the body. In a fully lactating woman secreting 800 ml day<sup>-1</sup> of milk

containing 4% fat, the mammary gland synthesizes approximately 32 g of triglyceride daily or approximately 6 kg, 10% of the weight of the woman, in a typical 6-month lactation. The fatty acids for triglyceride synthesis are synthesized from glucose or derived from the plasma lipids by the action of lipoprotein lipase. Once available in the mammary alveolar cells, fatty acids are either bound to a fatty acid-binding protein or activated by combination with coenzyme A (CoA) and then bound to an acyl-CoA-binding protein. Activated fatty acids are joined with glycerol-3-phosphate by transacylases located in the endoplasmic reticulum to form triglycerides, which enter the cytoplasm as protein-coated structures called cytoplasmic lipid droplets.

These structures are translocated to the apical membrane, where they are enveloped by a novel budding process that leads to their release as membrane-bound lipid droplets known as milk fat globules. The fatty acid composition of milk triglycerides reflects differences in maternal diet. Medium-chain (C8–14) fatty acids are synthesized only in the mammary gland using glucose (or acetate in ruminants) as a substrate, whereas long-chain fatty acids are derived from the plasma. Nigerian women who have high-carbohydrate, low-fat diets have significantly more medium-chain fatty acids in their milk than Western women who consume a high-fat diet (Table 2).

### Transcytosis Pathway (III)

Transport of proteins and other macromolecules by transcytotic pathways involves endocytic uptake of substances at the basal membrane, formation and maturation of endosomes, and sorting to lysosomes for degradation or to the apical recycling compartment for exocytosis at the apical membrane. The best-studied molecule in this regard is IgA. IgA is synthesized by plasma cells in the interstitial spaces of the mammary gland or elsewhere in the body and binds to receptors on the basal surface of the mammary alveolar cell; the entire IgA–receptor complex is endocytosed and transferred to the apical membrane, where the extracellular portion of the receptor is cleaved and secreted together with the IgA. It is thought that many other proteins, hormones, and growth factors that find their way into milk from the plasma are secreted by a similar mechanism.

### Transmembrane Pathway (IV)

Transport processes for sodium, potassium, and chloride exist on the basal and apical plasma membranes of alveolar epithelial cells. Uptake mechanisms for calcium, phosphate, and iodide, however, are thought to be limited to the basal membrane. The mammary

epithelial cells possess a GLUT1 glucose transporter and a sodium-dependent glucose transporter. The GLUT1 transporter is thought to mediate glucose transport at the basal and Golgi membranes, but it does not contribute to glucose transport at the apical membrane. Both sodium-dependent and sodium-independent amino acid transport mechanisms analogous to those found in other organs are located in the basolateral component of the mammary epithelium. It is unclear whether apical membranes have similar transport mechanisms for amino acids, and it is unknown how amino acids enter milk.

### Paracellular Transport Pathway (V)

Pathway V (Figure 2) involves the passage of substances between epithelial cells rather than through them, and for this reason it is designated the paracellular pathway. During full lactation the passage of even low-molecular-weight substances between alveolar cells is impeded by the gasket-like tight junction structures that join the epithelial cells tightly, one to another. During pregnancy, with mastitis and after involution, the tight junctions become leaky and allow components of the interstitial space, such as sodium and potassium, to pass unimpeded into the milk, which is sometimes useful in diagnosing breast-feeding problems.

## Regulation of Milk Synthesis, Secretion, and Ejection

Milk volume production is a primary indicator of lactational function; the most precise methods for measuring the volume of milk produced involve weighing infants before and after each feed for 24 h or longer or using an isotope dilution technique with stable isotopes. Clinically, the amount of milk that can be expressed with a breast pump or the change in infant weight after a single feed can be used as a rough index. The volume of milk secreted by women exclusively breast-feeding a single infant at 6 months postpartum is remarkably constant at approximately 800 ml day<sup>-1</sup> in populations throughout the world. Mothers of twins, and occasionally even triplets, are able to produce volumes of milk sufficient for complete nutrition of their multiple infants, and studies of wet nurses indicate that at least some women are capable of producing up to 3.5 l of milk per day. However, if infants are supplemented with foods other than breast milk, milk secretion is proportionately reduced. This point is illustrated in Figure 3, which shows that milk volumes gradually decline during weaning and increase as the feeding frequency increases. These observations illustrate the important principle that the volume of milk secretion in lactating women is regulated by infant demand. If milk cannot be removed from the breast, local mechanisms cause an inhibition of milk secretion and downregulation of milk synthetic machinery. With partial removal of milk on a consistent basis, these local factors adjust milk secretion to a new steady-state level. If milk removal ceases for extended periods, involution sets in and the gland loses its competency to secrete milk.

### Hormonal Control of Milk Synthesis and Secretion

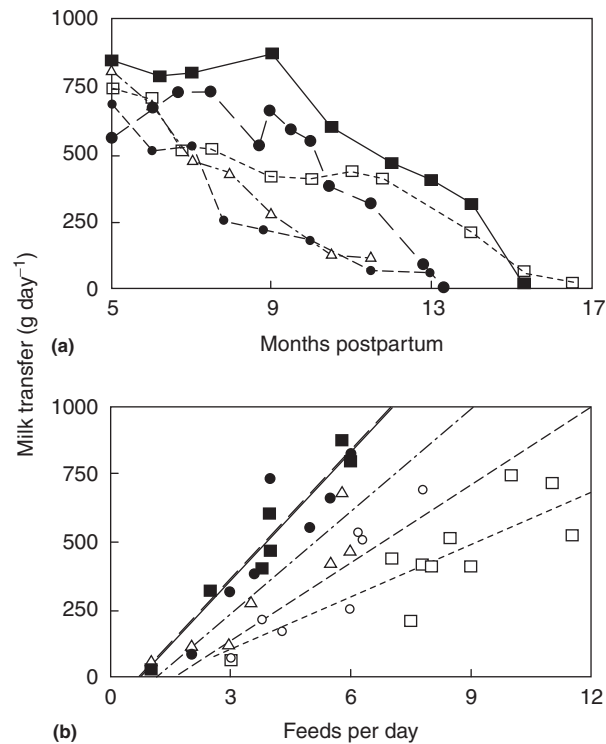

In most species, the presence of high levels of plasma prolactin appears to be essential for lactation. In rats, the ergot alkaloid bromocriptine (an inhibitor of prolactin release from the pituitary) inhibits lactation, and in women it inhibits the onset of lactation when given in appropriate doses. How prolactin influences lactation is not known in any detail. However, it appears to promote both the survival of mammary epithelial cells and the synthesis of macromolecular milk components. In addition, prolactin is an osmoregulator in some species of fish, birds, and amphibians and may function to maintain solute transport in the mammary gland. Maintaining high calcium levels in milk is also dependent on parathyroid hormone-related protein-dependent mobilization of calcium from maternal stores.

### Local Control of Synthesis and Secretion

The neurotransmitter, serotonin, functions as an intrinsic homeostatic regulator of lactation, reducing milk production when production rates exceed removal rates, such as during weaning. Serotonin has been shown to be synthesized by mammary epithelial cells in mice and cattle and is found in milk. Elevated levels of serotonin have been demonstrated to directly reduce milk production and inhibit the expression of genes encoding milk protein components. In humans, elevated serotonin levels associated with the use of serotonin reuptake inhibitor-based antidepressants have been shown to delay secretory activation. Understanding this regulatory system may be very important in helping women to increase or maintain their milk supply, particularly in the postpartum period.

### Regulation of Milk Ejection

When the infant is suckled, afferent impulses from sensory stimulation of nerve terminals in the areolus travel to the central nervous system, where they promote the release of oxytocin from the posterior pituitary. This neuroendocrine reflex can be conditioned, and in women, oxytocin release is often associated with stimuli such as the sight or the sound, or even the thought, of the infant. The oxytocin is carried through the bloodstream to the mammary gland, where it interacts with specific receptors on myoepithelial cells, initiating their contraction and expelling milk from the alveoli into the ducts and subareolar sinuses. The passage of milk through the ducts is facilitated by longitudinally arranged myoepithelial cell processes whose contraction shortens and widens the ducts, allowing free flow of milk to the nipple. Milk is removed from the nipple not so much by suction as by the stripping motion of the tongue against the hard palate. This motion carries milk through the teat into the baby's mouth. The letdown response is

**Figure 3** Changes in milk volume during weaning and in response to increased feeding frequency. (a) Milk volume transfer as a function of time postpartum. (b) Relation between feeding frequency (feeds per day) and the milk volume. Data from five breast-feeding dyads; each symbol represents an individual dyad. decreased by psychological stress or pain, which interferes with oxytocin release. Oxytocin also appears to be involved in regulating maternal behavior in laboratory animals and may play a similar role in humans.

### Initiation of Lactation

Pregnancy transforms the mammary gland from a simple ductal tree into a highly efficient exocrine organ with expansive lobuloalveolar structures. This transformation is hormonally regulated and involves changes in the cellular composition of the mammary gland and alterations in the structural, cellular, and biochemical properties of alveolar cells that are critical to the development of efficient solute transport and secretory functions. Alveolar epithelial cells begin to differentiate into secretory cells at midpregnancy in most species. The differentiation process occurs heterogeneously and has been divided into initiation and activation phases based on differences in the composition of mammary secretions, gene expression, and the structural and functional properties of alveolar cells. Alveolar cells become capable of limited secretion of some milk components during the initiation phase, which in humans is detected by measurement of increased concentrations of lactose and  $\alpha$ -lactalbumin in the plasma. Copious milk secretion, however, is induced during the secretory activation phase (sometimes called lactogenesis II) that occurs in response to the decrease in serum progesterone levels. In rodents and ruminants, this decrease is closely associated with parturition; in humans, it occurs after parturition.

### Changes in Milk Composition during Secretory Activation

Secretory activation is reflected in dramatic modifications of the solute composition of milk and increased secretory volume, which in turn reflect the maturation of secretory mechanisms and transport pathways during this period. In women, there are three temporally distinct changes in milk composition at the onset of lactation. The earliest is a decrease in sodium and chloride concentrations and an increase in the lactose concentration of milk (Figure 4). These modifications occur immediately after delivery and are largely complete by 72 h postpartum. They precede increases in milk volume by at least 24 h and can be explained by closure of the tight junctions that block the paracellular pathway. Blocking this pathway prevents lactose, generated by the epithelial cells, from passing from the lumen of the alveolus to the plasma, and it prevents sodium and chloride from directly entering the lumen from the interstitial space. These changes result in the reduction of sodium and chloride and an elevation of lactose concentrations in the

**Figure 4** Changes in milk composition and volume in women during secretory activation and early lactation. Reproduced from McManaman JL and Neville MC (2003) Mammary physiology and milk secretion. *Advanced Drug Delivery Reviews* 55: 630–641.

mammary secretion. The increased lactose concentration is reflective of decreased water entering the lumina as monovalent ion secretion decreases rather than increasing the lactose secretion rate. Secondly, the rates of secretion of slgA and lactoferrin into milk of women are elevated soon after delivery. The concentrations of these two important protective proteins remain high, comprising as much as 10% of milk, for the first 48 h after birth. The concentration of each protein diminishes rapidly after day 2, both from dilution as milk volume secretion increases and from actual reduction in their rates of secretion, particularly of immunoglobulins.

Although both these proteins are found at high concentrations in colostrum, they are likely to be secreted by different mechanisms; lactoferrin, an endogenous protein of alveolar cells, is secreted by the exocytotic pathway (pathway I), whereas slgA, a plasma-derived protein, is secreted by receptor-mediated transcytosis (pathway III). In addition, the peak secretion rate of lactoferrin occurs at the same time as that of lactose and the major milk proteins, whereas slgA secretion peaks 1 day earlier, indicating the possibility that the exocytotic and transcytosis pathways are regulated differently during early lactation. The third phase occurs approximately 36 h postpartum and is associated with massive and concerted increases in milk volume and the rates of synthesis and secretion of almost all the components of mature milk, including, but not limited to, lactose, protein (mainly casein), lipid, calcium, sodium, magnesium, potassium, citrate, glucose, and free phosphate. Considering that the secretion of these substances involves the actions of several distinct transport pathways and biosynthetic processes, such tightly synchronized increases imply the presence of a common activation switch for coordinating their activities.

### Hormonal Control of Secretory Activation

The decrease in progesterone around parturition is generally agreed to be required for the onset of milk secretion. In humans, it is known that removal of the placenta, the source of progesterone, is necessary for the initiation of milk secretion. In swine, timing of the increase in milk lactose correlates closely with timing of the decrease in plasma progesterone at parturition. Exogenous progesterone prevents lactose and lipid synthesis in mammary glands of pregnant rats and sheep after the removal of their ovaries, the source of progesterone in these species. Progesterone also suppresses  $\beta$ -casein expression in the rat mammary gland during pregnancy and the decrease in progesterone levels is linked to increased  $\beta$ -casein synthesis at parturition. Receptors for progesterone are not detected in lactating mammary tissues, which explains why progesterone does not inhibit established lactation. It is likely that the decline in progesterone is insufficient to activate secretion and that the actions of other hormones, including prolactin and glucocorticoids, are necessary to complete this process. In all *in vitro* mammary systems, insulin and corticoids, in addition to prolactin, are necessary to maintain the synthesis of milk components. Furthermore, cortisol replacement is required for maintenance of milk production in adrenalectomized animals. An early notion that a surge of glucocorticoids is the initiator of lactation is likely incorrect because the increase in cortisol seen in unanesthetized women associated with the stress of labor is complete by the time milk volume begins to increase to any extent. Because secretory activation proceeds at parturition in severely diabetic rats, a role for insulin in lactogenesis as opposed to metabolic adjustments during lactation seems improbable. In summary, the most

reasonable interpretation of the data from both animal and human studies is that the hormonal trigger for lactogenesis is a decrease in progesterone in the presence of maintained prolactin. Because postpartum prolactin levels are similar in both breast-feeding and non-breast-feeding women, the basic process appears to be initiated whether or not breast-feeding occurs. The caveat, of course, is that the mammary epithelium must be sufficiently prepared by the hormones of pregnancy to respond with milk synthesis.

### **Delays in Secretory Activation**

A delay in the onset of milk secretion is a problem for the initiation of breast-feeding in a significant number of parturient women. A number of pathological conditions may delay secretory activation in women, including cesarean section, diabetes, obesity, and stress during parturition. The role of cesarean section is controversial, but if there is one, it is likely to have only a modest effect. However, poorly controlled diabetes, stress from delivery, or obesity are associated with significant decreases in early milk production. Because each of these conditions is related to higher blood glucose, hyperglycemia may be an underlying factor in the delay in lactation. However, once it is established, women with diabetes do not have a problem in maintaining lactation. Thus, compensatory factors may override initiation defects to ensure infant nutrition in these disorders.

## Key points

- Premature infants are high nutrition risk as they have minimal nutrient stores and are born during a time of accelerated growth
- Inadequate nutrition and growth failure during the neonatal period negatively affect cognitive and developmental outcomes
- Immature gastrointestinal tracts, medical instability, and inability to take food by mouth can make the preterm infant dependent on nutrition support
- Most preterm infants will require parenteral nutrition as a bridge until full enteral feeds are established

## Glossary

**Low birth weight infant** Infant born weighing less than 2500 g; very low birth weight infants weigh less than 1500 g at birth; extremely low birth weight infants weigh less than 1000 g at birth

**Necrotizing enterocolitis (NEC)** A spectrum of disease characterized by ischemic necrosis to the mucosal barrier of a neonate's intestines, often associated with significant inflammation, pneumatosis, and possible rupture or perforation of the intestine.

**Parenteral nutrition** Intravenous infusion of nutrients and fluid

**Premature infant** Infant born before completing 37 weeks gestation

**Trophic feedings** Non-nutritive quantities ( $10\text{--}20\text{ mL kg}^{-1}\text{ day}^{-1}$ ) of enteral feeds given for a predetermined time (3–7 days) before beginning the advancement to full enteral feeds

## Introduction

Infants born prematurely have numerous nutritional risk factors. Nutrient stores are accumulated during the third trimester of pregnancy; therefore, preterm infants have minimal energy, protein, fat, vitamin, and mineral reserves. The infant may also be a product of a pregnancy complicated by diminished uterine blood flow, thus further compromising the infant's nutrient stores at birth. The metabolic rate of the preterm infant is elevated due to the predominance of metabolically active tissue and minimal fat stores. Protein, fat, and glucose needs are very high to provide adequate energy for metabolism, fat deposition, and growth. The preterm infant has excessive evaporative losses and increased urinary losses, which increase fluid needs significantly compared to late preterm or term infants. The gastrointestinal tract of the preterm infant is very immature with delayed production of enzymes (Mobassaleh et al., 1985; Shulman et al., 1986), poor gastric emptying, and uncoordinated peristalsis. To further complicate the provision of nutrients, preterm infants have episodes of metabolic instability, including hypo- and hyperglycemia, poor lipid clearance, and electrolyte disturbances. The preterm infant also has high rates of stressful events, including respiratory distress, hypoxemia, hypercarbia, and sepsis. Infants born prematurely require nutrients to be delivered through parenteral and enteral nutrition support, due to the fact that they have an immature gastrointestinal tract and lack the ability to take food by mouth. Moreover, early nutrition support and growth in the early neonatal period have been associated with improved developmental and health outcomes.

## Growth

Similar to full term infants, preterm and low birth weight infants lose 8–15% of their body weight in the first 4–6 days of life due to diuresis, and subsequently take approximately 2–3 weeks to regain birth weight. The smallest infants lose the greatest percentage of weight and subsequently can take the longest time to return to birth weight (Bell and Acarregui, 2008). The goal of nutrition support is to provide sufficient nutrients to achieve fetal growth rate. Table 1 shows the goal growth velocity based on birth weight. Adequate and optimal growth remains a struggle for preterm infants due to their complex medical needs. Most preterm and low birth weight infants show significant delays in growth due to the inability to provide adequate nutrients, due to fluid status and medical instability, especially in the first few weeks following birth. Over the past several years, improvements in neonatal management and a more aggressive approach to nutrition have accelerated growth, but it still lags behind the fetal growth rate. Growth velocity in the infant is the greatest between 25- and 30-weeks gestation. If the infant is undernourished after birth, during this key period of accelerated growth, an increased supply of nutrients may be necessary to achieve catch-up growth to prevent the poor outcomes associated with postnatal growth failure. While protein and energy are key nutrients for growth, vitamins, minerals, and electrolytes must also be supplied in adequate amounts to contribute to optimal growth. For example, despite calorie and protein intake, insufficient sodium and zinc intake may lead to insufficient weight gain and linear growth (Alshaikh et al., 2021; Segar et al., 2018). Preterm infants require parenteral nutrition to supply nutrients with the gradual transition to a combination of parenteral and enteral nutrition, and finally to full enteral nutrition. The preterm infant is at highest risk for growth failure during the transition period. Extra attention needs to be made to ensure appropriate protein, energy and nutrients are supplied during this phase of nutrition.

## Energy needs

Several factors impact the energy needs and metabolic rate of the preterm infant, these factors are summarized in Table 2. Resting metabolic rate accounts for the greatest percentage of energy needs. Resting metabolic rate is equivalent to basal metabolic rate plus some of the energy used for growth; estimates have ranged from 45 to 60 kcal kg<sup>-1</sup> day<sup>-1</sup> (188–251 kJ kg<sup>-1</sup> day<sup>-1</sup>) (AAP, 2009). The energy cost of activity ranges between 2% and 12% of the total energy expenditure. The smaller, more premature infants are at the lower end of the range whereas the older preterm infant has increased activity and therefore a higher expenditure. Although preterm infants are cared for in a thermoneutral environment within an isolette, energy is still lost to thermoregulation during

**Table 1** Expected growth velocity.

Weight (g)	Goal weight gain (g kg <sup>-1</sup> day <sup>-1</sup> )
500–700	21
700–900	20

Total	85–130

AAP (2009).

nursing care and medical procedures. After infants are weaned from the isolette, there may also be energy lost to thermoregulation during bathing and feeding. The energy cost of growth includes tissue synthesis as well as the energy stored in tissues. The estimates for growth needs vary widely depending on the composition of weight gain in the infant. For the enterally fed infant, the thermic effect of food and fecal loss contribute to total energy need. The estimated calorie and protein intakes required to achieve fetal weight gain are listed in [Table 3](#).

## Parenteral nutrition

The gastrointestinal tract of the preterm infant is immature, requiring the gradual and/or delayed initiation of EN. During this period, enteral nutrition alone will not meet the nutritional needs of the preterm infant, thus requiring supplemental PN. Infants whose birth weights are less than 1500 g (g) are often at higher risk of delayed enteral nutrition; therefore, the preterm infant is at risk for long term PN dependence to prevent catabolism, maintain lean body mass, support metabolism, and achieve growth until adequate enteral feeds can be established.

In infants whose birth weight is between 1500 and 2000 g, may also require PN especially if the initiation or progression of enteral feeding is likely to be prolonged or delayed. Historically, PN was delayed for several days after birth due to metabolic instability of the infant and concern for tolerance of the components in the solution. More recently, the early use of PN has been recommended, ideally within 24 h after birth. This practice minimizes the interruption of nutrient delivery and the catabolism that occurs after preterm delivery.

PN can be administered by two different routes, a peripheral line or a central line. There are both risks and benefits associated with each route. The osmolarity is limited to less than 1000 osmoles per liter ([Dugan et al., 2014](#)). Peripheral line osmolarity limits can impede nutrient composition in PN. Peripheral lines also require vigilance on the part of staff to prevent infiltrates and line replacements. Central PN is recommended when it is anticipated that it will be used for greater than 5–7 days. Central access is intended for more long term management, however complications such as pneumothorax, pleural effusions, and increased risk of sepsis are associated with central lines. [Table 4](#) summarizes a comparison of peripheral PN and central PN.

## Components of PN

PN solutions contain dextrose, amino acids, lipids, electrolytes, vitamins, and minerals.

### Glucose

Glucose, provided as a dextrose solution, is the predominant energy source in PN. It is the main energy substrate for the fetus as well as the neonate after birth. Preterm infants often require more glucose than the term infant due to the higher brain to body weight ratio and the additional energy requirements for the central nervous system. Glycogen stores are very limited in the preterm and low

**Table 3** Estimated calorie and protein intakes to achieve fetal weight gain.

Body weight (g)	Energy (kcal kg <sup>-1</sup> day <sup>-1</sup> ) (parenteral–enteral)	Protein (g kg <sup>-1</sup> day <sup>-1</sup> ) (parenteral–enteral)	Protein/energy (g 100 kcal <sup>-1</sup> ) (parenteral–enteral)
500–700	89–105	3.5–4	3.9–3.8
700–900	92–108	3.5–4	4.1–3.7

**Table 4** Risks and benefits of parenteral nutrition routes.

Peripheral	Central
<ul style="list-style-type: none"> <li>• Adequate for short-term use</li> <li>• Dextrose limited to 10–12.5%</li> <li>• Can provide 80–85 kcal kg<sup>-1</sup> day<sup>-1</sup> if adequate fluid available</li> <li>• Possible complications</li> <li>• Intravenous line can infiltrate and cause deep skin sloughing</li> <li>• Requires nursing vigilance to care for intravenous line</li> <li>• Can require multiple intravenous attempts</li> </ul>	<ul style="list-style-type: none"> <li>• Recommended with PN required for greater than 5–7 days</li> <li>• Requires placement of central line/PICC</li> <li>• Able to meet estimated needs if adequate fluid available</li> <li>• Possible complications</li> <li>• Sepsis</li> <li>• Line complications: pleural effusions, pneumothorax</li> </ul>

birth weight infant; therefore, they require a continuous source of glucose to prevent hypoglycemia. This should be initiated at a rate of 4–6 mg kg<sup>-1</sup> min<sup>-1</sup> (0.033 mmol kg<sup>-1</sup> min<sup>-1</sup>) and can be advanced 1–2 mg kg<sup>-1</sup> min<sup>-1</sup> (0.0055–0.011 mmol kg<sup>-1</sup> min<sup>-1</sup>) each day to an optimum of 12–14 mg kg<sup>-1</sup> min<sup>-1</sup> (0.066–0.78 mmol kg<sup>-1</sup> min<sup>-1</sup>) as long as the infant does not become hyperglycemic. Above this rate, glucose is not used for energy, but rather fat deposition, an inefficient process that can result in increased energy expenditure and carbon dioxide production (Mesotten et al., 2018).

Difficulties with glucose stability are a common problem in preterm infants due to decreased energy stores, increased gluconeogenesis due to stress, decreased insulin secretion, and insulin resistance. When hyperglycemia occurs, the glucose infusion rate should be decreased; however, the rate should not be decreased below 4–6 mg kg<sup>-1</sup> min<sup>-1</sup> (0.022–0.33 mmol kg<sup>-1</sup> min<sup>-1</sup>) as this is the minimum supply rate necessary to provide adequate energy to the brain. Usually, the infusion of amino acids improves glucose tolerance by decreasing glucose production, stimulating insulin secretion, and enhancing insulin action. The use of continuous insulin infusions to treat hyperglycemia is controversial, however may be considered to treat hyperglycemia when GIR is already limited.

### Protein

The early administration of protein to the preterm infant is one of the changes that have occurred over the last decade. Early studies of amino acid administration in preterm infants in the 1960s and 1970s raised the concern for protein toxicity because these infusions were associated with acidosis, azotemia, and hyperammonemia, thus causing a delay in the routine administration of protein. However, the above conditions were most likely the result of the preparations being casein or fibrin hydrolyzates. In the late 1980s, crystalline amino acid solutions specifically for use in infants were designed to mimic the plasma amino acid level comparable to that of a postprandial breast-fed infant. TrophAmine is currently the recommended amino acid solution for use with preterm and low birth weight infants as it contains taurine, a semi-essential amino acid in premature infants. It has a higher ratio of essential to nonessential amino acids, thus resulting in improved nitrogen balance and protein synthesis. Moreover, TrophAmine has been shown to reduce the incidence and degree of PN-associated cholestasis, and has a lower pH, thus enhancing calcium and phosphorus solubility (Lenz and Mikrut, 1988; Wright et al., 2003).

The early administration of amino acids is crucial as the preterm infant suffers protein losses of between 0.9 and 1 g kg<sup>-1</sup> day<sup>-1</sup> starting as soon as the placental supply is cut off (Embelton, 2007). The infusion of amino acids, along with glucose, decreases protein catabolism and prevents negative nitrogen balance with as little as 1–1.5 g kg<sup>-1</sup> day<sup>-1</sup> (Embelton, 2007). It has also been shown that the infusion of 3 g kg<sup>-1</sup> day<sup>-1</sup> within the first 2 days of life results in increased protein synthesis, suppressed protein breakdown, and produced plasma aminograms similar to those of the breast-fed infant (Denne and Poindexter, 2007).

Therefore, protein should be started on the first day of life, ideally, in the first few hours of life once intravenous access is obtained, at 3 g kg<sup>-1</sup> day<sup>-1</sup> and advanced to 3.5–4 g kg<sup>-1</sup> day<sup>-1</sup> to achieve *in utero* accretion rates.

### Cysteine

The amino acid cysteine is a conditionally essential nutrient in preterm infants because they have low cystathionase activity. Cystathionase, an enzyme, is necessary to convert methionine to cysteine. This amino acid is unstable in liquid solutions, so commercially available crystalline amino acid solutions do not contain cysteine. Plasma levels of cysteine are low in infants receiving cysteine-free PN. Cysteine hydrochloride is soluble and stable in aqueous solutions for a short period of time and often added to PN solutions when prepared. An additional advantage is that the addition of cysteine decreases the pH of the PN solution, which allows for the addition of more calcium and phosphorus.

### Lipids

Lipids are the most concentrated source of calories in the PN solution. Traditionally, lipid emulsions were comprised of soy bean and safflower oil. Recently, the utilization of alternative and blended lipids in preterm infants has gained popularity. These alternative lipids vary in composition and have been shown to reduce PN related cholestasis. The two widely used alternative lipids are SMOFlipid and Omegaven. SMOFlipid is 4-oil lipid emulsion and is a blend of soybean oil, medium chain triglycerides (MCT), olive oil, and fish oil. It has been shown to reduce the incidence of PN-related cholestasis in the infant population (Diamond

et al., 2017; Rayyan et al., 2012). Omegaven is 100% omega-3 fatty acids from fish oil and has been shown to reverse the effects of PN related cholestasis (Diamond et al., 2009; Park et al., 2015).

When using standard lipid emulsions, 20% emulsions are recommended for use in preterm and low birth weight infants as they contain less phospholipid than the 10% emulsion. Phospholipid interferes with the rate of lipid hydrolysis, leading to elevated serum triglycerides. Lipids are critical for central nervous system development and when infused with the PN solution, they may prevent phlebitis. Lipids are dosed to prevent essential fatty acid deficiency and as an energy source. Maximum lipid clearance occurs when lipids are infused over 24 h. Starting recommendations vary, but it is generally accepted to start with  $1 \text{ g kg}^{-1} \text{ day}^{-1}$  within the first 24 h of life and advance to an optimum of  $3 \text{ g kg}^{-1} \text{ day}^{-1}$ ; however, safety of initiation at  $3 \text{ g kg}^{-1} \text{ day}^{-1}$  has been demonstrated (Ibrahim et al., 2004). Preterm infants have optimal protein retention when approximately 30–40% of calories are provided as lipids. Plasma triglycerides can be used to monitor lipid clearance. It is generally accepted that levels below  $250 \text{ mg dL}^{-1}$  indicate adequate clearance. Lipoprotein lipase and hepatic lipase are the primary enzymes for clearance of intravenous lipid. These activities are inducible by low-dose heparin, which is usually present in central PN solutions. In infants with hypertriglyceridemia, the provision of  $0.5\text{--}1 \text{ g kg}^{-1} \text{ day}^{-1}$  of lipid is adequate to prevent essential fatty acid deficiency when a standard soybean lipid emulsion is used. When using alternative lipids or blends the minimum dosing as well as tolerable dose varies, therefore imperative to check the recommended dose from the specific manufacturer.

### Carnitine

Carnitine is necessary for the transport of long-chain free fatty acids into the inner mitochondrial membrane, and for oxidation of fatty acids in the mitochondria. Carnitine is considered a conditionally essential nutrient because the preterm infant has decreased carnitine synthesis capability and has low plasma and tissue concentrations. Carnitine is found in human milk and formula; therefore, deficiencies can develop in 6–10 days after birth in less than 34 weeks' gestation infants without enteral feedings. There is no clear consensus as to the benefit to adding it to PN. Its use should be considered in all infants less than 34 weeks' gestation, those receiving long-term PN without enteral feedings, and those with hypertriglyceridemia.

### Electrolytes

Electrolytes are added to the PN solution when the infant undergoes initial diuresis and is losing electrolytes in urine. Hyper- and hyponatremia within the first 48 h of life usually reflects fluid status and not excess or suboptimal provision of electrolytes. Very immature infants and those on diuretics may require additional amounts to maintain normal plasma concentrations. Chloride and acetate need to be dosed based on electrolyte levels. The very young preterm infant may need a higher proportion of acetate due to urinary bicarbonate losses. Later, when chronic diuretics are used, a greater proportion of chloride may be needed.

### Calcium, phosphorus, and magnesium

Calcium and phosphorus are added to PN solutions to meet the minimum need for bone mineralization and cellular function. Calcium and phosphorus are relatively insoluble in solution together, making it difficult to provide adequate levels of these minerals to meet the needs of the preterm infant. Cysteine and TrophAmine are utilized in PN solutions to increase the solubility and improve the provision of calcium and phosphorus in PN. During the third trimester the average accretion rate of calcium in the fetus is normally about  $100\text{--}120 \text{ mg kg}^{-1} \text{ day}^{-1}$  and  $50\text{--}65 \text{ mg kg}^{-1} \text{ day}^{-1}$  for phosphorus. This level of accretion is difficult to match in the extrauterine environment, more-so in PN dependent infants given restrictions with volume and solubility. Infants on prolonged PN may develop osteopenia and fractures. For optimal absorption and utilization of both calcium and phosphorus, a ratio of 1.3–1.7 mg of calcium per every 1 mg of phosphorus is recommended. The usual dose of magnesium is  $0.3\text{--}0.5 \text{ mEq kg}^{-1} \text{ day}^{-1}$  ( $0.3\text{--}0.5 \text{ mmol kg}^{-1} \text{ day}^{-1}$ ).

### Trace minerals

Zinc and copper deficiencies occurred in some preterm infants before these trace elements were routinely added to PN solutions. There is very little research that defines the parenteral requirements of trace minerals in preterm infants. The current recommendations for trace minerals are summarized in Table 5.

### Vitamins

Like trace minerals, the recommendations for intake of vitamins are not based on randomized trials, but are based on the best information available. Infants receiving these parenteral intakes in Table 6 do not develop deficiencies or evidence of excessive intake.

The suggested initiation and advancement of PN in the preterm infant is summarized in Table 7.

## Enteral nutrition

The early initiation of enteral nutrition has been shown to benefit premature infants. The rate of feeding advancement and type of feeds may result in feeding intolerance or necrotizing enterocolitis (NEC). NEC is a major cause of morbidity and mortality in preterm infants. The incidence of this disease is estimated to be between 8% and 10% of preterm infants. The cause of NEC is still fully understood, however likely multifactorial, including enteral feeds, hypoxia, ischemia, patent ductus arteriosus, and infection. It is known that delayed enteral feeding has a negative effect on gastrointestinal structure and function. Lack of enteral nutrition can

Folate ( $\mu\text{g}$ )	56
Vitamin B <sub>12</sub> ( $\mu\text{g}$ )	0.3

Total dose should not exceed the amounts provided by 5 mL of reconstituted MVI Pediatric (Armor Pharmaceutical Co., Chicago, IL, USA): 700  $\mu\text{g}$  vitamin A, 7  $\mu\text{g}$  vitamin E, 200  $\mu\text{g}$  vitamin K, 10  $\mu\text{g}$  vitamin D, 80 mg ascorbic acid, 1.2 mg thiamin, 1.4 mg riboflavin, 1.0 mg pyridoxine, 17 mg niacin, 5 mg pantothenic acid, 20  $\mu\text{g}$  biotin, 140  $\mu\text{g}$  folic acid, and 1  $\mu\text{g}$  vitamin B<sub>12</sub>.

Task Force for the Revision of Safe Practices for Parenteral Nutrition, Mirtallo, J., Canada, T., Johnson, D., Kumpf, V., Petersen, C., Sacks, G., Seres, D., Guenter, P., 2004. Safe practices for parenteral nutrition. *J. Parenter. Enteral Nutr.* 28(6), p. S39–S70.

**Table 7** Suggested initiation and advancement of parenteral nutrition for the preterm infant.

<i>Component</i>	<i>Initial</i>	<i>Advancement per day</i>	<i>Goal</i>
Dextrose ( $\text{mg kg}^{-1} \text{ min}^{-1}$ )	6–8	1–2	12–14
Protein ( $\text{g kg}^{-1} \text{ day}^{-1}$ )	2–3	1	3.5–4
Lipids ( $\text{g kg}^{-1} \text{ day}^{-1}$ )	1	1	3

induce gastrointestinal atrophy, depresses gut hormone secretion, and delays the maturation of gastrointestinal motility. There benefits of early enteral feeding includes endocrine adaptation, the accelerated maturation of gut motility patterns, the provision of luminal nutrients, and possible benefits to the immune system. In fact, early enteral nutrition may enhance feeding tolerance and may actually decrease the incidence of NEC.

### Trophic feedings

A strategy that has been extensively studied since the late 1980s is trophic feeding, also referred to as minimal enteral nutrition or gut priming. This method involves giving the infant small volumes of feedings, approximately  $10\text{--}20 \text{ mL kg}^{-1} \text{ day}^{-1}$ , for a period of 3–7 days before beginning to advance to full enteral feedings. The benefits found are greater energy intake, earlier attainment of full enteral feedings, improved growth, decrease in PN-related complications, reduced risk of infection, and earlier hospital discharge. Furthermore, infants who receive trophic feedings have no increased incidence of NEC (Oddie et al., 2021). Many clinicians have adapted variations of this practice; some with a shortened period of trophic feeds, others reserving this practice for the smallest, most preterm and liable infants while employing advancement of feeds in larger, more stable infants. Once minimal enteral nutrition has been established and the infant is stable enough to advance feedings, it is generally considered a safe practice to increase

feedings by 20–30 mL kg<sup>-1</sup> day<sup>-1</sup> while using PN for the balance of intake until an adequate enteral intake has been established and tolerated.

### Feeding route

Preterm infants lack the ability to orally feeds due to their inability to coordinate sucking, swallowing, and breathing until 32–34 weeks gestation therefore tube feedings must be used. Jejunal feeding was a popular method for feeding infants during the 1970s to early 1980s. It was felt that this method would minimize the risk of reflux and aspiration. This method is now generally reserved for infants in whom reflux and aspiration is complicating chronic lung disease or those who have poor gastric emptying. Now, most infants are fed using an orogastric or nasogastric tube. Orogastric tubes are often used in the lowest weight infants as the feeding tube may occlude one naris and impair nasal breathing.

### Feeding selection

Human milk is the preferred type of feeding because of its well-established health benefits for the infant as well as those who lactate. Human milk is nutritionally superior to infant formula due to its increased bioavailability and protective effects against several comorbidities including NEC. Human milk contains many biologic components such as immunoglobulins, cytokines, growth factors, hormones, and oligosaccharides. Benefits to the infant also include improvements in gastrointestinal function, digestion and absorption, cognitive and visual development, host defense as well as enhanced parental-infant bonding.

However, despite human milk being the optimal feeding choice for infants, it is insufficient to meet the nutritional needs of the growing preterm infant alone. Unfortified human milk does not supply sufficient quantities of protein, energy, fatty acids, minerals, and other micronutrients that are needed for preterm infants to achieve optimal fetal growth and adequate bone mineralization. There are fortifiers available that can be added to human milk to improve nutrient intake. The use of these fortifiers has been associated with improved intake of protein and subsequent nitrogen retention, improved intake of minerals, subsequent bone mineralization, and improved growth.

If human milk is not available, the feeding of choice becomes either donated human milk or preterm infant formulas. The use of donated human milk has been associated with decreased incidence of NEC compared to preterm infant formulas however is costly and depending on state may require hospitals to acquire a tissue license. Preterm infant formulas have greater protein content and are cow's milk whey predominantly. The carbohydrate is a mixture of lactose and glucose polymers, and the fat a mixture of both long-chain and medium-chain triglycerides for improved nutrient absorption. The concentration of minerals, electrolytes, and vitamins is increased to meet the estimated nutrient needs of the preterm infant when fed in an amount to provide 120 kcal kg<sup>-1</sup> day<sup>-1</sup>. Infants fed preterm infant formulas have improved growth over those fed term formula.

### Feeding delivery

Infants can be enterally fed via either continuous infusions or bolus. There are risks and advantages for both feeding modalities. It is commonly believed that continuous feedings are better tolerated. Continuously fed infants have been found to take longer to achieve full volume feeds and have decreased growth when compared with bolus fed infants (Wang et al., 2020). Bolus feedings have been associated with improved gastric emptying, and more mature intestinal motility patterns in addition to being the more physiologic option (Lucas et al., 1986). Because it causes infants to have cyclical surges of gastric hormones and insulin, promoting gastrointestinal tract development. Bolus or intermittent feeding may be more beneficial for low-birth weight infants. It is difficult to compare feeding tolerance between continuous and bolus feeds infants due to differences in the criteria used, more studies are needed to determine the best feeding delivery method for premature infants.

Table 8 summarizes the indications for bolus vs. continuous enteral feeding.

**Table 8** Review of feeding delivery methods via NG or OG.

<i>Bolus</i>	<i>Continuous</i>
<p>Advantages:</p> <ul style="list-style-type: none"> <li>• Appropriate for most premature infants</li> <li>• Simple delivery with minimal equipment</li> <li>• Physiologic feeds, ideal for those starting to take food by mouth</li> <li>• Can be done at home</li> </ul> <p>Possible contraindications:</p> <ul style="list-style-type: none"> <li>• Malabsorption</li> <li>• Dumping</li> <li>• High aspiration risk</li> <li>• Frequent emesis</li> </ul>	<p>Advantages:</p> <ul style="list-style-type: none"> <li>• Generally, well tolerated</li> <li>• Increased absorption and reduce dumping for those with intestinal disease</li> <li>• Can reduce aspiration risk for those who are high risk</li> </ul> <p>Possible contraindications:</p> <ul style="list-style-type: none"> <li>• Poor weight gain for infants fed human milk given the separation and adherence of fat to the tubing</li> <li>• More equipment and room for malfunction</li> </ul>

### Monitoring feeding tolerance

Feeding tolerance among preterm infants must be closely monitored given the high risk of gastrointestinal complications such as NEC. The presence of gastric residuals is one factor that is frequently used, but because preterm infants have poor gastric emptying, amounts less than 50% of a previous feed should not be considered significant. Other indicators include increase in abdominal girth, the absence of active bowel sounds, the presence of blood in the stool, a change in the number or quality of stools, and the presence of emesis. A careful exam is warranted if these symptoms are present.

### Vitamin, mineral, electrolyte supplementation

Preterm and low birth weight infants who are fed fortified human milk or preterm infant formulas may require supplemental doses of vitamins, minerals, or electrolytes. Most commonly supplemented include iron, vitamin D, calcium, phosphorus, and sodium chloride. The specific dosing for each supplement should be based on recommended intake, laboratory results, and current provision. **Table 9** provides enteral nutrient requirements of commonly supplemented vitamins and minerals for preterm or low birth weight infants with comparison of the RDA/AI for infants aged 0–6 months.

	<i>Espghan 2010<sup>a</sup></i>	<i>RDA/AI (age 0–6 months)<sup>b</sup></i>
<b>Vitamins</b>		
Vitamin A (mcg/kg)	400–1100	400
Vitamin D (mcg/d)	20–25	5
Vitamin E (mg/d)	2.2–11	4
Vitamin K (mcg/kg)	4.4–28	2
<b>Minerals</b>		
Calcium	120–140 mg/kg	210 mg/d

### Monitoring nutritional status

The nutritional status and growth of the preterm infant should be monitored throughout the hospitalization. The fluid and caloric intake should be monitored daily, body weight should be recorded daily, length and head circumference measured weekly, and all three measurements plotted on standardized growth charts. If growth is inadequate, the volume, caloric density, or protein content

**Table 9** Periodic monitoring of nutritional status.

<i>Indicator</i>	<i>Frequency</i>
Weight	Daily
Length	Weekly
Head circumference	Weekly
Electrolytes	Daily until stable, then 1–2 times weekly
Albumin	Weekly
Bili/transaminases	Weekly (while on PN)
Calcium, phosphorus, magnesium, alkaline phosphatase	Weekly
Hemoglobin/hematocrit	Weekly
Reticulocyte	

of feeds should be increased. Supplementation of vitamins, minerals, or electrolytes may also be introduced/increased to support growth as deficiencies of iron, zinc, and sodium can lead to poor growth despite calorie intake. Biochemical measurements should also be assessed periodically. **Table 9** summarizes the recommended schedule for monitoring anthropometrics and biochemical measurements.

## Conclusions

Preterm infants have specialized nutritional needs. Nutrition support must be initiated as soon as possible after birth to achieve optimal outcomes. It needs to be continuously assessed to ensure that the best possible nutritional support is provided to promote optimal growth and subsequent developmental outcomes.

## Introduction

It is widely accepted that weight at birth is a key indicator of fetal and neonatal health, both for individuals and populations. The strong association between low birth weight and perinatal mortality and morbidity is well recognized, and there is growing evidence about the different determinants and health consequences of conditions resulting in low birth weight. Knowledge of these epidemiological associations progressively increased over the course of the last 100 years. In the USA, the practice of weighing babies at birth was introduced at the end of the nineteenth century when low-birth-weight babies were categorized as *premature* and usually left unattended with minimal or no intervention attempted to prevent their deaths. This practice and the incorporation of information on birth weight and gestational age into the birth certificate in the mid-twentieth century resulted in irrefutable evidence that *prematurity* was the most significant cause of infant deaths at national level.

Awareness of the importance of low birth weight as a predictor of infant mortality led to the findings suggesting that low birth weight could be due to a restriction of the normal process of fetal growth, to delivery before the full term of gestation, or through a combination of both factors. Based on this evidence, the World Health Organization (WHO) made a distinction between the condition of low birth weight (birth weight less than 2500 g) and prematurity (delivery at less than 37 completed weeks, i.e., 259 days). A further development was the concept of small for gestational age (SGA) that better describes babies affected by intra-uterine growth restriction (IUGR). SGA is defined as a birth weight below the 10th percentile for a given gestational age based on a sex-specific reference population. Although these distinctions and definitions are commonly applied in developed countries, their use is more problematic in developing countries where information on gestational age is often nonexistent or unreliable. This data limitation represents a major obstacle to the development of effective prevention and treatment efforts because IUGR and preterm delivery have different determinants and prognoses, as well as different epidemiological distributions which vary by country and socioeconomic status.

Before discussing the causes, prevalence, and prevention of low birth weight it is important to understand how its two components (gestational age and fetal growth) can be correctly identified and quantified for epidemiological and clinical purposes, and the major methodological limitations in capturing this information.

## Assessment of Gestational Age and Fetal Growth. Methods and Limitations

Preterm birth is defined as delivery before 37 completed weeks (259 days). To accurately differentiate between preterm and term delivery it is crucial to have a reliable estimate of gestational age. Sonographic determination is presently the most accurate method to estimate gestational age. When ultrasonography is not available, gestational age can be determined by patient's recall of the time of last menstrual period, physical examination of the size of the uterus, and examination of the neonate. These alternate methods can be used alone or in combination, but are often inaccurate.

Early pregnancy sonographic estimation of gestational age is also crucial for estimation of fetal growth in utero, which is assessed by evaluating the size of several fetal anatomical parameters and comparing those measurements with the normal ranges at specific gestational ages obtained from reference populations with growth that can be considered unaffected by pathological conditions. Alternatively, fetal growth can be assessed by the anthropometrical evaluation of the neonate. Several classification systems have been proposed for newborn birth weight. The simplest categorizes newborns <2500 g as having a low birth weight, but this

classification does not enable differentiation between infants born SGA and infants who are small because they are born preterm. A second classification system based on reference charts of birth weight at different gestational ages groups infants into the categories of SGA, adequate for gestational age (AGA), and large for gestational age (LGA). Because these categories are based on percentile distributions of a reference population, a proportion of normal, constitutionally small, newborns in the lower tail of the normal fetal growth distribution will be miscategorized as growth restricted. The interpretation of the birth weight data using this system is also complicated by inaccuracies in the estimation of gestational age at delivery and by the pathological processes that could affect the size of infants born early in gestation.

## Causes

Low birth weight results from either IUGR or preterm delivery, and, in some cases, from a combination of the two. These two conditions are likely caused by various and possibly independent etiopathological factors.

The definitive etiology of preterm delivery has not yet been determined, making it difficult to identify women at risk and to develop and implement effective preventive strategies. Available evidence shows that a complex range of factors such as pregnancy complications, health care practices, and socioeconomic conditions are implicated in preterm births. Preeclampsia, fetal distress, fetal growth restriction, abruptio placenta, fetal death, placenta previa, and multiple gestations, for example, are all associated with preterm delivery, either spontaneous or induced. Developments in obstetric and neonatal care and the consequent increase in obstetric interventions including infertility treatments have been linked with the increase in the rates of preterm delivery observed in recent years. Psychological stress and other socioeconomic factors such as poor nutrition, cigarette smoking, alcohol and drug abuse, young maternal age, poverty, and short stature have also been found to be possible causes. Genetic factors are likely to be involved in the etiopathogenesis of preterm delivery given that the condition tends to recur in families and that prevalence varies across races. The possible role of infection in triggering preterm delivery has been suggested by several studies, which show associations between preterm delivery and amniotic fluid and chorioamniotic infection, bacterial vaginosis, genitourinary chlamydial infection, and periodontal disease. Despite the biological plausibility of these associations, their causal relationship has not been definitely proved by unequivocal scientific evidence.

Conditions associated with IUGR include but are not limited to fetal infections, congenital malformations, chromosomal abnormalities, chemical teratogens, vascular disease such as preeclampsia, chronic renal disease, chronic hypoxia, placental and cord abnormalities, and multiple fetuses. Present knowledge of IUGR is limited by the challenges of differentiating between constitutional and environmental determinants of fetal growth. This limitation complicates the investigation of the role of maternal size and genetic factors in IUGR. Small women tend to have smaller babies. There is evidence that intergenerational effects on birth weight are transmitted through the maternal line, suggesting a genetic effect. However, poor maternal nutrition and social deprivation have also been proven to be related to small maternal size and impaired fetal growth. Similarly, the relationship between fetal size and race may be mediated by a combination of genetic and environmental factors. Carefully designed studies are needed to better determine the contribution of genetic and environmental determinants to the process of fetal growth.

## Health Consequences

Low birth weight, either due to preterm delivery or IUGR is associated with poor neonatal health outcomes including higher rates of mortality. Neonatal mortality levels are indirectly associated with gestational age at delivery and birth weight.

Preterm birth is one of the major causes of neonatal mortality and morbidity. Of the estimated 8.795 million deaths in children younger than 5 years worldwide in 2008, 41% (3.575 million) occurred in neonates, and the most important single cause was preterm birth complications (12%, 1.033 million, UR 0.717 million–1.216 million). Mortality rates due to preterm birth are correlated with the overall level of neonatal mortality in a specific country. In low resource countries with high neonatal mortality rates (>45 neonatal deaths per 1000 live births), preterm birth is responsible for approximately 20% of all neonatal deaths with the other 80% attributable mainly to infections and birth asphyxia. In more developed countries, where neonatal mortality rates are below 15 deaths per 1000 live births, preterm birth is the cause of up to 40% of neonatal deaths since deaths due to infection and birth asphyxia are largely prevented. Although the proportion of neonatal deaths attributable to preterm birth is higher in developed countries, the majority of preterm birth related deaths occur in low resource settings because of lack of access to preventive and therapeutic interventions. This discrepancy between rich and poor countries is also reflected in the mortality differentials in late preterm births (between 32 and 37 weeks). Although late preterm infants in developed countries have a survival rate similar to full-term infants, the chance of survival of such infants in low resource settings is minimal.

The negative effects of preterm delivery and IUGR often persist throughout infancy and childhood, impacting the individual child, the entire family, the health care system, and society in general. Studies have also shown a relationship between low birth weight and an increased risk of cardiovascular disease, high blood pressure, obstructive lung disease, diabetes, high cholesterol concentrations and renal damage, indicating that the effects of low birth weight may extend into adulthood.

## Epidemiology

Aggregate data on low birth weight rates show marked differences in underlying causes between geographical areas. Most low birth weight infants born in developed countries are due to preterm delivery, whereas a substantial proportion of low birth weight in developing countries is related to IUGR.

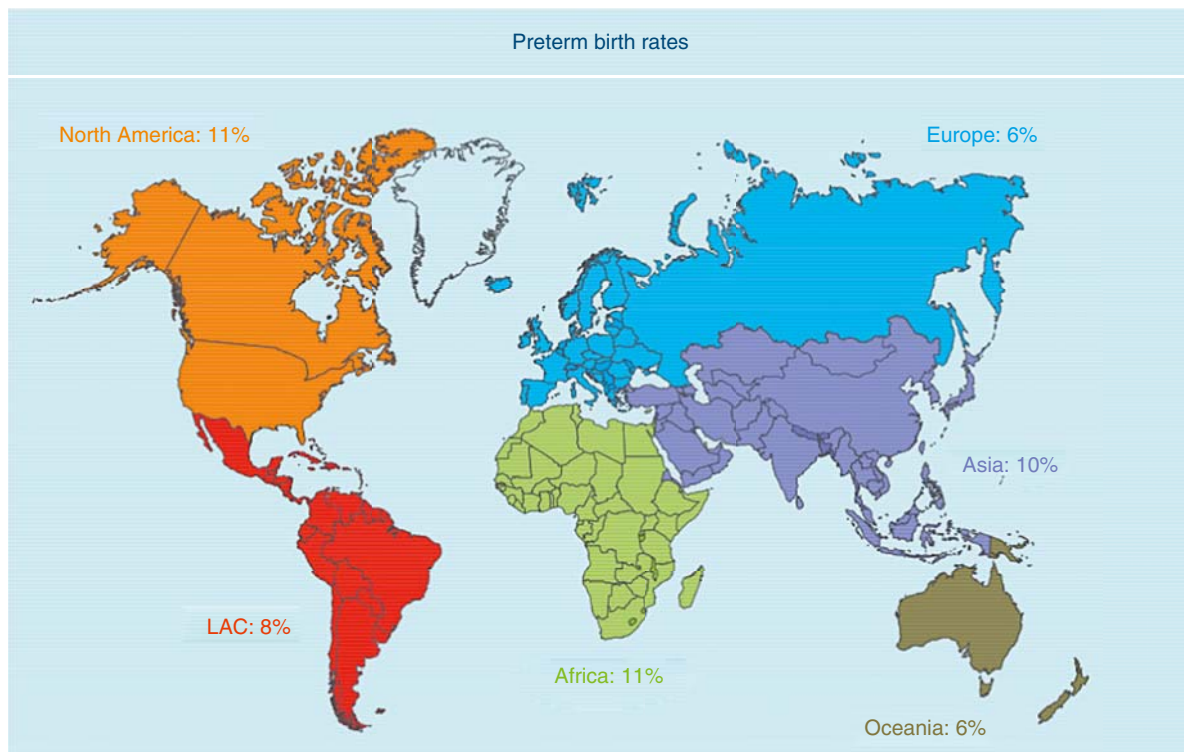

The first global and regional estimates of preterm birth rates were recently published. We now know that approximately 13 million newborns are born prematurely every year. This figure represents 9.6% of all births and is a conservative measure as it is based on estimates of the risk in normal pregnancies. **Figure 1** shows the estimated rates in the six major regions of the world. The highest rates are in North America and Africa. The greatest absolute numbers of preterm births (**Figure 2**) occur in Africa and Asia, the two world regions with the highest number of births and fertility rates.

These global and regional estimates mask important disparities between and within countries. In the US, for example, African and American women are more than twice as likely to deliver preterm than Caucasian women, a difference that accounts for a major proportion of the variation in infant mortality between the two racial groups.

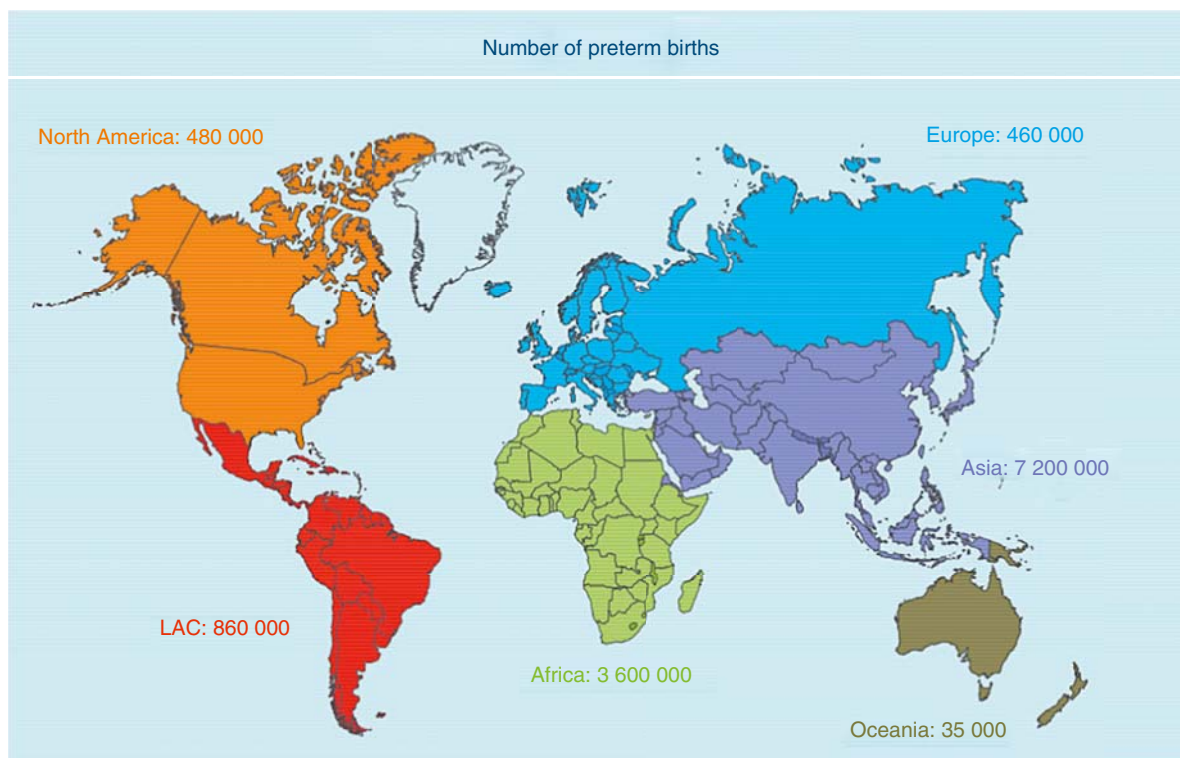

Preterm birth rates are increasing in many developed countries. Although the causes of this trend are not fully elucidated, changes in clinical practices such as increased use of assisted reproductive techniques, and the rising rates of cesarean sections and induced deliveries have been associated with increases in preterm deliveries.

## Prevention

Results from clinical trials provide the most powerful scientific evidence to guide policy and program development and implementation. Interventions aimed at preventing low birth weight targeted at preterm delivery and IUGR have not proven to be effective by randomized clinical trials. The multicausal nature of these conditions is likely responsible for single interventions not showing an effect of enough magnitude to be detected by medium sized clinical trials. Thus appropriate combinations of interventions should be a priority for evaluation in the context of large, methodologically sound trials. Available evidence shows that some interventions may be effective and their combined implementation may have a significant public health impact. Interventions likely to be beneficial to prevent IUGR are smoking cessation, antimalarial chemoprophylaxis in primigravide women, and balanced protein energy supplementation. Treatment of urinary tract infection, placement of circumferential stitches on a structurally weak uterine cervix (cerclage), and treatment of bacterial vaginosis in high-risk women have been shown to be effective in preventing preterm birth. These interventions are applicable only to a small number of high risk women and their overall effect on the general population is likely to be limited.

**Figure 1** Preterm birthrates.

**Figure 2** Number of preterm births.

In the next paragraphs, nutritional interventions to prevent preterm delivery and IUGR will be reviewed with the aim of identifying potentially effective interventions and suggesting possible mechanisms that may explain the link between maternal nutritional status and low birth weight. The focus will be on the review of randomized clinical trials which provide the most unbiased epidemiological evidence on the effectiveness of interventions. Clinical trials testing the same or similar interventions can be pooled together to estimate an overall effect by means of systematic reviews of published and unpublished studies and meta-analysis.

### Nutritional Interventions to Prevent Preterm Delivery

Of the nutritional interventions during pregnancy that have been tested by clinical trials to prevent preterm delivery, only calcium and fish oil supplementation appear promising. Nutritional counseling and magnesium supplementation are likely to be effective, but methodological limitations in the analysis of the clinical trial results means definitive conclusions cannot yet be made. Most of the other interventions hypothesized to potentially prevent preterm delivery such as protein and energy supplementation, protein and energy restriction, salt restriction, iron or folate supplementation, zinc supplementation and vitamin A supplementation have not been proven effective.

### Nutritional Interventions to Prevent IUGR

Of the interventions tested through randomized clinical trials to prevent IUGR, balanced energy protein supplementation has been shown to reduce the risk of SGA by approximately 30%. On the basis of these results it has been proposed that universal balanced energy supplementation should be provided to women in areas with high prevalence of maternal undernutrition to prevent impaired fetal growth. There is some evidence that magnesium and calcium supplementation may be effective. For calcium supplementation, the evidence is still not clear whether the observed effect on reducing the risk of low birth weight is due to a direct effect on fetal growth or mediated by a prolongation of gestational age at delivery. Other interventions such as nutritional counseling, energy protein restriction, salt restriction, iron or folate supplementation, fish oil supplementation, zinc supplementation, Vitamins E, C, and D supplementation have not shown any preventive effect. High protein supplementation in women of low socioeconomic status in the USA has been associated with an increase in the rate of SGA infants, suggesting that nutritional supplementation may, in some cases, have potentially harmful effects. This finding warrants further investigation.

## **Conclusions**

Low birth weight, due to preterm delivery or IUGR, represents a major public health problem for developing and developed countries. Access to adequate obstetric and neonatal care has been shown to reduce the mortality and morbidity associated with these two conditions. Public health efforts should aim at improving the quality and availability of such services, particularly in developing countries where the absolute numbers of low birth weight babies is highest and access to needed care is lowest. Among nutritional interventions to prevent low birth weight, only balanced energy protein supplementation has been shown to be effective in reducing the risk of SGA and should be provided to all women living in areas with high prevalence of maternal undernutrition.

Research efforts should focus on elucidating the etiological factors responsible for preterm delivery and IUGR. Despite the considerable burden of disease related to these conditions, very little progress has been achieved in identifying their causes. This information is essential for developing and implementing effective preventive and therapeutic interventions with universal application and that could benefit the most vulnerable populations of women and newborns.

## Nutrition during the preschool years

### Key points

- Children between one and five years of age are rapidly growing and developing, and attain several developmental milestones sensitive to dietary intakes during this period
- Stunting, underweight and wasting remain highly prevalent globally
- The proportion of children with excess weight continues to increase
- Iron deficiency and anemia are also persistent major issues in this age group
- Although COVID-19 affected only a small proportion of children directly, the ramifications of this pandemic include major indirect effects particularly in the context of nutrition

### Introduction

The “preschool period” extends from one year to approximately 5 years of age. It is a time when children are changing from wholly dependent infants to mobile individuals who communicate their needs verbally and eat independently. Poor nutrition during this period has lifelong physical and psychological effects. Undernutrition was also directly or indirectly implicated in approximately 45% of 5.2 million deaths that occurred in children under five globally in 2019 (WHO, 2020a).

Young children face many challenges: their nutrient requirements are relatively high, yet intake is frequently threatened, particularly in low-income settings. Infections, particularly diarrheal disease, respiratory infections, and malaria may simultaneously induce loss of appetite and reduced intake while increasing energy expenditure and nutrient losses. Measles, case counts of which have been at an all-time high over the past few years, can severely impact young children; most of the 207,500 measles deaths in 2019 were among children under 5 years of age, particularly those living in low-resource settings and who are undernourished (WHO, 2020c). Additionally, the COVID-19 pandemic has had a profound negative impact on dietary quality and nutrition status in children and is expected to have ripple effects for years to come. The need to fuel catch-up growth after infection can further increase requirements.

Paradoxically, the rising prevalence of obesity in higher income countries and settings undergoing economic transition is also believed to have its origins in early life; accelerated weight gain in the preschool years is associated with an increased risk of cardiovascular and metabolic complications later in adult life. Therefore, the early years particularly those before the second birthday, i.e., the first 1000 days of life, represent a “window of opportunity” for investment in nutrition.

## Faltering growth

Growth monitoring is a fundamental aspect of both child health surveillance and pediatric clinical care. It is based on the premise that the growth trajectory of a healthy child follows the percentile channels described by a reference or “standard” such as that described by the World Health Organization International Growth Reference of 2006 (WHO, 2009).

Overall healthy children become leaner and the amount of fat mass decreases while fat-free mass increases. There are also changes in the proportionate growth of organ systems. The brain continues to grow at a greater velocity than somatic tissues, particularly during the early preschool years. By age two it has attained approximately 80% of its adult size and by age five, and 90%. Linear growth velocity varies, approximately reaching 9 cm per year at the end of the second year, reaching 50% of adult height at two years of age; 9 cm per year at the end of the third year; and 5–8 cm per year thereafter until puberty. Average weight gain in healthy children is 7 g body weight per day by 24 months of age and remains at around 2–3 kg per year until adolescence.

Linear growth faltering in children under five continues to be a major global health issue despite reducing stunting from 33% to 22% over the past two decades (UNICEF/WHO/WB, 2021). Unfortunately, these achievements in the decrease of linear growth faltering, as well as the prevalence of underweight and wasting, are at risk of being undone due to the COVID-19 pandemic. Stunting reflects recurrent or long-term undernutrition, while underweight and wasting result from acute or recurring malnutrition or and/disease; it is thought among children who survive episodes of wasting during COVID-19 that linear growth is likely to be affected. Suboptimal growth in the preschool years also contributes to stunting in later childhood and adult short stature, which can perpetuate the intergenerational cycle of undernutrition in that shorter mothers give birth to smaller offspring. Further, some studies have shown that stunted children are likely to develop obesity and other chronic diseases in adulthood, in settings undergoing nutritional transition.

The causes of growth faltering are complex and partly determined by the environment in which the child lives. For example, in urban slums settings, challenges may include high mobility, recurrent acute infection, poor sanitation and food shortage. Infections contribute to poor nutrient intakes, increasing the risk of growth faltering. Low micronutrient status is common in this age group, particularly in lower-resource settings, and often manifests as deficiencies of iron, zinc, vitamins A and D. Additional risk factors for poor growth may include maternal education, child’s gender in that most studies show more male children are malnourished than female children, household income, and family size.

## Developmental milestones in relation to diet

Developmental progress through the preschool years is closely linked to nutritional status because it determines how the child eats, selects food, and expends energy. Equally, poor nutritional status is a common consequence when developmental progress is delayed or halted.

As they enter the preschool years children begin to walk. By age two children can climb stairs, by age three they can ride a tricycle, and by four they run with sufficient balance and skill to avoid obstacles. In keeping with these advances, physical activity level (PAL, the total energy expenditure divided by basal metabolic rate) rises from approximately 1.40 (sedentary) to 1.55 (light activity) between one to five years of age. Children also develop their eating skills in the preschool years. At one year, most children can drink from a cup without a lid, albeit with some spillage. Toward the end of the first year, children should be able to pick up food with their hands and transfer it to the mouth. At this age they can also begin to use a spoon. The ability to use spoon and fork together or chopsticks normally appears toward the end of the second year and by four they are used accurately but not until five years or so can the child be expected to use these utensils.

With the cessation of breastfeeding and/or formula and the introduction of solid foods, the child’s gut microbiome—the bacteria present in the human gastrointestinal tract, as well as their genes—undergoes shifts in the number and types of bacteria present. These shifts may depend on type of weaning food consumed, baseline gut microbial composition, and other factors such as birth mode and infant feeding type. Research on the early childhood gut microbiome has increased over the last several years, with studies supporting the links between diet, the gut microbiome, and immune system development. For example, a child’s immune cells may learn to distinguish pathogens from harmless antigens from dietary inputs which are processed by gut microbiota, in addition to environmental, and other exposures a child may encounter as they mature. Increasing dietary diversity may therefore benefit both the child and their gut microbiome.

## Dietary recommendations

Infant and young child feeding guidelines recommend exclusive breastfeeding until age 6 months, at which point solid complementary foods may be introduced into the diet while partial breastfeeding continues until at least 12 months of age (WHO, 2021c). Between 15 and 24 months of age, approximately 60% of energy comes from solid table foods, with milk being the leading source (25%) of daily energy. Milk consumption decreases with older age, with increasing dietary diversity of solid foods. The American Academy of Pediatrics recommends that children 1–4 years of age be given three main meals and two to three snacks throughout the day. In an encouraging trend, country-specific guidelines are being formulated for this age group, including the recent 2020–2025 Dietary Guidelines for Americans recommendations.

Unfortunately, foods low in micronutrient density such as cookies, salty snacks, and candy often contribute significant amounts of energy as refined carbohydrate and fat along with salt in the diets of young children, as high as 28–48% of daily energy intake. Processed meats and bread may further increase saturated fat and salt intake. Indeed it can be difficult to keep salt intakes in diet of young children within the target population average (2 g per day, 1–3 years; 3 g per day, 4–6 years), particularly where there is reliance on commercially prepared foods. Sweetened beverages may additionally offer significant amounts of sugar; preferably water should be provided between meals and milk or fruit juice (diluted to 50%) with meals.

In terms of macronutrients, children one to three years of age are recommended to consume 1.05 g protein per kg per day, and at four years of age to decrease intake to 0.95 g/kg/day. Fat intake restriction should be avoided before two years of age due to developmental demands. After two years of age, fat should approximate 30% of total energy.

Adequate micronutrient intake is critical for proper growth and development. Approximately 21% of toddlers and 40% of preschool children are given some type of daily micronutrient supplement by their parents or guardians, however it is important to fully assess the child's diet before giving potentially unnecessary supplements. For children who cannot consume a well-balanced diet, vitamin and mineral supplements should be considered.

## Excess weight

Overweight and obesity are defined as abnormal or excessive fat accumulation that may impair health (WHO, 2021d). In children under five years of age, obesity and overweight is defined as weight-for-height greater than three and two standard deviations above the WHO Child Growth Standards median, respectively. Despite becoming a concern several decades ago, the epidemic of childhood overweight and obesity remains an important issue. Over the last 45 years there has been a remarkable increase globally in the proportion of young children who are overweight or obese, including 39 million (5.7%) children under age five in 2020. Overweight and obesity is on the rise across both high-income countries as well as low- and middle-income countries, particularly in urban areas. In Africa, where more than one-quarter of overweight children live, the number of overweight children under five increased by almost 24%. Half of overweight or obese children under five lived in Asia between 2000 and 2019. With the rise of overweight and obesity comes an increase in hidden hunger—deficiencies in micronutrients with simultaneous overconsumption of energy in the form of empty calories, which may impact risk of and responses to infection; gut health; cognition and brain development, and body composition. Reduced physical activity, lower socioeconomic status and changing food systems (for example, food deserts and food swamps limiting access to healthy food) are part of an obesogenic environment, which promotes overweight and obesity.

Short term consequences of excess weight in childhood include a higher likelihood to suffer from psychological comorbidities, allergy and asthma, low-grade systemic inflammation, liver complications, and metabolic and cardiovascular risk factors. Overweight and obesity in childhood also brings long term consequences, including persistence of excess weight and increased risks of cardiovascular diseases, diabetes, cancers, and other musculoskeletal disorders.

The 2016 Report of the Commission on Ending Childhood Obesity has developed a comprehensive, integrated package of recommendations, including: (1) implement comprehensive programs that promote the intake of healthy foods and reduce the intake of unhealthy foods and sugar-sweetened beverages by children and adolescents; (2) implement comprehensive programs that promote physical activity and reduce sedentary behaviors in children and adolescents; (3) integrate and strengthen guidance for noncommunicable disease prevention with current guidance for preconception and antenatal care, to reduce the risk of childhood obesity; (4) provide guidance on, and support for, healthy diet, sleep and physical activity in early childhood to ensure children grow appropriately and develop healthy habits; (5) implement comprehensive programs that promote healthy school environments, health and nutrition literacy and physical activity among school-age children and adolescents; (6) provide family-based, multicomponent, lifestyle weight management services for children and young people who living with obesity. However, work is still ongoing to expand the evidence basis and develop additional policy approaches (WHO, 2021b). The World Health Organization Guideline Development Group is currently outlining recommendations for the treatment and management of children and adolescents with obesity.

## Micronutrient deficiency

Globally, preschool children are particularly at risk of deficiency in many micronutrients including iron, zinc, iodine, vitamin A, and vitamin D, leading to substantial morbidity and mortality. Often, these deficiencies coexist. Impacts on dietary quality and food security due to the COVID-19 pandemic has resulted in additional micronutrient malnutrition, the full extent of which is currently unknown.

## COVID-19

Though the coronavirus that causes COVID-19 affects only a small proportion of children directly, the ramifications of this pandemic include major indirect effects particularly in the context of nutrition. Social and economic inequalities, as well as food insecurity, already on the rise globally, have been further exacerbated by the COVID-19 pandemic. This has raised concerns

for both extremes of malnutrition: increasing pediatric obesity, particularly in middle- and high-income countries, as well as deepening undernutrition in poorer countries, undoing decades of global progress. It is estimated that undernutrition will increase by an additional 6.7 million children in 2020, as well as an additional 10,000 child deaths per month. Additionally, the lockdowns associated with the pandemic may result in a difficult-to-reverse sedentary lifestyle and poor dietary quality in almost all children, from those living in higher income settings to lower resource areas. Children who have migrated to Western countries may face initial undernutrition at arrival, and subsequently become overweight in these settings.

Among infants and children who have suspected or confirmed COVID-19, all recommended infant and young child feeding practices remain the same: exclusively breastfeed for the first 6 months, introduce complementary foods from 6 to 2 years of age, and continue breastfeeding up to or beyond 2 years of age (WHO, 2020b). Mothers with suspected or confirmed COVID-19 and isolated at home should continue with the aforementioned recommended feeding practices (UNICEF, 2020). Currently, there is no evidence of SARS-CoV-2 transmission through breastmilk, and preliminary studies have found that SARS-CoV-2 neutralizing IgA and IgG antibodies persist in breast milk for at least 6 weeks after vaccination against the virus.

### Iron deficiency and anemia

Anemia (hemoglobin less than  $11.0 \text{ g dL}^{-1}$ ) (WHO, 2011) is estimated to affect 42% of children under five globally (WHO, 2021a). In 2019 the prevalence of anemia in under-five children is particularly high (44 to nearly 80%) in Sub-Saharan Africa and South Asia (WHO, 2021e), while in the United States the figure is closer to 6%; in the UK, 15%; in South America, 12–35%, and in Australia and New Zealand, around 13–15% (WHO, 2021e). Iron deficiency is the most common cause of anemia, while deficiencies in folate, vitamin A, vitamin B12, as well as hemoglobinopathies, parasites, and infectious diseases contribute to anemia prevalence (WHO, 2021a).

By six months of age, an infant's iron stores are depleted and iron intake from external dietary sources is required. Early cessation of breastfeeding with dependence on cow's milk, and complementary foods low in iron content contribute to low intake, which is compounded by increased losses during gastrointestinal infection. Severe anemia may be a manifestation of malabsorption, for example, a consequence of celiac disease, particularly if associated with weight faltering. Iron deficiency occurs at twice the rate of iron-deficiency anemia; with or without anemia, depressed levels of body iron early in life has several short- and long-term consequences. On the cellular level, iron is crucial for respiration, energy production, DNA synthesis, and cell proliferation; functionally, iron plays a role in cognitive development, school achievement, immune function, and physical performance. Oral iron therapy raises iron status but must be used with caution in areas with a high prevalence of malaria. Some studies have shown potentially detrimental effects of oral iron supplements and fortificants on the gut microbiome of young children living in low-resource settings in Africa, such as increases in the abundance of potential pathogens, decreases in beneficial microbes such as *Bifidobacteria*, and gastrointestinal distress. Further research on this phenomenon is required.

### Rickets and vitamin D deficiency

Given there are no national registrations of rickets cases, few population level data on the global prevalence of rickets exist. Further complicating this issue is the lack of internationally accepted diagnostic criteria, which can involve health history, physical exam, radiographs, and biochemical testing. In the US and Europe, the prevalence of rickets declined over the last century due to vitamin D fortification programs but over the last two decades a resurgence has been reported in the UK and other countries. Several factors are thought to have contributed to this increase in rickets prevalence. For example, less sun exposure (due to time indoors and sunscreen as well as air pollution); and global migration and rural to urban migration, particularly among those with higher skin melanin content living in temperate climates. Regional databases, spanning periods within 1967–2016 recently reviewed by WHO in 2019 (WHO, 2019), show a wide range of rickets prevalence, from 1% out of 20,000 children aged 1–15 years in 2008 in Bangladesh, to upwards of 50% in Kenya in 2014. Softening of the bone matrix in rickets predisposes to fractures and to bony deformities such as bowed legs and delayed closure of the cranial sutures. Deficiency of vitamin D may result in other clinical presentations in young children including hypocalcemia-related seizures and stridor. Low vitamin D status throughout pregnancy is associated with low infant vitamin D status at birth. Poor intake of vitamin D-rich foods or supplements through infancy may further increase risk.

Vitamin D deficiency is defined by the presence of a plasma 25-hydroxycholecalciferol concentration  $<50 \text{ nmol L}^{-1}$ . Levels above this threshold are unlikely to be associated with bone disease. For other health outcomes such as immune function or atopy, concentrations below  $75 \text{ nmol L}^{-1}$  are considered insufficient; however, further research is required in this area. Prevention of vitamin D deficiency and rickets may be achieved by vitamin D supplements and adequate sun exposure. The National Academies of Science, Engineering and Medicine (NASEM) recommends that pregnant and breastfeeding women, as well as children over one year of age, consume a recommended dietary allowance (RDA) of 600 IU daily. In the US, the RDA is 10 mcg (400 IU) before age 1 and 15  $\mu\text{g}$  (600 IU) thereafter. In India, the estimated average requirement for children beginning at age one year is 10  $\mu\text{g}$  (400 IU) per day. Similarly, China recommends children from two weeks to two years old to receive 400 IU daily and be fed vitamin D-fortified food from age zero to three years.

Policy on the use of supplements in infants varies between countries. In the UK it is recommended that all breastfed infants should be given a supplement of 7  $\mu\text{g}$  per day by seven months of age, starting earlier than this if the mother's vitamin D status

is uncertain, and continuing until at least four years of age. In high-risk groups, for example, those with dark skin or those with reduced sunlight exposure, supplementation should continue through childhood.

In some other European countries and the USA, supplementation from birth is recommended. In the US and Canada, vitamin D fortification of infant formula is mandatory (1–2.5 µg/100 kcal (40–100 IU) and 1–2 mcg/100 kcal (40–80 IU), respectively). Infants who are not breastfed do not require supplementation until consumption of infant formula (which is fortified with vitamin D) falls below 500 mL per day. Many foods including dairy products, orange juice, and plant milks are fortified with vitamin D (about 3 µg (120 IU) per cup), and breakfast cereals contain added vitamin D.

## Food allergy and intolerance

“Food allergy” and “food intolerance” may both occur in young children and cause serious clinical manifestations. In both, the child exhibits a reproducible adverse response to a food or food component; in the case of allergy this is immunologically mediated, whereas a variety of mechanisms may explain intolerance. The latter include pharmacological responses to food components or inability to metabolize a food component (e.g., hereditary fructose intolerance or lactose intolerance).

Food allergy, like asthma, allergic rhinitis, and atopic dermatitis is usually mediated through release of immunoglobulin E (IgE) in response to antigen exposure, and thus manifests with immediate symptoms when the offending food is ingested: these may include swelling and erythema of the face, lips, and tongue, periorbital or generalized edema, and rarely anaphylactic shock. Acute gastrointestinal symptoms such as vomiting, pain, or diarrhea may also occur. Sometimes symptomatology is more chronic, for example, worsening of wheezing or eczema. Symptoms resolve when the food is omitted from the diet and recur when it is reintroduced. It is important, however, to stress that neither maneuver should be attempted without professional supervision.

Dietary challenge is not always necessary to establish the diagnosis, as skin prick testing or specific IgE measurement can be helpful if the clinical history is strongly suggestive. Most young children grow out of egg or milk allergies by school age, but nut, fish, soy, and wheat allergies are generally more persistent and may remain a problem into adult life. Serial measurement of specific IgE can be helpful in determining whether resolution is likely. Parents may need to be provided with an adrenaline injection device and instructed in its use. Desensitization through subcutaneous administration of specific antigens may prove an effective therapy where allergic symptoms persist.

In 2017, the National Institute of Allergy and Infectious Diseases, along with 25 professional organizations, federal agencies, and patient advocacy groups, published three sets of updated guidelines to address the prevention of peanut allergy across groups with varying risk factors for allergy. Infants who have severe eczema and/or egg allergy comprise the highest risk group, and are recommended to be introduced to peanut at 4–6 months of age, ideally after allergy testing for peanut-specific IgE or skin prick test (guideline #1). Infants with mild to moderate eczema should be introduced to peanut around 6 months of age (guideline #2). Finally, infants who do not have eczema or other food allergy, who are not at increased risk, are recommended to be exposed to peanut “freely” into the diet with other solid foods (guideline #3). These guidelines are a reversal from the 2000 American Academy of Pediatrics guidelines which advised high-risk infants to completely avoid peanut until age 3; however, there was no convincing evidence for delaying introduction to peanut beyond 4–6 months of age, resulting in updated guidance.

## Conclusions

Undernutrition and micronutrient deficiency remain a major cause of morbidity and mortality in children between 1 and 5 years of age, while the number of children with excess weight continues to rise. These nutrition issues have been directly and indirectly exacerbated by the COVID-19 pandemic. Focusing efforts on improving child health, and supporting adequate dietary and nutrient intake, particularly in this age group, remains a priority.

## Glossary

**Dietary supplements** Dietary supplements may be single elements or nutrients, or may be complex mixtures, including herbals and botanicals of uncertain composition.

**Fatigue** Exercise, if sufficiently intense or prolonged, will inevitably result in fatigue, which has both subjective and objective components. The nature of fatigue depends on exercise type and on individual training status, but typically includes events localized to the active muscles as well as effects on the central nervous system.

**Glycogen** Glycogen, a long-chain, highly-branched polymer of glucose, is the storage form of carbohydrate in the human body. It is present primarily in skeletal muscle (up to 300–500 g) and in liver (typically 70–100 g in the fed state).

**Hydration** Euhydration refers to normal or desirable body water content and electrolyte balance. Positive (hyperhydration) and negative (hypohydration) excursions from euhydration are both associated with impaired performance and with health risks. Dehydration is the process of water loss from the body.

**Training** Training involves a systematic program of exercise with the aim of achieving an improvement in performance. The key characteristics of a training program are the intensity, duration and frequency of the individual training sessions. Performance outcomes are specific to the type of stimulus applied and proportional to the training load.

## Introduction

In 2010, the International Olympic Committee issued a consensus statement on nutrition in sport, which began with the following words: “Diet significantly affects athletic performance”. This is a bold and unambiguous statement, leaving little room for doubt, but there are other, more important factors that will determine the outcome of sporting contests. Talent, motivation, training, tactics, and many other considerations are much more important. It is clear, however, that when all else is equal, nutrition can make the difference between victory and defeat. The role of nutrition, and the eating strategies that should be adopted, will vary greatly between sports and will vary also according to the level of competition, the training load and the competition schedule, so athletes may need the help of qualified professionals to ensure good nutrition strategies. For those who exercise for health and enjoyment rather than in pursuit of fame and wealth, a sound nutrition strategy also has much to offer.

Many different issues arise in considering the interactions between diet and exercise. In considering the role of diet in the athlete's life, two main issues must be considered, each of which gives rise to many subordinate questions. The first question is how the demands of training affect the body's requirement for energy and nutrients: This then has implications for body composition (including the body content of fat, muscle, and bone), for the hormonal environment and the regulation of substrate metabolism, and for various disease states that are affected by body fatness, nutrient intake, and other related factors. The second question is how nutritional preparation can influence performance in competition.

## Nutrition for Training

The aim of training is to improve performance, and the effectiveness of a training program will depend on the intensity, duration, and frequency of the training sessions that are completed. Training is designed to induce highly specific adaptations that address the limitations to exercise performance and move those boundaries so that performance improves. It was thought that the primary aim of nutrition support in training was to allow better recovery between training sessions so that the total training load could be increased. It is now recognized, however, that more training is not always better – it brings an increased risk of injury and chronic fatigue. Instead, nutrition strategies are aimed at allowing greater adaptations to the training stimulus, or to allow the same training adaptation with less training.

Sound nutrition strategies can also make exercise feel easier. This is especially important to those who exercise for health: If the exercise feels hard, it is unlikely to be repeated and the duration will be cut short. It is well established that some simple strategies, such as ensuring an adequate carbohydrate (CHO) status and maintaining good hydration status, will reduce the subjective perception of effort.

## Protein Requirements

In most cases, training adaptations aim to change the structure and function of the muscles engaged in the exercise task, though all the body's tissues are affected. As the structure and function of muscles are dictated by their protein composition, the training response involves an increased net breakdown of proteins that are not required and an increased net synthesis of those proteins that contribute to exercise performance. The weightlifter wants bigger muscles with more actin and myosin to increase force-generating capacity. The marathon runner does not want bigger muscles: instead, a greater content of oxidative enzymes and more capillaries to increase oxygen and substrate delivery. Smaller muscle fibers – to reduce the diffusion distance from the capillary to the fiber – and a decrease in total mass are both desirable outcomes.

The idea that protein requirements are increased by physical activity is intuitively attractive, and high-protein diets are a common feature of the diets of many sportsmen and women. The available evidence does show an increased rate of oxidation of the carbon skeletons of amino acids during exercise, especially when CHO availability is low. Protein contributes only approximately 5% of total energy demand in endurance exercise, but the absolute rate of protein breakdown is higher than at rest (where protein contributes about the same fraction as the protein content of the diet, which is typically approximately 12–16% of the total energy intake) because of the higher energy turnover. It is often recommended that athletes engaged in endurance activities on a daily basis should aim to achieve a protein intake of approximately  $1.2\text{--}1.4\text{ g kg}^{-1}\text{ day}^{-1}$ , whereas athletes engaged in strength and power training may need as much as  $1.6\text{--}1.7\text{ g kg}^{-1}\text{ day}^{-1}$ . There is no evidence of benefits from a daily intake of more than  $2\text{ g kg}^{-1}$ . This compares with an estimated average requirement of approximately  $0.6\text{ g kg}^{-1}\text{ day}^{-1}$  in sedentary people and a recommended intake of approximately  $0.8\text{--}1.0\text{ g kg}^{-1}\text{ day}^{-1}$  for those who take no exercise.

In strength and power sports such as weightlifting, sprinting, and bodybuilding, the use of high-protein diets and protein supplements is especially prevalent, and daily intakes in excess of  $2\text{--}4\text{ g kg}^{-1}$  are not unusual. Scientific support for such high intakes is generally lacking, but those involved in these sports are adamant that such high levels of intake are necessary, not only to increase muscle mass, but also to maintain muscle mass. This apparent inconsistency may be explained by Millward's adaptive metabolic demand model, which proposes that the body adapts to either high or low levels of intake, and that this adjustment to changes in intake occurs only very slowly. This means that individuals, such as strength and power athletes, who consume a high-protein diet over many years, will find that any reduction in protein intake will result in a loss of muscle mass. This is because of an upregulation of the activity of the enzymes involved in protein oxidation to cope with the high intake: activity of these enzymes remains high when there is a sudden decrease in intake, leading to a net catabolic effect.

Protein synthesis and degradation are both enhanced for some hours after exercise, and the net effect on muscle mass will depend on the relative magnitude and duration of these effects. Several recent studies have shown that ingestion of small amounts of protein (typically approximately 20–40 g) or essential amino acids (approximately 10 g) either before or immediately after exercise will result in net protein synthesis in the hours after exercise, whereas net negative protein balance is observed if no source of amino acids is consumed in the immediate postexercise period. These observations have led to recommendations that approximately 20 g of mixed protein should be consumed immediately after exercise. It is important to recognize, though, that the control condition in most of these studies has involved a relatively prolonged (6–12 h) period of fasting before and after the exercise bout, and this does not reflect the normal behavior of athletes. Individuals who consume foods containing CHO and proteins in the hour or two before exercise may not further increase protein synthesis if additional amino acids or proteins are ingested immediately before, during, or after exercise.

Various high (30%) protein, high (30%) fat, low (40%) CHO diets have been promoted for weight loss, and some diets even suggest almost complete elimination of CHO from the diet. Some of these diets have been specifically targeted at athletes, accompanied by impressive claims and celebrity endorsements. Proposed mechanisms of action of these diets include reduced circulating insulin levels, increased fat catabolism and altered prostaglandin metabolism. The high-protein content of these diets may contribute to increased satiety, but it seems more likely that they may achieve weight loss simply by restricting dietary choice and therefore reducing energy intake. These diets can be effective in promoting short-term weight loss, primarily by restricting

energy intake (typically to 1000–2000 kcal day<sup>-1</sup>). There is not any evidence to support improvements in exercise performance, and what evidence there is does not support the concept.

## Fat and CHO

A more recent development has been the suggestion that training on a high-fat diet can enhance endurance performance. The theory is sound, but the experimental evidence does not support the theoretical advantage. CHO is an essential fuel for the brain, red blood cells, and a few other tissues and is also an important fuel for muscle during high-intensity exercise. At rest and during low-intensity exercise, most of the energy demands of skeletal muscle can be met by fat oxidation, but the contribution of CHO, and especially of the muscle glycogen, increases as the rate of energy demand increases. The muscle glycogen stores are small, however, and once the glycogen content of the exercising muscles reaches very low levels, the work rate must be reduced to a level that can be accommodated by fat oxidation. In high-intensity exercise, essentially all of the energy demands are met by CHO metabolism. Repeated short sprints therefore place high demands on the muscle CHO store, most of which can be converted to lactate within a few minutes.

CHO is stored in the body in the form of glycogen, primarily in the liver (approximately 70–100 g in the fed state) and in the skeletal muscles (approximately 300–500 g, depending on muscle mass and preceding diet). These stores are small relative to the body's requirements for CHO. CHO supplies approximately 45% of the energy in the typical Western diet. This amounts to approximately 200–300 g day<sup>-1</sup> for the average sedentary individual, and is adequate for normal daily activities. In an hour of hard exercise, however, up to 200 g of CHO can be used, and sufficient CHO must be supplied by the diet to replace the amount used. Replacement of the glycogen stores is an essential part of the recovery process after exercise: if the muscle glycogen content is not replaced, the quality of training must be reduced, and the risks of illness and injury are increased. Low muscle glycogen levels are associated with an increase secretion of cortisol during exercise, with consequent negative implications for immune function.

Reducing the CHO availability forces the muscle to rely more on fat oxidation for energy supply and restricting the availability of CHO will result in an increased capacity of the muscle to oxidize fat. This can be achieved by feeding a low-CHO diet that meets the total energy demand through an increased fat intake or by feeding an energy-deficient diet. The training studies that have been completed suggest that training on a low-CHO diet impairs some of the adaptations that take place in muscle in response to training, even though the capacity for fat oxidation is increased. Even restoration of the muscle glycogen content by a short period of high-CHO intake does not allow the same performance capacity as when training was performed with adequate CHO availability. The recommendation that athletes consume a high-CHO diet during periods of intensive training therefore remains in place. When rapid recovery is a priority, especially when the interval between successive training sessions is no more than a few hours, replacement of CHO should begin as soon as possible after exercise with CHO foods that are convenient and appealing. Thereafter, the diet should supply sufficient CHO to replace the amount used in training and to meet ongoing demands of other tissues. Some recommendations for CHO intake after training or competition are shown in Table 1. It is important to remember that not all athletes need a high-CHO diet at all times: when training consists of mostly technical work, the total energy expenditure and the demand for CHO may be low. For the athlete with very high levels of energy expenditure in training, the exercise intensity will inevitably be reduced to a level where fatty acid oxidation will make a significant contribution to energy supply and fat will provide an important energy source in the diet. Once the requirements for protein and CHO are met, the balance of energy intake can be in the form of fat. Fat also serves other important functions in the diet. As well as providing essential fatty acids, it acts as a vehicle for the transport of fat-soluble nutrients. Some athletes try to minimize their fat intake, but this is not wise.

The high-CHO diet recommended for the physically active individual coincides with the recommendations of various expert committees that a healthy diet is one that is high in CHO (at least 55% of energy) and low in fat (less than 30% of energy). However, where energy intake is either very high or very low, it may be inappropriate to express the CHO requirement as a fraction of energy intake. With low-total energy intakes, the fraction of CHO in the diet must be high, but the endurance athlete with a very high energy intake may be able to tolerate a higher fat intake. Recommendations, as in Table 1, should be framed in absolute amounts relative to body mass, i.e., grams of CHO per kg body mass.

The type of CHO eaten is generally much less important than the amount. It is valuable to choose nutrient-rich CHO foods and to add other foods to recovery meals and snacks to provide a good source of protein and other nutrients. The presence of small amounts of protein in recovery meals may promote additional glycogen recovery when CHO intake is less than optimal or when frequent snacking is not possible. Protein at this time may also stimulate protein synthesis in muscles, as described above.

**Table 1** Suggested carbohydrate intakes for athletes in training

---

Immediate post-exercise recovery (0–4 h): 1 g per kg body mass per hour, consisting of several small snacks
Daily recovery (moderate duration/low-intensity training): 5–7 g kg <sup>-1</sup> day <sup>-1</sup>
Daily recovery (moderate–heavy endurance training): 7–12 g kg <sup>-1</sup> day <sup>-1</sup>
Daily recovery (extreme training): 4–6 h or more per day): Up to 10–12 g kg <sup>-1</sup> day <sup>-1</sup>

---

CHO-rich foods with a moderate to high glycemic index (GI) provide a readily available source of CHO for glycogen synthesis, and should be the major fuel choices in recovery meals.

## **Vitamins and Minerals**

Many micronutrients play key roles in energy metabolism, and high rates of energy turnover – up to 20–100 times the resting rate – may be required in the active muscles during hard exercise. Although an adequate vitamin and mineral status is essential for normal health, marginal deficiency states may be apparent only during periods of metabolic stress. Prolonged strenuous exercise performed on a regular basis may also result in increased losses of essential nutrients in sweat or urine, or may increase the rate of breakdown, resulting in the need for an increased dietary intake. An increased food intake to meet energy requirements will generally increase dietary micronutrient in proportion to energy intake, but not all athletes have high-energy intakes. Athletes who restrict food intake to control or reduce body fat levels may have low-energy intakes over prolonged periods. Some athletes may also eat monotonous diets, with a limited range of foods in the diet, thus increasing the risk of an inadequate micronutrient intake. Supplementation with micronutrients may be warranted in some instances, but normally only where specific deficiencies have been demonstrated by biochemical investigations and where dietary modification is not an option.

Individuals who are very active may need to pay particular attention to their intake of iron and calcium. Iron deficiency anemia affects some athletes engaged in intensive training and competition, but it seems that the prevalence is similar in athletic and sedentary populations, suggesting that exercise *per se* does not increase the risk. The implications of even mild anemia for exercise performance are, however, significant. A fall in the circulating hemoglobin concentration is associated with a reduction in oxygen carrying capacity and a decreased exercise performance. Low serum ferritin levels are not associated with impaired performance, however, and iron supplementation in the absence of frank anemia does not influence indices of fitness. Routine iron supplementation is not wise, as too much may be harmful.

Osteoporosis is now widely recognized as a problem for both men and, more especially, women, and an increased bone mineral content is one of the benefits of participation in an exercise program. Regular exercise results in increased mineralization of those bones subjected to stress and an increased peak bone mass may delay the onset of osteoporotic fractures; exercise may also delay the rate of bone loss. Estrogen plays an important role in the maintenance of bone mass in women, and prolonged strenuous activity may result in low estrogen levels, causing bone loss. Many very active women also have a low body fat content and may also have low-energy (and calcium) intakes in spite of their high-activity levels. All of these factors are a threat to bone health. The loss of bone in these women may result in an increased predisposition to stress fractures and other skeletal injury and must also raise concerns about bone health in later life. It should be emphasized, however, that this condition appears to affect only relatively few athletes, and that activity is generally beneficial for the skeleton.

In recent years it has increasingly been recognized that vitamin D may be needed in supplemental form when sun exposure is inadequate, and this may apply especially to those athletes who spend long periods training indoors and to those who live in high latitudes. Intakes of most other nutrients can be met from food sources, but athletes may need advice from qualified professions to identify their nutrition needs and to develop an eating strategy that will meet those needs.

## **Water and Electrolyte Balance**

Prolonged strenuous exercise in a warm environment poses a major challenge to the body's homeostatic mechanisms. Only approximately 20–25% of the energy available from substrate catabolism is used to perform external work, with the remainder appearing as heat. At rest, the metabolic rate is low: Oxygen consumption is approximately  $250 \text{ ml min}^{-1}$ , corresponding to a rate of heat production of approximately 60 W. Heat production increases in proportion to metabolic demand, and reaches approximately 1 kW in strenuous activities such as marathon running (for a 70 kg runner at a speed that takes approximately  $2\frac{1}{2}$  hours to complete the race). To prevent a catastrophic rise in core temperature, heat loss must be increased correspondingly and this is achieved primarily by an increased rate of evaporation of sweat from the skin surface. In hard exercise in hot conditions, sweat rates can reach  $3 \text{ l h}^{-1}$ , and trained athletes can sustain sweat rates in excess of  $2 \text{ l h}^{-1}$  for many hours. This represents a much higher fractional turnover rate of water than that of most other body components. In the sedentary individual living in a temperate climate, approximately 5–10% of total body water may be lost and replaced on a daily basis. When prolonged exercise is performed in a hot environment, 20–40% of total body water can be turned over in a single day. In spite of this, the body water content is tightly regulated, and regulation by the kidneys is closely related to osmotic balance.

Along with water, a variety of minerals and organic components are lost in variable amounts in sweat. Sweat is invariably hypotonic relative to plasma and the main electrolytes lost are sodium and chloride, at concentrations of approximately  $15\text{--}80 \text{ mmol l}^{-1}$ . A range of other minerals, including potassium and magnesium, as well as trace elements, are lost in small amounts. Sweat rate and sweat composition both vary greatly between individuals. Some athletes may lose up to 10 g of salt (sodium chloride) in a single training session, and may train in these conditions twice per day. Others doing the same training will lose no more than 1 g of salt. High-salt losses may be related to development of muscle cramps in some, but not all, individuals, and additional salt intake may be helpful for susceptible individuals. Salt losses must be replaced from foods and drinks, though the use of salt supplements is seldom necessary.

Failure to maintain hydration status has serious consequences for the active individual. A body water deficit of as little as 1–2% of total body mass can result in a significant reduction in exercise capacity, especially in endurance exercise performed in warm weather. Endurance exercise is affected to a greater extent than high-intensity exercise, and muscle strength is not adversely affected until water losses reach 5% or more of body mass. Hypohydration greatly increases the risk of heat illness, and also abolishes the protection conferred by prior heat acclimation.

Many studies have shown that the ingestion of fluid during exercise can significantly improve performance. Adding an energy source in the form of CHO confers an additional benefit by providing an energy source for the working muscles. Addition of small amounts (perhaps approximately 2–8%) of CHO, in the form of glucose, sucrose, or maltodextrin, will promote water absorption in the small intestine as well as providing exogenous substrate that can spare stored CHO. Recent evidence suggests that addition of fructose in addition to glucose, sucrose, or maltodextrin will increase intestinal absorption of CHO and can enhance performance. The addition of too much CHO will slow gastric emptying and, if the solution is strongly hypertonic, may promote secretion of water into the intestinal lumen, thus delaying fluid availability. Voluntary fluid intake is seldom sufficient to match sweat losses, and palatability of fluids is therefore an important consideration. It is not necessary to consume enough fluid during exercise to match sweat losses, as a body mass deficit of 1–2% is unlikely to have adverse consequences. If exercise is prolonged and sweat losses high, the addition of sodium to drinks may be necessary to prevent the development of hyponatremia. Ingestion of large volumes of plain water is also likely to limit intake because of a fall in plasma osmolality leading to suppression of thirst.

Replacement of water and electrolyte losses incurred during exercise is an important part of the recovery process in the postexercise period. This requires ingestion of fluid in excess of the volume of sweat lost to allow for ongoing water losses from the body. Reestablishment of water balance requires replacement of solute, especially sodium, losses as well as volume replacement. If food containing electrolytes is not consumed at this time, electrolytes, especially sodium, must be added to drinks to prevent diuresis and loss of the ingested fluid.

## Dietary Supplements

The use of nutritional supplements in athletes and in the health-conscious recreationally active population is widespread, as it is in the general population. Many different supplements are used by athletes with the aim of improving or maintaining general health and exercise performance. In particular, supplement use is often aimed at promoting tissue growth and repair, promoting fat loss, enhancing resistance to fatigue, and stimulating immune function. Most of the supplements that are sold to athletes have not been well researched, and both safety and efficacy remain open to question for many of these products. Anyone seeking to improve health or performance would be better advised to ensure that they consume a sound diet that meets energy needs and contains a variety of foods. A recent development of concern to athletes is the finding of various prohibited doping agents in what should be legitimate sports nutrition products. A wider concern are the recent reports of serious health issues related to the use of various supplements.

Supplements for which there is good evidence of beneficial effects on performance in some specific situations include caffeine, creatine, and buffering agents, but the risk of an inadvertent positive doping result must always be considered. Supplement use in young athletes is discouraged, and the focus should be on choosing a varied, nutrient-rich diet to provide all the nutrients essential for growth while maintaining a healthy body composition.

## Nutrition for Competition

A detailed consideration of nutrition strategies for competition in all sports is beyond the scope of this brief review. For athletes preparing for competition, a reduction in the training load and the consumption of a high-CHO diet in the past few days are recommended: This will maximize the body's CHO stores, and should ensure optimum performance, not only in endurance activities, but also in events involving short-duration high-intensity exercise and in field games involving multiple sprints. Beginning competition in a well hydrated state is generally beneficial, and is essential in events lasting longer than approximately 30 min in warm environments. Regular intake of fluids should be based on the individual needs identified during training or previous competition.

## Key points

- Available quantitative values for nutrient-based Dietary Reference Intakes (DRI) for infants age birth to one year have not been revised since 2005 except for calcium, vitamin D, sodium and potassium.
- In the United States and Canada, recent infant feeding recommendations have been based on evidence reviews with some harmonization across agencies and comparatively have general consistency in their recommendations within and between countries.
- Guidance on infant nutrient requirements and feeding practice recommendations is critical to optimize development during the early critical stages of growth. There is an urgent need to expand the evidence base upon which such guidance is developed.

## Glossary

**Adequate Intake (AI)** The recommended average daily intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate; used when a recommended dietary allowance cannot be determined

**Dietary Reference Intakes (DRI)** The nutrient reference values developed by the Institute of Medicine that comprise four nutrient-based reference values that can be used to assess or plan the diets of healthy people. The reference values include the four other Glossary terms defined here

**Estimated Average Requirement (EAR)** The average daily nutrient intake level that is sufficient to meet the nutrient requirements of half of the healthy individuals in a particular life stage and gender group.

**Recommended Dietary Allowance (RDA)** The average daily nutrient intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a particular life stage and gender group.

**Tolerable Upper Level (UL)** The highest average daily nutrient intake level that is likely to pose no risk of adverse health effects to almost all individuals in the general population. As intake increases above the UL, the potential risk of adverse effects may increase

**Dietary Guidelines for Americans (DGA)** The most recent DGA are for 2020–2025

## Introduction

Optimal nutrition in the first 1000 days from conception to 24 months of age is a key factor in the attainment of normal trajectories of growth and development and to reduce risk of common non-communicable diseases (NCDs) (Christian et al., 2015; Garmendia et al., 2014). Recently, the importance of nutrition and lifestyle in the preconception period to optimize pregnancy and offspring health has also been emphasized (Stephenson et al., 2018). This article will focus on the state of knowledge of nutrition guidance after birth to two years for normal healthy newborn infants.

Nutrient-based reference values of dietary requirements often referred to as dietary standards are produced by many countries as well as key international agencies such as the Food and Agriculture Organization/World Health Organization (FAO/WHO) (United Nations University, 2004). For infants, the recommended reference values for nutrient intakes are usually intended for term-born, healthy, and normally growing infants who have a birth weight of more than 2500 g (and thus not small for gestational age). In this article, the nutrient requirements outlined reflect the Dietary Reference Intakes (DRIs) for the US and Canada as published by the Institute of Medicine (IOM). With the exception of calcium and vitamin D in 2011 (IOM, 2011) and sodium and potassium in 2019 (NASEM, 2019), the DRIs for all other nutrients have not been updated since 2005, although revision of the macronutrients is to begin in 2022.

The DRIs serve as the scientific basis for the development of many food-based dietary guidelines or recommendations. For infants, such feeding recommendations provide guidance on what, when and how to introduce specific foods to infants have been published by professional societies and some government agencies for many years. The National Academies of Sciences, Engineering and Medicine recently reviewed existing dietary recommendations in its report on Feeding Infants and Children from Birth to 24 Months: Summarizing Existing Guidance. A consensus study report (NASEM, 2020).

This article provides an overview of key concepts and examples of the nutrient-based DRIs specific for infants, the new approaches to establishing food-based feeding recommendations/guidelines for infants, and future needs for additional research to provide for a rigorous evidence-based review to underpin both nutrient requirements and feeding guidelines for infants.

## Dietary reference intakes for infants

For infants, evaluation of evidence to establish the DRIs consistently revealed a paucity of appropriate studies on which to base an Estimated Average Requirement (EAR) or tolerable upper level (UL). A Recommended Dietary Allowance (RDA) could not be calculated if a value for the EAR was not established, in which case the recommended intake was based on an Adequate Intake (AI). The nutrient recommendations for infants from birth through 6 months of age for all nutrients except for energy were set as an AI, a value based on “an observed or experimentally determined estimate of nutrient intake by a group of infants who are apparently healthy and assumed to be maintaining normal growth”. An AI value does not reflect an average requirement but rather an intake based on approximations or estimates of nutrient intakes that are assumed to be adequate.

For infants from birth to one year of age, human milk was employed as the reference model for setting AI values for breast-fed infants and no specific dietary recommendations were provided for formula-fed infants. The mean intake of a nutrient was calculated based on the average concentration of the nutrient in human milk from 2 to 6 months of lactation using consensus values from several reported studies, multiplied by an average volume ( $0.780 \text{ L day}^{-1}$ ) of human milk. The predicted daily volume of breast milk ingested by an infant was based on observational studies that used test weighing of full-term infants. For infants aged 7–12 months, the AI for many nutrients was based on mean observed nutrient intake from human milk in the second 6 months ( $0.6 \text{ L day}^{-1}$ ), in addition to the published values for intake of nutrients from complementary or weaning foods if such data were available. It is important to highlight that questions have arisen recently about the values used for both the nutrient composition of human milk and the volume of milk ingested at different ages in setting the original AIs for infants. In a recent review, Allen et al. (2018) compared milk micronutrient values and the assumptions taken to derive micronutrient intakes for infants and lactating women by the IOM, the WHO/FAO and United Kingdom and the European Food Safety Authority and concluded that currently available data on the micronutrient composition of human milk is inadequate to derive reliable reference values for the DRIs and for other countries. This was attributed in part to the fact the data used was based on small sample sizes leading to a wide range of concentrations within studies, limited longitudinal studies and variability in collection and analysis methods (Allen et al., 2018; Hampel et al., 2018). These authors concluded that reference values for human milk composition across lactation need to be developed based on a multi-center study in well-nourished women not reliant on nutrient supplements and followed for 4–6 months of lactation and called for the striking of a new multicenter study to establish reliable reference values for human milk nutrients (Allen et al., 2018).

The approach used to develop an EAR or AI for nutrients for which intake data were not available for those aged older than 6 months, was to extrapolate from intake estimates of older children or adults using the formula with adjustments for metabolic body size, growth, and variability:

$$\text{EAR}_{\text{infant or child}} = \text{EAR}_{\text{child or adult}} \times F,$$

where  $F = (\text{weight}_{\text{infant or child}} / \text{weight}_{\text{child or adult}})^{0.75} (1 + \text{growth factor})$  or occasionally by extrapolating up from intake of breast-fed infants with similar adjustments using the formula

$$AI_{6-11 \text{ months}} = AI_{0-5 \text{ months}} \times F,$$

where  $F = (\text{weight}_{6-11 \text{ months}} / \text{weight}_{0-5 \text{ months}})^{0.75}$ . The extrapolation model varied across nutrients (Atkinson and Koletzko, 2007). Finally, for a few nutrients, such as iron and zinc, sufficient metabolic data were available to derive an EAR using modeling or factorial methods.

When possible, a DRI called the tolerable UL was defined as “the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in the general population” (IOM, 2007). Chronic consumption of nutrients above the UL increases the potential risk of adverse effects, the latter varying by nutrient. For infants, data were only available to reliably estimate ULs for vitamins A and D and the minerals fluoride, selenium, zinc, iron (IOM, 2007), and now revised for vitamin D and calcium in (IOM, 2011). Although adequate data were not available to define an UL for infants for other nutrients, it is important to note that intake nutrients for which an UL does not exist should only be consumed from food or formula and not from supplements. Also notable is that the UL for iron for infants is only relevant to intake from supplements and not foods.

## Summary of DRIs for infants: macronutrients—energy, carbohydrate, fat, protein, and amino acids

### Energy

The estimated energy requirement (EER) for infants was derived by summing the predicted total energy expenditure (TEE) and energy deposition for growth. Because the energy needs for growth decelerate with advancing age, an equation for EER was established for three age intervals during the first year of life (Table 1). The TEE is calculated using an equation based on energy expenditure measured by doubly labeled water and adjusted for weight of the child. The EER is then the sum of TEE for an individual child plus the predicted energy deposition for age (Table 1). No adjustment for physical activity was included in the EER for infants. Examples of the EER for males and females using the reference weights are shown in Table 1 for infants at five age intervals during the first year of life. At most ages beyond the first 2 months of life, the values for EER exceed the average energy provided (500 kcal) by human milk assuming a volume of intake ( $0.780 \text{ L day}^{-1}$ ) from human milk.

The energy requirements of infants during the first year of life recommended in the FAO/WHO/UNU report (United Nations University, 2004) are remarkably similar to that of the DRI report (IOM, 2005) as the approaches included the same parameters. In both the reports, estimates of TEE were based on the analysis of experiments using doubly labeled water and calculated by monthly age intervals, to which an assessment of energy deposition for growth was added.

### Carbohydrate

The AI for carbohydrate for infants through 1 year of age is based on the average carbohydrate intake from human milk and complementary foods for the 7–12-month age group (Table 2). Although the carbohydrate from human milk is almost exclusively lactose and that from infant’s formula may be lactose, sucrose, or glucose polymers alone or in combination, there is no evidence that non-lactose-containing formulas vary from lactose present in human milk with regard to available energy.

**Table 1** DRI estimated energy requirement (EER) for infants (IOM, 2005).

<i>Equations</i>		
0–3 months	$(89 \times \text{weight of infant (kg)} - 100) + 175$ (kcal for energy deposition)	
4–6 months	$(89 \times \text{weight of infant (kg)} - 100) + 56$ (kcal for energy deposition)	
7–12 months	$(89 \times \text{weight of infant (kg)} - 100) + 22$ (kcal for energy deposition)	
<i>Calculated EER for age using reference weights for age</i>		
<i>Age (months)</i>	<i>Males (kcal day<sup>-1</sup>)</i>	<i>Females (kcal day<sup>-1</sup>)</i>
1	472	438
3	572	521
6	645	593
9	746	678
12	844	768

DRI, Dietary Reference Intake; EER, Estimated Energy Requirement.

**Table 2** DRI for macronutrients for infants—carbohydrate, protein, fat, and essential fatty acids (IOM, 2005).

Nutrient <sup>a</sup>	0–6 months	7–12 months
	g day <sup>-1</sup>	
Carbohydrate, AI	60	95
<b>Protein</b>		
AI	9.1	–
RDA	–	13.5
Total fat, AI	31	30
Linoleic acid ( <i>n</i> -6), AI	4.4	4.6
$\alpha$ -Linolenic acid ( <i>n</i> -3), AI	0.5	0.5

DRI, Dietary Reference Intake; AI, Adequate Intake; RDA, Recommended Dietary Allowance.

<sup>a</sup>No upper levels of nutrients were set for any macronutrients.

### Fat

As for other nutrients, the AI for fat intake is based on the average intake of fat from human milk alone or in addition to complementary foods after 7 months of age (Table 2). Although infant formulas are designed to contain a percentage of energy as fat similar to human milk (approximately 50%), the type of fat in formulas varies widely, including sources such as safflower, sunflower, soybean oil, and coconut and palm oils, usually in some combination.

### Linoleic acid (*n*-6) and $\alpha$ -linolenic acid (*n*-3)

The *n*-6 (linoleic) and *n*-3 (linolenic) fatty acids are essential for maturation of the developing brain, retina and other organs both in utero and in early life of infants. Linoleic acid serves as a precursor of arachidonic acid (AA) and linolenic acid as a precursor of docosahexaenoic acid (DHA), which collectively are referred to as the long chain polyunsaturated fatty acids (LCPUFA). While humans have the capacity to metabolize the precursor fatty acids to AA and DHA, the capacity for such endogenous synthesis appears limited in the fetus and newborn infant during rapid development. Human milk is a natural source of both fatty acid families, including the long-chain polyenoic derivatives DHA and AA. The pattern of all fatty acids in human milk, including the polyenoic fatty acids, is dependent on the maternal diet. The AI established for infants for *n*-6 and *n*-3 fatty acids is based on the average content in human milk reported for North American women with the addition of that from complementary foods during months 7–12 (Table 2).

Since the DRI for *n*-6 and *n*-3 fatty acids DRI was developed in 2005 (IOM, 2005) numerous investigations have explored whether supplementation of infant formula with LCPUFA is of benefit to the development of infants. In a systematic review and meta-analysis of 15/31 randomized trials identified ( $N = 1889$ ), for infants born full-term no beneficial effects or harms of the added LCPUFAs on neurodevelopment outcomes nor consistent benefits to visual acuity were identified (Jasani et al., 2017). While this suggests LCPUFAs are not necessary additions to term infant formula, many marketed formulas are available with added DHA and AA.

### Protein

For infants aged 0–6 months, the AI for protein is based on the intake from human milk. For infants aged 7–12 months, sufficient information was available from nitrogen balance studies and protein deposition to derive an EAR based on the factorial method. For both males and females, this averaged to 1.1 g protein per kg body weight day<sup>-1</sup>. The RDA was set as the EAR+2 standard deviations (based on coefficients of variation observed in adults), which yielded a value for protein intake of 1.5 g kg<sup>-1</sup> day<sup>-1</sup>. Because the absorption and digestibility of protein contained in the infant formula may be less efficient than that from the human milk, the quantity of protein contained in infant formulas may have to be adjusted depending on the protein source used (Table 2).

### Amino acids

The DRI for the essential (indispensable) amino acids for infants was derived from the content of human milk for ages 0–6 months. For older infants, an EAR was derived for these amino acids using a factorial estimate that was based on the amino acid needs for growth or protein deposition, with adjustments for efficiency of protein deposition and maintenance requirement. The RDA was determined by adding the coefficient of variation derived for maintenance and protein deposition to the value for the EAR. No values were set for UL for any of the amino acids. A summary of the AI and RDA for the indispensable amino acids of infants is provided in Table 3.

### Other macronutrients

For infants, no DRI was set for saturated fat, monounsaturated fat, *trans*-fatty acids, cholesterol or dietary fiber. Although some dietary fiber is present in the diet after solid foods are introduced, there are no data on fiber intakes in such young age groups and no theoretical basis exists, which establishes a need for fiber at less than 1 year of age.

**Table 3** DRI for indispensable (essential) amino acids (IOM, 2005).

Amino acid <sup>a</sup>	0–6 months AI (mg kg <sup>-1</sup> day <sup>-1</sup> ) <sup>b</sup>	7–12 months RDA (mg kg <sup>-1</sup> day <sup>-1</sup> )
Histidine	23	32
Isoleucine	88	43
Leucine	156	93
Lysine	107	89
Methionine + cysteine	59	43
Phenylalanine + tyrosine	135	84
Threonine	73	49
Tryptophan	28	13
Valine	87	58

DRI, Dietary Reference Intake; AI, Adequate Intake; RDA, Recommended Dietary Allowance.

<sup>a</sup>No upper levels were set for any of the indispensable amino acids.

<sup>b</sup>AI values shown as amino acid in mg kg<sup>-1</sup> day<sup>-1</sup> can be converted to milligram amino acid per day by multiplying with the reference weight of 6 kg for infants 0–6 months of age.

### Macrominerals: calcium, phosphorus, magnesium, and fluoride

The AI for infants for the “bone” minerals are summarized in Table 4. The content of human milk was used as the basis to derive the AI for calcium, phosphorus, and magnesium for infants aged 0–6 months and with the addition of intake from complementary foods for those aged 7–12 months (IOM, 1998). For calcium, the values were updated in 2011 (IOM, 2011) but only changed to 200 mg day<sup>-1</sup> compared to 220 mg day<sup>-1</sup> likely due to a slightly different value used for the concentration of calcium in breast milk. The AI value of 200 mg day<sup>-1</sup> for breast-fed infants from 0 to 6 months was substantiated by considering that average calcium absorption in infants is around 60% thus yielding retention of calcium of 120 mg day<sup>-1</sup>, a value approximately 20% higher than the estimated accretion of calcium for an infant of about 100 mg day<sup>-1</sup>. An UL for calcium for infants 0–6 months was set at 1000 mg day<sup>-1</sup>, a conservative estimate given the paucity of data available (IOM, 2011). For infants aged 6–12 months, recent data on calcium intakes from solid foods for formula-fed infants were used to add to the intake from breast milk to yield an AI of 260 mg day<sup>-1</sup> (IOM, 2011). A UL was set at 1500 mg calcium/day although based on only one study (IOM, 2011).

For fluoride, intake from human milk was the reference for the first 6 months only (IOM, 1998). After 6 months, the AI for fluoride was set at 0.5 mg day<sup>-1</sup> based on the evidence of the benefit of fluoride intake for the prevention of dental caries (Table 4). The UL of 0.7 mg day<sup>-1</sup> for 0–6 months, and 0.9 mg day<sup>-1</sup> was based on risk of developing fluorosis of the anterior teeth.

### Microminerals/trace elements

The DRIs for microminerals and trace elements as published in 2001 (IOM, 2001) are summarized in Table 5. The AI for iron for ages 0–6 months is based on the concentration of iron in human milk albeit low (approximately 0.35 mg L<sup>-1</sup>) but assumes that the infant is born with maximal iron stores due to transplacental transfer of iron from an iron-replete mother. If the latter conditions do not apply, then an exogenous source of iron such as iron drops may be required. For infants aged 7–12 months, an EAR and RDA were developed based on a factorial modeling method that summed basal loss of iron with needs for growth, increasing hemoglobin mass, and iron stores. This value was then adjusted for iron bioavailability using a factor of 10% for infants due to a medium bioavailability of iron from infant cereals, which are generally the major dietary source of iron in weaning foods before meats are introduced. An UL was established (Table 5) for iron based on the risk of adverse gastrointestinal side effects from supplemental (not food) iron.

For zinc, an AI was based on the human milk model only for the 0–6 months age group (Table 5). The zinc content of human milk declines rapidly during the first 6 months (from 4 to 1.2 mg L<sup>-1</sup>), so the AI was based on a milk zinc concentration of 2.5 mg L<sup>-1</sup>. This value cannot be directly applied to infants being fed with cow milk- or soy-based infant formulas because zinc

**Table 4** DRI for minerals for infants—calcium and phosphorus (IOM, 2011), magnesium and fluoride (IOM, 1997).

Nutrient	0–6 months	7–12 months
	AI (mg day <sup>-1</sup> )	
Calcium	200	260
Phosphorus	100	275
Magnesium	30	75
Fluoride	0.01	0.5

DRI, Dietary Reference Intake; AI, Adequate Intake; UL, Upper Level was not determinable due to lack of data of adverse effects in infants except for fluoride which was set at 0.7 mg day<sup>-1</sup> for 0–6 months and 0.9 mg day<sup>-1</sup> for 7–12 months.

**Table 5** DRI for micronutrient/trace minerals for infants—chromium, copper, fluoride, iodine, iron, manganese, molybdenum, selenium, and zinc (IOM, 2001).

	0–6 months	7–12 months
Nutrient	mg day <sup>-1</sup>	
<b>Chromium</b>		
AI	0.2	5.5
UL	ND	ND
<b>Copper</b>

<b>Selenium</b>		
AI	15	20
UL	45	60
<b>Zinc</b>		
AI	2	—
RDA	—	3
UL	4	5

DRI, Dietary Reference Intake; AI, Adequate Intake; ND, Not Determinable due to lack of data of adverse effects in infants; RDA, Recommended Dietary Allowance; UL, Upper Level.

absorption is significantly lower from these feeds compared with human milk. The EAR for the 7–12 months age group was set using a factorial method that summed obligatory losses with requirements for growth and adjusted for fractional absorption of dietary zinc from human milk and complementary foods. The RDA was derived by adding twice the coefficient of variation of 10% to the EAR (2.5 mg day<sup>-1</sup> of zinc) for infants aged 7–12 months (Table 5). An UL was set for zinc based on the possibility of an adverse effect of high-zinc intakes on copper status.

For the trace elements, such as chromium, copper, iodine, manganese, molybdenum, and selenium, an AI was set for infants of age 0–6 months based on the human milk model (Table 5). For the age group 7–12 months, data on intake from complementary foods were only available to set an AI for chromium, copper, and selenium (Table 5). For iodine and molybdenum, the AI represents an extrapolation up from the AI values for the age group 0–6 months based on differences in metabolic body weight (kg<sup>0.75</sup>). For manganese, the AI represents an extrapolation down from the AI for adults as described previously (Table 5). Owing to the lack of relevant information, no UL values for infants younger than 1 year were established for chromium, copper, iodine, manganese, or molybdenum, but intakes of these nutrients should be limited to foods and not supplements. An UL was established for selenium due to the known chronic toxicity of excessive selenium ingestion, which is manifested clinically as brittleness and loss of nails and hair. The UL was set for infants based on the highest known intake of selenium from human milk and adjusting for a reference infant weight (Table 5). The UL value pertains to intake from both foods and supplements.

The trace elements such as arsenic, boron, nickel, silicon, and vanadium are known to have a role in human metabolism, but due to lack of information, DRI values, including UL, could not be established for infants.

#### **Fat-soluble vitamins: A, K, E, and D**

For the DRIs for vitamins A, K, (IOM, 2001) and for vitamin E (IOM, 2000) (Table 6), the AI for infants aged 0–6 months was based on the human milk model as previously described. For vitamins A, K, and E, the AI for infants aged 7–12 months was extrapolated up from the values for infants aged 0–6 months using a reference weight for infants at this age. Notably, the AI was set assuming that the infants had received a prophylactic injection of vitamin K just after birth, a routine in North America since vitamin K is not readily transferred to the fetus while in utero, and human milk is relatively low in vitamin K.

**Table 6** DRI for fat-soluble vitamins (IOM, 2000, 2001, 2011).

<i>Nutrient</i>	<i>0–6 months</i>	<i>7–12 months</i>
<b>Vitamin A (mg day<sup>-1</sup>)</b>		
AI	400	500
UL	600	600
<b>Vitamin D (IU day<sup>-1</sup>)</b>		
AI	400	400
UL	1000	1500
<b>Vitamin E (mg day<sup>-1</sup>)</b>		
AI	4	5
UL	ND	ND
<b>Vitamin K (mg day<sup>-1</sup>)</b>		
AI	2.0	2.5
UL	ND	ND

DRI, Dietary Reference Intake; AI, Adequate Intake; ND, Not Determinable due to lack of data of adverse effects in infants; UL, Upper Level.

A revision of the AI for vitamin D was made in 2011 (IOM, 2011). This AI was not based on the content of human milk as it contains only marginal amounts of vitamin D. The AI for vitamin D of 10 µg (400 IU) day<sup>-1</sup> was set for infants from 0 to 12 months, based on this intake being associated with maintenance of serum 25-hydroxyvitamin D level higher than 30 nmol L<sup>-1</sup> and likely closer to 50 nmol L<sup>-1</sup>, which represents a vitamin D status that is above that usually associated with clinical rickets in infants. For breast-fed infants to meet the AI of 400 IU of vitamin D per day, they must be provided with a vitamin D supplement. For formula-fed infants, intake of nearly 1000 mL day<sup>-1</sup> is required to achieve the AI for vitamin D because infant formulas in North America are regulated to contain 400 IU L<sup>-1</sup> of liquid formula. The UL of vitamin D intake is 25 µg (1000 IU) day<sup>-1</sup> for 0–6 months and 38 µg (1500 IU) day<sup>-1</sup> for 7–12 months (Table 6) which included using an uncertainty factor of 0.5 (IOM, 2011).

#### **Water-soluble B vitamins, folate, choline, and vitamin C**

The AIs for infants aged 0–6 months for most water-soluble vitamins (Table 7) were based on the content of human milk (IOM, 1998). This approach may be problematic for water-soluble B vitamins, in which the milk content is dependent on maternal intake of vitamins (Allen et al., 2018; Hampel et al., 2018). An example of clinical relevance is a vegan mother who may have subclinical vitamin B<sub>12</sub> deficiency and produce vitamin B<sub>12</sub>-deficient milk. For vitamin C, the effect of maternal supplementation on milk content remains uncertain, but available reports do not indicate that excessive amounts of vitamin C are secreted in milk, even in mothers taking supplements of 1000 mg or more. For those aged 7–12 months, the AI for thiamin, riboflavin, niacin, folate, pantothenic acid, and choline was derived by extrapolating down from values for older children or adults due to a lack of information of dietary intake of these nutrients from solid foods. Tolerable ULs for infants were not established for any of the water-soluble vitamins.

#### **Water and electrolytes**

Optimal water intake in infants is more critical than at any other period of life. Not only do infants have a higher total body water content per body mass than children or adults but also they have a higher water turnover rate, a less well-developed sweating mechanism, and little ability to indicate when they are thirsty. The AI for water intake of infants aged 0–6 months is 0.7 L day<sup>-1</sup> and is based on the water content of human milk. Assuming that the infants are breast fed on demand, infants will drink to meet their thirst needs; thus, even in hot and humid climates, supplemental water may not be required. The AI for water intake of 0.8 L day<sup>-1</sup> set for infants aged 7–12 months is based on the sum of the water content of human milk, complementary foods, and beverages, the latter obtained from reported food intakes from surveys in the USA (IOM, 2005).

For sodium and potassium, the updated values for infants 0–6 months established in 2019 (NASEM, 2019) remain based on the human milk model with an AI of 110 mg day<sup>-1</sup> for sodium and 400 mg day<sup>-1</sup> for potassium. For 7–12 months, the AI for sodium is 370 mg day<sup>-1</sup> and for potassium 860 mg day<sup>-1</sup> based on the sum of observed intakes from human milk and complementary foods. No ULs were established for infants due to the lack of data on adverse effects of these nutrients on infant health. However, particularly because the renal excretory capacity of young infants may not be able to handle excessive amounts of ingested electrolytes, the DRI report notes that the intake of sodium, chloride, and potassium should be limited to human milk (or infant formula) and solid foods appropriate for age.

#### **Dietary guidelines/recommendations for infants**

Dietary guidelines or recommendations for infants provide food-based information on what, when and how to introduce complementary foods to infants and young children. The introduction of complementary foods, especially solids and eventually finger foods, is important for infants to develop normal oral and motor skills related to eating and to achieve the recommended nutrient requirements that may be low in breast milk (e.g., protein or iron). Such dietary guidelines are generally targeted to health care

providers (e.g., physicians, nurse practitioners, dentists, dietitians) and or parents and guardians, early care and education providers, program administrators, or a combination of audiences.

The recent consensus study report from NASEM on Infant Feeding provided an insightful overview of existing food-based dietary guidelines that included review of 43 guideline documents on recommendations for what, when and how to feed infants and young children that were available on the internet from 26 agencies in 7 high income countries plus the WHO (NASEM, 2020). Overall, there was a high degree of consistency across countries in the recommendations on various aspects of infant as detailed in the report (NASEM, 2020) and summarized by Jimenez and colleagues (Jimenez et al., 2021). Canada (Health Canada et al., 2014, 2015) and the US (USDA and USDHHS, 2020) have some of the most recently published infant feeding recommendations. In general, such guidance on infant feeding has not been based on use of systematic review methodology and infrequently has involved a harmonized approach across agencies or professional societies either within a country or across countries. However, a trend is emerging for inclusion of both methodological processes. In the US, for the first time, the 2020–2025 Dietary Guidelines for Americans included nutrition guidance for pregnant women, infants and young toddlers from birth to 24 months which are based on systematic reviews that addressed specific questions and were published in peer reviewed nutrition journals (USDA and USDHHS, 2020). The 2014–2015 Canadian nutrition recommendations for infants from birth to 24 months were not developed using systematic reviews but were based on a duplicate search of the literature, followed by a consensus process that included extensive citations to substantiate the report's feeding recommendations which were targeted to health professionals, parents and caregivers. The Canadian recommendations are, however, an excellent example of a harmonized effort across agencies as they were developed by an Infant Feeding Joint Working Group, comprised of representatives from Health Canada, the Canadian Pediatric Society, the Dietitians of Canada, and the Breastfeeding Committee for Canada (Health Canada et al., 2014, 2015).

Despite the different underlying methods to develop the infant feeding recommendations, there was great consistency in key recommendations for most topic areas between the US and Canada as summarized in Table 8. Indeed, based on the summary of existing guidance on infant feeding across 26 agencies in seven countries conducted by NASEM (NASEM, 2020; Jimenez

**Table 8** Comparative examples of current infant feeding recommendations between Canada (Health Canada et al., 2014, 2015) and the United States (USDA and USDHHS, 2020).

Recommendation topic	Health Canada 2014 and 2015	Dietary Guidelines for Americans 2020–2025
Age grouping	Specific recommendations for: <ul style="list-style-type: none"> <li>- Birth–6 months</li> <li>- 6–24 months</li> </ul>	Recommendations for birth to 23 months <ul style="list-style-type: none"> <li>- Separate section on eating patterns for 12–23 months</li> </ul>
Guidance on breastfeeding	Exclusive breastfeeding for 6 months; continued up to 2 years or longer with appropriate foods	Exclusive breastfeeding for about the first 6 months; continued to at least 1 year or longer if desired
Supplements	Vitamin D of 400 IU (10 mcg)/day with breastfeeding	Vitamin D of 400 IU (10 mcg)/day with breastfeeding
First complementary foods; timing and type	Begin at 6 months with a focus on iron-rich meat, meat alternatives, and iron-fortified cereal	Begin at about 6 months with nutrient dense foods rich in iron and zinc; to not introduce foods before 4 months or after 6 months Tips on responsive feeding to offer developmentally appropriate foods
Potentially allergenic foods	Foods containing common allergens (peanuts, fish, wheat, cow milk products, soy and eggs) may be fed from about 6 months	Introduction of allergenic foods (peanuts, egg, cow milk products, tree nuts, wheat, fish and soy) should be introduced
Cow milk as main beverage	Not before 9–12 months	Not until 12 months or later

et al., 2021), there were more consistencies than inconsistencies across recommendations. Any differences reflect slight variations in age ranges suggested.

### Research needs

For nutrient-based dietary reference values for infants, there is an urgent need for revision since only the DRI for calcium, vitamin D, sodium and potassium have been revised since the first DRI report in 1997. The first step is to conduct evidence reviews to determine if sufficient new research is available to substantiate revising individual nutrient requirements. Each of the individual DRI reports highlighted research needs in a concluding article but whether such research has evolved remains to be determined. Because infants and children are not just “little adults,” the DRI values must be carefully defined for the specific stages of growth and development and with consideration for nutritional programming that occurs in early life in response to dietary exposures as our knowledge of this area becomes more complete.

With regard to food-based infant feeding guidelines, evidence gaps related to lack of existing evidence or inconsistencies in existing research were identified in the NASEM report on infant feeding (NASEM, 2020) and summarized in a recent paper (Atkinson et al., 2021). Areas identified for future research include the following:

- the effects of breastfeeding beyond the first year
- the consequences of replacing infant formula with cow’s milk at 9 months vs 12 months, among formula-fed infants and partially breastfed infants
- how to identify and appropriately treat infants at risk of iron deficiency
- does high dose vitamin D supplementation in lactating women meet infant needs
- how to achieve nutritional adequacy for infants weaned to vegetarian or vegan diets
- how to provide adequate iodine without excessive exposure to salt
- responsive feeding research to support guidance on elucidating reliable child development indicators that identify when infants are ready to be introduced to complementary foods.

### Conclusion

Guidance on the specific nutrient needs and on how to meet those nutrient needs by types of foods and feeding practices for infants and young children is critical to ensure optimal growth and development, especially in the first two years of life (Darling et al., 2020; Stephenson et al., 2018). This requires both nutrient-based dietary reference values that provide quantitative amounts of nutrients such as the DRIs, and nutrition recommendations on what, when and how to feed infants. The DRIs are the scientific basis for the translation of the quantitative values into amounts of food (the what), for specific age groupings according to growth needs and developmental functioning (the when). Nutrition guidelines or recommendations must extend beyond these topics to provide guidance on the form and presentation manner of food for infants (the how). The paucity of past research in infant feeding has limited the scientific rigor with which both the DRIs and infant feeding recommendations were developed but there are signs the state of the science is improving. Global harmonization of derivation of nutrient-based requirements is encouraged (Yaktine et al., 2020). Harmonization of infant feeding recommendations/guidelines within countries (such as done in Canada) and across

countries would elevate translation and dissemination of information to a new level. The communication, dissemination and implementation of guidelines is critical and must consider ethnicity, socioeconomic status, as well as regional food availability and security (Jimenez et al., 2021).

## Key points

- Adolescence marks a stage of physical, mental and intellectual development, with nutrient recommendations being higher than at any other stage throughout the life cycle.
- Increased nutritional requirements in adolescence, combined with a tendency toward less healthy eating patterns, make this group susceptible to vitamin and mineral inadequacies.
- Adolescence is an opportune time to instill healthy eating patterns that can persist into adulthood.
- Obesity in adolescence is not just restricted to high-income countries and has short and long-term implications for the individual.

## Introduction

There are approximately 1.2 billion adolescents worldwide. Although they differ by nationality, culture, education and wealth, adolescents share similar developmental experiences. The normal transition from childhood to adolescence consists of hormonal changes, physical growth, sexual development and an expansion of emotional and cognitive skills. In addition, adolescents begin to seek independence and develop a social life that is separate from the family unit, both of which will influence eating habits. Skipping breakfast and eating away from the home are common among adolescents, as are the consumption of high energy snacks, drinks and fast foods, particularly in richer nations. These foods, however, are limited in important vitamins and minerals; and can be energy-dense which contributes to excess weight gain. As adolescence is a time of peak growth requiring additional energy, protein and key micronutrients, optimal nutrition is essential. There is also a need for nutrition education to guide adolescents toward balanced dietary habits that support future disease risk reduction, and can be maintained during adulthood.

## Physical growth

Adolescence refers to the life stage from approximately 10 to 19 years during which there are changes in physical, cognitive, social and emotional development. Adolescence can be divided into two stages, early and late adolescence. During early adolescence, there is enhanced physical growth (height and weight), pubertal changes in males and females, and the onset of menstruation in girls. In late adolescence, physical growth continues for boys and girls, though at a much slower rate in girls.

Monitoring these changes can be achieved using growth charts. The World Health Organization (WHO) growth charts, originally designed for children up to 5 years of age, are universal as there are similar patterns of growth among subpopulations exposed to similar environments. However, genetic, nutritional and maternal factors can impact the growth of children and adolescents. Therefore, some countries have developed their own growth charts for adolescents, such as Canada, the United States and the United Kingdom. Examples of these are provided in [Appendix 1: examples of growth charts for adolescents](#) section.

Before puberty, girls and boys acquire bone mass at a similar rate. After puberty, boys tend to acquire a greater amount of bone mass than girls. Peak bone mass is the maximum amount of bone tissue a person achieves throughout their life, usually by age 18–25 years. Higher bone mass is thought to be protective against the risk of osteoporosis later in life—a condition that mainly affects females but also some males ([National Institute of Health, 2018a](#)). Peak bone mass is determined mainly by genetics, sex, nutritional intake, endocrine status, physical activity and health status during growth. With regards to nutrition, bone formation requires amino acids and an adequate supply of energy. The main bone forming minerals include calcium, phosphorus, magnesium and iodine. Also, vitamins C, D and K are required for the formation of mineral crystal and collagen—a type of protein found in the bone matrix. These vitamins are also involved in cartilage formation and bone metabolism. Other recommendations to optimize bone development include having a body weight in the healthy range and being physically active ([Redmond and Schoenmakers, 2019](#)). The WHO recommends children and adolescent to do at least 1 h per day of moderate to vigorous intensity, mostly aerobic physical activity. Exercises that strengthen muscle mass and bone should be incorporated into adolescent's lifestyles at least 3 times per week ([WHO, 2020b](#)).

## Obesity

Overweight and obesity refer to excessive fat accumulation that may impair an individual's health. Body mass index (BMI) is a commonly used proxy of weight-for-height to classify overweight and obesity and is calculated as an individual's weight (kg) divided by height squared ( $m^2$ ). BMI is typically used for assessing overweight and obesity in adults but is not useful on its own in children and adolescents due to the continuing growth that occurs throughout this period. Instead, BMI is only meaningful when plotted on sex- and age-specific growth charts. For adolescents, overweight is defined as BMI-for-age that is greater than one standard deviation above the WHO growth reference median. Obesity is defined as two or more standard deviations above the reference median. In country-specific growth charts, such as those for the UK, overweight and obesity are defined as being above the 91st and 98th centiles, respectively. In epidemiological studies, obesity and overweight may be defined at the 95th and 85th centiles, respectively ([Stewart and Gillespie, 2019](#)). Section [Appendix 1: examples of growth charts for adolescents](#) summarizes growth chart cut-offs for overweight and obesity for a selection of countries.

In 2016, over 340 million children and adolescents were overweight or obese and, according to the [WHO report \(2020a\)](#) on childhood obesity, the issue affects every country in the world. The most rapid growth is occurring in low- and middle-income countries, particularly in the Middle East, Southern Africa and the Pacific Islands. The number of young people aged 5–19 years living with obesity is estimated to rise to over 250 million by 2030, with China and India accounting for over a third of this increase. In the United States, approximately 20% of 6–19-year-olds are defined as obese.

Although the prevalence of obesity is starting to flatten in many countries, especially in Europe, most children and adolescents will not outgrow the condition. A longitudinal study that tracked BMI from childhood revealed that nearly 80% of children with severe obesity at one examination remained severely obese at the next ([Freedman et al., 2018](#)). Likewise, a meta-analysis of 37 studies investigated the use of BMI to predict the likelihood that obese children will become obese adults. The authors found that obesity persisted from childhood onwards, with most obese adolescents continuing to be obese in adulthood ([Simmonds et al., 2015](#)). The health consequences of overweight and obesity have been well documented. Obesity increases the risk of developing several non-communicable diseases, namely hypertension, coronary heart disease, type 2 diabetes and sleep apnea. Longitudinal research highlighted that adults have a better cardiovascular health profile if they were never overweight or obese, or at least only in childhood or adolescence ([Quinte et al., 2019](#)). In addition, adolescents can experience behavioral and emotional problems related to obesity, affecting their quality of life and societal opportunities.

A position paper by a European pediatric expert group ([Verduci et al., 2021](#)) concluded that certain dietary patterns enhanced the risk of obesity including consumption of SSB (but not 100% fruit juices at appropriate intakes), breakfast skipping, large portion sizes, snacking on energy-dense foods, sedentary behavior (including excess use of technology) and lack of regular physical activity. The position paper made recommendations to improve young people's diets as a means of preventing obesity. However, many adolescents around the world face obstacles accessing and affording healthy diets ([UNICEF, 2019](#)).

## Eating patterns

Eating a varied and balanced diet and establishing healthy eating patterns can have a significant effect on adolescents' health by optimizing growth, supporting normal physical and intellectual performance, and helping to maintain a healthy weight. In contrast, there are a number of unhealthy eating patterns common in adolescence which can hinder health, such as skipping breakfast, excess consumption of fast foods and low consumption of fruit and vegetables. These eating patterns are influenced

by a range of factors including food preferences, cost, convenience and peer influences. Since eating habits and food preferences established in adolescence tend to continue into adulthood, it is a very opportune time to promote healthful eating patterns (WHO, 2016).

### Less healthy options

In developed countries, adolescents' diets are characterized by less healthy food choices, especially sugar sweetened beverages (SSB), fast foods and high fat/sugar/salt snacks. Skipping breakfast is associated with an overall lower intake of folic acid, vitamin D, calcium and iron, as well as fiber. However, adolescents who regularly consume breakfast have been found to snack less and have a lower likelihood of being overweight or obese. Moreover, research (systematic reviews) has shown that breakfast consumption has beneficial effects on cognitive performance and academic outcomes. In spite of this, skipping breakfast is very common among adolescents worldwide with boys being more likely to eat breakfast than girls. At age 11, approximately 70% of boys and girls eat breakfast every weekday but by age 15, this reduces to 62% and 52% for boys and girls respectively (Dye, 2017; WHO, 2016).

Fast food is frequently consumed by adolescents and can be energy dense, high in sodium and sugar, and low in fiber and micro-nutrients. The prevalence of fast food consumption was examined in a large study with over 153,000 young adolescents from 54 low- and middle-income countries. The results showed that 55% ate fast food at least one day per week, while 10% ate fast food 4–7 days per week (Li et al., 2020). During 2015–2018, over 35% of children and adolescents in the US consumed fast food on a given day (Ostchega et al., 2020). In addition to the direct effects of consuming fast food, this dietary pattern is linked with higher consumption of SSB and low consumption of fruit and vegetables (Li et al., 2020). While the consumption of energy dense foods is certainly a risk factor for obesity, the Foresight Report shows that it is a complex, multifaceted system involving biological, social and environmental factors (Butland et al., 2007).

Numerous studies suggest that the consumption of SSB is directly associated with weight gain, overweight and obesity in adolescents (Keller and Bucher Della Torre, 2015). Worldwide, evidence shows that young people consume a large quantity of SSB; for example, almost 80% of adolescents surveyed consumed SSB daily in a nationally representative population of Americans. In China, two-thirds of over 53,000 children and adolescents reported that they consumed more than 7 servings of SSB per week. The European Academy of Pediatrics and the European Childhood Obesity Group recommend that the consumption of SSB should be limited in favor of water and non-sweetened drinks. Not only can SSB contribute to weight gain but also the high sugar content and low pH contributes to dental caries and enamel erosion (Dereñ et al., 2019). The development of dental caries occurs due to the metabolization of sugar by oral bacteria, producing acid which demineralizes the hard tissues of the teeth. Limiting free sugar intake to less than 10% of total energy intake, ideally less than 5%, minimizes the risk of dental caries throughout life (WHO, 2017).

### Body image and eating disorders

Adolescents typically have concerns about the appearance of their bodies, particularly in relation to their physical appearance and size. This concern is exacerbated by societal or peer pressure for thinness, dieting or musculature which can result in a minority of cases developing overly restrictive eating habits. Girls may experience pressure to become thin while boys feel they must be large and muscular, both of which have the potential to exacerbate disordered eating (Fleming et al., 2020), which often begins in adolescence (WHO, 2018a). Two sets of diagnostic criteria for eating disorders are in use: the Diagnostic and Statistical Manual of Mental Disorders (DSM-5), published by the American Psychiatric Association, and the International Classification of Diseases (ICD-10), published by the WHO. Both manuals list the criteria for the major eating disorders: anorexia nervosa, bulimia nervosa and binge-eating disorder.

With anorexia nervosa, people severely restrict or avoid food, or eat very small quantities of particular foods. People with anorexia nervosa may see themselves as being overweight even when they are extremely underweight. Over time, this can cause thinning of the bones, anemia and muscle wasting. At the most extreme outcome, medical complications due to starvation may be the cause of mortality. People with bulimia nervosa have frequent episodes of consuming large amounts of food, followed by behaviors that compensate for the overeating such as fasting, forced vomiting, excessive exercise or use of laxatives or diuretics. People with bulimia nervosa may have a chronically inflamed throat, worn tooth enamel, gastrointestinal problems and electrolyte imbalance. Finally, binge-eating involves eating unusually large amounts of food but it is not followed by fasting, purging or excessive exercise. Consequently, those with binge-eating disorder are usually overweight or obese (National Institute of Health, 2018b).

The lifetime prevalence of eating disorders among US adolescents aged 13–18 years is 2.7% and is more prevalent among females (3.8%) than males (1.5%) (National Institute of Health, 2017). In Mexico, the lifetime prevalence of anorexia nervosa, bulimia nervosa and binge-eating disorder among adolescents is 0.5%, 1.0% and 1.4%, respectively (Kolar et al., 2016). In the UK, prevalence estimates for anorexia nervosa range from 0.3% to 0.6% (Petkova et al., 2019). In Portugal, the prevalence of anorexia nervosa among adolescents is 0.4% (Smink et al., 2012). Although, eating disorders are more common among girls, it is not clear if the disorder is under-detected in boys. Anxiety, depression and low self-esteem which are often seen in adolescence are associated with eating disorders. The long-term consequences of eating disorders can include detriment to the cardiovascular, gastrointestinal, endocrine, renal and neurological systems.

### Vegan and vegetarian diets

Vegetarianism and veganism have increased in popularity and are growing social movement. Generally, vegetarians do not eat meat, poultry or fish but typically eat eggs and dairy foods. Vegans refrain from eating any animal-derived products and may extend this to other aspects of life e.g., avoiding use of animal-sourced clothing, medicines or household products. The prevalence of vegetarianism ranges from 5% in the US/UK and 8% in Canada, to 30% in India (Paslakis et al., 2020) which may be largely attributed to strict Hindus being lacto-vegetarians (vegetarian but includes dairy). In Europe, the prevalence of vegetarianism is on the rise. While specific data on adolescents are scarce, there has been an apparent rise in interest in young people according to social media and campaigns by vegan/vegetarian organizations. In a national health survey in Germany, 6% of girls and 2% of boys aged 14–17 years reported eating a vegetarian-type diet (Schürmann et al., 2017).

Both the British Dietetic Association and the US Academy of Nutrition and Dietetics agree that vegetarian and vegan diets are appropriate at all stages of the life cycle, although this is not a universal view and expert bodies from some European countries have raised concerns about vegan diets in younger age groups. The Spanish Pediatric Association suggest that it is safe to follow a vegetarian diet at any age but advise young children to follow an omnivorous diet or at the very least, an ovo-lacto-vegetarian diet (Redecillas-Ferreiro et al., 2020). With any restrictive diet, inadequate intakes can occur and vegetarianism or veganism are no different. There are a number of nutrients that may be a cause for concern if the diet is not adequately planned. Firstly, protein quality is a concern. While soy protein has a high digestibility, this is not the case for protein in cereals, pulses, nuts and seeds which need to be combined to ensure a broad range of essential amino acids. Hence vegan adolescents will require more protein or specific combinations of protein-rich foods than their vegetarian or omnivorous peers (Agnoli et al., 2017). Another issue in vegetarian and vegan diets relates to omega-3 fatty acids. Oily fish is an excellent source of very long chain omega-3 fatty acids, such as eicosapentaenoic acid and docosahexaenoic acid which are incorporated directly into body cells and which support the synthesis of anti-inflammatory immune compounds. Vegetarian and vegan sources of alpha-linolenic acid—a shorter chain omega-3 fatty acid—include nuts, seeds, dark green vegetables, soya products and rapeseed oil. Alpha-linolenic acid must be converted into eicosapentaenoic acid and docosahexaenoic acid in the body but the process is inefficient and inhibited by the amount of omega-6 fatty acids in the diet. Thus, plasma levels of very long chain omega-3 fatty acids are often lower in vegetarians and vegans compared with fish and meat eaters, although the health implications of this are unclear.

There are a number of minerals and vitamins that are essential for adolescents but may not be supplied in sufficient quantities by a vegetarian or vegan diet. Iodine can be found in plant foods but levels vary depending on soil quality. In general, foods tend to be higher in iodine if they are grown closer to the ocean. Vegans are advised not to use seaweed or kelp as a source of iodine but to consider a dietary supplement. For calcium, tofu and calcium-enriched milk alternatives are excellent sources as well as kale, whole-grain bread (fortified) and sesame seeds and almonds. Spinach is high in calcium but is poorly absorbed as the calcium is bound to oxalate. In contrast, the absorption of calcium from low-oxalate foods such as broccoli, kale and cauliflower can be up to 50%. Iron, which will be discussed in more detail later, is another mineral of particular concern for adolescents. Vegetarian diets mostly consist of non-heme sources of iron which is not as efficiently absorbed as heme sources of iron originating from animal origin foods. Vegetarians can access non-heme sources of iron such as cereals, nuts, seeds, legumes and fortified foods such as breakfast cereals, as well as foods rich in vitamin C which enhance the absorption of non-heme iron (Hood, 2019). Lastly, as vitamin B12 is present only in foods of animal or microbiological origin, vegans depend on fortified foods, fermented foods or supplements, whereas vegetarians can choose fortified foods as well as dairy products and eggs as a source of vitamin B12 (Agnoli et al., 2017).

### Nutrient inadequacy and potential consequences

In countries where dietary surveys are available, the evidence suggests that adolescents have the least well-balanced diets of all the age groups. This is as a result of inappropriate food choices favoring high energy dense, low nutrient-dense foods and drinks. According to UNICEF (2019), only a third of school-aged adolescents in low- and middle-income countries consume fruit regularly while a fifth eat vegetables once a day or less. In contrast, over 40% consumed SSB at least once a day. This, combined with other eating behaviors during adolescence, may result in nutrient inadequacies. Likewise, in Europe and Canada, nearly 50% of adolescents reported that they do not eat fruits nor vegetables every day. Roughly 16% of adolescents consumed SSB every day. Not only can these dietary patterns drive excess body weight, but can put adolescents at greater risk of failing to achieve recommendations for micronutrients, particularly iron, calcium, iodine, vitamin D and folate.

#### Nutrients of concern: iron

Iron deficiency is an area of concern in adolescence. For normal physical development and rapid growth, adolescents require increased intakes of certain vitamins and minerals. Iron is particularly important, especially for post-menarche girls. Iron deficiency anemia (IDA), which affected roughly 619 million adolescents in 2013, can result in shortness of breath, fatigue or chest pain. Adolescents are at an even greater risk of anemia in areas where early marriage and childbearing is common. In addition to IDA, iron deficiency can be associated with frequent infections, behavioral problems and developmental delay.

The European Food Safety Authority (EFSA) has set a population reference intake (PRI) of iron for boys (11 mg/day) and girls (13 mg/day) aged 12–17 years old. The US National Institute of Health recommend 11 mg/day for boys and 15 mg/day for girls

aged 14–18 years old. The PRI set by EFSA are the same as reference nutrient intakes (RNIs) used in the UK and recommended dietary allowances (RDAs) used in the United States. The PRI refers to the amount of nutrient that is adequate for virtually all people within a population. Average intakes of iron among 11–17-year-old girls in Europe range from approximately 7.7 mg/day in Denmark to 14.9 mg/day in Germany. Including supplements, mean intakes ranged from 9 mg/day in the UK to 15.7 mg/day in Germany. For boys, mean daily dietary and supplemental intakes of iron ranged from 10.8 mg in the UK to 18.8 mg in Germany.

### Nutrients of concern: bone health

As a consequence of accelerated skeletal development during adolescence, the demand for calcium during this period is higher than at any other stage of life. Approximately 99% of the body's calcium supply is stored in the bones and teeth as calcium hydroxyapatite. There is a constant remodeling process that occurs in bone through the removal of old bone (resorption) and formation of new bone (ossification). The balance between bone removal and bone deposition changes with age. As bone formation exceeds resorption during childhood and adolescence, it is critical that an adequate supply of calcium and other bone related nutrients is achieved to ensure an optimal peak bone mass. The PRI for calcium in Europe is 1150 mg/day for adolescents aged 11–17 years. There are differences between countries as some reflect calcium requirement differences for boys and girls, such as in the UK, whereas the RDA in Canada and the US is the same for males and females (1300 mg/day). Therefore, it is important that an individual follows their respective government's advice for all nutrition recommendations.

Vitamin D is well recognized due to its effect on bone health. The biologically active metabolite of vitamin D is 1,25 (OH)<sub>2</sub>D which is involved in the maintenance of calcium and phosphorus homeostasis. This is essential for bone health throughout the life cycle. Bone accretion and growth occurs in infancy and childhood, as well as rapid bone accrual during adolescence. Thus, vitamin D, along with calcium, is essential during adolescence and throughout adulthood to maintain healthy bones and prevent bone loss. Despite this, vitamin D deficiency has become a global public health problem, particularly among children and adolescents. Low vitamin D status may be due to limited endogenous synthesis of vitamin D (as a consequence of lack of appropriate sun exposure) and reduced intakes of vitamin D-rich foods, such as oily fish, eggs and fortified foods/drinks. Endogenous synthesis and dietary intake alone are normally insufficient for maintaining appropriate blood levels across the year. Hence, vitamin D supplementation is often required and some countries, such as the UK, overtly recommend year-round supplemental intakes. The recommended intake differs by country with dietary reference values for adolescents ranging from 5 µg to 20 µg (200–800 IU) per day.

### Nutrients of concern: folate

Folate is a B vitamin which is essential for amino acid metabolism, methylation reactions and DNA/RNA biosynthesis. Rich food sources of naturally occurring folate include green leafy vegetables, citrus fruits, beans and legumes. Folic acid is the synthetic version of folate which is more stable and bioavailable. Thus, it is commonly found in supplements, and fortified foods including flour and breakfast cereals. Folate is particularly important for pre-pregnant females as it is a critical nutrient for the prevention of neural tube defects; the most common being spina bifida and anencephaly which often result in fetal death or severe disability. Therefore, girls of reproductive age who may become pregnant are advised to take a 400 µg supplement of folic acid pre-conceptually until the 12th week of pregnancy, on top of food sources of folate. However, there are a number of barriers to achieving this. Naturally occurring food folates have limited bioavailability and can be unstable during cooking, while many pregnancies in adolescence are unplanned resulting in girls failing to take folic acid supplements in the recommended window of development for the neural tube (McNulty et al., 2019). Lastly, skipping breakfast (source of folic acid if fortified cereals are chosen) combined with a low consumption of vegetables are common among adolescents.

### Nutrients of concern: iodine

Iodine is a trace element that is an essential component of thyroid hormones, which regulate protein synthesis and are needed for skeletal and central nervous system development. Insufficient iodine intake causes the thyroid stimulating hormone to remain elevated, leading to goiter, an enlargement of the thyroid gland. This enlarged gland reflects the body's attempt to trap iodine and produce thyroid hormones (National Institute of Health, 2021). The consequences of iodine deficiency for adolescents may delay physical development and impair mental function (Zimmermann, 2009). The highest levels of iodine deficiency disorders occur in Sub-Saharan Africa, South Asia, the Middle East and North Africa regions (WHO, 2018b). Groups at risk of inadequate iodine status include vegans or those who eat negligible amounts of seafood, dairy products and eggs, since these are among the best sources. Other groups at risk include those who do not use iodized salt – a common public health strategy to control iodine deficiency in many countries (National Institute of Health, 2021).

### Improving adolescents' diets

Investing the time and resources to promote healthy eating in adolescents not only improves health in this age group, for example by supporting normal growth, lowering the risk of obesity, and boosting nutrient adequacy, but helps to establish better eating habits in the long term which can help to prevent non-communicable diseases. Wholegrains, fruits, vegetables, oily fish, dairy

foods, lean meats, eggs, plant-based proteins and sugar-free fluids (water, tea) should be promoted over those foods currently preferred by adolescents in many countries, particularly SSB, fast foods, confectionery, savory snacks and sweetened baked goods. Dietary interventions should consider a whole dietary approach and focus on increasing whole grain, fruit and vegetable consumption (Doherty et al., 2021). However, diet is one component of a multifaceted problem. Interventions combining diet, physical activity and behavioral components are considered to be best practice in the prevention of obesity in adolescence. A systematic review assessed the effects of dietary, physical activity and behavioral interventions on overweight and obese adolescents, locating 44 randomized controlled trials which met the inclusion criteria. Body weight was lowered by approximately 3.7 kg in trials of holistic interventions with moderate quality evidence (Al-Khudairy et al., 2017).

A growing number of studies have started to use social media in nutrition interventions for adolescents and young adults. A systematic review of mostly randomized controlled trials found that 11 out of 16 interventions had short-term positive effects on nutrition-related, clinical or behavioral outcomes. Social media was used to facilitate communication and social support. Online discussions were also used in some studies, whereas others employed smaller group interactions using Facebook, Twitter and WhatsApp. Some of the positive results included weight loss, reduction in SSB intake and screen time, as well as improvements in fruit and vegetable intake (Chau et al., 2018).

## Conclusion

In conclusion, the evidence on adolescence and associated nutritional problems reveals:

- Adolescents are prone to unhealthy eating patterns including an excess consumption of SSB and fast foods, as well as skipping breakfast and having low intakes of fruits, vegetables and nutrient-rich foods.
- Vegetarianism and veganism are increasing in popularity but may result in low intakes of essential nutrients if diets are not appropriately planned. Hence additional support may be needed for young people intending to follow these types of diets.
- Iron, calcium, iodine, vitamin D and folate are among the nutrients of particular concern for adolescents—in some cases supplementation may be warranted.
- Obesity in adolescence is a worldwide major public health issue which increases the risk of several non-communicable diseases.
- Holistic interventions combining advice on diet, physical activity and behavioral aspects seem to be most effective for preventing and treating overweight and obesity in adolescence.

## Appendix 1: examples of growth charts for adolescents

Country	Boys	Girls	Cut offs
Canada	Boys (2–19 yrs) BMI	Girls (2–19 yrs) BMI	Overweight: >85th centile; obese: >97th centile
India	Boys (0–18 yrs) height and weight	Girls (0–18 yrs) height and weight	Overweight: 85th centile; obese: 97th centile
United Kingdom	Boys 2–18 yrs BMI 2–20 yrs	Girls 2–18 yrs BMI (2–20 yrs)	Overweight: >91st centile; obese: >98th centile; undernutrition/small build: <2nd centile
United States	Boys (2–20 yrs) stature for age weight for age BMI for age	Girls (2–20 yrs) stature for age weight for age BMI for age	BMI ranges: overweight: ≥85th centile; obese: ≥95th; normal/healthy: 5th–85th; underweight: <5th

### Human Aging and Nutrition

The World Health Organization (WHO) defines the ‘elderly’ as persons of 60 years of age and older. The elderly constitute a rapidly expanding segment of populations in both developed and developing countries. This is the combined result of ever-longer survival and dramatic reductions in fertility rates. Regardless of age, people must respond to their feelings of hunger and thirst by consuming foods and beverages. This eating and drinking behavior also serves to provide the nutrients to nourish the body. The amount of a nutrient that must be ingested and absorbed to maintain an adequate and appropriate body composition varies with age across the life span, depending on basic underlying physiological and metabolic processes specific to the chronological stage of life. Similarly, the degree to which we retain and conserve, or excrete or degrade, absorbed nutrients is influenced by chronological age and biological aging.

As a consequence of this new demographic reality, attention is being focused belatedly on gerontology and its nutritional biology; this, in turn, is reflected in very recent efforts to refine our knowledge of the amounts of various macro- and micronutrients that the aging body requires (nutrient requirements) and of the amounts that must be consumed in the diet to provide for sufficient uptake of these nutrients (nutrient recommendations).

### Successful Aging, Normative Aging, and Frailty

From an epidemiologic and demographic, as well as an economic and humanitarian standpoint, the ideal contribution of life-long nutrition would be to a situation of ‘compression of morbidity,’ first enunciated by J. Fries. It strives to keep individuals functional, independent, and free of chronic illness, until the final moments of their lives, and thus reduces to a minimum the burden of disability and dependency suffered by older persons, their families, and the society that contributes to their maintenance.

A disclaimer has traditionally been appended to the official pronouncements of recommended nutrient intakes (RNIs); whether they are from national or international expert panels, the prescriptions are meant to apply to ‘healthy’ individuals. Nutrient needs in disease conditions are considered to be a clinical matter, and are related to the pathological processes in question.

When it comes to older persons, the exigency of being ‘healthy’ becomes immediately problematic. Advanced age is associated with increased susceptibility to chronic and degenerative illnesses. Most persons over 60 years of age have two or three diagnosed chronic illnesses, and are receiving multiple medications. Maintaining a rigid definition of ‘healthy’ for application of nutrient recommendations in later life would exclude almost everyone from coverage by general nutrient-intake standards.

In fact, the older the cohort of individuals examined, the more heterogeneous are individuals of the same chronological age in their physical and cognitive functioning. Over the last two decades, general domains of classifications have come into usage to embrace the heterogeneity of aging populations: successful aging; usual aging; and frail aging. Successful aging has been defined as multidimensional, ‘encompassing the avoidance of disease and disability, the maintenance of high physical and cognitive function, and sustained engagement in social and productive activities.’ It may involve aspects of resilience and wisdom, as well. Usual aging involves an accumulation of ailments and loss of function that is ‘typical’ or ‘normative’ for older persons surviving to later

life. Frailty is the far extreme of disability and dependency associated with major physical and cognitive decline in which disease and senescent processes become irreversibly established.

A prominent and optimistic school of thought suggests that exposures to behavioral and environmental factors that modify risk of disease and dysfunction determine one's position in these alternative outcomes in the aging process. In this view, more optimal nutrient intake, food selection, and life-style choices could reduce the heterogeneity, retaining more individuals in the successfully aged category for most of their life span. Others consider that genetic constitution may be as important in determining the course of aging as any positive or negative influences during our lifetime.

## Overview of Specific Factors of Aging Influencing Nutritional Requirements

The discussion of nutrient requirements and recommended dietary intakes of nutrients in older persons has proceeded on both the theoretical and empirical level. Since the peak years for human reproduction occur before middle age, and well before older age begins, the forces of natural selection, governing fecundity in reproduction cannot exert themselves for the Darwinian selection of traits favoring longevity in the evolution for any traits related to longevity *per se* or physiological sustained function. Hence, there has been little or no evolutionary selection for nutrient requirements to achieve advanced age or for long-term survival. It is more for the preservation of comfort and function for those surviving to advanced age that the optimization of nutrition intakes for the elderly would apply, that is, for humanitarian and public health importance in the face of the physiological and anatomic changes of senescence.

As early as the 1970s, nutritional scientists advanced the proposition that requirements for different macro- and micronutrients changed with age. A large number of conjectures based on an emerging scientific understanding of senescent physiology have been advanced. It has been suggested that the decreased physical activity and physical conditioning associated with the body composition changes attendant to aging sets the stage for alterations in requirements in both amounts and relative proportions of protein and the energy-yielding macronutrients. Decreased gastric secretory capacity has a negative influence on the absorption of calcium, iron, and vitamin B<sub>12</sub>. Changing intestinal motility and digestive function evoked considerations of distinct increases and decreases of nutrients to compensate for the senescence of the intestinal tract, with particular interest in dietary fiber. Attention to compensatory intake for all of the nutrients involved in skeletal mineralization has come to the fore in relation to the recognized tendency to bone mineral loss with advancing age.

The immune and host defense system has been a major focus of gerontological nutrition. Increased intakes of both vitamin E and zinc, well above the normally recommended level, have stimulated certain immune functions in studies involving older volunteers. More recently, evidence for enhanced immune function in older individuals from physiological doses of zinc has been reported. Zinc may act to fortify the responsiveness of lymphocytes to stress. Impaired interferon and interleukin-2 responses may be the mechanisms whereby low zinc status impairs immune function in elderly humans. Additionally, vitamin D seems to play a role in the regulation of the aging immune system in the area of antibody and cytokine responses. Cognitive function declines with advancing age, and it has even been suggested that the adjustment of nutrient intake can favorably affect the retention of memory and cognitive function in older persons. Results of association studies and intervention trials have been mixed and inconclusive. The adequate intake (AI) of B-complex vitamins, particularly those related to homocysteine metabolism (vitamin B<sub>12</sub>, folic acid, vitamin B<sub>6</sub>, riboflavin), are associated with mental function in older age. It has also been suggested that older individuals need more *n*-3 fatty acids for preserving cerebral cellular anatomy related to cognition. A prospective trial of B-vitamin and *n*-3 fatty acids in older French adults found positive effects in the subsegment with a history of cerebral strokes. Implications for a role of vitamin D in preserved cognition with advancing age have emerged in human studies. Animal research suggests that both vitamin D and K may be important in conserving central nervous system function with aging. For several nutrient effects in immunity, cognition, and other areas, an interaction with a biomarker of a genetic polymorphism seems to be important.

## Nutrient Intake Recommendations in Later Life

Comprehensive recommendations for macro- and micronutrients with differential attention to older persons have arisen from a collaboration between the US and Canada, and from expert panels serving the United Nations (UN) System. Each panel has set out its methodology and definitions and then presented tables of quantitative estimates. The recommendations for persons considered elderly in the respective systems are outlined below.

## Definitions Surrounding Recommended Intakes of Nutrients

An important advance in establishing nutrient intake recommendations relates to the semantics. There has been a refining of the operational definitions of terms related to nutrient intakes. RNIs are set by the agencies of the UN System and are considered to be the intakes of nutrients required to satisfy the requirements of nearly all healthy persons of a given age, sex, and physiological condition, and should be universal for all regions of the globe. In 2006, a way to calculate (retrofit) the population-relevant estimated average requirement (EAR) to the UN System was published.

The Food and Nutrition Board of the Institute of Medicine in the US took a new approach in 1997 in which they applied the new dietary reference intakes (DRI) to micro- and macronutrient intakes. This work was undertaken jointly with Canada. It began with an assessment, where possible, of the EAR, defined as “the average daily nutrient intake level estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group.” The EAR is critical for an assessment of the risk of a nutrient deficiency problem at the population level. The traditional criterion used for decades, the recommended dietary allowance (RDA), is preserved. It is defined in the DRI process as “the average daily nutrient intake level sufficient to meet the nutrient requirement of nearly all (97 to 98%) healthy individuals in a particular life stage and gender group.” When an EAR cannot be established from which to derive a formal RDA, the DRI process has a ‘fall-back’ category known as AI; this is defined as “a recommended average daily nutrient intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate.” A new classification scheme involving a range of intakes was created specifically for energy, electrolytes, and liquids: the acceptable macronutrient distribution ranges (AMDRs).

For the first time, a specific and well-defined process to delimit levels of excess intake of nutrients and dietary substances was defined by the DRI process as the upper tolerable intake levels (UL). The UL is ‘the highest average daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in the general population.’ It is considered that as intake increases above the UL, the potential risk of adverse effects increases. To date, the UN System’s process has dealt much less explicitly with issues of excessive intake of nutrients and dietary substances.

### Established Recommended Intakes for Older Persons

In earlier versions of the RDAs for the US population (up to the 10th edition in 1989), the nutrient recommendations for all healthy adults over 51 years of age were combined as a single value. For the UN System, the age threshold in the early editions was 50 years or older. Concerted efforts to refine our understanding of nutrient requirements for older adults have been made over the past two decades. This allowed the US–Canada DRI process to establish categories for men and women aged 70 years and older. For the WHO/Food and Agriculture Organization (FAO) process, a specific estimation for individuals over 65 years has been provided in the 2004 micronutrient recommendations.

Given the magnitude of the theoretical considerations regarding senescence and aging physiology that have been raised by various authors, what is really surprising is the paucity of specific instances in which the recommended intakes of nutrients for men or women in the ‘elderly category’ are considered to be different from persons in the next youngest age category. Composite tables for men (Table 1) and women (Table 2) are given for all of the nutrients and dietary substances expressed in the US–Canada DRIs and in the UN system for RNIs.

### Macronutrients

In the DRI system, a universal, individual protein requirement was established as 0.80 g of good-quality protein per kilogram of body weight per day independent of age. No evidence for altered protein requirements with older age has been found. Moreover, it is recommended that the contribution of protein to total energy intake should not exceed 30%. The US Food and Nutrition Board also established an amino acid pattern in 2002. It specifies the density ( $\text{mg g}^{-1}$  protein) of seven indispensable (essential) amino acids (histidine, isoleucine, leucine, lysine, threonine, tryptophan, and valine) and for two amino acid combinations (methionine+cysteine, phenylalanine+tyrosine). This pattern is universal from age 1 year to the extremes of older age without modification.

It has long been recognized that energy recommendations cannot be made on a group basis, as each individual has his or her own daily energy requirement dependent on the amount of energy one is forced to expend with metabolic reactions, food processing, and physical exertion. In the DRI process, this is recognized in an effort to individualize the estimation of energy intake. Estimated energy requirement (EER) is based on the amount of energy needed to maintain energy balance in relation to one’s total energy expenditure. The DRI process for the US and Canada has published general EER equations (multidimensional nomograms) by which a reasonable estimate of an individual energy requirement can be calculated. There are general equations for adult men and women (over 19 years of age), based on consideration of physical activity level, weight, and height. In addition, there is an age term in the general EER, which is attached to a negative (minus sign) term in the equation. This signifies that energy requirements decline as a function of advancing years.

Although dietary fiber is not considered to be an ‘essential’ nutrient, the DRIs give a recommended level for intake. Curiously, in light of the active discussion of the role of fiber for the elderly in colonic function, the recommendations for intake by men decline from 38 to 30  $\text{g day}^{-1}$  and in women from 25 to 21  $\text{g day}^{-1}$  after 50 years. These are continued throughout the 70-year period, as well. This is a consequence of the fiber recommendations being pegged to total average energy intake.

### Water

It is recommended in the DRI as an AI that males over the age of 70 require 2.6 l and females 2.1 l of water per day; this is a decline from the 51–70-year age group, where the daily water intake recommendations were 3.7 l and 2.6 l, respectively. It is further

suggested that males and females over 70 years of age derive 81% of their daily water allowance from beverages and 19% as the metabolic water from foods. This is consistent throughout adulthood from age 19 years. Hence, there is no consideration of a higher requirement for water intake with older age. With respect to the electrolytes, no differences in AIs exist across the ages in adulthood.

## Micronutrients

A number of recommendations (RDAs or AIs) change with advancing age in the DRI system; this is indicated by the bold type in **Tables 1 and 2**. The change in recommendations occurs at either age 50 or 70 years. In women over 50 years, the RDA for dietary

<sup>d</sup>Recommendation in the form of adequate intake.

<sup>e</sup>Assumes a 10% bioavailability of iron from the diet.

<sup>f</sup>Based on the assumption of a moderate bioavailability of zinc.

iron decreases from 18 to 8 mg day<sup>-1</sup>; there is no change in requirement for the 70-year plus age group. This lower value is the recommendation for adult men of all ages. The fact that the menopause allows women to replenish iron stores depleted by an adulthood of monthly menstrual blood loss accounts for this lower RDA in older women.

The senescence of the skeletal system and the reduction of bone mineral content with age are a major nutritional concern in gerontological nutrition. In recent revisions of the recommendations, evidence for the need for increases in both vitamin D and calcium for older persons has led to changes in the estimates of requirements for these nutrients in later life. Within the DRI system the RDA for vitamin D for males and females over 70 years has recently been raised from 15 to 20 μg. The RDA for adults over 51–70 years is now 15 mg, as it is for young adults as well. Similar increases in vitamin D intake with age are recommended by the FAO/WHO and represent a progression from 5 μg in young adulthood to 10 μg after mid-century to 15 μg after 65 years. With respect to

calcium, the recommended levels increase from 1000 mg for younger adults to 1200 mg at age 50 years and beyond in the DRI system, and from 1000 to 1300 mg in the FAO/WHO standards. These are justified based on the higher propensity for skeletal fractures after 70 years of age associated with epidemiological evidence of widespread vitamin D deficiency in this age group, and evidence showing a reduction in bone loss with daily calcium intakes exceeding 1000 mg after midlife.

With respect to chromium, it is interesting that the estimation of an AI declines with advancing age. The AI for persons over 70 years in the DRI is the same as that for individuals between 51 and 70 years, but it is  $5 \mu\text{g day}^{-1}$  higher for the 19–50 years age range. This reduction is tied to the lower energy demands for individuals over 50 years of age.

The upper tolerable UL for phosphorus in the DRI system is  $3000 \text{ mg day}^{-1}$  for both men and women over 70 years as compared to  $4000 \text{ mg day}^{-1}$  for adults in the 19–70 years age group. This lower tolerance is explained by the greater prevalence of impaired renal function in advanced old age. Recently, moreover, the DRI has lowered the UL for calcium to 2000 mg beyond age 50 years, which is 500 mg below the level for ages 19–50 years.

Magnesium intake recommendations in the FAO/WHO guidelines decline for individuals over 65 years by  $30 \text{ mg day}^{-1}$  compared to those in the 51–65 years age group. An anomalous finding for the magnesium RDA in the DRI system, which applies to all adult age groups, is that the UL for magnesium has been set at 350 mg. This is only 30 mg higher than the 320 mg daily recommended for older women, and is 70 mg lower than the 420 mg daily intake recommended for older men.

### Dietary Guidelines for Function, Health, and Disease Prevention

If indeed the motivation for our dietary intake is hunger and thirst, and the primary evolutionary purpose is fulfilling nutritional needs, the manner in which we eat has important consequences for function, health, and disease prevention. The discipline of nutritional epidemiology has emerged over the past 30 years to assess associations between the selection of foods in the diet and probability and risk of suffering from poor physical function or ill health. Various features of eating behavior, from the size of portions to the number of repasts consumed in a day, to the frequency of consumption of foods with protective or noxious characteristics, have been implicated in function and health. Since aging represents an independent risk factor for disease and dysfunction, the effects of the dietary pattern become ever more manifest as an individual ages. Recent epidemiological research has shown that compliance or behavior concordant with healthy eating guidelines are associated with lower later life incidences of certain cancers, cataracts, diabetes, hypertension, stroke, and cardiovascular diseases, as well as overall survival. Moreover, there is intense interest in whether and how dietary pattern in addition to nutrition influence the maintenance of memory and cognitive function with aging.

These suggestions and recommendations have been codified and promoted by various entities focused on specific pathological situations, such as guidance for a healthy cardiovascular system by the American Heart Association or cancer prevention by the World Cancer Research Fund. In its Technical Report 916, Diet, Nutrition and the Prevention of Chronic Diseases, an expert committee of the UN agencies provides generic guidelines for reducing the risk of six important noncommunicable diseases. National bodies have also established dietary guidelines for healthful eating. They are often projected to the public in the form of emblems such as plates, rainbows, or pyramids, with visual representation of the relative proportion of various food-groups to consume, with lesser intakes of foods with salt, saturated fats, and high-energy density foods, and greater intakes of grains, fruits, and vegetables. More elaborated justifications and instructions can be found in the published forms in paperback editions or online on the Internet. Such is the case for the Dietary Guidelines for Americans in its 2011 edition.

The notion is that one adheres throughout life, even from childhood, to the tenets of these guidelines. Robert Russell and colleagues constructed a food guidelines pyramid, which specifically focused on the health of the elderly with more generous allowances in some areas (e.g., vitamin E, dietary fiber, liquids) and more extreme restrictions (e.g., sodium, solid fats), but it was based more on a potpourri of published findings about nutrient and food associations than any systematic review with agency backing.

### Barriers to Meeting Recommended Nutrient Intakes and Healthful Dietary Intake Patterns by Older Persons

The late Professor Doris Calloway, in the early 1970s, commented: “People eat food, not nutrients.” This highlights the paradoxes in considering and enumerating the objectives of dietary intake at the level of the chemical composition, whereas most members of the general public are uninformed as to the nutrient composition of the foods and beverages in their diets.

Elderly persons face a number of challenges in meeting their RNIs. In the first instance, they are likely to be those with the least sophisticated or available knowledge of the nutrients required and the food sources to provide them. The social, economic, and physiological changes imposing on the lives of persons surviving to advanced age pose logistical problems for their selecting and purchasing a diet. Economic dependency and the limited incomes of older persons may restrict their access to high-quality foods. Social isolation, depression, and impaired mobility, as well as chewing difficulties, may limit the variety of items included in the diet with advancing age. In some circumstances, it may be that free-living and independent elders are relatively less able to optimize their nutrient intake and dietary pattern compared to the more dependent individuals served or fed in institutional settings.

The exigencies of consuming a healthful diet for the prevention of chronic diseases, emphasizing a plant-based diet rich in whole grains, fruits, and vegetables, limits the nutrient selection that would be obtained from an even wider variety of foods and food groups. Specific essential fatty acids, and certain minerals (calcium, zinc, selenium) and some vitamins are far less nutrient dense

in foods of vegetal origin, setting a dilemma between consuming for nutrient adequacy and prevention of degenerative disease. Two nutrients with accentuated requirement levels in later life – vitamin D and calcium – have so few rich dietary sources that the elderly may be able to afford or assimilate, that supplemental forms will most likely be required.

## Future Considerations

The DRI recommendations are specifically derived for the populations of the US and Canada in North America. The RNI of the UN System are meant to be universal across the entire world. With respect to meeting nutrient intakes, increased selection of fortified foods by older individuals may contribute to the closing of any intake gaps or deficits. Fortified food consumption, however, has a number of caveats. The need for iron is one nutrient requirement that decreases with advancing age, at least for postmenopausal women. It may actually be that both sexes would benefit from a lesser burden of exposure to the oxidant effects of iron with advancing age. Similarly, the folate requirement has been set with interest in reproductive matters (prevention of neural tube defects), which are of no biological relevance in later life. Some, as yet inconclusive, evidence that colonic and prostatic tissues may receive dangerous proliferative stimulation from folic acid, the pharmaceutical form of the vitamin, has been reported. On the safety side of the equation, however, the effective upper tolerable levels for certain nutrients in later life may prove to be lower than those for younger members of the adult population.

The slight majority of the living elderly are currently to be found in the low income, largely tropical regions of the world in which 80% of the global population reside; this shift is due to rise rapidly over the next two decades. With specific reference to low-income societies, a number of caveats apply to the estimation of nutrient intake recommendations for the elderly across the world. If the “applies only to healthy individuals” disclaimer were applied to the developing world, then virtually no older people would qualify as eligible for coverage by any nutrient recommendations system. However, rather than abandon the effort for nutrient intake guidance, an attempt should be made to take into account the influences of life-long climatic issues (heat, humidity) and ecological factors (parasites, recurrent infections) on nutrient needs in later life.

Nature *versus* nurture issues will also continue to be debated with regard to nutrient requirements, especially in later life. The revelation of the human genome (complete genetic code), has given rise to the issues of ‘nutrigenomics’ and ‘nutrigenetics’; theoretically, it could soon be possible to understand individual variation in needs for and tolerances of essential and nonessential nutrients and dietary bioactive substances. The significance of this potential for the already aged person, however, is likely to be limited for two reasons. First, the accumulative effects of nutrient imbalance will already have been established. Second, the economic and intellectual wherewithal to access and execute such individualized prescriptions for nutrient intakes and dietary patterns will likely escape the majority of older persons with limited financial means. Hence, further refinements in recommended intakes for older persons are likely to remain at the public health level for this segment of the population, and will involve establishing evidence that increased intakes of specific nutrients and will have health-protective effects or function-enhancing properties.

### The Aging of the Population and its People

The maximal human life span is approximately 120 years. Approaching this degree of longevity, however, was not a prominent feature in the evolutionary phases of our species, *Homo sapiens*. The imperative was to survive the various mortal hazards long enough to reproduce and provide initial care for the offspring. The twenty-first century has ushered in an unprecedented longevity. The life expectancy of infants born today in Western Europe or Japan is more than 75 years. The most rapidly increasing population segment in the world today is the centenarian. By the year 2020, there will be more than 1 billion people older than 60 years of age, constituting 13.3% of the global population, and three-quarters of them will be living in developing countries.

Many people are living a long time, but not all of them are healthy and functional throughout their lifespan. Chronic disability and the cost of health services and custodial care are a growing burden on the economies of developed and developing countries alike. To understand the pathological aspects of advancing age, the normative pattern of changes in physiological function in older persons is an essential benchmark.

### The Nature of Senescence

Aging has been described as “a series of time-related processes that ultimately bring life to a close,” that is, a process of physiological ‘wearing out.’ Physiology is the basis of human functionality as well as of our susceptibility to disease. The late gerontologist, Nathan Shock, established the principle of a progressive decline in physiological reserves as a consequence of ‘normal’ aging, recognizing that the rate of decline differed markedly among the body’s organ systems. In fact, one cannot really separate the concept of the physiology of older persons from the physiology of the aging process itself. Similarly, the high prevalence of chronic diseases in older persons challenges our ability to discriminate ‘normative’ senescence from pathophysiological changes.

The origin of physiological changes in older persons begins within the domain of cellular senescence. The extension to tissue and organ levels originates in what we interpret to be the physiological changes of human aging. Major advances in our cellular and molecular understanding of basic aging processes have been made in recent years.

### **Cellular Senescence**

In most tissues, with the notable exception of neural tissue, healthy cells are replicating cells, which are capable of mobilizing at least 20 enzymes and proteins that must be preassembled to initiate deoxyribonucleic acid (DNA) synthesis for cell division. An irreversible state of growth arrest known as replicative senescence is the fundamental basis of cellular aging. Such senescent cells remain viable and metabolically active, but their genomic function and protein expression are distinct from that of normal, proliferating cells. Iron accumulates in senescent cells, possibly contributing to the greater oxidative stress and cellular dysfunction seen in senescent cells. Senescent cells also express proinflammatory enzymes, an internal process that could possibly contribute to the aging process; intercellular adhesion molecules, which are part of the inflammatory response, are overexpressed in association with senescent cells and aging tissue.

### **Telomeres and Telomerase**

Telomeres are small units composed of the tandem DNA repeats and associated proteins, which cap the end of linear chromosomes and are responsible for maintaining chromosome length. They provide stability to the chromosome and protect against DNA loss associated with cellular replication. The mechanism of replicative arrest of senescent cells has been related to changes in the function of telomerase, a nuclear enzyme that synthesizes and maintains the telomeres. Shortening and uncapping of these structures, related to the number of past cell divisions, renders the DNA strand incapable of replication.

### **Apoptosis**

Another factor involved in aging at the cellular level is the orderly 'retirement' of cells. For every cell that divides in, another would somehow have to make space for the extra cell in order to maintain numerical stability in the organ. This is achieved by a process of programmed cell death, known as 'apoptosis.' Cell senescence disrupts these apoptotic processes. Necrosis, by contrast, is cell death due to injury or noxious stimuli. Diseases of aging may favor the necrotic process.

### **Mitochondrial Senescence and Oxidative Stress**

The intracellular mitochondria, organelles involved in energy metabolism, are central to the process of cell senescence. They are also involved in regulating thermogenesis, calcium buffering, and integrating apoptosis. With aging, mitochondria become less efficient, partly due to mutations in the cell nucleus, derepressing the expression of proteins that compete with mitochondrial function. This disrupts energy metabolism for the cell and makes the mitochondria more porous, releasing reactive oxygen species into the rest of the cell. The mitochondrial production of reactive oxygen species is inversely proportional to longevity in animals. The oxidative activity also damages the mitochondria themselves. Mitochondria have their own DNA strands, and these accumulate mutations with age. In tissues dependent on progenitor (stem) cells, mitochondrial DNA mutations can disrupt replication.

Free radicals and reactive oxidative species can produce mutations in nuclear material and oxidize proteins and lipids throughout the cells. Aging involves an accumulation of oxidative damage at the cellular level, if not an increase in its intensity as well. The thiol-containing antioxidant mechanisms, typified by glutathione but represented by a number of sulfur-containing species, represent an important buffer against intracellular free radicals, but decline with age due to downregulation of their synthetic enzymes. Confirming the cellular trend to oxidative stress in aging cells, clinical biomarkers of oxidation, and antioxidant mechanisms reveal that systemic oxidative stress increases with aging characterized by lower concentrations of vitamins E and C and carotenenes as well as lower activities of Cu–Zn-superoxide dismutase, catalase, and glutathione peroxidase.

## **Physiological Changes Occurring in Tissues and Organ Systems with Human Aging**

Physiology has classically been organized around organ systems. According to this convention, the important features of the age-associated changes are enumerated and synthesized, with implications for human nutrition.

### **Integumentary Tissues**

The integumentary tissues (skin, hair, and nails) cover and protect the body. Two of the more classical and reproducible manifestations of aging can be seen in this system. The depigmentation of hair to gray or white is an almost universal aging effect given its sufficient survival. Wrinkling of the skin, due to alteration in connective tissue composition, is another consequence of aging; it should be assessed by the changes in skin texture only in the nonsun-exposed regions of the body. Beyond the cosmetic consequences of the aging integumentary tissues, wound healing is a health-relevant consideration. Healing of wounds is slower with

increasing age, but the resulting scars have the same tensile strength. Reduced recruitment of vessels of the microvascular is a function of aging.

The skin is an endocrine organ. Vitamin D is produced from the conversion of 7-hydroxy-cholesterol to cholecalciferol in the dermis of the skin. The efficiency of vitamin D decreases with age, such that older persons need a longer exposure to solar radiation to produce a given quantity of the vitamin.

### Pulmonary and Respiratory System

Compliance of the chest wall changes with age, which gets stiffer and less compliant. The muscular force of the diaphragm is reduced with advancing years. The combination of these two factors reduces the maximal amount of air that can be moved into and out of the lungs. This diminution in the so-called forced vital capacity of the lungs occurs as one gets older. There is less compliance, less recoil, and greater dead space. The original lung capacity, however, is sufficient to allow for sufficient gas exchange throughout life in the absence of underlying pulmonary disease. Nonetheless, the longitudinal Framingham Heart Study found an association between decrease in lung capacity and all-cause mortality.

The hygiene of the respiratory airways is somewhat compromised by a decreasing function of the microcilia of the bronchial epithelial cells. Because this mechanism is used to clear microbial pathogens, it has a direct influence on host defenses. Finally, because the basis of the respiratory system is an exchange of gases (oxygen, carbon dioxide, trace gases) with the bloodstream, any cardiovascular changes involving the side chambers of the heart will influence the overall gas exchange efficiency for the body.

### Cardiovascular and Circulatory System

For this system, it is necessary to separate the aging effects on the cardiac muscle and its apparatus from the aging of the vessels of the circulatory system, which transports blood to and from the heart. A characteristic of aging is a diminished resting cardiac output, which can have the combined bases of lower force of the cardiac muscle and a lesser oxygen demand for metabolism with diminished active cell mass. Aging of the myocardium reduces its capacity for cellular repair and replacement. With aging, elevations of noradrenaline (norepinephrine) associated with downregulation of  $\beta$ -1 receptors mimic the process of the failing heart. The compliance of the arteries emanating from the heart decreases with age. Stiffening of these vessels produces a progressive rise in the systolic blood pressure.

It is the circulation through smaller blood vessels and the generation of new vessels (neovascularization) that is a major concern with advancing years. The process of angiogenesis, through which new blood vessels are formed, is impaired during aging. The integrity of endothelial cells lining the vessels, the cascade of coagulation factors, and growth factors and neurochemical mediators, and their respective receptors are all altered by aging in the neovascularization processes.

### Oral Cavity and Alimentary Tract

The digestive tract is subject to functional changes with aging. Beginning in the oral cavity, loosening and loss of teeth is a frequent companion of aging. Saliva secretion decreases leading to relative degrees of xerostomia or dry mouth.

Reduced parietal cell function develops in older persons, but prior *Helicobacter pylori* infections are now thought to be a major cause of hypochlorhydria in later life. An important nutritional consequence of reduced gastric acid secretion is a lesser biological availability of iron. Because iron stores are generally replete in both men and women in later life, this has little practical nutritional impact. The reduced secretion of gastric intrinsic factor, however, contributes to vitamin B<sub>12</sub> deficiency, which is an important nutritional problem of older persons.

The capacity of the liver for biliary secretion and the pancreas for digestive enzyme and bicarbonate secretion begins adult life with a >90% excess of the necessary minimum. Secretory function declines with increasing age, but rarely falls below the minimal reserve capacity. The metabolic and detoxifying capacity of the human liver also has a reserve capacity and is not usually compromised by normal aging.

Intestinal motility is reduced with aging as a result of functional changes in the visceral nerves. With decreased transit, the residence time of the chyme on the absorptive surfaces is longer, compensating for any senescence in the mucosal uptake itself. The reduction in motility produces the most noticeable and notorious of the manifestations of intestinal health in older persons, namely reduced frequency of defecations.

### Musculoskeletal System

Bone mineral content declines with age; this aging process is known as 'osteopenia.' (It should be distinguished from the related pathological process in which bone architecture is altered, producing 'osteoporosis.') From the peak in the third and fourth decades, a 30% average decline in bone mineral density occurs through the ninth decade. In women, there is well-characterized acceleration of the rate of bone mineral loss immediately following the menopause. Decreasing levels of anabolic hormones may be associated with musculoskeletal atrophy and decrease in function that is observed in older women. This change in skeletal mineralization with aging is not associated with any apparent change in vitamin D nutriture as reflected in circulating levels of the vitamin.

The joints of the body undergo changes with the senescence of replacement of the cartilaginous substance, complicated by the pathological effects of cumulative use over the life span.

Recently, increasing attention has been given to the loss of muscle strength and substance with increasing age. Sarcopenia loss of lean body mass skeletal muscle mass replacement by fat mass decreased creatinine-to-height ratio in normative aging in healthy subjects diminished grip strength is a function of age. Reduction in muscle mass (sarcopenia obesity) is an important determinant of physical function and metabolic rate.

### **Renal and Urogenital System**

Renal creatinine and inulin clearance decreases with aging have been demonstrated for decades. These functional changes in filtration are associated with changes in the glomerular structure in the kidney. Circulatory senescence decreases blood flow to the kidneys, which further reduces the efficiency of renal clearance. The reserve capacity of these organs is such, however, that age-associated glomerular decline per se does not compromise the net excretion of nitrogenous waste.

Urine flow at the outlet is another aging consideration. The male urogenital system undergoes a characteristic aging change in the hypertrophy of the prostate gland, associated with decreased secretion of prostatic fluid. The anatomical consequence is a constriction in the passage through which urine flows from the bladder.

### **Gonads and Reproductive System**

It has been aptly stated by Harman that: "It is clear that aging results in alterations of endocrine physiology, which in turn appear to contribute to development of the senescent phenotype." Aging is associated with a decrease in pituitary hormone secretions. This decline explains, in part, the reduction in gonadal hormone production with aging. Primary aging of the testes and ovaries themselves accounts for the remainder of the changes. As the ovaries have a finite number of eggs, ovulation can only continue through the number of cycles that correspond to the original store of ova. Menopause ensues with the characteristic cessation of estrogenic hormone secretion. In both sexes, gonadal androgenic hormone production declines with consequent effects on libido.

### **Endocrine Systems and Metabolism**

As stated above, the pituitary gland is the hub of endocrine regulation. Important among the decline stimulation within the axis is that growth hormone (GH) secretion declines with increasing age, a condition termed 'somatopause.' The changes in the GH/insulin-like growth factor axis with aging produce changes in function, metabolism, and body composition analogous to the pathological GH deficiency seen in younger adults. Another change with age is the efficiency with which physical activity stimulates the secretion of GH.

The availability of hormones is not the only variable in endocrine signaling. Cellular and intracellular receptor function is complementary. An attractive explanation for the disordering of hormonal axes is oxidative damage to cell membranes, compromising the function of receptors.

Basal and resting metabolism and diet-induced thermogenesis are all reduced with increasing age. Changes in body composition, and the replacement of lean tissue with fat and the increasing visceral distribution of fat, as well as decreasing physical activity, influence these metabolic changes of aging. Basal metabolic rate declines in aging more than can be attributed to body composition changes and intracellular mitochondrial senescence may explain part of this discrepancy. For practical purposes, the standard oxygen consumption value equivalent to one metabolic equivalent, that is,  $3.5 \text{ ml min}^{-1} \text{ kg}^{-1}$ , is not appropriate for elderly people.

### **Hematopoietic and Immune System**

The formation of new red and white blood cells and platelets is one of the most proliferation-dependent physiological processes of the body. The various classes of circulating white cells are the underpinning of the host defense system, together with tissue macrophages, hepatic proteins, and the alimentary tract's mucosa.

#### **Hematological Aging**

The blood-forming organ is the bone marrow. Aging is associated with fatty infiltration of the marrow spaces in the long bones, but enough marrow remains to support the turnover of erythrocytes and red blood cell lines. The circulating red blood cell mass neither changes normally with advancing age nor does the normative peripheral white cell count or platelet number. As noted, iron stores tend to be abundant in later life; nutritional problems influencing red blood cell production are based on alterations in gastric function (vitamin B<sub>12</sub> malabsorption), which result in a macrocytic (megaloblastic) anemia.

#### **Immunological Aging**

Circulating phagocytic white blood cells counts do not reduce with aging but aging does influence the innate host defense system. Mucosal barrier functions are influenced by aging of the gut in its interaction with microflora. Although not reduced in number, aged macrophages and neutrophils have blunted intracellular signaling by specific receptors, decreased metabolic functions, and

impaired bacterial killing. Production of superoxide anion, chemotaxis, and orderly apoptosis of neutrophils is also disrupted by the disordered signaling. The tumor cell-destroying capacity of natural killer cells in the elderly is diminished.

More profound changes occur in the adaptive immune functions, which rely on the memory (T-cell) lymphocytic cell line. Life-long antigen exposure induces increases in the number of memory T-cells, but with enhanced reactivity against self-antigens, priming the individual for autoimmune disease. In healthy adults, immunoglobulin A concentration increases by  $0.2 \text{ g l}^{-1}$  per decade throughout life. The T-lymphocytes, however, respond more poorly to ongoing antigen assault in later life. Thymic involution associated with neural and hormonal changes of aging is an impediment to T-cell maturation in older persons. The basis of intrinsic function deficits of memory cells, however, has been ascribed to defective signaling and includes hyporesponsiveness to mitogen-stimulated proliferation and decrease in genetic suppression, allowing increased stimulation of inflammatory cytokines; the balance between pro- and anti-inflammatory cytokines shifts with aging, favoring the inflammatory pole, especially with the greater expression of interleukin 6. This has a negative systemic effect on bone metabolism, as well as dysregulating overall immune function.

Aging of mitochondria in the immune cell lines produces increased intracellular reactive oxygen species burdens. Finally, there is diminished programmed death (apoptosis) of immune cells and dysregulation of apoptosis-dependent functions.

### Central and Peripheral Nervous System

The integration of all senses and origins of all systemic coordination is a function of the brain and central nervous system. This is the one system in which proliferation of the primary cells (neurons) is not an issue after early childhood, although the supportive, nerve-tending (glial) cells continue to depend on replication and apoptosis for normal function.

#### Central Nervous System

The neurons of the brain continue to divide only through to the second year of life. Thereafter, the goal is to preserve the number and health of the cerebral nerve cell mass. Myelination of axons of nerve cells must be maintained throughout life. This is the function of the supporting cells (oligodendrocytes), which for more than 40 years continue to differentiate into myelin-producing cells. Free radicals pose a threat to these axon-tending cells, whose metabolic demands for producing the brain's cholesterol and maintaining its array of myelin sheaths render them particularly vulnerable to stress.

Positron emission tomography imaging of the aging brain has revealed and mapped the plethora of changes in blood flow and neurotransmitter metabolism that occurs with advancing years.

#### Special Senses

The special senses related directly to the cranial nerves (vision, hearing, taste, and smell) experience age-related change. With respect to vision, the most typical of all biological aging changes is presbyopia, or the loss of accommodation function for the ocular lens with loss of capacity of the associated musculature. The consequence is loss of near-vision, which leads to the need for reading glasses or bifocal spectacles. A more important aging change related to the lens is the opacification that leads to cataract formation. The eye is designed to translate light energy into visual images, but the energy of light, particularly the ultraviolet  $\beta$ -rays of solar energy, damages ocular tissue. Thus, there is as a strong environmental component to the disarranging of the laminar stacking of the fibrillar proteins of the lens, which imparts its clear, transparent basis; consumption of diets high in antioxidant vitamins has been associated with the delay in cataract formation.

Age-related hearing loss is a feature of biological aging. It affects the cochlear neural structures and leads to loss of acuity, especially for higher pitched tones. It is speculated that apoptosis of the most vital neural cells drives this hearing loss, based on mutations in the mitochondria due to life-long free-radical stress.

Taste and smell acuity decline with aging, both in sensitivity and in accuracy of recognition. Because these combined senses account for the recognition of flavors, their diminution with age could affect appetite and reduce the enjoyment of meals.

#### Cognitive Function

The intellectual, reasoning, and memory functions of the cerebral cortex decline with increasing age. This has been a universal observation in general elderly populations. The debate is whether this is a consequence of neurodegenerative diseases (pathological change) or a biological correlate of aging (senescence). Continued intellectual stimulation has been posited as an approach to retard cognitive decline, and a role for B-complex vitamins and antioxidants has been advanced.

#### Peripheral Nervous System

Vibratory perception in the peripheral extremities is the classical index of peripheral nervous decline with aging. Less well appreciated is the effect of aging on pain perception, in which there can be a numbing of sensation or, less commonly, an accentuation of perception. Pain perception from the visceral organs is often dulled, which can have adverse implications for the early detection of organic diseases. All of the peripheral nerve dysfunction can result from the compensatory sprouting of axonal limbs to compensate for the loss of motor neurons. This is well directed at first, but with further aging, the synaptic connections are poorly directed and motor function suffers as a consequence.

### Drug Metabolism

The metabolism of drugs and pharmacological agents is not the purview of any single organ system. Older persons tend to be prescribed increasing numbers of medications with advancing age. Important changes in drug metabolism occur with aging. Metabolism and disposition of drugs change with age. This involves age-associated decrease in the function of some, but not all, cytochrome P-450 enzymes. Among the pharmacokinetic and pharmacodynamic changes that occur with advancing age are reductions in renal and hepatic clearance and an increased effective half-life of lipid-soluble drugs. The older population shows increased sensitivity to some psychotropic drugs and anticoagulants, with the frail elderly being more susceptible than healthy elders.

### Synthesis and Conclusion

The number of older people is increasing in all regions and all societies of the world. Advancing age produces senescent changes in cellular function that are reflected in a declining capacity of all physiological systems. The increased prevalence of disease in older population aging is a major risk factor for disease but does not necessarily lead to age-related diseases.

All physiological systems are intrinsically interrelated in maintaining the health and function of the organism. Aging is associated with a loss of complexity in the dynamics of many physiological systems. It has been speculated that the basis for the syndrome of frailty in older persons may result from a reduced ability to adapt to internal and external stresses of daily life due to the loss of dynamic coordination among the interrelated physiological systems.

The alterations in physiological functions with aging have important implications for absorbing, retaining, and utilizing nutrients. The extent to which dietary patterns and nutrient intakes are accelerating or retarding the rates of functional decline is a matter of ongoing investigation in gerontological nutrition and physiology.

The subject of energy metabolism in human pregnancy has received extensive consideration for more than 60 years, dating back to early work that assessed the contribution of fetal metabolism to the overall energy costs of pregnancy. Since then, the emphasis of much work has been on separating and quantifying the different components of gestational energy needs and on establishing appropriate recommendations for the energy requirements of pregnant women, with the intention of quantifying average amounts. Deviations from average values were mostly regarded as undesirable biological or measurement noise that needed to be overcome by studying large samples of women to get a more precise estimate of the mean values. These interindividual variations in the metabolic responses to pregnancy are increasingly recognized as biologically significant ‘plasticity’ that has true adaptive value in enabling women to carry a pregnancy to term under a wide range of nutritional conditions. The shorter- and longer-term consequences of such adaptations are being explored as part of fetal and infant origins of adult disease hypotheses.

## Extra Energy Costs of Pregnancy

The question of how much extra dietary energy a pregnant woman needs is closely linked to the question of the amount of weight she should gain during pregnancy. This in turn is linked to her age and to her prepregnant body mass index as a proxy for energy status.

Hyttén and Leitch's theoretical estimations of the overall energy costs of human pregnancy published more than 30 years ago have subsequently been experimentally validated as reasonable average values, and they have been adopted by many national and international bodies as a partial basis for developing recommended energy intakes in pregnancy. The costs can be divided into three main components: the energy deposited as new tissue in the conceptus, the energy deposited as fat, and the energy required to maintain this new tissue.

### Tissue Deposition

Weight gain during pregnancy consists of the fetus, placenta, and amniotic fluid (the products of conception) and the extra growth of several maternal tissues. The deposition of fat in pregnancy is presumed to help meet the extra energy demands of lactation. The total energy deposited as new tissue, excluding maternal fat, averages approximately 49 MJ (11 700 kcal). If an average maternal fat gain of 2.6 kg is assumed, then the estimate of the total energy deposited as new tissue during an average pregnancy is approximately 174 MJ (41 600 kcal; Table 1).

### Maintenance Energy Costs of Pregnancy

Because of the increase in tissue mass, the body's oxygen consumption also increases during pregnancy. Estimates suggest that the increase in oxygen consumption is equivalent to an extra 187 (45), 414 (100), 620 (148), and 951 (230) kJ day<sup>-1</sup> (kcal) at 0–10,

10–20, 20–30, and 30–40 weeks of gestation, respectively. The total maintenance cost for an average human pregnancy is approximately 150 MJ (35 800 kcal); (Table 2).

### Theoretical Total Metabolic Costs of Pregnancy

Compared to many other mammals, humans have a relatively small and usually single infant, which develops during a long gestation period. The energy stress to the mother is therefore low per unit time. The 49 MJ of energy deposited as the products of conception represents only 4 or 5 days of food intake for the mother. Humans also differ from most other mammals because their large fat stores can help meet some of these costs. The theoretical total metabolic costs (i.e., due to extra tissue and increased metabolism) of pregnancy are approximately 335 MJ (80 000 kcal), or 1.25 MJ day<sup>-1</sup> (300 kcal). This value does not make any allowance for changes (increases or decreases) in energy expended on physical activity. It is assumed that the majority of the energy costs of human pregnancy are met by behavioral adjustments in energy metabolism rather than increased energy intake. This assumption has formed the basis for energy intake recommendations, some of which are summarized in Table 3. It should be noted that the 1985 estimates used by World Health Organization (WHO)/Food and Agriculture Organization (FAO)/United Nations University (UNU) are under revision. Future recommendations may separate the obligatory costs (e.g., by fixed increments for basal metabolic rate (BMR) and tissue deposition) and differences in physical activity (based on PAL values).

### Longitudinal Studies of the Energy Costs of Pregnancy

#### Fat Deposition

The increase in maternal fat stores is by far the largest contributor to the energy cost of tissue deposition. It is also the most variable. Although the average increase for a well-nourished woman who has an uncomplicated pregnancy and healthy infant is approximately 3 kg, a large number of studies have reported ranges of –2 to 8 kg and standard deviations of 2–4 kg. There is also a wide range in fat deposition between different populations, particularly when those from developed and developing countries are compared. Fat is very energy dense and therefore changes in body fat stores have a large impact on the energy costs of pregnancy. A loss of 2 kg saves approximately 78 MJ (18 600 kcal), whereas a gain of 8 kg costs approximately 312 MJ (74 600 kcal). Women most likely to need an energy reserve to help meet the costs of lactation are often those who are least able to deposit spare energy as fat in pregnancy. Conversely, women who store large amounts of fat during pregnancy are least likely to need to use it during lactation. They are often able to increase food intake and/or decrease physical activity instead. Studies have shown that excess energy intake during pregnancy results in excess maternal weight (and fat) gain. Postpartum retention of excess fat has implications for the development of obesity and its comorbidities such as type 2 diabetes.

#### Basal Metabolic Rate

The cumulative increase in BMR can comprise a large part of the total energy costs of pregnancy. Although 150 MJ is a good estimate of the average energy cost of maintenance for a well-nourished woman, there is a very wide range. This has an important influence on the extra daily requirements for individual women. Studies in which BMR has been measured every 6 weeks from prepregnancy to 36 weeks of pregnancy have shown very marked differences. In some women, there is the expected response to pregnancy – an

immediate and progressive increase in BMR. In other women, BMR actually decreases or increases only slightly in the early stages of pregnancy and does not increase substantially until late gestation. This offsets the later increase in BMR such that there is actually a slight net saving of energy over the entire gestation period in some of these 'energy-sparing' women. The total net cost of maintenance, estimated as the cumulative area under the curve represented by the rise in a mother's BMR above the prepregnancy baseline metabolic rate, is negative or only very small. Data indicate that this between-subject variability is found in women from both well-nourished and marginally nourished populations. However, 'energy-sparing' and 'energy-profligate' responses dominate in marginally and well-nourished women, respectively. There is a more than fivefold range between the most energy-profligate and the most energy-sparing women.

In addition to the wide variability in changes in BMR between individual women, there are also wide variations between different populations. Well-nourished affluent women from developed countries tend to show an energy-profligate increase in BMR. In marginally nourished thinner women from developing countries the increase in BMR is delayed and/or preceded by a decline in early pregnancy. The total maintenance costs of pregnancy in these studies range from +210 MJ (+50 000 kcal) to -45 MJ (-11 000 kcal).

### Diet-Induced Thermogenesis

A reduction in diet-induced thermogenesis (DIT) may be a mechanism by which energy is saved during pregnancy. However, when expressed as a proportion of energy intake, DIT remains essentially unaltered during pregnancy and any changes are small and unlikely to be biologically significant.

**Table 3** Examples of current recommendations for energy intakes during pregnancy

	<i>Trimester(s)</i>	<i>Increment, MJ day<sup>-1</sup> (kcal day<sup>-1</sup>)</i>	<i>Total for pregnancy, MJ (kcal)</i>	<i>Qualifying comments</i>
FAO/WHO/UNU (1985)	All	1.20 (300)	336 (80 300)	For healthy women who reduce activity Energy and protein requirements are undergoing revision (interim report published 2004)
	All	0.84 (200)	235 (56 150)	
United Kingdom (1991)	Third	0.80 (190)	74 (17 000)	Underweight women and those not reducing activity may need more
United States and Canada (2002)	First	Adult EER+0		For women aged 19–50 years
	Second	Adult EER+160 kcal (8 kcal week <sup>-1</sup> ×20 weeks)+180 kcal		EERs for pregnant adolescents are based on EER for 14- to 18-year olds
	Third	Adult EER+272 kcal (8 kcal week <sup>-1</sup> ×34 weeks)+180 kcal		EER is based on total energy expenditure in the nonpregnant state; increments for pregnancy are 8 kcal week <sup>-1</sup> for total energy expenditure and 180 kcal day <sup>-1</sup> for tissue deposition

EER, estimated energy requirement.

### Energy Cost of Activities

Results from a number of longitudinal studies have shown that the cost of non-weight-bearing activity changes little until very late pregnancy. From approximately 35 weeks, the gross costs (which include changes in BMR) increase by approximately 11% and net costs by approximately 6%. The gross and net costs of weight-bearing exercise (treadmill walking and standardized step testing) remain fairly constant during the first half of pregnancy and then increase progressively by approximately 15–20% at term.

### Behavioral Changes in Physical Activity

It has frequently been assumed that a behavioral reduction in the energy expended on physical activity helps to counteract the increases in expenditure due to increased body weight, and in some women this leads to saving of energy that largely meets the costs of pregnancy. However, although relatively small changes in activity patterns can potentially result in significant energy savings, there is little evidence that this occurs to a large extent. A possible reason for this is that affluent women are habitually so sedentary that there is little scope for further reduction. In contrast, in developing countries habitual levels of physical activity are high and there is therefore more potential for behavioral reductions. However, many women are likely to be unable to reduce their physical activity because of the constraints imposed by a subsistence livelihood, where farm work is obligatory for survival.

This topic has been one of considerable debate in recent years, particularly because longitudinal studies that have measured total energy expenditure with doubly labeled water have shown that many women increase the energy expended on physical activity during pregnancy, and that any decreases are not sufficient to counterbalance the energy costs of pregnancy due to tissue (fat) deposition and maintenance energy metabolism. It has been recommended that the data used by the WHO should be revised to take account of changes in energy expended on physical activity and to separate these energy costs from those of maintenance and tissue deposition. The Dietary Reference Intakes for the United States and Canada have already incorporated these changes (Table 3).

### Between-Country Comparison of the Metabolic Costs of Pregnancy

The average costs across different populations result in a wide range of energy needs from –30 MJ (–7000 kcal) to 523 MJ (125 000 kcal). Studies found that the average costs in the well-nourished groups were similar to the current international assumption of 336 MJ (80 000 kcal). These studies have also shown that the amount of prepregnancy body fat is strongly correlated with both the maintenance costs and the total metabolic costs of pregnancy. The combined costs of maintenance, fat deposition, and conceptus across studies from different countries drawn from emerging and affluent nations show that the energy cost of fat deposition also varies according to the state of affluence and is positively correlated with variations in maintenance requirements.

This flexibility in energy metabolism acts in a protective manner, with undernourished women showing significant energy-sparing adaptive strategies that tend to normalize energy balance. Body fat content is one of the measures of fitness for reproduction; fertility is suppressed in undernourished women. However, future unfavorable conditions cannot be anticipated and pre- or early pregnant fatness may be indicative of overall nutritional status and energy balance during pregnancy.

These relationships suggested the existence of a mechanism that can monitor the mother's prepregnancy energy status and adjust the homeorhetic changes in maternal metabolism accordingly. The discovery of leptin provides a plausible mechanism by which peripheral energy status can be centrally monitored and may coordinate the metabolic responses to pregnancy. It is clear that in addition to its role in the regulation of adipose tissue, appetite, and metabolic rate; leptin plays a significant role in several components of the reproductive axis. Evidence suggests that it plays a key role in pregnancy, including the modulation of fetal growth.

### Individual Variability in the Total Energy Costs of Pregnancy

Because of the marked differences between individuals in the different components of the energy costs of pregnancy (changes in BMR, body fat, and energy expended on physical activity), the total energy costs, and therefore energy requirements, are also variable. Studies of well-nourished women indicate that the total extra energy costs of pregnancy average 418 MJ (100 000 kcal), considerably higher than the estimates in Table 3, and there is a large range from 34 to 1200 MJ (8000–287 000 kcal). These values are probably representative of many women in developed countries. They show that it is impossible to prescribe energy intakes for individual women because it cannot be predicted how they will respond metabolically (BMR and fat) or behaviorally (physical activity and food intake) to pregnancy.

### Implications of Energy-Sparing Adaptations for Mother and Infant

Human energy metabolism is particularly adaptable during pregnancy, with early/prepregnancy body 'fatness' being a major determinant. The adaptive strategies that maintain energy balance seem to be a coordinated biological system in which energy-sensitive modulations in metabolism help to sustain human pregnancies and protect fetal growth in highly marginal environmental circumstances. However, the existence of such mechanisms should not be misinterpreted as suggesting that maintenance of optimal

nutritional status in pregnant women is not a priority because the adaptive mechanisms of the women will cope. It cannot be assumed that pregnant women will have energy-sparing alterations in metabolism and/or that physical activity decreases. Any adaptations that do occur should not be overinterpreted as suggesting that this is the case. The possible long-term detrimental effects must also be considered. The biochemical and physiological processes that are downregulated in the mother causing the suppression in BMR are unknown and there may be long-term consequences to her health and that of her infant.

The associations between maintenance needs, pregnancy weight gain, and prepregnant fatness indicate that a target weight gain of 12.5 kg is associated with maintenance costs of approximately 160 MJ (38 000 kcal). Although individual women or populations may have lower maintenance requirements, these may be associated with inadequate weight gain and low-birth-weight infants. A major determinant of birth weight is maternal weight gain, and the single most important determinant of infant survival is birth weight. Although birth weight is relatively well preserved at different planes of nutrition, weight alone is an inadequate measure of an infant's overall condition at birth. Even subtle nutritional influences on the fetal environment may have long-term consequences.

As mentioned previously, pregnancy weight gain is a critical component of the overall energy costs of pregnancy. The issue of whether pregnancy weight gain drives, or is driven by, the metabolic changes is interesting, but it is clear that women who consume marginal diets have small weight gains and that women from poorer countries have much lower percentage weight gains despite having lower initial body weights. Extremes of weight gains during pregnancy may have several consequences, which may or may not be mediated directly through an effect on birth weight. Other effects of weight gain may be more subtle and may be mediated through qualitative effects on fetal growth and development at different stages of intrauterine growth. There is a considerable body of evidence that suggests that many chronic adult diseases have their origins in fetal and infant nutrition, which has refocused attention on early life as a critical period in human development.

## Key points

- To review recommended macronutrient and micronutrient intakes during pregnancy
- To identify research gaps and opportunities.

## Introduction

Maternal nutrition during pregnancy is a critical public health priority across the globe. The first 1000 days, starting at conception, marks a time period of enormous potential but also vulnerability. Inability to meet nutrient requirements during pregnancy can have serious short- and long-term effects on maternal and child health and development (Victora et al., 2021). Indeed, it is now understood that epigenetic effects of nutrient imbalances during pregnancy can affect the health of the offspring for the remainder of their life. Most of the research that provides information on nutrient requirements during pregnancy has been conducted in high-income countries, although trials in low income countries have been important in revealing the adverse effects of poor maternal nutrition and the benefits of nutrient interventions. There is an unacceptably high rate of pregnancy complications many of which may be prevented by improved maternal nutrition, including anemia, low birth weight, birth defects, and preeclampsia.

## Recommended nutrient intakes for pregnancy

The most recent and best-described recommended intakes of nutrients during pregnancy are those of the Institute of Medicine, developed for the United States and Canada, which are the main set presented in this article (Table 1). Many other countries have their own sets of recommendations, as do organizations such as the Food and Agriculture Organization (FAO)/World Health Organization (WHO) and the European Economic Community. However, many of these, including FAO/WHO, do not provide EARs.

**Table 1** Recommended Dietary Allowances (RDAs) for nonpregnant women and Estimated Average Requirements (EARs), RDAs, and upper limits of nutrients for pregnant women.

	<i>AI/RDA,<sup>a</sup> adult nonpregnant woman</i>	<i>EAR, pregnancy</i>	<i>AI/RDA,<sup>a</sup> pregnancy</i>	<i>Upper limit, pregnancy</i>
Energy (kcal)	2000–2200 <sup>b</sup>	+340 (trimester 2) +452 (trimester 3)	—	—
Energy (MJ)	8.37–9.21 <sup>b</sup>	+1.42 (trimester 2) +1.89 (trimester 3)	—	—
Protein (g kg <sup>-1</sup> )	0.8	0.88	+1.1	None
Vitamin A (μg RAE, retinol activity equivalents)	700	550	770	3000
Vitamin D	600 IU (15 μg)	400 IU (10 μg)	600 IU (15 μg)	4000 IU (100 μg)
Vitamin E (mg α-tocopherol)	15	12	15	1000
Vitamin K (μg)	90	—	90	None
Vitamin C (mg)	75	70	85	2000
Folate (μg dietary folate equivalents)	400	520	600	1000 from fortified food + supplements
Thiamin (mg)	1.1	1.2	1.4	None
Riboflavin (mg)	1.1	1.2	1.4	None
Vitamin B6 (mg)	1.3	1.6	1.9	100 as pyridoxine
Niacin (mg NE)	14	14	18	35
Vitamin B <sub>12</sub> (μg)	2.4	2.2	2.6	None
Pantothenic acid (mg)	5	—	6	None
Biotin (μg)	30	—	30	None
Choline (mg)	425	—	450	3500
Calcium (mg)	1000	800	1000	2500
Phosphorus (mg)	700	580	700	3500
Magnesium (mg)	320	290	350	+350 from supplement
Iron (mg)	18	22	27	45
Zinc (mg)	8	9.5	11	40
Iodine (μg)	150	160	220	1100
Copper (μg)	900	800	1000	10,000
Selenium (μg)	55	49	60	400
Chromium (μg)	25	—	30	None
Fluoride (mg)	3	—	3	10
Manganese (mg)	1.8	—	2	11
Molybdenum (μg)	34	40	50	2000

<sup>a</sup>Values are Recommended Dietary Intakes (RDAs) except for pantothenic acid, biotin, and choline, where value is an Adequate Intake.

<sup>b</sup>Assuming moderately active woman. Actual requirements vary by weight and height. Requirements increase throughout pregnancy and the higher end of the range is recommended during the third trimester.

Adapted from Institute of Medicine, National Academies Press, for the United States and Canada (<http://www.nap.edu>).

The set of Dietary Reference Intake recommendations developed by the Institute of Medicine includes several values. The EAR is the intake required to meet the nutrient needs of 50% of a population group (e.g., pregnant women). It is an important value for two reasons. First, it is the value used to estimate the prevalence of inadequate intakes of a nutrient in a population group; the percentage of a group consuming less than the EAR of a nutrient is the percentage with an inadequate intake. For energy, the Estimated Energy Requirement (EER) is equivalent to the EAR because adding a margin of safety would lead to overweight. Second, the RDA is calculated by adding two standard deviations (assumed 20% of the EAR when unknown) to the EAR. The RDA should meet the requirements of 97.5% of a population group. The Tolerable Upper Level (UL) for a nutrient is the intake above which there is a risk of adverse effects. **Table 1** shows the RDAs for nonpregnant women for comparison, and the EARs, RDAs, and ULs for pregnant women.

## Energy

Maternal energy requirements increase during pregnancy due to higher basal energy expenditure as well as energy deposition in maternal and fetal tissues. Basal metabolism of the mother is higher due to the increased work by the lungs and heart and because

of the metabolism of the fetus and uterus. A longitudinal study by Butte et al. found that basal metabolic rate increased by  $10.7 \pm 5.4$  kcal per week of gestation, mostly in the second and third trimesters. On average, the fetus requires approximately  $68 \text{ kcal day}^{-1}$ . The substantial variability in basal energy expenditure among individual women is caused mainly by differences in fat-free mass (including maternal skeletal muscle mass and fetal tissue). The cumulative increase in basal energy expenditure during pregnancy is positively correlated with maternal fatness and weight gain. Energy requirements for the thermic effect of feeding are not different from those of nonpregnant women, nor is there much change in the total energy cost of activity. Although the increasing body weight of the mother means that the energy cost of each activity is higher, the net effect is canceled out by the fact that after approximately 25 weeks of gestation women tend to become less active. The longitudinal study by Butte et al. suggests that energy expenditure in physical activity decreases by approximately  $100\text{--}200 \text{ kcal day}^{-1}$  in women with a low or normal body mass index before pregnancy and by an average of more than  $400 \text{ kcal day}^{-1}$  in those with a high body mass index ( $>26 \text{ kg m}^{-2}$ ).

In deriving the recommendations for the United States and Canada, the EER during pregnancy is accepted to be the sum of the Total Energy Expenditure (TEE) of the nonpregnant woman, measured using a doubly labeled water technique, plus an estimated median change in TEE of 8 kcal per week, plus  $180 \text{ kcal day}^{-1}$  to cover energy deposited in maternal and fetal tissues. In the first trimester of pregnancy, TEE changes little and weight gain is small, so the energy requirement is increased only during the second ( $340 \text{ kcal/d}$ ) and third trimesters ( $452 \text{ kcal/d}$ ). There is no RDA or UL because energy intakes greater than the EER may lead to undesirable weight gain.

The EER for pregnancy is as follows:

Trimester 1: nonpregnant EER + 0 kcal

Trimester 2: nonpregnant EER + 160 kcal (based on  $8 \text{ kcal per week} \times 20 \text{ weeks}$ ) + 180 kcal

Trimester 3: nonpregnant EER + 272 kcal (based on  $8 \text{ kcal per week} \times 34 \text{ weeks}$ ) + 180 kcal

These formulas represent average requirements in trimesters 1 and 2. If a more precise estimate of requirements is needed at a specific stage of gestation, instead of the mean increment of 160 kcal in trimester 1 and 272 kcal in trimester 2, the actual weeks of gestation can be multiplied by 8 kcal per week.

Recently, there have been calls to provide additional guidance for women based on their prepregnancy nutritional status ([National Academies of Sciences Engineering and Medicine, 2020](#); [Most et al., 2019](#)). Prepregnancy body size may influence energy storage requirements. Most et al. suggest women with obesity do not need to increase energy intake and may even need slight reduction in intake to meet weight gain recommendations. Further research is needed to guide clinical guidance ([Most et al., 2019](#)).

## Protein

The turnover of body protein is higher after approximately 13 weeks of pregnancy, and the mother adjusts by losing less nitrogen as urea even during the first trimester. A woman who gains 12.5 kg of body weight has deposited 925 g of protein that comprises of the following components: the fetus 440 g, the uterus 166 g, expanded maternal blood volume 81 g, the placenta 100 g, and the increment in extracellular fluid, 135 g, and perhaps some additional protein in muscle. The EAR for all age groups is  $0.88 \text{ g}^{-1} \text{ kg}^{-1} \text{ day}^{-1}$  protein or 21 g of additional protein/day. The RDA is 1.1 g protein per kg per day or  $25 \text{ g day}^{-1}$ .

One-third of the total protein deposition during the 40 weeks of pregnancy occurs in the second trimester and two-thirds in the third trimester. By the end of the third trimester, the US–Canada recommendations assume that an additional consumption of 17 g protein per day is required to meet the needs for protein deposition, and as about half of this occurs during the second trimester this amounts to  $8 \text{ g day}^{-1}$ . It is also assumed that no additional protein is needed in trimester 1, but for the last two trimesters consumption of an additional  $21 \text{ g day}^{-1}$  (a total of  $1.1 \text{ g kg}^{-1} \text{ day}^{-1}$ ) is recommended.

New estimates of protein needs have recently been discussed using the new amino acid oxidation methodology ([National Academies of Sciences Engineering and Medicine, 2020](#)). Stephens et al. provides evidence to suggest increasing EAR for protein in early ( $1.22 \text{ g/kg/day}$ ) and late pregnancy ( $1.52 \text{ g/kg/day}$ ) ([Stephens et al., 2015](#)). Further research is required to confirm recommendation and to determine amino acid requirements during pregnancy ([Elango and Ball, 2016](#)). It should be noted that maternal balanced energy protein supplements are one of the recommended interventions for undernourished women during pregnancy. As highlighted in the 2021 Lancet Nutrition Series, balanced energy protein supplementation during pregnancy was associated with a 40% reduction in LBW, 61% reduction in stillbirths and a 29% reduction in SGA ([Keats, 2021](#); [Lassi, 2020](#)) in these populations.

No UL has been set for protein, including for pregnancy, in the US–Canada recommendations due to lack of data on harmful effects. However, some earlier studies noted adverse pregnancy outcomes when high-protein supplements were given to relatively well-nourished pregnant women, so caution in this regard is certainly warranted.

## Folate

Maternal folate requirements increase markedly during pregnancy due to utilization of the vitamin in cell division in the mother and fetus, single-carbon transfer reactions, and deposition in the fetus. The risk of women giving birth to an infant with a neural tube defect (NTD) is significantly reduced if women consume folic acid supplements before conception through approximately the first 4–6 weeks of pregnancy—during the time of neural tube closure. Some women are at greater risk of producing an infant with this birth defect, especially when their folate intake is rather low. Because such women are unaware of this risk unless they have had

a previous NTD delivery, the recommendation is that all women who are capable of becoming pregnant consume at least 400 µg of folic acid daily from supplements, fortified food, or both in addition to consuming food folate from a varied diet.

In pregnancy, the recommendation is for all women to consume an additional 200 µg of synthetic folic acid (equivalent to 400 µg of dietary folate due to the higher bioavailability of the synthetic form) in addition to the RDA for the nonpregnant woman of 400 µg day<sup>-1</sup>. This amount was shown to prevent plasma homocysteine from becoming elevated during pregnancy and to maintain normal folate concentration in red blood cells. The UL of 1000 µg day<sup>-1</sup>, the same as for nonpregnant women, is set to avoid potential exacerbation of vitamin B<sub>12</sub> deficiency.

In addition to its importance for lowering risk of NTDs in the periconceptional period, there is evidence that adequate folate status, which is important for maintaining normal plasma homocysteine concentrations, lowers the risk of other delivery problems and birth defects, including preeclampsia, preterm delivery, very low birth weight, club foot, and placental abruption. Currently 63 countries across the globe that include the United States and Canada have mandatory wheat flour fortification with folic acid ([Global Fortification Data Exchange, www.FortificationData.org](https://www.fortificationdata.org/)). Despite strong evidence, it is estimated that only 23% of Folic Acid-Preventable Spina Bifida and Anencephaly is being prevented through folic acid programs ([Kancherla et al., 2021](#)). Further advocacy and prioritization is required for scaling up fortification efforts to vulnerable populations.

### Other B vitamins

Several B vitamin deficiencies cause homocysteinemia, notably folic acid, vitamin B<sub>12</sub>, riboflavin, and vitamin B<sub>6</sub>. Importantly, homocysteinemia is associated with adverse pregnancy outcomes. In a large retrospective study in Norway, for example, women in the highest 25% of plasma homocysteine concentrations had significantly more placental abruption, stillbirths, very low birth weight and preterm infants, preeclampsia, club foot, and NTDs in their offspring compared to women with values in the lowest 25%. Supplementation with folic acid up to 500–600 µg day<sup>-1</sup> lowers plasma homocysteine, but few studies have been done on the other B vitamins. Of these, it is most difficult for poor women to obtain their dietary vitamin B<sub>12</sub> requirement because this vitamin is found only in animal source foods, such as meat and dairy products.

The recommended intakes of most B vitamins and choline are increased above nonpregnant values as shown in [Table 1](#). The increases are based on evidence for higher maternal requirements (in the case of thiamin, riboflavin, niacin, and vitamin B<sub>6</sub>) and for fetal and placental deposition of the vitamin (thiamin, riboflavin, niacin, vitamin B<sub>6</sub>, vitamin B<sub>12</sub>, and choline). There is growing research on the importance of choline during pregnancy for birth outcomes and child cognitive function ([Caudill et al., 2018](#); [National Academies of Sciences Engineering and Medicine, 2020](#)). Further research on potentially raising the AI for choline may be merited.

UL values, the same as for nonpregnant women, have been set for niacin when consumed as nicotinic acid in supplements based on a “flushing” reaction and for choline based on cholinergic reactions and a fishy body odor.

### Vitamin A

The increment in vitamin A requirements during pregnancy is based on the relatively small amount of the vitamin that is found in fetal liver at birth. The liver content is assumed to be 36 µg, mostly accumulated during the last 3 months of gestation. Using an estimated 70% absorption of the vitamin from the maternal diet, the EAR is 50 µg RAE above the 500 µg RAE requirement for the nonpregnant woman, and the 770 µg RAE RDA is 70 µg higher.

In wealthier regions of the world, vitamin A deficiency during pregnancy is rare. Rather, there is more concern about the potentially adverse effects of consuming excessive amounts of the vitamin. Based on the potential for retinol excess to cause birth defects (malformations), especially if high doses are consumed early in pregnancy, a UL of 3000 µg day<sup>-1</sup> is set for all women who may become pregnant as well as those who are pregnant. This intake is unlikely to be achieved with natural food, although it would be possible if large amounts of liver, foods fortified with the vitamin, or supplements were consumed. The World Health Organization (WHO) does not recommend routine supplementation of vitamin A in the prenatal period. However, vitamin A supplementation during pregnancy is recommended in areas where vitamin A deficiency is a severe public health problem (≥5% of women in a population have a history of night blindness, or if ≥20% of pregnant women have a serum retinol level <0.70 µmol/L) to prevent night blindness ([WHO, 2016](#)).

### Vitamin D

Vitamin D is important for maintaining normal blood levels of calcium and phosphate for general cell functioning and bone health. Maternal transfer of vitamin D to fetus during pregnancy is essential for acquired infant stores at birth. Those women who obtain adequate exposure to ultraviolet light do not need higher amounts during pregnancy. However, if usual intake declines below ≈150 IU (3.8 µg) per day at high latitudes (where there is little ultraviolet radiation in the winter, such as in France), evidence of low maternal 25(OH)D and infant vitamin D depletion has been observed at delivery. Among women with more highly pigmented skin, such as African Americans, or those who are veiled, the prevalence of vitamin D deficiency near term (circulating 25(OH)D < 25–50 nmol L<sup>-1</sup>) is 30–70%, compared to 5–20% in lighter skinned populations.

The effect of maternal depletion in pregnancy on fetal bone mineralization remains controversial; the Institute of Medicine committee concluded that maternal vitamin D status does not have a major influence on calcium transfer to the fetus. Poor

maternal vitamin D status in pregnancy has been implicated as a risk factor in a number of diseases of childhood and adult life, in part because risk of the diseases varies with season. These include multiple sclerosis, schizophrenia, type I diabetes and some cancers. However, a definitive link with maternal vitamin D status has not been proven.

The IOM recommendations for vitamin D were last updated in 2011 (IOM, 2011). For both adolescent and adult women is to continue to consume the amount recommended for nonpregnant women, 15  $\mu\text{g}$  (600 IU  $\text{day}^{-1}$ ). The UL of 100  $\mu\text{g}$  (4000 IU  $\text{day}^{-1}$ ) is the same as before pregnancy, and is based on the fact that this level of intake will not cause serum 25(OH)vitamin D to exceed 125–150  $\text{nmol L}^{-1}$ , which is at the high end of serum concentrations associated with the lowest risk of adverse events such as all-cause mortality.

The WHO does not recommend routine vitamin D supplementation during pregnancy (WHO, 2020, 2016; Palacios et al., 2019). Current guidelines recommend women meet requirement through a healthy balanced diet and advise that sunlight is the most important source of vitamin D. For pregnancy women with suspected vitamin D deficiency, including populations with limited direct sun exposure, WHO recommends providing 200 IU (5  $\mu\text{g}$ ) per day, which is the WHO and FAO recommended nutrient intake (WHO and FAO of the UN, 2004). Note, this is lower than the current IOM recommendations. Vitamin D requirements and supplementation remains an active area of research with critical gaps in our current knowledge.

### Vitamin C (ascorbic acid)

The EAR for nonpregnant women is based on the intake that attains the maximum neutrophil concentration of ascorbic acid. Maternal plasma vitamin C concentrations decline during pregnancy, probably as a result of normal hemodilution. Oxidized ascorbic acid is transferred from the maternal circulation to the fetus, where it is retained in the reduced form. Although vitamin C deficiency in pregnancy is rare in most situations, it has been associated with increased risk of premature rupture of the membranes and infections, preterm birth, and eclampsia. However, clinical trials have not shown a benefit of higher doses of vitamin C during pregnancy. Smokers have lower levels of ascorbic acid in their serum and amniotic fluid. Women who smoke more than 20 cigarettes per day and regular aspirin users may require twice as much, as may heavy users of alcohol and street drugs. The UL of 2000  $\text{mg day}^{-1}$  is based on prevention of diarrhea and gastrointestinal disturbances that occur with high intakes.

### Vitamin E

There is no increase in the recommended intake of vitamin E during pregnancy, so the RDA remains at 15  $\text{mg}$  of  $\alpha$ -tocopherol per day for all ages. There have been no reports of deficiency of vitamin E during pregnancy nor any evidence of benefit from maternal supplementation. The UL is 1000  $\mu\text{g day}^{-1}$  of any form of the vitamin taken as a supplement, extrapolated from data showing that high levels cause hemorrhaging in rats.

### Calcium

It is clear that changes in maternal calciotropic hormones and calcium metabolism (i.e., increased intestinal absorption and reduced urinary calcium excretion) enable the fetus to be supplied with adequate amounts of this mineral, and that little change in maternal intake is needed. Nor is there a correlation between the number of pregnancies a woman has and her risk of bone fracture. Thus, for the United States and Canada there is no increase in recommended calcium intakes for pregnancy and the RDA remains at 1300  $\text{mg day}^{-1}$  for women aged 14–18 years and 1000  $\text{mg day}^{-1}$  for the 19–50-year-old group (IOM, 2011).

The UL for calcium in pregnancy is the same as that for the nonpregnant woman, 2500  $\text{mg day}^{-1}$ . This safe level is set based on the risk of kidney stones.

The WHO however recommends daily calcium supplementation (1.5–2.0  $\text{g}$ ) for pregnant women in settings with low dietary calcium intake based on evidence of benefit for improved birth outcomes (WHO, 2016). Recent systematic reviews of controlled trials confirm that calcium supplementation reduces risk of pre-eclampsia by 55% (RR 0.45, 0.19–1.06) (Keats, 2021). However, this intervention is not widespread and there remain gaps on the ideal formulations and implementation strategies to enhance program effectiveness.

### Phosphorus

The efficiency of phosphorus absorption increases by 15% during pregnancy. The term infant contains approximately 17  $\text{g}$  of phosphorus at birth, mostly in bone and water. The physiological adaptations of the mother that increase calcium retention also help to supply the fetus with more phosphorus. There is no evidence that the EAR needs to increase over that recommended for nonpregnant women, so the RDA for women aged 14–18 years is 1250  $\text{mg day}^{-1}$  and for those aged 19–50 years it is 700  $\text{mg day}^{-1}$ . Based on the need to avoid high serum phosphorus concentrations, and the fact that phosphorus absorption is more efficient in pregnancy, the UL is set at 3500  $\text{mg day}^{-1}$ , slightly lower than the 4000  $\text{mg day}^{-1}$  for nonpregnant women.

## Magnesium

It is assumed that the gain in fat-free mass in pregnancy (7.5 kg) is associated with a greater deposition of magnesium. If this tissue contains  $470 \text{ mg kg}^{-1}$ , after adjustment for a bioavailability of 40%, the EAR is an increase of  $35 \text{ mg day}^{-1}$  for pregnant women of all ages, and the RDA is 10% higher than this; for women aged 14–18 years, the EAR and RDA, respectively, are 335 and 400 mg; for those aged 19–30 years, these values are 290 and 350 mg; and for those 31–50 years, they are 300 and 360 mg.

The UL for magnesium in pregnancy is set at  $350 \text{ mg day}^{-1}$  taken as a supplement, based on the potential for higher doses of magnesium salts to cause an osmotic diarrhea.

## Iron

Incremental iron requirements for the mother and fetus are relatively well established, although how these requirements should be met is more controversial. It is generally accepted that the mother needs to absorb an additional  $6 \text{ mg day}^{-1}$  to supply the amount retained by the fetus (300 mg) and placenta (60 mg) and that used to synthesize additional maternal erythrocytes (450 mg) and replace blood loss during delivery (200 mg). Some iron is saved by the lack of menstruation in pregnancy. The fetus obtains iron from the placenta in a process that involves iron transfer from maternal transferrin to transferrin receptors on the placenta, endocytosis of holotransferrin, and release of iron into the fetal circulation. Maternal iron absorption and transfer to the fetus increases during the second and third trimesters. This process is upregulated if the mother is iron deficient; however, maternal iron deficiency does reduce the amount of fetal iron stored at birth and available to the fetus during the first months of life.

The EAR for pregnancy is set at  $23 \text{ mg day}^{-1}$  for adolescents and  $22 \text{ mg day}^{-1}$  for adult women, and the RDA is  $27 \text{ mg day}^{-1}$  for both groups. Although the requirement is mainly increased in the last trimester, it is important to build iron stores early and to avoid high doses later, so the higher intake recommendation is distributed throughout pregnancy. The UL is the same as that for the nonpregnant woman and is based on the need to avoid gastrointestinal distress.

Anemia is an important global health problem affecting 38% of all pregnant women and low maternal Hb ( $<110 \text{ g/L}$ ) has been associated with a range of poor birth outcomes (low birth weight, preterm birth, small-for-gestational-age (SGA), stillbirth, and perinatal and neonatal mortality) and adverse maternal outcomes (postpartum hemorrhage, preeclampsia, and blood transfusion) (Young et al., 2019; Stevens et al., 2013). In most countries, iron supplements are recommended routinely for all pregnant women as a strategy to reduce anemia during pregnancy, but only approximately 50% of anemia among pregnant women is responsive to iron supplementation (Stevens et al., 2013), and this can be highly variable across different settings. The amount of iron in prenatal supplements was recently reduced from 60 mg to 30 mg of elemental iron along with 400 g (0.4 mg) of folic acid based on evidence to prevent maternal anemia, puerperal sepsis, low birth weight, and preterm birth (WHO, 2016). The higher dose of 60 mg iron is however still recommended in settings with a high prevalence of anemia ( $>40\%$ ). The WHO also recommends intermittent oral iron and folic acid supplementation with 120 mg of elemental iron and 2800 g (2.8 mg) of folic acid once weekly for pregnant women if daily iron is not acceptable due to side-effects, and in populations where less than 20% of women are anemic. The WHO advises context-specific examination of the etiology of anemia be conducted in order tailor anemia reduction strategies to different settings. WHO hemoglobin cut-offs for defining anemia are currently being re-examined and remains an active area of research (Garcia-Casal et al., 2019; Young et al., 2019; Ohuma et al., 2020).

## Zinc

The estimated additional zinc required for pregnancy is approximately 100 mg, equivalent to 5–7% of the mother's body zinc, part of which is obtained through more efficient intestinal zinc absorption. Approximately half of this is deposited in the fetus. The EAR for pregnant women is based on an additional requirement of  $2.7 \text{ mg day}^{-1}$  during the last 10 weeks of gestation. The UL is based on evidence of impaired copper status at high intakes, as for nonpregnant women.

Zinc plays critical roles in cell division, hormone metabolism, protein and carbohydrate metabolism, and immunocompetence. Because zinc deficiency in pregnant animals causes birth defects and fetal growth retardation, there has been considerable effort to determine the effects of human zinc status on pregnancy outcome, especially in developing countries, where zinc intakes are often inadequate.

In general, however, meeting recommended zinc intakes is more difficult but more critical for women whose diets are low in animal source foods and higher in fiber. High intakes (supplements) of iron and calcium may also impair zinc absorption and therefore increase requirements.

While the WHO does not recommend zinc supplementation as part of routine ANC, it is recommended in the context of rigorous research (WHO, 2021). Although a previous review of randomized controlled trials found a reduced risk of preterm birth (Ramakrishnan et al., 2014) current WHO recommendations were informed by a recent systematic review including over 18,000 women from 25 randomized controlled trials (Carducci et al., 2021) that concluded that there was inadequate evidence on zinc supplementation on maternal and newborn health outcomes. In the review, there was low-certainty evidence that zinc supplementation in pregnancy had little to no difference in reducing the risk of preterm births, stillbirths, or mortality. In addition, there remain critical gaps in our understanding of interactions of zinc supplementation with other iron and calcium supplements during pregnancy.

**Iodine**

In the many countries with endemic iodine deficiency, which include parts of the United States, Canada, and substantial areas of Europe and many other industrialized and developing countries, there is clear potential for the harmful effects of this deficiency to emerge during pregnancy. The most damaging effect of iodine deficiency is on the brain of the fetus because iodine is required for thyroid hormone, which in turn affects myelination and function of the developing central nervous system. The clinical expression of severe maternal iodine deficiency during pregnancy is cretinism, including severe mental retardation, deaf mutism, short stature, and spasticity. Injections of iodized oil before midpregnancy have markedly reduced cretinism and neonatal mortality in areas of severe iodine deficiency. Universal salt iodization is the recommended strategy for addressing iodine deficiency. In most countries, Universal Salt Iodization has reduced the prevalence of cretinism substantially. However, the effectiveness of salt iodization is dependent on country-level regulations (mandatory vs. voluntary), level and choice of fortificant, and coverage. WHO and UNICEF recommend iodine supplementation for pregnant women in countries where less than 20% of households have access to iodized salt (WHO and UNICEF, 2007). In settings where 20–90% of households have access to iodized salt WHO and UNICEF recommend efforts to accelerate salt iodization or providing an iodine supplement or fortified foods for vulnerable populations. In the United States, there is a worrisome trend of declining status and pregnant women have insufficient intake according to WHO criteria (Perrine et al., 2019).

The EAR for pregnancy is set at  $160 \mu\text{g day}^{-1}$  and the RDA at  $220 \mu\text{g day}^{-1}$  for the United States and Canada based on the amount needed to prevent increased thyroid size in previously deficient women. The UL is  $1100 \mu\text{g day}^{-1}$ , the same as for nonpregnant, nonlactating women, and it is based on the need to avoid elevated thyroid-stimulating hormone concentrations. In 2008 the WHO increased its recommendation by  $50 \mu\text{g day}^{-1}$ – $250 \mu\text{g day}^{-1}$ , and established  $500 \mu\text{g day}^{-1}$  as the intake above which no additional health benefit could be expected.

**Trace elements: copper, selenium, chromium, fluoride, manganese, and molybdenum**

Copper is required for the function of many enzymes, primarily oxidases. In pregnancy, an increased intake of this mineral is recommended to cover deposition of approximately  $18 \text{ mg day}^{-1}$ , most of which is in fetal liver. The UL ( $10,000 \mu\text{g day}^{-1}$ ) is the same as for nonpregnant women, based on the need to prevent the liver damage that occurs with high intakes.

Recommended intakes of selenium for adults are based on the criterion of maximizing plasma glutathione peroxidase activity. Based on an estimated selenium content of the fetus of  $1000 \mu\text{g}$ , across pregnancy this would require that an additional  $4 \mu\text{g day}^{-1}$  be consumed. The EAR is therefore increased from  $45$  to  $49 \mu\text{g day}^{-1}$  and the RDA from  $55$  to  $60 \mu\text{g day}^{-1}$ . The UL is determined on the basis of hair loss and brittle nails, which occur at higher levels of intake, and is the same as that set for nonpregnant women.

Chromium is required for normal insulin metabolism. There are no data from which to derive a recommendation for pregnancy, so an increase of  $5 \mu\text{g day}^{-1}$  is recommended (as an AI) based on the additional weight and tissue chromium gained in pregnancy. No UL was set due to lack of documented adverse effects in humans.

For fluoride, there is no evidence that increasing the AI in pregnancy above that for the nonpregnant woman will benefit fetal tooth or bone content or afford protection against later tooth decay in the child. The UL is set at  $10 \text{ mg day}^{-1}$  to avoid fluorosis (discoloration of tooth enamel, joint pain, and skeletal abnormalities).

Manganese is required for bone formation and the normal metabolism of amino acids, lipids, and carbohydrates. The AI for pregnancy, estimated from the manganese content of maternal weight gain, is  $2 \text{ mg day}^{-1}$ . The UL is based on avoidance of elevated blood manganese and neurotoxicity, and it is not increased for pregnancy.

Recommended molybdenum intakes, based on the mineral's role as a cofactor for several enzymes, increase by  $16 \text{ mg day}^{-1}$  in pregnancy to cover the increment in fetal and maternal weight. The UL is derived from adverse reproductive effects seen in animals.

**Water and electrolytes**

The US–Canada recommended intake of water for pregnant women is based on median intake from a large national survey in the United States. The AI of  $3 \text{ L day}^{-1}$  is anticipated to come from foods ( $0.7 \text{ L}$ ) and beverages ( $2.3 \text{ L}$ ). No UL was set because individuals stop drinking once their intake is adequate.

The AI for sodium in pregnancy is  $1500 \text{ mg day}^{-1}$  based on an intake level to cover daily losses, provide adequate intakes of other nutrients, and maintain normal function. The UL of  $2300 \text{ mg day}^{-1}$  is based on the adverse effects of higher intakes on blood pressure in susceptible members of the population.

The AI for potassium in pregnancy ( $4.7 \text{ g day}^{-1}$ ) is set at a level that will lower blood pressure, reduce the extent of salt sensitivity, and minimize the risk of kidney stones. There is no evidence that adverse effects of potassium are seen with high intakes from food and no UL was set, but potassium supplements can cause high blood potassium in some chronic diseases, such as renal disease and type 1 diabetes.

**Summary**

In the US–Canada recommendations, the recommended intakes are increased for most, but not all, nutrients during pregnancy. However, the recommendations are often based on less than ideal experimental data, in part due to the difficulty of conducting experiments on pregnant women.

For most nutrients, it is likely that some population groups may have higher requirements than those recommended in [Table 1](#), notably women bearing more than one fetus or adolescents (see the Institute of Medicine volumes for specific recommendations for this age group). To meet the recommended nutrient increases, dietary quality often needs to be improved during pregnancy. It is often advised that pregnant women should also take iron supplements and/or a multiple vitamin–mineral supplement. The specific benefits of supplementation in pregnancy, optimal timing, and optimal doses are still somewhat controversial and the subject of ongoing research. Currently, some countries recommend routine supplementation for all pregnant women, whereas others recommend supplementation only when there is evidence of anemia, other nutritional deficiencies, a poor diet, or other problems such as drug or alcohol abuse.

## Glossary

**Endothelium** Thin layer of cells lining the blood vessels.

**Imprinting** Parent of origin specific marking or expression of genes.

**In utero** In the uterus.

**Intrauterine growth restriction (IUGR)** Pathological deviation from normal growth.

**Trophoblast** Placental cells formed from the outer part of the blastocyst.

**Vesicle** Spherical preparation of membrane bilayer used to study transport.

**Villi** Hair- or finger-like projection from a cell which increases the surface area.

## Fetal Nutrient Requirements

Prenatal development can usefully be divided into two periods; the embryonic period, which covers the first eight weeks of life and the fetal period, which lasts from the 9th week of gestation until term. During the latter period the fetus is entirely dependent on the

**Figure 1** Nutrient exchanges between the maternal circulation, placenta, and fetus.

placenta for its supply of nutrients (Figure 1). The fetus has an absolute requirement for the same essential nutrients as the adult but the adequacy of supply is particularly critical during *in utero* life when all the structures of the body are being established. In addition, because of the particularly high demand for some strictly nonessential nutrients these may be considered as 'conditionally essential' if the rate of utilization exceeds the fetal capacity for *de novo* synthesis.

The placenta has to maintain the supply of all nutrients at a rate adequate to allow fetal growth to proceed along its optimum trajectory. It also has to provide an appropriate mix of nutrients to meet the needs of the fetus at the different stages of pregnancy. For example, in the first two-thirds of pregnancy the fetus deposits mainly protein whereas in late gestation fat takes over as the dominant form of deposition (Figure 2).

**Figure 2** Changes with gestational age in placental exchangeable surface area and umbilical blood flow (a), accretion of fat and protein in the fetus (b), and the components of fetal energy requirements.

The availability of individual nutrients to the fetus depends not only on the maternal dietary intake but also on the function of the placenta and the many physiological and biochemical adaptations, which occur during pregnancy (Figure 2). An understanding of placental function and its interaction with diet is essential to the setting of appropriate dietary guidelines for pregnancy.

## The Human Placenta

The human placenta is a hemochorial, villous type where the maternal blood enters the intervillous space *via* the spiral arteries and flows directly around the terminal villi of the fetal circulation without any intervening maternal vessel wall. The surface area available for exchange gradually increases throughout pregnancy, reaching approximately 10–15 m<sup>2</sup> in the last trimester (Figure 2). The nature of the exchangeable surface of the placenta also changes throughout gestation. Mature intermediate villi appear toward the end of the second trimester and the terminal villi – the main site of feto-maternal exchange – develop a few weeks later. The rate of fetal blood delivery to the placenta (umbilical flow) also increases with gestational age. It is approximately linearly related to fetal weight, and hence the fetal nutrient requirement, throughout gestation (Figure 2).

The human placenta typically weighs approximately half a kilogram at term. However, its physical bulk belies the delicate nature of the separation between the maternal and fetal circulations, which consists of only two cell layers; the syncytiotrophoblast and the capillary endothelium. The endothelium allows the passage of nutrients through pores within the interendothelial cleft and therefore is not a significant barrier to nutrient exchange between the maternal and fetal circulations. The effective barrier between the circulations is a thin trophoblastic sheet in the form of a syncytium (a tissue in which the cytoplasm of constituent cells is continuous), known as the syncytiotrophoblast. Between 10 weeks and term the thickness of the villous trophoblast falls from approximately 10 µm to 4 µm. Over the same period the overall materno–fetal diffusion distance drops from 40 µm to 5 µm. Any substance crossing between the maternal and fetal circulation has to pass through this barrier, which consists of two membranes; the microvillus membrane (MVM) facing the maternal blood and basal membrane (BM) facing the fetal blood. The surface area of the maternal facing MVM is approximately five- to six-times that of the fetal facing BM. There are other cell types and structures within the placenta, such as maternal myometrium and decidua, connective tissue, Hofbauer cells, and persisting cytotrophoblast cells, which contribute to the metabolic activity and nutrient requirements of the placenta but which are not thought to be significant barriers to transport.

## Methods Used to Study Placental Function

Direct measurement of placental nutrient transport function in human pregnancy is practically and ethically extremely difficult to achieve and the available techniques require a tradeoff between physiological relevance and the quality of the information derived. Stable isotope labeled amino acids and fatty acids have been administered to the mother and their appearance measured in the cord blood. Such studies are clearly physiologically relevant but their interpretation is severely constrained by the number of sequential cord blood samples which can be taken. Placental function is often inferred by measurements of concentration differences in the maternal and fetal circulations. Measurements of arterio–venous differences across the umbilical cord can be made at cesarean section but, given the significant changes in placental function during development, their relevance to the younger placenta is not clear. Cord blood nutrient levels can be measured at earlier stages of development using the invasive method of cordocentesis but this procedure carries risks and may only be justified when carried out opportunistically as part of a clinical test, and this in turn may bias the population sample toward those with fetal or placental pathology. An important limitation to the interpretation of placental function from such ‘snapshot’ measurements is that the cord blood nutrient status is the net result of both placental delivery and fetal utilization. A number of *in vitro* approaches to the study of placental function are also available. The dually perfused placenta has the advantage that it retains the cellular structure and metabolic activity of the syncytiotrophoblast and the placental vascular structure. This preparation also allows the nutrient composition of the maternal and fetal circulation to be controlled and transfer rates to be measured dynamically using isotopic tracers. However, the placenta tends to be very mature, the efficiency of perfusion cannot be assumed to exactly mimic the *in vivo* situation. Also, care has to be taken to ensure that the composition of the maternal and fetal perfusates are made up in such a way that they are relevant to the form in which nutrients are actually transported in the maternal and fetal circulations. Vesicles formed from the syncytiotrophoblast are particularly well suited to the detailed study of nutrient transport mechanisms under highly controlled conditions. Finally, there is the identification and characterization of individual transport proteins.

## The Mechanisms of Placental Nutrient Transport

The transport of individual nutrients across the placenta generally depends on the same principles and the presence of the same or similar transport systems to those in the tissues and organs of the adult although there are some additional factors specific to the placenta (Figure 3). In particular, unlike most tissues in the adult where either uptake or export dominate at any given time, the syncytiotrophoblast whose primary function is transport has to do both simultaneously.

**Figure 3** Factors affecting nutrient transfer across the syncytiotrophoblast. These include: (1) maternal and fetal blood flow, (2) the concentration gradient across the syncytiotrophoblast for nutrients and, where relevant, their transporters in the maternal and fetal circulations, (3) the concentration of transport proteins to facilitate or actively transport nutrients, (4) the exchangeable surface area, (5) the rate of diffusion of some nutrients across membranes without the intervention of transport proteins, (6) metabolism (utilization and *de novo* synthesis) within the placenta, and (7) the rate of nutrient utilization by the fetal tissues.

The placental transport systems for the macronutrients (carbohydrate, fat, and protein) have been extensively studied. Glucose transport within the placenta appears to be mediated exclusively by the GLUT1 transporter, which has been located on both the MVM and BM. GLUT3 and GLUT4 are also present in the placenta but not in the syncytiotrophoblast itself. They are located on the vascular endothelium and the intervillous stromal cells, respectively. The syncytiotrophoblast also contains a wide range of amino acid transporters; system A, ASC, Asc, B<sup>0</sup>, b<sup>0</sup>+, L, N, Gly, y<sup>+</sup>, y<sup>+</sup>L, and X<sub>AG</sub> and β. A number of fatty acid binding proteins are also found in the placenta. Of these proteins FAT/CD36 and FATP have been located on both the MVM and BM but there is also a placenta specific protein (p-FABPpm), which has been located exclusively on the MVM. This p-FABPpm is similar in size (~40 kDa) to the ubiquitous FABPpm found in most mammalian cells but it has a different amino acid composition.

The driving force, which results in the net transfer of nutrients to the fetus is different for different nutrients and this is reflected in their transplacental gradients (Figure 4). Where the nutrient concentrations are lower in the cord than maternal blood this has been cited as a reason to supplement the mother but in many cases it is precisely this gradient which drives placental nutrient transfer. Glucose is thought to flow down a concentration gradient from the mother to the fetus and this process of 'facilitated diffusion' is mediated by GLUT1. Unlike glucose the concentration of most amino acids in the fetal circulation is greater than that in the maternal circulation suggesting some form of active transport. For many amino acids the concentration is even higher within the placenta than the fetal circulation and the key gradient generating step for amino acids is the active transport across the MVM. The amino acids can then diffuse down a concentration gradient into the fetal circulation, and to some extent back to the mother. The concentration of water-soluble vitamins and lactate in the fetal circulation also exceeds that in the maternal circulation.

Like glucose, the fats and fat-soluble vitamins also flow down a concentration gradient from the mother to the fetus mediated by the various fatty acid transport proteins. However, unlike glucose or the amino acids, fat-soluble compounds can also cross the syncytiotrophoblast, and all other membranes for that matter, by simple diffusion and partition without the intervention of a carrier protein. The role of the fatty acid binding proteins appears to be to improve the efficiency of this process. The key factor in understanding the driving force for the placental transfer of fat-soluble nutrients is that these compounds are only sparingly soluble in water (13 μM for C18:0 at 37 °C) and have to be transported in the plasma in hydrophobic binding sites on carrier proteins. The partition of fats between the maternal and fetal circulations is largely determined by the relative abundance of available hydrophobic binding sites within those compartments. Because only NEFA is thought to cross membranes, it is the NEFA concentration gradient which is most relevant to the transplacental flow of fatty acids. The concentration of NEFA in the maternal plasma at term is approximately three-times that in the fetal circulation but the concentration of its primary carrier protein, albumin, is actually 10–20% higher in the fetal circulation. This results in a ratio of NEFA to albumin on the fetal side of the placenta of around a quarter of that on the maternal side at term. The fat-soluble vitamins (A, E, and D) are also present in the fetal circulation in lower concentrations than in the maternal circulation. These materno–fetal concentration differences for the macronutrients develop gradually throughout gestation.

It is less easy to generalize about the transplacental gradient for minerals as some are at a lower concentration in the fetal circulation (Se, Cu, Ba) some are higher (Ca, Zn, Be, Rb) and some are about the same (Co, Mg, Mo, Sn, Bi, Cd, Cs, La, Li, Pb). Iron is particularly important during pregnancy and its concentration in the fetal venous blood leaving the placenta is almost three-times that of the maternal serum. Iron is transported in the serum on the transport protein transferrin and, like the fats and fat-soluble vitamins, its rate of transfer may be influenced by the availability of free binding sites.

**Figure 4** The relative concentration of nutrients in the maternal and fetal circulations. The concentration differences for each nutrient class are represented by the area of the circle in the fetal circulation relative to the maternal circulation. Apart from glucose the relative concentrations of individual nutrients within the nutrient groups are shown as segments of the circle. For triglyceride the fractions are saturated (SFA) monounsaturated (MUFA), essential (EFA) and long chain polyunsaturated fatty acids (LCPUFA). For vitamin E the fractions are  $\alpha$ -tocopherol ( $\alpha$ -toc),  $\gamma$ -tocopherol ( $\gamma$ -toc) and  $\delta$ -tocopherol ( $\delta$ -toc). For vitamin A the fractions are  $\beta$ -carotene, ( $\beta$ -car), and  $\alpha$ -carotene ( $\alpha$ -car).

### Epigenetics and the Placenta

There is growing interest in the role of epigenetics, and imprinting in particular, in controlling placental function and nutrient delivery to the fetus. The vast majority of human autosomal genes are thought to be equally expressed from the two parental alleles. In the imprinted genes the expression pattern is different for the maternally and paternally derived alleles, with information on the parental origin of each allele being retained in the conceptus through epigenetic mechanisms. Epigenetics encompasses a collection of mechanisms that control gene function and chromatin structure without altering the nucleotide sequence of DNA and the most commonly studied is DNA methylation. Imprinted genes make up only approximately 1% of all human genes. Their main functions include control of placental function, fetal growth, and brain development but the way in which the imprint is acquired and propagated is not fully understood. Much of what is known about imprinting and developmental epigenetics comes from studies in mice, though data from human reproduction are increasingly available. Although there are important differences between species, particularly in the timing of epigenetic events, a number of themes appear to be universal. Following demethylation and

genome wide *de novo* methylation at the embryonic pregastrulation stage, striking differences in the methylation status of embryonic cell lineages within the early embryo are apparent. The trophoblast lineages, which give rise to the placenta, typically achieve a much lower level of methylation than the heavily methylated somatic cells, which give rise to the fetal tissues. Such differences, and the parent of origin specificity of the imprinted genes, have given rise to the main hypothesis that seeks to explain the phenomenon of imprinting in placental mammals. The 'conflict theory' of imprinting is based on the premise that the function of the imprinted genes is to control resource allocation to the fetus. The logic being that the mother is more likely to pass on her genes if she spreads her body resources over a number of pregnancies whereas the father's genes are more likely to be successful in evolutionary terms if they maximize resource allocation to his offspring, even at the mother's expense. Paternally expressed imprinted genes are generally thought to enhance fetal growth by promoting resource allocation to the conceptus whereas maternally expressed imprinted genes are thought to protect the maternal resources by suppressing fetal growth. Experimental data to support this model has been obtained in mice, but it has yet to be confirmed in detail for humans.

### Placental Selectivity

One of the key functions of placental nutrient transport is to maintain the most appropriate balance of nutrients in the fetal circulation and the balance of nutrients transferred by the placenta may be as important as the overall transfer capacity in influencing the pattern of fetal growth. Nutrients such as the fatty acids and amino acids occur in many forms yet they are translocated across membranes by a relatively small number of transporter molecules (Figure 3). This nutritional 'bottleneck' results in competition for transfer and the possibility of placental selectivity. An example of the resulting change in nutrient quality can be seen in the increase in the relative proportion of the essential to nonessential amino acids in the fetal circulation compared to the maternal circulation (Figure 4). The same is true of the fat-soluble vitamins where the relative concentration of the most biologically active form is increased in the fetal circulation. In the case of the fatty acids it is the long chain polyunsaturated fatty acids (LCPUFAs) such as arachidonic acid [20:4 n-6; AA] and docosahexaenoic acid [22:6 n-3; DHA], which perform most of the essential functions in the fetus. Although the overall concentration of the lipid classes are greatly reduced in the fetal circulation the critical LCPUFA make up a greater proportion of total fatty acid in the fetal circulation. In the case of the fatty acids the placenta has multiple mechanisms including preferential binding of LCPUFA by p-FABPpm, selective uptake by the syncytiotrophoblast, intracellular metabolic channeling of individual fatty acids, and selective export to the fetal circulation, which allow it to preferentially deliver DHA and AA to the fetal circulation.

### Placental Metabolic Activity

Although the barrier between the maternal and fetal circulation is effectively only one cell thick, the placenta is a substantial organ, made up of many cell types. It is extremely active metabolically and has its own requirement for nutrients and this is consistent with the observations that the surface area of the maternal facing membrane (MVM) is approximately five-times greater than that of the fetal facing membrane (BM), that the concentration of expression of GLUT1 is greater on the MVM, that the MVM contains additional fatty acid binding proteins, which are not present on the BM, and that the amino acid transporters act to produce the maximum amino acid gradient across the MVM. The metabolic transformations within the placenta are intimately linked to fetal metabolism and represent another way in which the placenta can regulate nutrient transport availability within the fetal circulation.

In late pregnancy the overall contribution of fat to whole body oxidation is reduced and this is thought to result from the preferential utilization of carbohydrate and amino acids such as glutamate as an energy source in the feto-placental unit and the sparing of fatty acids to maximize fetal accretion of the critical LCPUFA in particular. The inter-relationships between the placenta and fetus are particularly complex for the amino acids. The placenta is a net user of serine, glutamate, leucine, isoleucine, and valine and there is significant interconversion of alanine, pyruvate, and lactate between the placenta and fetal tissues. The concentration of lactate in the fetal circulation is considerably greater than that in the maternal circulation and a considerable proportion of the glucose taken up by the placenta is converted into lactate before export into the fetal circulation for use by the fetus. The placenta takes up serine from both the maternal and fetal circulation, converting this into glycine and exporting it into the fetal circulation for oxidation by the fetal liver and there is significant cycling of glutamate and glutamine between the placenta and fetal liver. This partition of the various segments of metabolic pathways between the placenta and fetal tissues is a general phenomenon and in many respects the feto-placental unit can be considered as a metabolic whole with the placenta acting as an extra fetal organ in addition to its role as a simple nutrient transporter. Metabolic activity in the feto-placental unit is also responsive to nutrient supply and fetal demand. For example, AA is an important precursor of the prostacyclins, prostaglandins, thromboxanes, and leukotrienes, which play key roles in pregnancy. When the maternal circulation of AA is low there is net uptake by the placenta of AA from the fetal circulation, presumably to maintain placental synthesis of these important compounds.

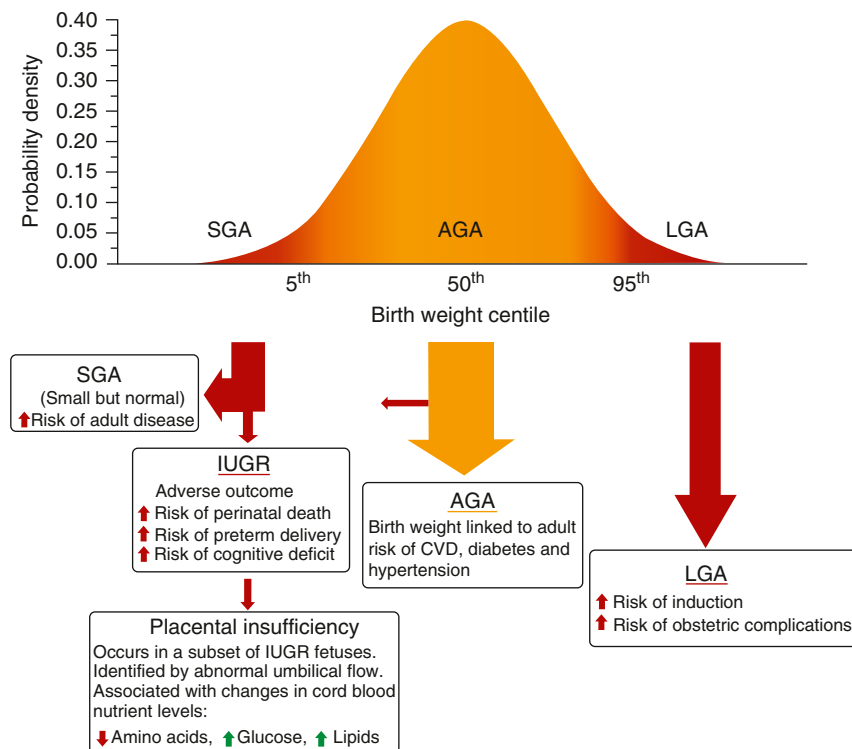

## Placental Buffering of Maternal Dietary Intake

In cases where the increased demand for nutrients during pregnancy is not met by the diet alone the shortfall may be made up from the maternal stores and the placenta may play a role in orchestrating some of the maternal nutritional adaptations in pregnancy (Figure 3). For example, placental derived leptin is a potent stimulator of lipolysis and there is evidence that the rate of export into the maternal circulation is controlled to allow the placenta to modulate its own substrate supply in response to the fetal demand for fats. The various homeostatic mechanisms within the placenta and their interaction with maternal physiological adaptations during pregnancy act to ensure a constant supply of substrate to the fetus, free of large diurnal fluctuations corresponding to the timing of maternal meals, and to protect the fetus against a transiently poor intake during critical periods of fetal growth. These adaptations help the mother to meet the full fetal requirement for nutrients such as LCPUFA and iron while consuming apparently poor diets.

## Placental Insufficiency and Fetal Growth

Low birth weight is a significant public health problem in developing countries where maternal nutrition may be marginal or poor. Low birth weight resulting from poor nutrition is also a concern in industrialized societies but maternal deficiency here is relatively rare and potentially a more important public health issue relating to nutrition in pregnancy is the apparent epidemiological association between birth weight and adult disease susceptibility (cardiovascular disease, diabetes, and hypertension). The highest risk is associated with the lowest birth weight but, because of the nature of the normal distribution, in terms of the numbers potentially affected in adult life it is the small variations in the normal birth weight range, which have the largest public health implications. A causal connection between birth weight and adult disease has been proposed in the 'fetal origins' hypothesis which is that fetal undernutrition in middle to late gestation, leads to disproportionate fetal growth and programs later disease susceptibility. The close association between birth weight and placental weight has led to speculation that the placenta may limit fetal growth within the normal weight range. However, the available evidence suggests that the capacity of the normal human placenta to transport macronutrients exceeds the fetal requirement and that a considerable proportion of transport function would have to be lost before it became limiting for fetal growth.

Intrauterine growth restriction (IUGR) resulting from utero-placental insufficiency is a serious pathology, which is associated with a greatly increased risk of adverse outcomes including perinatal mortality and morbidity, impaired mental, visual and aural

**Figure 5** The normal distribution of birth weights and relative risks associated with babies who are small for gestational age (SGA), appropriate for gestational age (AGA), large for gestational age (LGA) and those subjected to intrauterine growth retardation (IUGR) and the relationship to placental insufficiency.

development, autism, and cerebral palsy and strongly associated with serious adverse maternal outcomes especially pre-eclampsia (Figure 5). IUGR is often detected indirectly by measuring abnormal umbilical artery flow velocity waveforms and abnormal fetal heart rate. The abnormal waveforms are thought to result from increased vascular resistance associated with abnormal arteriolar tree and villi branching and a reduction in the villous capillary tree. Pregnancies in which these abnormalities are observed are also associated with fetal hypoxia and reduced concentrations of glucose and amino acids in the fetal circulation and reduced activity of the system A amino acid transporter within the placenta. However, *in vitro* studies have shown that the hypoglycemia observed in some IUGR fetuses is not caused by a decreased glucose transport capacity within the placenta (expression and activity of GLUT1) and IUGR fetuses are actually hypertriglyceridemic compared to their appropriately grown counterparts. The fetal blood concentrations of the trace elements are also either normal or elevated in IUGR. Thus although it is possible that the placenta from IUGR fetuses may limit the supply of amino acids there is no evidence that placental delivery is the first limiting factor in the supply of glucose, lipids, or trace elements. IUGR is a complicated syndrome in which almost all aspects of placental and fetal metabolism are altered and many researchers have emphasized the primary importance of the fetal hypoxia and its effects on fetal metabolism rather than a simple limitation of placental nutrient transfer capacity.

There is considerable uncertainty about the magnitude of the problem of IUGR. The lowest 5–10% of weight for gestational age babies may be referred to as small for gestational age (SGA) but babies in this range need not be growth retarded. They may be naturally small and have no increased risk of adverse outcome. Conversely, a baby born within the apparently normal birth weight range could have suffered growth retardation *in utero* if its genetic potential was for a higher birth weight (Figure 5). The true incidence of IUGR resulting from utero-placental insufficiency is therefore unknown but if it is defined in relation to umbilical flow or fetal heart rate abnormalities then it is only a fraction of even those in the lowest 5% of weight for gestational age that are affected by utero-placental insufficiency. At the other end of the spectrum babies who are large for gestational age (LGA) are at higher risk of adverse obstetric outcomes and early developmental problems but there is no evidence that LGA or macrosomic babies are produced as a result of a primary alteration in the placenta.

## The Role of the Fetus

The nutrient composition of the human diet varies enormously between populations yet the healthy human newborn is essentially the same the world over. The available evidence points to extensive homeostatic mechanisms at work within the placenta to ameliorate some of the variations in the quality of the maternal diet by regulating the mix of nutrients to the developing fetus. However, these mechanisms can only operate on the nutrients already available in the maternal circulation. The maternal diet and maternal circulating concentrations of many nutrients are major determinants of the concentrations in the fetal circulation and the fetus clearly has the ability to cope with relatively large variations in nutrient availability in the cord blood. The fetus also plays an active role in regulating placental nutrient transfer. The rate of placental nutrient transport is directly influenced by the transplacental concentration gradient, which is in turn largely determined by the rate of uptake by the fetal tissues. Another major determinant of placental nutrient transfer is the umbilical blood flow, which is approximately linearly related to the fetal weight, and hence the fetal nutrient requirement, throughout gestation. Finally, the most intimate connection between the fetus and the placenta is the way in which different parts of metabolic pathways and cycles are distributed between the placenta and fetal tissues, mainly the fetal liver. Thus although the placenta has to provide the correct mix of nutrients in sufficient quantities to support fetal growth and development throughout pregnancy it is the fetus itself, which ultimately regulates many key aspects of placental nutrient transfer function.

- Synopsis of the pathophysiology of pre-eclampsia with emphasis in possible nutritional pathways involved
- Introduction to strategies for early detection of pre-eclampsia
- Current knowledge of associations between pre-eclampsia and nutritional factors

### Introduction

Hypertensive disorders of pregnancy (HDPs) defined as systolic blood pressure  $\geq 140$  and/or diastolic blood pressure  $\geq 90$  after 20 weeks of gestation (Garovic et al., 2021) are one of the main causes of maternal and fetal/neonatal morbidity, increasing the odds of myocardial infarction, stroke, spontaneous coronary artery dissection, peripartum cardiomyopathy, small for gestational age, stillbirth, preterm delivery, placental abruption and postpartum hemorrhage, as well as the odds of maternal mortality (Garovic et al., 2021). The incidence of HDPs varies depending on the socio-demographic index, countries with low socio-demographic index having higher incidence ( $70.6 \times 10^4$  population) than those with high socio-demographic index ( $10.9 \times 10^4$  population) (Wang et al., 2021), and the prevalence of eclampsia, one of the most severe forms of HDPs, was reported as 50–151 per 10,000 deliveries in developing countries, but 1.6–10 per 10,000 deliveries in developed countries (Fishel Bartal and Sibai, 2020).

### Risk factors

Age and race: HDPs affect most the extremes of reproductive age. Adolescent pregnancy (Leppalahti et al., 2013) is considered a risk factor for developing HDPs. On the other hand, women  $\geq 35$  years were found to have a higher risk of pre-eclampsia (PE) (Laminpaa et al., 2012; Schimmel et al., 2015), and those  $\geq 40$  yrs, increased risk of late-onset post-partum PE (Bigelow et al., 2014; Koo et al., 2012; Khalil et al., 2013). African American (Shen et al., 2005; Liu et al., 2014), Hispanic (Bigelow et al., 2014) and Indigenous women (Johnson and Louis, 2020) are more likely to develop HDPs.

Obstetric and medical history: A review and meta-analysis of 92 studies described obstetric and medical conditions that increase the risk of PE, describing risk ratios [95% confidence interval (CI)] (Bartsch et al., 2016). Obstetric risk factors comprised history of

PE [8.4 (7.1–9.9)], multifetal pregnancy [2.9 (2.6–3.1)], prior stillbirth [2.4 (1.7–3.4)], first pregnancy [2.1 (1.9–2.4)], history of placental abruption [2.0 (1.4–2.7)] and assisted reproduction [1.8 (1.5–2.1)]. Maternal medical conditions such as chronic hypertension [5.1 (4–6.5)], pregestational diabetes mellitus [3.7 (3.1–4.3)], obesity [2.8 (2.6–3.1)], chronic kidney disease [1.8 (1.5–2.1)], and autoimmune disorders such as systemic lupus erythematosus [2.5 (1.0–6.3)] and antiphospholipid syndrome [2.8 (1.8–4.3)] have also been associated with increased the risk of PE (Bartsch et al., 2016).

Genetic and fetal factors: Family and racial predispositions to the disease have prompted an examination of polymorphisms at the maternal and fetal levels that might be increasing the risk of HDPs and/or PE (Broughton Pipkin, 1999). Some polymorphism variants in genes for angiotensin I and II (Li et al., 2015), nitric oxide synthase (Qi et al., 2013; Groten et al., 2014), methylenetetrahydrofolate reductase (Wang et al., 2013), coagulation factor V, leptin receptor (Fong et al., 2014), FMS-like tyrosine kinase 1, methylenetetrahydrofolate reductase, and vitamin-D receptor (Guan et al., 2022) among others have been associated with increased risk of PE. Fetal factors for the development of HDPs, such as carrying a male fetus and multiple pregnancies, have been reported; also, genetic disorders in the offspring such as Beckwith-Wiedemann syndrome and trisomy 13, have been related with higher risk of HDPs, whereas trisomy 21 might reduce the risk (Petry et al., 2014).

Diet: A Western dietary pattern The Dietary Approaches to Stop Hypertension (DASH) diet is known to improve blood pressure in non-pregnant populations (Wiertsema et al., 2021). It recommends a high daily intake of fruits, vegetables and grain products, the daily inclusion of low-fat dairy products and moderate intake of meats, poultry, and fish in the diet, as well as nuts, seeds, and legumes (Lin et al., 2003). A higher score in the intake of the components of the DASH diet was associated with lower diastolic blood pressure in mid-pregnancy and with better feto-placental vascular function in late pregnancy, but was not associated with HDPs in a low-risk European population (Wiertsema et al., 2021). However, a hospital-based study in China found an inverse relationship between the adherence to DASH diet and the odds of PE (Cao et al., 2020). A higher adherence to the New Nordic Diet, which promotes the high intake of organic legumes, vegetables, fruit, whole grains, seafood, potatoes, nuts, herbs and other Nordic-produced foods (Jensen et al., 2015), was associated with low relative risk of PE only in nulliparous women, but also was associated with preterm delivery in multiparous women (Hillesund et al., 2014).

The Mediterranean diet is typically known as being high in unprocessed plant foods (fruits, vegetables, legumes, nuts, whole grain cereals, and olive oil); low to moderate in fish/shellfish; infrequent intake of red meat, animal fats, vegetable oils, and processed foods and low intake of red wine (Villani et al., 2019). However, a recent meta-analysis of randomized-controlled trials involving 2277 subjects found no effect of the Mediterranean diet with PE (Zhang et al., 2021). In low-medium income countries, the evidence of a Western diet (high sugar, fried/processed goods) increasing the odds of HDPs is inconclusive; however, the low or no-intake of fruits respectively increased by 2.3 and 2.6 times the odds of PE compared with women who consumed fruits and vegetables during their pregnancies (Kinshella et al., 2021a). Moreover, evidence of a healthy diet pattern (high intake of fruits, vegetables and low-fat dairy) was associated with 51–82% reduced incidence of PE (Kinshella et al., 2021a).

## Classification of HDPs

The classification of HDPs slightly differs among guidelines from North American, Latin American and Europe. In general, guidelines align with the International Society for the Study of Hypertension in Pregnancy (ISSHP) (Brown et al., 2018), that classifies HDPs in four categories:

1. Pre-existent chronic hypertension: Hypertension that is present prior to the pregnancy or before week 20 of gestation
2. Gestational hypertension: Hypertension after 20 weeks of gestation without manifestations of complications
3. Preeclampsia—*de novo* or superimposed on chronic hypertension: New onset of hypertension after week 20 of gestation, associated with proteinuria or one or more severe complications
4. White coat hypertension: Elevated blood pressure that is only present during the physical examination in a clinic or office; it does not require antihypertensive medication.

PE is the most severe form of HDPs (Cicero et al., 2015). PE is a multisystemic disease occurring exclusively during pregnancy after week 20 of gestation (Lambert et al., 2014), during the peri-partum time or up to 42 days after delivery (Vilchez et al., 2015). It is characterized by *de novo* appearance of hypertension, with blood pressure measured at least twice with an interval of at least 4 h (Lambert et al., 2014).

PE has also been subclassified using different criteria, such as the presence/absence of intra-uterine growth restriction, its origin (placental vs. maternal), its association with later maternal cardiovascular disease or immunological/genetic subtypes (Roberts et al., 2021). Most generally accepted, PE can be classified as severe when the systolic blood pressure is  $\geq 160$  or diastolic blood pressure  $\geq 110$  mmHg (Poon et al., 2019) or one of the following signs of systemic disease is present:

- Proteinuria, defined as  $\geq 300$  mg/24 h (gold standard) or  $\geq 1+$  on reagent strip, is a diagnostic criterion for PE in some country guidelines (Scott et al., 2020), but is not an absolute requirement for the diagnosis of PE (Magee et al., 2014; ACOG, 2013; Tranquilli et al., 2014), because pathophysiological features of PE can be present before the kidney involvement is severe enough to induce proteinuria (Chaiworapongsa et al., 2014), and because proteinuria might not be present in complications such as eclampsia, acute renal failure or pulmonary edema (Thornton et al., 2010).

- Other maternal organ involvement: Central nervous system (severe headache and/or hyperreflexia with clonus, altered mental status), liver (double or more liver transaminases), kidney [creatinine  $>90 \mu\text{mol/L}$ , or double of previous creatinine, or oliguria ( $<500 \text{ mL/d}$ )], hematological complications [thrombocytopenia (platelet count  $<150,000/\mu\text{L}$ )] (Poon et al., 2019), or new onset of visual impairment with retinopathy, retinal detachment, or cortical blindness (Abu Samra, 2013).
- Utero-placental involvement: Fetal growth restriction, stillbirth or abnormal umbilical artery Doppler wave (Poon et al., 2019).

The detection and urgent treatment of those signs are important given that they predict the imminent development of two forms of severe PE that increase the risk of maternal and perinatal morbidity and mortality (Vigil-De Gracia et al., 2015):

- Eclampsia, the occurrence of generalized tonico-clonic seizures at the end of pregnancy, during labor or postpartum in women with PE (Lipstein et al., 2003), and
- HELLP syndrome, an acronym for Hemolysis, Elevated Liver enzymes and Low Platelets, results from a thrombotic microangiopathy, with consumptive thrombocytopenia and the formation of thrombi in small vessels (Balsak et al., 2015).

However, as PE can quickly worsen to produce complications, the term “severe PE” has been intentionally avoided from some country guidelines, to encourage a close survey of all women with PE (Scott et al., 2020).

Furthermore, PE can also be classified as early when starting  $<34$  weeks, and late when starting  $\geq 34$  weeks of gestation, as they differ based on associated risk factors, biophysical and biochemical markers, uterine artery blood flow measured by artery Doppler velocimetry and in pathological lesions found in the placenta (Ogge et al., 2011). According to this classification, early onset PE would be characterized by deficient remodeling of uterine spiral arteries, impaired placental development and intra-uterine growth restriction, whereas late onset PE would be mainly characterized by maternal endothelial dysfunction, both early and late processes leading to systemic inflammatory response (Aneman et al., 2020). With advanced knowledge in the pathophysiology of PE, new sub-classifications involving different stages of the disease have been proposed and are currently under investigation (Staff, 2019).

## Pathophysiology of preeclampsia

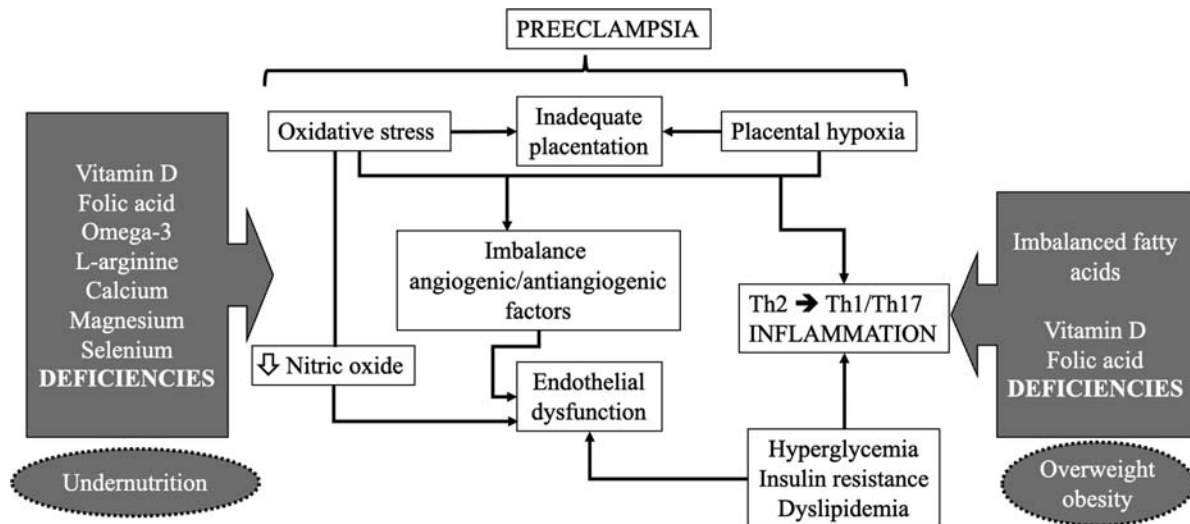

Despite extensive research, the exact etiology of PE has not yet been elucidated. Current knowledge of PE recognizes it as a multi-causal and heterogeneous syndrome (Redman, 2011) with two main possible etiologies depending on the early- or late-onset gestational age at diagnosis. Subsequently, two stages of PE have been classically recognized: (a) poor placentation, and (b) endothelial dysfunction and clinical syndrome (Tranquilli and Landi, 2010; Cheng and Wang, 2009). The first stage of misplacentation can start as early as two weeks gestation, where cytotrophoblast fails to properly invade and remodel maternal spiral arterioles, producing a shallow placentation with narrow maternal vessels and relative placental ischemia (Rana et al., 2019). Also, a premature unblocking of spiral arteries that normally occurs about 8 weeks could impair placental growth due to oxidative stress instead of decreased perfusion (Redman et al., 2020). Independently of the origin of placental injury, the primary effect seen in clinical PE is the imbalance between proangiogenic and antiangiogenic factors leading to maternal endothelium dysfunction (Agarwal and Karumanchi, 2011). Fig. 1 summarizes the main dietary factors associated with the pathophysiology of PE.

## Angiogenic and antiangiogenic factors

Angiogenic and antiangiogenic factors have been the subject of extensive research in the last decade, and have been considered as part of international guidelines for early detection of PE (Verlohren and Droge, 2020). Placental growth factor (PlGF), which belongs to the VEGF cytokine family, is a proangiogenic protein expressed in the syncytiotrophoblast that promotes the vasculogenesis process (Cerdeira and Karumanchi, 2012) and is normally found in high concentrations in the first weeks of pregnancy with a decrease after this time (Jardim et al., 2015). Soluble fms-like tyrosine kinase (sFlt-1) is an antiangiogenic protein produced by the syncytiotrophoblast that binds to the PlGF receptor circulating form, preventing its interaction with endothelial receptors, leading to endothelial cell dysfunction and vasoconstriction (Jardim et al., 2015; Verlohren and Droge, 2020). In normal pregnancies, sFlt-1 increases at the end of pregnancy but is elevated earlier in preeclamptic pregnancies (Levine et al., 2006). The prospective observational study PROGNOSIS, conducted in 14 countries, found that the ratios sFlt-1 to PlGF  $>38$  had a sensitivity of 66.2% and specificity of 83.1% for predicting PE withing 4 weeks (Zeisler et al., 2016) and has been proposed for integration into clinical practice (Suresh and Rana, 2021).

## Inflammation

Inflammatory responses are cornerstones in the pathophysiology of PE. In normal gestations, the modulation of the immune response, with a hormonal/placental-induced shift from a T-helper (Th) 1 toward a Th2 immune response is needed for appropriate development of pregnancy (Hegde, 1991; Sykes et al., 2012). Under normal conditions, naïve T-cells differentiate into regulatory T cells (Treg) (Ghaebi et al., 2017), creating the shift toward a Th2 biased state. However, depending on the cytokine milieu, this physiologic response could turn into the production of pro-inflammatory Th17 cells (Saito et al., 2010) and Th1 cells (Chau et al., 2016), leading to adverse pregnancy outcomes.

**Fig. 1** Flowchart of key processes in the pathophysiology of preeclampsia. Inadequate placentation is associated with placental hypoxia and oxidative stress that leads to an imbalance between angiogenic and antiangiogenic factors. Misplacentation results in endothelial dysfunction and inflammation, that are responsible for clinical manifestations of preeclampsia. Some maternal nutritional deficiencies have been predominantly associated with processes of oxidative stress (vitamin D, folic acid, omega-3 fatty acids, L-arginine, calcium, magnesium, selenium), and with inflammation (imbalanced omega-3/omega-6 fatty acids, deficiencies in vitamin D and folic acid). Overweight and obesity usually coexist with hyperglycemia, insulin resistance and dyslipidemia, which also have been associated with the endothelial dysfunction and inflammation observed in preeclampsia.

The reduced placental perfusion in PE induces the release of pro-inflammatory cytokines (Hong et al., 2021). Excessive activation of peripheral and placental neutrophils and monocytes that produce high amounts of pro-inflammatory cytokines such as interleukin (IL)-1 $\beta$ , IL-6 and IL-8, has been observed in PE (Perez-Sepulveda et al., 2014), whereas IL-10, an anti-inflammatory cytokine, has been observed decreased in PE (Nath et al., 2020). Syncytiotrophoblast microparticles in maternal circulation (Martinez-Varea et al., 2014), damage-associated molecular patterns such as uric acid, high-mobility group box 1, IL-1 and cell-free fetal DNA resulting from placental damage (Nadeau-Vallee et al., 2016) have been proposed as “sterile” sources of inflammation. Moreover, maternal infections, via Toll-like receptors activation, have also been proposed as triggers of the immune response observed in PE (Laresgoiti-Servitje, 2013). Notably, *Helicobacter pylori* (Nourollahpour Shiadeh et al., 2019), periodontal, vaginal and urinary infections can induce the production of pro-inflammatory cytokines and other cellular mediators that can lead to endothelial dysfunction and PE (Nourollahpour Shiadeh et al., 2017). Recently, the placental microbiome has been shown to be important in maintaining a healthy pregnancy, and dysbiosis of local bacterial community has been proposed as source of inflammation that leads to HDPs (Beckers and Sones, 2020). Also, SARS-COV-2 during pregnancy has been associated with elevated odds of HDPs (Conde-Agudelo and Romero, 2021). Current research supports the screening and early treatment of common maternal infections as part of the prevention strategies for adverse pregnancy outcomes including PE.

### Oxidative stress

Oxidative stress has been proposed as one of the main components in the etiology of PE (Godhamgaonkar et al., 2021). Reactive oxygen species (ROS) resulting from the reduction of molecular oxygen at the mitochondrial level are involved in cellular signaling and are increased during normal pregnancy (Pereira et al., 2015). ROS formation that exceeds antioxidant activity induces endothelial adhesion of leukocytes and platelets, and the release of cytokines and antiangiogenic factors (Matsubara et al., 2015). Therefore, ROS are tightly controlled by antioxidant host defenses (Sanchez-Aranguren et al., 2014) including enzymatic antioxidant molecules such as superoxide dismutase, glutathione peroxidase and catalase, and non-enzymatic antioxidants such as glutathione, carotenoids, flavonoids, vitamins C and E (Valko et al., 2007).

It has been reported that oxidative stress can inhibit endothelial nitric oxide synthase (NOS), decreasing the availability of nitric oxide (NO) (Guerby et al., 2021). NO is produced by endothelial cells from the amino acid L-arginine through the activation of NOS, producing L-citrulline as byproduct (Vallance and Chan, 2001), a process that depends on calcium (Lopez-Jaramillo et al., 2018). Upregulated by high estrogen concentrations during pregnancy, NO helps in the maintenance of vascular tone and increasing uterine blood flow, produces vasodilatation and anticoagulation (Matsubara et al., 2015). In PE, there is decreased NO availability due to its rapid degradation and consequent decreased endothelium-relaxation (Guerby et al., 2021).

## Abnormal lipid metabolism

During normal pregnancy, the anabolic metabolism associated with increased maternal adipose tissue, insulin resistance, peripheral adipose tissue lipolysis and a trend to ketone utilization are mechanisms that spare glucose for fetal supply, expressed as an increase in maternal free fatty acids and lipoprotein triglyceride content (Barrett et al., 2014). In PE, this normal metabolic response is exaggerated, presenting with lower fasting and higher postprandial glucose concentrations, increased insulin resistance, hypertriglyceridemia and high circulating free fatty acids (von Versen-Hoeynck and Powers, 2007; Salzer et al., 2015; Hauth et al., 2011).

A higher degree of insulin resistance has been observed in early pregnancy in women who subsequently develop HDPs (Sierra-Laguado et al., 2007). Recently, the role of hyperinsulinemia in the immune response during PE has been reviewed. Both hyperglycemia and hyperinsulinemia possess the capacity to trigger a pro-inflammatory response; hyperinsulinemia could promote the differentiation of Th17 cells and the function of cytotoxic T cells while decreasing the formation of regulatory T cells, enhancing a pro-inflammatory environment and predisposing to PE (van Niekerk et al., 2021).

The association of hyperlipidemia with PE has been confirmed by two recent meta-analyses, one with African women (Tesfa et al., 2020b) and another with a multiethnic population (Spracklen et al., 2014). They found that total cholesterol, triglycerides, low-density lipoprotein (LDL) and very-low density lipoprotein (VLDL) were increased, and high-density lipoprotein (HDL) were decreased in pregnancies with PE compared with normal pregnancies. It has been proposed that accumulation of free fatty acids and triglycerides in endothelial cells, with the release of prostaglandins and nitric oxide, leads to the endothelial dysfunction observed in PE (Wojcik-Baszko et al., 2018). Moreover, it has been proposed that, similarly to atherosclerotic lesions, the formation of cholesterol crystals from oxidized LDL at the pre-eclamptic maternal-fetal interface are promoted through the activation of the Nod-like receptor protein (NLRP3) inflammasome, triggering a pro-inflammatory response (Silva et al., 2020). As the NLRP3 pathway exacerbates oxidative stress and endothelial dysfunction, its inhibition has been seen as a possible therapeutic target in the treatment of PE (Nunes et al., 2021).

Adipose tissue secretes adipokines such as adiponectin, leptin and TNF- $\alpha$ , molecules that mediate metabolic processes, including lipid and glucose metabolism, inflammation, vascular homeostasis, endothelial function and placental angiogenesis (Daskalakis et al., 2020), all reasons why their role as mediators in the pathophysiology of PE has been proposed (Gutaj et al., 2020). Adiponectin is mainly synthesized by adipocytes, but is also produced in placenta and fetal tissues (Herrera and Ortega-Senovilla, 2014). Adiponectin possesses *anti*-apoptotic, antioxidant and *anti*-inflammatory properties (Pheiffer et al., 2021), increases insulin sensitivity, reduces serum free fatty acids, triglyceride and glucose concentrations, and inhibits monocyte adhesion (Roberts et al., 2011). However, studies exploring associations between adiponectin and PE show conflicting results with authors finding no association (Dalamaga et al., 2011), decreased (Mori et al., 2010) and increased adiponectin (Fasshauer et al., 2008; Salimi et al., 2014; Liu et al., 2012) in women with PE.

Whereas the use of adiponectin as a biomarker of PE requires further research, leptin has been consistently found increased in PE (Daskalakis et al., 2020). Leptin is a hormone produced by the placental trophoblast, maternal and fetal adipose tissue (Taylor et al., 2015). Through hypothalamic influence, leptin modulates satiety, decreases appetite and body weight; leptin also participates in angiogenesis and in the amino acid transport system in the placenta (Taylor et al., 2015). Its role as angiogenic factor, increasing placental perfusion and nutrient transport, and the inhibition of apoptosis of trophoblastic cells in PE, have led to the proposal that hyperleptinemia could be a compensatory mechanism for reduced placental dysfunction in PE and that it could be used as an early marker of the disease (Taylor et al., 2015; Miehle et al., 2012; Daskalakis et al., 2020). Novel adipokines chemerin, visfatin, resistin and apelin have been found involved in angiogenesis, regulation of blood pressure and triggering of the pro-inflammatory response and are under investigation regarding their role in PE (Estienne et al., 2019).

Essential fatty acids linoleic acid and  $\alpha$ -linolenic acid (ALA) through desaturation and elongation by delta-6 and delta-5 desaturases, are converted into long chain polyunsaturated fatty acids (LC-PUFAs) omega-6 fatty acids (linolenic acid, arachidonic acid—AA), and omega-3 fatty acids (eicosapentaenoic acid—EPA and docosahexaenoic acid—DHA) respectively. Essential fatty acids are components of phospholipids and crucial for the function of cellular and subcellular membranes (Carvajal, 2014). It is known that whereas omega-3 LC-PUFAs (from green vegetables, oily seeds, fish and grass-fed animal products) have *anti*-inflammatory properties, omega-6 LC-PUFAs (from vegetable and hydrogenated oils and non-grass-fed animal products) have pro-inflammatory properties, and that these groups compete as substrates for the same enzymes (Mauro et al., 2022). Most studies on bioactive lipids and PE have found an increase of n-6 and a decrease in n-3 free fatty acids in PE. PUFAs including AA, EPA, DHA and the platelet *anti*-aggregator and vasodilator prostacyclin (PGI<sub>2</sub>) are reduced in PE, whereas the platelet aggregator and vasoconstrictor thromboxane A<sub>2</sub> is increased in women with PE (Das, 2015).

Supplementation with omega-3 fatty acids has the potential to modify the placental environment by improving nutrient transport capacity, modulating the inflammatory response, and affecting oxidative stress with increases or decreases, depending on dosage, timing and background diet, particularly in overweight and obese women (Rasool et al., 2021). A recent Cochrane review found a reduced risk of PE with omega-3 LC-PUFA (RR 0.84, 95% CI 0.69 to 1.01) after analyzing 20 trials, but the evidence was of low-quality (Middleton et al., 2018). A more recent meta-analysis found a significant effect of omega-3 on reducing the risk PE only when restricting analyses to studies in low-medium income countries (Kinshella et al., 2021a). To date, evidence is insufficient to advise supplementation with essential fatty acids for the prevention of PE.

### Plasma volume dysregulation

During normal pregnancy, plasma volume steadily increases (de Haas et al., 2017). The increased plasma volume is favored by physiologically elevated concentrations of renin, angiotensin II and aldosterone (Birukov et al., 2019). There is also an increase in maternal cardiac output, vasodilation and decreased peripheral resistance (Gyselaers et al., 2018). These changes are driven by concomitant increase in nitric oxide production and vascular resistance to angiotensin II which leads to the physiologic fall of blood pressure during the first trimester (Armanini, 2012). Of interest, plasma volume expansion is lower in pregnancy-induced hypertension and PE (de Haas et al., 2017; Gyselaers et al., 2018). As a result of decreased plasma volume expansion, higher hemoglobin concentrations can be observed in preeclamptic patients (Ng et al., 2019), and it is known that the use of iron supplementation increases the erythrocyte mass (Means, 2020). Moreover, it has been suggested that excessive iron intake or high iron status may amplify oxidative stress and produce programmed cell death mediated by iron-dependent lipid peroxidation of cell membranes in the placenta (ferroptosis) (Ng et al., 2019; Erlandsson et al., 2021), contributing to the development of HDPs.

### Early detection of HDPs

In an attempt for early detection of women at risk of HDPs, first-trimester algorithms including clinical and laboratory biomarkers have been developed. Recently, the Community-Level Interventions for Preeclampsia (CLIP) trials developed in India, Pakistan and Mozambique found that the visit-to-visit systolic and diastolic blood pressure variability was associated with increased odds of hypertension during pregnancy (Magee et al., 2021).

Elevated mean arterial pressure [ $\text{MAP} = \text{diastolic} + 1/3 (\text{systolic} - \text{diastolic})$ ] has also been reported to have a higher predicted value for the detection of PE among low-risk pregnant women than systolic or diastolic blood pressure (Sunjaya and Sunjaya, 2019). MAP was associated with gestational age, maternal age, weight, height, Afro-Caribbean racial origin, cigarette smoking, family history of PE, history of PE in the previous pregnancy, interpregnancy interval, chronic hypertension and diabetes mellitus in a population of European women (Wright et al., 2015). MAP was also positively associated with maternal weight-by-height classification, intake of multiple nutrient supplements, TNF-alpha, protein deficiency and the presence of the parasite hookworm, whereas negative associations with the presence of *Trichomonas vaginalis* and *Ascaris* in an indigenous population with high prevalence of infections, nutrient deficiencies and low plasma volume (González-Fernández et al., 2020). Therefore, MAP is able to capture a series of factors predisposing to hypertension during pregnancy, and represents a feasible, non-invasive, cost-effective screening tool for early detection of HDPs.

It has been proposed that the best biomarker combinations for the prediction of PE may include maternal risk factors, MAP, uterine artery pulsatility index and serum PlGF (Poon et al., 2019), which has reported detection rates of 90% for the prediction of early PE, with a 10% false-positive rate (Chaemsaihong et al., 2020) and that can be used to start prophylactic treatment with low-dose aspirin and calcium to reduce the risk of PE. Finally, the Preeclampsia Integrated Estimate of Risk (PIERS) are predictive models aiming to reduce adverse pregnancy outcomes (mortality or life-threatening conditions) by improving the diagnosis and initial management of PE for adverse pregnancy outcomes (von Dadelszen et al., 2009). The models include gestational age at presentation, clinical signs (blood pressure and dipstick proteinuria) and symptoms (chest pain/dyspnea, headache or visual disturbances, vaginal bleeding with abdominal pain) to be applied in low-resource settings, as well as biomarkers (oxygen saturation, platelet count, creatinine and aspartate transaminase concentrations) when available (von Dadelszen et al., 2011). PIERS models have been validated in well-resourced (von Dadelszen et al., 2011) and minimally resourced settings (Lim et al., 2015) demonstrating a good- [area under a receiver operating characteristic curve ( $\text{AUC} > 0.80$ )] to-excellent accuracy ( $\text{AUC} > 0.90$ ) (von Dadelszen et al., 2009).

### Association between nutritional factors and preeclampsia

Nutritional factors intervene in key processes of placental formation, endothelial function and inflammation, therefore, recent research has focused on the role of nutrition in the pathophysiology of PE as possible therapeutic targets.

#### Overweight and obesity

Overweight and obesity are independently associated with HDPs (Vats et al., 2021; He et al., 2020). There is epidemiological evidence of the association of HDPs and high BMI, which is considered one of the major risks for PE in the United States (Ananth et al., 2013) and in low-middle income countries (Bilano et al., 2014; Tesfa et al., 2020a).

It has been proposed that pre-pregnancy obesity or excessive weight gain during pregnancy might trigger inflammation (Pare et al., 2014) and increase insulin resistance (Lopez-Jaramillo et al., 2018), leading to misplacental, placental hypoxia and ischemia, the placental release of antiangiogenic factors and further endothelial dysfunction, characteristics of PE (Lopez-Jaramillo et al., 2018; Spradley et al., 2015). Also, as dysregulated adipokine production occurs in obesity where the role of adipokines in PE has been explored (Gutaj et al., 2020; Perez-Perez et al., 2018; Tilg and Moschen, 2006). Decreased adiponectin and

increased leptin were observed in obese women with PE, whereas normal weight pregnant women with PE showed increased adiponectin (Hendler et al., 2005).

Despite clear evidence of the increased risk of PE with overweight and obesity, interventions addressing maternal BMI during pregnancy show conflicting results. A meta-analysis of 23 trials looking at the effect of diet and exercise on the risk of HDPs or PE (Syngelaki et al., 2019), but another meta-analysis of 106 studies showed that moderate/intense exercise but not exercise plus cointerventions, was able to reduce the odds of PE (OR: 0.62, 95% confidence interval: 0.52–0.75) compared with no exercise (Davenport et al., 2018).

### Maternal undernutrition

There is evidence that maternal undernutrition, in particular low protein intake is associated with increased risk of PE (Bej et al., 2013). Particularly, L-arginine and L-citrulline, which are available in protein-rich foods, are usually deficient in low-resource settings (Weckman et al., 2019). In contexts where undernutrition and infection coexist, a common pathway for the development of pregnancy complications involving the dysregulation of the arginine-NO biogenesis has been proposed (Weckman et al., 2019). On the other hand, high-protein supplementation during pregnancy has been associated with decreased fetal growth (Mousa et al., 2019; Kramer and Kakuma, 2003) and is not recommended. It is also possible that higher rates of undernutrition and reported low intakes of calcium, iron, folate, magnesium, zinc and selenium found in developing countries, as well as the reduced risk of HDPs with balanced diets, might help to explain the higher prevalence of HDPs in resource-limited settings (Kinshella et al., 2021a), but more research is needed to identify the influence of maternal undernutrition on HDPs.

### Vitamins

**Vitamin A:** Vitamin A comprises a group of fat-soluble compounds, where retinol and retinyl esters are obtained from animal sources, and provitamin A carotenoids and beta-carotene from plants (Baker et al., 2018). Retinoic acid, the active derivative of vitamin A, is a regulator of the human trophoblast during placentation (Huebner et al., 2018). Vitamin A also interacts with the innate and adaptive immune systems, acting as immune-modulator (Wiseman et al., 2016). Therefore, vitamin A deficiency may have an impact on placental function, tissue inflammation and structural development (Thoene et al., 2020). However, vitamin A supplementation is not recommended during pregnancy due to its potential teratogenic effect, except in regions where vitamin A deficiency is a public health concern (Bastos Maia et al., 2019). Carotenoids, beta-carotene and lycopene are antioxidants that have been shown to protect against free radical damage and were found in lower serum concentrations in preeclamptic women compared with normal pregnancies (Palan et al., 2001). A mechanistic pathway of vitamin A favoring the decidualization process by suppressing sFlt-1 has been proposed (Rajakumar et al., 2020) but large studies supporting the use of vitamin A supplementation for the prevention of HDPs or PE are lacking (Kinshella et al., 2021b).

**Vitamin D:** Vitamin D is a group of fat-soluble sterols, comprising ergocalciferol (D2) and cholecalciferol (D3), the latter being synthesized in humans in the skin, acquired in the diet (fish, fish liver oil, egg yolk, mushrooms) or through supplements. Liver 25-hydroxylation of D2 and D3 give rise to 25-hydroxyvitamin D or calcitriol, the main circulating form of vitamin D. Calcitriol is classically known for its role in bone metabolism, but parallel functions of vitamin D as immune modulator and cardiovascular protector have been recognized (Poniedziałek-Czajkowska and Mierzyński, 2021). In pregnancy, vitamin D regulates genes and the immune response associated with appropriate implantation, trophoblast invasion and implantation tolerance (Schroder-Heurich et al., 2020). There is evidence from cohort, case-cohort and nested case-control studies that higher maternal vitamin D concentrations are associated with lower risk of developing HDPs (Zhao et al., 2022), and a meta-analysis suggested an association between higher vitamin D and reduced risk of PE (Hyppönen et al., 2013). However, vitamin D combined with calcium has shown to increase the risk of preterm birth (Kinshella et al., 2021b). Current evidence on supplementation of vitamin D during pregnancy for the prevention of HDPs is inconclusive (Poniedziałek-Czajkowska and Mierzyński, 2021).

A possible protective role of vitamin D in PE could be related with a suppressive effect on the renin synthesis, the amelioration of insulin resistance, the improvement of endothelial vasodilatation, the inhibition of anticoagulant activity, and the modulation of macrophage activity and cytokine production (Colonese et al., 2015). It is worth noting that randomized controlled trials of appropriate design and quality to determine the usefulness of vitamin D supplementation for the prevention of HDPs are lacking to date (Kiely et al., 2020), and that the WHO does not currently recommend vitamin D supplementation to improve maternal or perinatal outcomes (World Health Organization, 2016).

**Vitamin E:** Vitamin E comprises lipid-soluble compounds - tocopherols and tocotrienols, from which alpha-tocopherol is the major form of vitamin E in plasma, whereas gamma-tocopherol is the most abundant in the diet, mainly acquired from soybean and corn oil (Gagne et al., 2009). Vitamin E is also available in the fat of meat, nuts, some cereals and green leafy vegetables. Vitamin E protects cell membrane phospholipid fatty acids from oxidation by reactive oxygen species, thus preventing oxidative stress (Rumbold et al., 2015a). The antioxidant activity of gamma-tocopherol is superior to alpha-tocopherol, which can have pro-oxidant activity that is prevented by vitamin C (Gagne et al., 2009). The interaction of vitamin C with vitamin E allows the recycling of oxidized vitamin E back to its useful form (Rumbold et al., 2015a). As placental oxidative stress and lipid peroxidation have been involved in endothelial cell dysfunction in HDPs (Salles et al., 2012), antioxidants could theoretically help for the prevention of the disease. However, a WHO multicenter randomized trial in women from developing countries at high risk of PE, showed no association of supplementation with vitamins C and E for the reduction of HDPs (Villar et al., 2009). An international trial of

antioxidants in the prevention of PE (INTAPP) found no reduction in PE or gestational hypertension with vitamin C and E supplementation but an increased risk of fetal loss and preterm pre-labor rupture of membranes (Xu et al., 2010). A meta-analysis of clinical trials for the use of vitamins E and C during pregnancy found no reduction of the risk of PE, but an increase in the risk of gestational hypertension (Conde-Agudelo et al., 2011). The latest Cochran review on vitamin C (Rumbold et al., 2015b) and vitamin E (Rumbold et al., 2015a) demonstrated no effect of supplementation of these vitamins alone or combined for the prevention of PE. Most recent research discriminating isoforms of vitamin E has found that vitamin E and C supplementation increased alpha-tocopherol but decreased gamma-tocopherol which could help to explain the failure of supplementation to prevent HDPs (Bilodeau et al., 2021).

**Folic acid and vitamin B12:** One-carbon metabolism is fundamental for cardiovascular health and for fetal development during pregnancy. It depends on folic acid and vitamin B12 to convert homocysteine (Hcy) to methionine, which is later converted to S-adenosyl methionine, the major donor for DNA, RNA, lipids and protein methylation (Mahmood et al., 2021). Hcy accumulation due to deficiencies in folic acid and B12 can lead to adverse pregnancy outcomes including PE (Dai et al., 2021). Proposed mechanisms for the association of Hcy and PE include endothelial dysfunction or vascular damage, given that Hcy decreases the production of nitric oxide, promotes platelet aggregation and promotes atherogenesis (Mahmood et al., 2021).

Folic acid supplementation in early pregnancy contributes to a healthy placental implantation, cell division, angiogenesis, trophoblast invasion and vascular relaxation, and supplementing after the first trimester, folic acid may protect against elevated Hcy (Bullock et al., 2018), therefore preventing the development of HDPs. However, there is no conclusive agreement in the use of folic acid supplementation for the prevention of PE. In a systematic review and meta-analysis, two randomized controlled trials showed decreased risk of PE in women supplemented with folic acid compared with placebo, but pooled risk ratios of cohort studies did not show a significant effect (Hua et al., 2016). Another meta-analysis showed that, in observational studies, folic acid supplementation lowered the odds of PE compared with non-supplemented women (Bullock et al., 2018). The FACT—Folic Acid Clinical Trial, a large multi-country randomized controlled trial, observed that 4–5.1 mg of folic acid supplementation beyond the first trimester did not prevent the developing of PE; results did not change when adjusting for confounders or dividing analyses by country (Wen et al., 2018). Most recent studies have found that PE was associated with lower folic acid and higher Hcy but not B12 (Olapeju et al., 2020; Liu et al., 2020; Serrano et al., 2018). Current literature supports the need for studies with sophisticated designs to confirm the protective effect of folic acid/B12 on the prevention of PE.

### Minerals and trace elements

**Sodium:** Given that the renin-angiotensin-aldosterone system is influenced by dietary salt, and the secretion of aldosterone is stimulated by adrenocorticotrophic hormone and potassium, it has been proposed that excessive sodium combined with low potassium intakes during pregnancy could adversely affect placental development (Birukov et al., 2019), favoring the development of PE. However, studies on sodium intake during pregnancy have generated opposing results. A Cochrane review including two trials found insufficient evidence to advise lower salt consumption during pregnancy for the prevention of PE (Duley et al., 2005). More recently, lower sodium intake during pregnancy was associated with lower risk of HDPs (Arvizu et al., 2020), however, the evidence for restricting sodium intake for reducing the risk of PE is insufficient and is not recommended (ACOG, 2020).

**Calcium and Magnesium:** Calcium supplementation is one of the few recommended approaches for the prevention of PE (World Health Organization, 2016), and magnesium sulfate is the keystone treatment in the prevention of seizures in preeclamptic women (Lambert et al., 2014), indicating the importance of these two micronutrients in the pathophysiology of PE.

It has been observed that traditional calcium-enriched foods were associated with low incidence of PE in indigenous populations, which led to finding an associations between low intakes of calcium, hypocalcemia or hypocalciuria with HDPs (Hofmeyr et al., 2018). A low calcium intake may increase blood pressure by stimulating the parathyroid hormone and/or the release of renin leading to vasoconstriction, or via increasing magnesium concentrations (Hofmeyr et al., 2018). However, experimental studies have shown that calcium supplementation may reverse endothelial cell activation induced by trophoblastic debris in preeclamptic placenta, and that the protective action of calcium on PE may be related its *anti-inflammatory* effect and its role as a cofactor of NOS (DeSousa et al., 2015).

Overall, studies converge in observing a protective effect of calcium supplementation on PE and gestational hypertension (Sun et al., 2019). The last Cochrane review concluded that calcium, at dosage  $\geq 1$  g/d, may reduce the risk of PE, particularly in those women with low-calcium diets and at high risk of PE (Hofmeyr et al., 2018), but there is not sufficient evidence that starting supplementation before or during early pregnancy adds to the benefits of calcium supplementation in the second half of pregnancy (Hofmeyr et al., 2019). However, supplementation with low doses of calcium (500 mg/d) showed a reduction in high blood pressure and the risk of PE, but the evidence is limited and needs to be confirmed by large/high-quality trials (Hofmeyr et al., 2018). Calcium for PE prevention is included in some country guidelines, but recommendations vary depending on the level of risk and/or baseline calcium intake; as reviewed by Scott et al. some guidelines recommend calcium supplementation in women with low calcium intake regardless of the risk of PE (The World Health Organization, Canada, Ireland, Tunisia and the European Society of Cardiology), others only in moderate to high risk women regardless their calcium intake (Society of Obstetric Medicine of Australia and New Zealand), or low intake and intermediate or high risk of PE (Basil, ISSHP and New Zealand) (Scott et al., 2020).

The use of magnesium for PE prevention has been less studied. A recent meta-analysis including seven randomized-controlled trials found that oral magnesium supplementation during pregnancy could reduce the risk of PE in women at high-risk of the disease (Yuan et al., 2021), but large randomized controlled trials are needed to validate these findings. The underlying mechanistic

explanation might be related with a decreased endothelial growth factor and decreased oxidative stress with experimental chronic use of magnesium, but further research is warranted (Yuan et al., 2021).

**Iron:** Iron requirements during pregnancy increase due to increase in maternal and fetal needs for erythropoiesis and for fetal growth, and iron deficiency is a known cause of adverse pregnancy outcomes, such as low birth weight, prematurity and intrauterine growth restriction where the benefits of supplementation during pregnancy have been well established (Means, 2020; Georgieff, 2020). Iron deficiency may impair placental function (Milman et al., 2016), but iron overload may produce oxidative stress and endothelial dysfunction (Shaji Geetha et al., 2020), both playing a role in the development of PE. A lower ferritin concentration was found correlated with lower prevalence of PE (Lao et al., 2000), and iron supplementation before 16 weeks' gestation has been associated with increased risk of *de novo* hypertension after 20 week's gestation (Jirakittidul et al., 2018). Therefore, caution should be made when supplementing pregnant women with iron, especially those with normal hemoglobin and/or with risk factors for developing HDPs.

**Trace elements:** Selenium is an essential trace element that makes part of enzymes involved in antioxidant defense mechanisms, redox regulation and thyroid hormone metabolism (Duntas, 2020). A meta-analysis of 16 studies from high and low-medium income countries previously showed increased risk of HDPs with lower serum selenium concentration and, in their sub-analysis of 3 randomized controlled trials where selenium supplementation (60–100 µg/d) took place, there was a reduced relative risk of PE (0.28, 95% CI: 0.09–0.84) (Xu et al., 2016). A more recent large study in a Norwegian population with sufficient dietary intakes and normal blood selenium concentrations, found no significant association between selenium intake from diet or supplements or blood selenium status with HDPs or PE (Holmquist et al., 2021).

A meta-analysis of 16 studies found that Asian women with PE had higher serum copper concentrations than controls (Song et al., 2017), whereas two meta-analyses including mainly Asian and African populations found lower serum zinc concentrations in preeclamptic women compared with controls (Ma et al., 2015; Tesfa et al., 2021). A recent meta-analysis of 5 studies found that urine iodine concentrations were lower in women with PE compared with controls, but no different risk of PE in women with iodine concentrations below the cut-off of 150 µg/L; authors acknowledged small sample sizes and heterogeneity of included studies (Busi-nge et al., 2021). The evidence on trace elements (separately or included in multiple micronutrient mixtures) as therapeutic agents to prevent PE is insufficient and they are not currently recommended (World Health Organization, 2016).

## Conclusion

Nutrients are involved in the pathophysiology of PE and addressing deficiencies and avoiding excesses of key macro- and micro-nutrients can have an impact on preventing the disease. Healthy diets and lifestyles aiming to fulfill pregnancy nutritional requirements, correcting undernutrition and controlling overweight should be promoted, starting before pregnancy and throughout gestation. The premise of no-harm should prevail over novel attractive approaches for supplementation. Of note, despite the evidence on some micronutrients decreasing the odds of HDPs, adverse effects of supplementation on fetal health need to be considered. This is the case for high-protein supplements and concomitant supplementation of calcium and vitamin D. In contrast, supplementation may have beneficial effects in women with specific nutritional needs which is the case for calcium, and possibly other minerals and vitamins. The potential benefits of supplementation also needs to discriminate among different types of HDPs, as well as different risk factors including overweight/obesity and macro/micronutrient deficiencies.

A comprehensive approach for pregnancy follow up that includes the evaluation of socio-demographic risk factors, MAP and ultrasound/biochemical biomarkers where available, could be complemented with counseling on balanced diet and exercise, in an effort to reduce the toll of HDPs, particularly PE, on maternal and fetal health.

### Key points

This chapter aims to

- Describe the terminology and general epidemiology pertaining to neural tube defects (NTDs).
- Provide knowledge and underpinning scientific evidence in relation to
  - The genetic and environmental factors implicated in NTD, and particularly the major role played by low maternal folate status;
  - The contribution of other risk factors, including, low vitamin B12 status, obesity, diabetes and certain drug treatments;
  - The biological mechanisms in the etiology and prevention of NTDs.
- Review the current evidence in relation to preventing first and recurrence of NTD, including
  - Nutrition considerations;
  - Effectiveness of folic acid interventions to optimize folate status via supplementation and fortification approaches.
- Provide an understanding of current folic acid policy globally and
  - Impacts on NTD prevalence;
  - Impacts on other health outcomes throughout the lifecycle;
  - Risk-benefit assessment for emerging policy.
- Describe current recommendations for the prevention of first occurrence and recurrence of NTDs.
- Generate well-reasoned conclusions in relation to policy to prevent NTDs worldwide through effective interventions.

### Glossary

**Anencephaly** Failure of the section of the neural tube to close in the area of the brain, causing the absence of a large part of the brain and skull. Anencephaly is uniformly fatal

**Craniorachischisis** A severe form of neural tube defect where the area in which the neural tube fails to close extends from the head down into the spine

**Encephalocele** A form of neural tube defect where there is failure of ossification of a portion of the skull. A sac like protrusion occurs which may contain only meninges (encephalocele) or brain tissue and meninges (meningoencephalocele)

**Iniencephaly** A severe form of neural tube defect in which the head is flexed in an upward gaze and both anencephaly and spinal defects are common

**Meningocele** A form of spina bifida. There is a failure of the neural tube to close in the area of the spine causing a defect in the vertebral arches through which cerebrospinal fluid filled meninges, but not neural tissue, protrude

**Myelomeningocele** A serious form of spina bifida. There is a failure of the neural tube to close in the area of the spine causing a defect in the vertebral arches through which cerebrospinal fluid filled meninges and neural tissue protrude

**Neural Tube Defects** Neural tube defects (NTDs) are birth defects of the brain and spinal cord which arise when the neural tube does not close properly during the first few weeks post-conception. The two most common forms of NTDs are spina bifida and anencephaly; other forms listed above are much rarer

**Spina Bifida** A main type of neural tube defect. Affects the spine and can happen anywhere along the spine where the neural tube does not completely close. Physical and intellectual disabilities can arise, ranging from mild to severe

### Introduction

Neural tube defects (NTDs) are the most common anomalies of the central nervous system, arising when the neural tube fails to close properly in the developing fetus, resulting in death or lifelong disability. The main categories of NTDs are spina bifida (a spinal cord defect) and anencephaly (a brain defect). Normally, the neural tube closes to form the brain and spinal cord within the first 28 days after conception. The type of lesion occurring in NTD depends on the portion of the neural tube that fails to close. Failure of the cranial portion to close causes anencephaly, a uniformly fatal brain defect, whereas failure of the more caudal neural tube to close causes myelomeningocele or meningocele (two forms of spina bifida). The severity of the defect depends on the location; in general, the higher the defect, the more severe the disability. Less common forms of NTD include encephalocele, iniencephaly, and craniorachischisis. Combinations of these lesions may be present in severely affected cases. Most children with NTDs who survive beyond birth will have serious disabilities.

### Epidemiology

It is estimated that 322,000 or more pregnancies worldwide are affected by spina bifida and anencephaly annually, at an average prevalence of about 20 cases per 10,000 births, corresponding to one in every 500 births globally (Blencowe et al., 2018). In low- and middle-income countries, the prevalence is estimated to exceed one in every 100 births. Furthermore, an estimated 60,000 NTD-affected pregnancies are electively terminated annually (after prenatal diagnosis), and another 60,000 result in stillbirths (Blencowe et al., 2018). In the past 50 years the prevalence of NTD has dropped significantly in high-income countries, particularly in regions that traditionally had high rates. The reason for this decline (which had actually started before the implementation of mandatory folic acid-fortification of foods) is likely due to improved diets (particularly with respect to folate intakes), prenatal diagnosis and access to termination. Because the neural tube closes very early in pregnancy (between the 3rd and 4th weeks post-conception), before many women are aware that they are pregnant, NTDs have been problematic to study and to prevent. In fact, prevention essentially requires that interventions be initiated before conception. As a result, public health policy in this area has proved to be challenging, especially considering that an estimated 50% of all pregnancies are unplanned.

### Genetic and environmental factors

Both genetic and environmental factors are known to be involved in the etiology of NTDs. Evidence for a genetic component comes from studies showing racial differences in prevalence, recurrence risks of approximately 10-times the general occurrence risk, higher rates in females and well recognized mendelian syndromes that include NTDs. Over 240 laboratory mouse strains exhibiting NTDs have been generated by single or multiple gene manipulations, further substantiating a strong genetic component. Nevertheless, the

majority of NTDs are isolated, consistent with a low penetrance etiology exhibiting unclear and probably variable genetic and environmental influences.

Marked variations in prevalence over time, between areas and across social classes, provide evidence of the importance of environmental factors in NTD. In particular, evidence for nutritional factors has accumulated since the 1960s. The observation that women of low socio-economic status were at increased risk of having a child with an NTD stimulated Smithells and coworkers several decades ago to examine diet as a risk factor and to measure vitamin levels in pregnant women (Smithells et al., 1983). Their findings, that women carrying affected fetuses had significantly lower red blood cell folate concentrations, stimulated many subsequent case-control studies and later clinical trials. The totality of evidence from these intervention and case control studies showed that periconceptional use of vitamin supplements containing folic acid reduced NTD rates by 35–71%. Folic acid is the synthetic form of the vitamin known as folate in its natural forms.

### Maternal folate status Table 1; Table 2

#### *Intervention studies with folic acid in the prevention of NTDs*

The definitive evidence for a protective effect of maternal folic acid supplementation in the prevention of recurrence and first occurrence of NTDs was established by two notable randomized controlled trials published in the early 1990s. The Medical Research Council trial (MRC, 1991) randomized women with a previous history of an NTD-affected fetus to one of four intervention groups: folic acid, other vitamins, both, or neither. The findings showed that the NTD recurrence rate in the two groups which received folic acid was significantly lower than the rate in the groups that did not receive folic acid (odds ratio 0.28; confidence interval 0.12–0.71), suggesting that 72% of recurrences could be prevented by folic acid. It is important to note that 28% of NTD recurrences were not prevented by the high folic acid dose (4 mg) administered daily in the trial; this dose is more than 10 times higher than dietary folate recommendations. The multivitamin combination without folic acid had no protective effect. Vitamin B<sub>12</sub>, closely related to folate within one-carbon metabolism, was not included in the multivitamin tablets. The Hungarian trial investigating the effect of folic acid on first occurrence of NTD (in women with no previous history), published one year after the MRC trial, found no NTD occurrences in the treatment group who were given 800 µg per day folic acid plus other vitamins including 4 µg vitamin B<sub>12</sub> (Czeizel and Dudás, 1992), whereas 6 NTD cases occurred in the placebo arm receiving a multimineral combination without folic acid or vitamin B<sub>12</sub>. The combined evidence from both trials proves a specific protective effect of folic acid against first occurrence and recurrence of NTDs, and points to a potential additional role of vitamin B<sub>12</sub> in NTD prevention, as will be discussed later. The major intervention trials of periconceptional folic acid supplementation and NTD risk are shown in Table 1.

#### *Observational studies of maternal folate status in relation to NTD risk*

Observational studies generally demonstrate that women who have had pregnancies affected by NTD have lower folate concentrations (both in plasma and red blood cells) compared to nonaffected mothers. In a large prospective study in Ireland (where rates of NTD are among the highest in the world), a woman's risk of having a child with an NTD was shown to be strongly associated with pregnancy concentrations of red blood cell folate in a continuous dose-response inverse relationship (Daly et al., 1995). Specifically, mothers with red blood cell folate concentrations below 150 ng/mL (340 nmol/L) in early pregnancy had more than eight times higher risk of having an NTD-affected child than those whose folate concentrations were over 400 ng/mL (906 nmol/L) (Table 2). Data modeled from folic acid intervention studies conducted in China (Crider et al., 2014) were consistent with the relationship between red blood cell folate concentrations and NTD risk as reported in the Irish study by Daly and co-workers. In 2015, the WHO drew on these studies to establish evidence-based guidelines for optimal folate concentrations in women for the prevention of NTDs. According to the WHO (2015) recommendations, in order to achieve the greatest prevention of NTDs at a population level, folate concentrations should be >400 ng/mL (906 nmol/L) in women of reproductive age. It is important to appreciate that the risk of NTD will be increased when maternal folate status is low but within the range typically classed as normal range according to widely accepted cut-off values to diagnose folate deficiency (i.e. serum folate <10 nmol/L and RBC folate <340 nmol/L). Thus low, but not necessarily deficient, maternal folate status is associated with a higher risk of NTD and women not conventionally classed as folate deficient can be at higher risk of an NTD-affected pregnancy.

### Maternal vitamin B<sub>12</sub> status Table 3

Although low maternal folate is considered the major contributing factor, the role of vitamin B<sub>12</sub> in NTDs is of particular interest because of its close metabolic relationship with folate. Notably, vitamin B<sub>12</sub> is required for folate re-cycling and intracellular retention, thus B<sub>12</sub> deficiency leads to a failure to retain folates within cells thereby disturbing one-carbon metabolism. There are no trials demonstrating that vitamin B<sub>12</sub> intervention can prevent NTDs. There is however considerable evidence to show that low B<sub>12</sub> may be implicated in NTD (Molloy et al., 2009). Several studies that examined maternal vitamin B<sub>12</sub> status, both during and after an NTD-affected pregnancy, suggest that low maternal B<sub>12</sub> status is an independent risk factor for having an NTD-affected pregnancy. Such studies showed differences in NTD risk by maternal vitamin B<sub>12</sub> status, measured as total circulating B<sub>12</sub> or as serum holotranscobalamin (holoTC) (the fraction of total B<sub>12</sub> that is destined for tissue uptake and cellular processes thus metabolically "active"). Also, lower amniotic fluid B<sub>12</sub> concentrations and lower B<sub>12</sub> binding capacity have been reported in NTD-affected pregnancies (Steen et al., 1998). The relevant studies with at least 50 NTD case mothers are summarized in Table 3. These studies indicate that there is an approximately three-fold increased NTD risk for mothers in the lowest quartile or quintile,

**Table 1** Intervention trials of periconceptional folic acid supplementation and NTD risk.

Study	Location	Design	Daily dose folic acid (mg)	Outcome: no. of NTDs	Relative risk	Comments

compared to the highest, of blood B<sub>12</sub> concentration. The reports that failed to show a relationship of B<sub>12</sub> status with NTD were either studies with low numbers (less than 50 case mothers) and therefore more likely lacked sufficient statistical power to demonstrate a significant effect, or were from an area of low indigenous NTD risk (e.g., Finland). Although it has been suggested that low concentrations of vitamin B<sub>12</sub> may merely be a reflection of a low folate status, the analysis of data from studies that measured both vitamins suggests that they are independent risk factors in NTD. Of note, one study found the highest risk of NTD in women who were in the lowest quartile for both folate and vitamin B<sub>12</sub> (Kirke et al., 1993).

**Table 3** Large case-control studies (>50 case mothers) assessing blood vitamin B<sub>12</sub> status in mothers of NTD-affected children.

## Other maternal risk factors for NTD

### Specific nutrients

Apart from folate and vitamin B<sub>12</sub>, other nutrients involved in one-carbon metabolism may play a role in NTD. Low maternal choline status has been implicated in several studies as a risk factor for NTDs. Choline has a close metabolic interaction with folate, and there is evidence that supplementation with one nutrient may ameliorate the deficiency caused by the other. As discussed below, riboflavin may also play a protective role in preventing NTD in women genetically at higher risk owing to a common folate polymorphism but this remains to be demonstrated (i.e. those homozygous for the 677C→T polymorphism in the gene encoding methylenetetrahydrofolate reductase (MTHFR), a folate-metabolizing enzyme that depends upon riboflavin (as flavin adenine dinucleotide; FAD) for its activity). Also, one mutant animal strain that has served as a model of NTDs for decades is resistant to folic acid but responsive to maternal periconceptional supplementation with inositol. Building on the data from animal models, a series of small clinical studies in high-risk women who had experienced previous NTD-affected pregnancies indicated that supplementation with inositol has value in increasing NTD prevention beyond that achievable by folic acid alone (Facchinetti et al., 2020). It is possible that the observed protection by folic acid intervention in some instances occurs through indirectly ameliorating the impairment in one-carbon metabolism caused by one of these other nutrients. Deficiencies of other nutrients, including vitamin C and zinc, have also been implicated in NTDs but the evidence is limited and the data are inconsistent.

### Obesity and diabetes

There are other potentially modifiable risk factors for NTDs. Women who are obese compared to those of normal body mass index (BMI) are more likely to have a child affected with an NTD (and indeed other malformations including congenital heart defects). Several studies reported a higher risk of an NTD-affected pregnancy in obese women, with meta-analyses of available studies concluding that obese compared with normal BMI women are at higher risk of fetal NTDs, with a three-fold higher risk for severely

obese women (Huang et al., 2017; Vena et al., 2021). The increasing prevalence of obesity globally may make obesity an important population health burden for NTDs in the future.

Diabetes mellitus is a well-known consequence of obesity and maternal pregestational diabetes poses increased risk for many congenital defects, including NTDs. Although the precise teratogenic mechanisms linking diabetes with NTD are poorly understood, good glucose control in diabetic women can reduce the risks of having pregnancies affected by NTDs and other birth defects. Of note, recent evidence from small clinical trials and experimental studies suggests that supplementation with myo-inositol (an insulin sensitizer) may have benefits in preventing the onset of gestational diabetes mellitus as well as reducing the risk of recurrence of NTDs (Facchinetti et al., 2020).

#### Other risk factors

The use of antifolate drugs is associated with an increased risk of NTDs. These medications, designed to antagonize folate metabolism and thus block one-carbon biosynthetic and methylation reactions, include methotrexate, aminopterin and trimethoprim, used in the treatment of malignancies, inflammatory disorders, bacterial infections and malaria. In addition, a range of other drugs can antagonize folate incidentally, as an adverse effect. Such drugs include anticonvulsant treatments (valproic acid, carbamazepine, phenobarbital, phenytoin and primidone) used to control seizures in epilepsy. Women taking these medications are thus considered an at-risk group for NTDs. Hyperthermia during pregnancy has also been associated with an increased risk of NTD.

### Biological mechanisms in the etiology and prevention of NTDs

The possible mechanisms underlying the involvement of folate/folic acid in the etiology and prevention of NTDs are examined in this section. The mechanisms to explain the beneficial effects of periconceptional folic acid against NTD have focused on the factors that could potentially impair normal folate metabolism, including polymorphisms in folate genes. Autoantibodies against folate receptors have also been implicated in pregnancies affected by NTD (Rothenberg et al., 2004).

#### Role of folate, vitamin B<sub>12</sub> and one-carbon metabolism

Folate is essential for one-carbon metabolism where it acts in various co-factor forms as an intermediary in the transfer of one-carbon groups for two important biological processes, namely, the provision of methyl groups for methylation reactions and the *de novo* synthesis of purines and thymidylate (dTMP) for DNA and RNA (Fig. 1). The vitamin B<sub>12</sub>-dependent enzyme methionine synthase is central to both the methylation and DNA synthesis components of one-carbon metabolism. Through this enzyme, vitamin B<sub>12</sub> and folate control the intracellular flux of one-carbon units between these two major metabolic cycles. Folate enters the cell as 5-methyltetrahydrofolate (5-methylTHF) and must release its methyl group through the methionine synthase reaction in order to be retained in the cell. As tetrahydrofolate (THF), it can then be polyglutamated and can accept one-carbon units from serine, formate, and other sources for use in nucleotide synthesis or regeneration of 5-methylTHF. The released methyl group from 5-methylTHF is used via methionine synthase, to methylate homocysteine, thereby producing methionine, which is then converted to S-adenosylmethionine for methylation of proteins, lipids, DNA, and many other cellular components. Deficiency, impaired function or limited cellular availability of folate or vitamin B<sub>12</sub> leads to an increase in intracellular homocysteine that culminates in higher plasma concentrations of this metabolite. Methylenetetrahydrofolate reductase (MTHFR) is a key folate-metabolizing enzyme that catalyzes the irreversible conversion of 5,10-methyleneTHF to 5-methylTHF, thereby committing one-carbon units to methylation reactions and away from DNA synthesis. MTHFR activity is dependent upon an adequate supply of riboflavin in its cofactor form flavin adenine dinucleotide (FAD). Thus, for folate to function within one-carbon metabolism, it interacts closely with vitamin B<sub>12</sub>, along with vitamin B<sub>6</sub> and riboflavin. Consequently, sub-optimal status of one or more of these B vitamins, or polymorphisms in folate genes, can impair one-carbon metabolism, even if folate intakes are adequate.

There are many ways in which abnormal one-carbon metabolism could result in abnormal closure of the neural tube. Neural tube closure is a highly complex developmental process, involving multiple cycles of cell proliferation and apoptosis; the details of which are not fully understood. Inadequate production of DNA for the embryo, lack of methyl groups for methylation reactions that regulate cell signaling, gene expression and activation or repression of apoptotic pathways are obvious candidates. Several studies found higher total homocysteine in maternal plasma or in amniotic fluid during NTD pregnancy (Stegers-Theunissen et al., 1991, 1995), suggesting that these women were less able to metabolize homocysteine. These biochemical studies point to a subtle alteration in folate homeostasis in families with NTDs and suggest that folic acid supplementation works by overcoming a metabolic block in folate related processes due to specific genetic variants within folate pathways. This hypothesis would explain the finding that both environment and genes contribute to NTD risk and has prompted an intensive investigation of genes encoding folate-related proteins as risk factors.

#### Folate-related genetic risk factors and risk of NTDs Table 4

Polymorphisms in folate genes have been studied in relation to NTD risk. Of these, an increased risk of NTD is most strongly associated with the 677C→T variant in the gene coding for the folate-metabolizing enzyme, MTHFR. This enzyme is key within one-carbon metabolism because it catalyzes the irreversible conversion of 5,10-methyleneTHF to 5-methylTHF, the essential folate

**Table 4** NTD association evidence involving high priority polymorphisms in a number of folate and vitamin B<sub>12</sub> candidate genes.

<i>Gene</i>	<i>Enzyme</i>	<i>Association with NTDs</i>
BHMT 742G → A	Betaine-homocysteine methyltransferase R239Q	Inconclusive maternal risk associations.
CBS 844ins68	Cystathionine β synthase	No reported risk association with NTD.
DHFR Intron 1	Dihydrofolate reductase (19 bp deletion)	Conflicting reports of risk association and protection.
FR $\alpha$ , FR $\beta$ , FR $\gamma$ Several SNPs	Folate receptors	No reported risk associations with NTD or biochemical changes in humans.
GCPII 1561C → T	Folyl- $\gamma$ -glutamate carboxypeptidase H475Y	Inconclusive maternal risk associations.
MTHFD1 1958G → A	Trifunctional C1 Synthase R653Q	Maternal risk factor for NTDs in some populations.
MTHFR 677C → T	5,10-Methylene tetrahydrofolate reductase A222V	Significant risk factor for NTDs in some but not all populations. Important cause of low folate status.
MTHFR 1298A → C	5,10-Methylene tetrahydrofolate reductase E429A	No clear risk associations that are independent of 677C → T.
MTR 2756A → G	Methionine Synthase D919G	May interact with other genes as a maternal risk factor but no clear independent risk.
MTRR 66A → G	Methionine synthase reductase I22M	Several studies show maternal risk associations and possible interactive effects with low B12 or other genes.
RFC-1 80G → A	Reduced folate carrier H27N	Inconclusive maternal risk associations. Possible interaction with maternal nutrient intake.
SHMT1 1420C → T	Serine hydroxymethyltransferase L474F	No reported risk association with NTD.
TCblR Several SNPs	Transcobalamin II receptor	Several rare polymorphisms conferred highly significant risk in one large population study.
TCII 776C → G	Transcobalamin II R259P	Inconclusive maternal risk associations. Several studies found changes in maternal serum TC II concentrations or in amniotic fluid during NTD affected pregnancies.
TSER (Promoter enhancer region)	Thymidylate Synthase (28 bp double or triple repeat)	Inconclusive maternal risk associations.

of this polymorphism, along with variations in dietary folate and riboflavin intakes (particularly owing to differences in food fortification practices) between countries, may explain observations of a clear association with NTD risk in some populations but not in others. Homozygosity for the *MTHFR* 677C → T polymorphism is estimated to account for approximately 13% of NTDs cases overall.

The role of other folate-related gene variants have been investigated in relation to NTDs. **Table 4** gives details of NTD association studies involving high priority single nucleotide polymorphisms (SNPs) in a number of folate and vitamin B<sub>12</sub> candidate genes. Perhaps not surprisingly, results from candidate gene studies have been rather inconclusive, with results rarely replicated in other studies. There are many reasons for this, such as the underlying low penetrance of the genetic effects, differences in genetic and environmental susceptibility between populations, and study design issues such as inadequate sample sizes and poorly matched controls. Also, because the precise biological mechanisms leading to NTDs are poorly understood, it is highly likely that alteration in the function of a gene with no apparent link to folate pathways could play a role in NTDs. A further problem is that nearly a third of all human genes have no known function, yet most of these un-annotated genes are conserved through evolution, indicating that nature has assigned them important functions. The emergence of genome-wide association study (GWAS) in more recent years can overcome many of the limitations of earlier candidate gene studies, and GWAS is now the focus of most investigations to identify genetic risk factors in NTD. The GWAS design has the advantage of being able to screen every region in the genome for association with NTDs and can detect variations that are clustered within case families compared with control groups.

## Prevention of NTD

### Nutritional considerations

Although the terms “folic acid” and “folate” are often used interchangeably, correctly speaking, folic acid refers to the synthetic form of the vitamin, while folate refers to the natural vitamin forms as found in plant and animal tissues and thus in food sources. The richest food sources are green leafy vegetables, asparagus, beans, legumes, liver and yeast. Folic acid is found in the human diet only in fortified foods and vitamin supplements but is readily converted to the natural cofactor forms of folate after its ingestion. There are however differences in the chemical structures between folic acid and the natural folate forms and these have important nutrition consequences. Folic acid is a fully oxidized molecule and is a monoglutamate, meaning that it contains just one glutamate moiety in its structure. Naturally occurring food folates, on the other hand, are a mixture of reduced folate forms (predominantly 5-methylTHF) and typically found as polyglutamates, containing a variable number of glutamate residues. As reduced molecules, natural food folates are inherently unstable outside living cells and have poor bioavailability (McNulty and Pentieva, 2010). In

addition to their limited bioavailability, food folates (particularly green vegetables) can be unstable during cooking, and this will substantially reduce the folate content of a food before it is even ingested (McKillop et al., 2002). Folic acid is more stable and more bioavailable compared with an equivalent amount of the vitamin eaten as naturally occurring food folates, and is the form used in food fortification. Therefore, fortified foods provide the most important dietary source of the vitamin.

The differences between food folates and folic acid have led to the development of “dietary folate equivalents” or DFE values, an approach devised to take into account the greater bioavailability of folic acid from fortified foods compared with naturally-occurring food folates. Dietary folate intakes and folate recommendations for population sub-groups in many countries, including the United States, are now expressed as DFEs. As discussed below, specifically for the prevention of NTD, there are recommendations for folic acid supplementation in women of reproductive age; this is additional to typical dietary folate intakes.

### **Interventions to optimize folate status**

The instability and poor bioavailability of food folates means that they have limited ability to influence blood folate concentrations and thus achieving optimal folate status is challenging (Cuskelly et al., 1996). To optimize folate status in women of reproductive age for preventing NTDs, folic acid intervention strategies are needed, for individuals and populations. As discussed above, folic acid, the vitamin form used in fortified foods and supplements, is very stable and highly bioavailable when ingested. Thus, depending on national fortification policy and/or access to fortified food, the folate status of populations can vary greatly from one country to the next and this is reflected in differences in health outcomes.

#### **Folic acid supplementation**

Specifically for the prevention of NTD, women are recommended to take 400 µg per day of folic acid from preconception until the end of the first trimester of pregnancy. Some women are considered to be at higher risk and thus are recommended to take higher folic acid doses. This includes women with a previous pregnancy affected by NTD and those taking certain anticonvulsant drugs known to interfere with folate metabolism. Studies show that folic acid supplementation is a highly effective means to optimize folate status in individual women who take their supplements as recommended. However, it is not an effective public health strategy for populations because in practice very few women take folic acid as recommended.

#### **Folic acid fortification**

Food fortification may be undertaken on a voluntary (at the discretion of the food manufacturer) or mandatory (regulated by a government) basis. Because folic acid is more stable and bioavailable than naturally-occurring food folates, folate biomarker status will reflect the folic acid intakes of individuals. At a population level, the observed differences in folate status between countries is primarily due to differences in exposure to folic acid-fortified foods, in turn reflecting local fortification policy. Folate status is found to be highest in countries with mandatory folic acid-fortification, followed by those with voluntary fortification, while folate status is lowest in countries where fortified foods are not consumed.

When folic acid-fortification is undertaken on a mandatory (i.e. population-wide) basis, it has proven itself to be highly effective as a means to increase folate status in that population. Data from the US National Health and Nutritional Examination Survey (NHANES), and from retrospective longitudinal studies in Canada, demonstrate that mandatory folic acid-fortification results in marked increases in both short-term (serum folate) and long-term (red blood cell folate) biomarkers of folate status (De Wals et al., 2007; Crider et al., 2018). With the first two years of mandating folic acid-fortification in the US (in 1998), a tripling in serum folate and an increase of 40–60% in red blood cell folate was observed. Correspondingly, the prevalence of low folate status in US women of reproductive age dropped from 21% and 30%, to 0.8% and 2.8%, for serum and red blood cell folate, respectively. Mandatory fortification with folic acid has produced similar results worldwide.

In countries that permit voluntary fortification with folic acid and other micronutrients, the consumer will have ready access to fortified foods (e.g., breakfast cereals). In such countries, folic acid-fortified foods have been shown to have positive and significant impacts on dietary intakes and status biomarkers in consumers of these foods. When consumed regularly, fortified foods are associated with significantly higher serum and red blood cell folate concentrations (Hopkins et al., 2015). Thus folic acid-fortification of food is highly effective as a means of optimizing folate status, but importantly, the benefit will be limited to only those individuals who choose to consume fortified products. In the UK, where there is voluntary (but not mandatory) fortification of foods with folic acid, the percentage of women with insufficient red blood cell concentrations (<906 nmol/L) to prevent folate-responsive NTD is estimated to be 83% in Northern Ireland, 81% in Scotland and 79% in Wales (Public Health England, 2017). Also, evidence from the National Adult Nutrition Survey in Ireland showed that non-consumers of FA from fortified food or supplements were at particularly high risk of suboptimal folate status (Hopkins et al., 2015), again using the cut-point of 906 nmol/L red blood cell folate to define optimal status. In contrast, mandatory fortification reaches everyone in a population and is therefore a much more effective strategy for optimizing folate status in women of reproductive age regardless of socioeconomic or racial factors.

### **Effects of folic acid policy globally**

As a result of the conclusive evidence of the benefits of folic acid against NTD, public health authorities globally have in place clear folic acid recommendations for women of reproductive age. The implementation of policy in this area is however problematic because, despite a proven benefit in NTD, there are concerns that folic acid could be harmful at high levels of exposure. The relative

success of the contrasting approaches in North America (mandatory food fortification) and Europe (supplementation) to prevent NTD provide important lessons for countries re-considering policy in this area.

### Effects on NTD prevalence

In Europe, policy to prevent NTD has proven to be largely ineffective. For over 25 years, in European countries, including the UK, Ireland, policy has been based on recommending women of reproductive age (and/or those planning a pregnancy) to take a supplement containing folic acid. However, as a sole public health measure and despite active health promotion campaigns over many years, folic acid supplementation has had little or no impact in preventing NTD at a population level. The lack of success of this approach is primarily because women typically start taking folic acid after the period of neural tube closure (i.e. the 3rd to 4th week of pregnancy). For many women, the early period when folic acid is protective against NTD may have passed before folic acid supplements are even started. An even greater challenge is that an estimated 50% of pregnancies are unplanned. Thus a large number of women are not protected and this has resulted in unacceptably high rates of NTD in European countries, where NTD rates were recently estimated to be 1.6 times higher than in regions of the world with mandatory folic acid-fortification policies in place. Of particular concern are reports that the incidence of NTD in Ireland—a country with one of the highest NTD rates in the world - is increasing in recent years (FSAI, 2016).

In contrast, a policy of folic acid-fortification of food on a mandatory basis (in place in 85 countries worldwide to date) is highly effective in preventing NTDs because it reaches all women, including those who have not planned their pregnancy. International evidence shows that wherever such a policy has been introduced, it has proved to be effective in reducing rates of NTD in that country. The effect of mandatory fortification programs on NTD rates has been striking, especially in Canada (and particularly so in Newfoundland and Nova Scotia where rates were highest before the implementation of fortification). It is worth noting that data from Canada are generally more accurate than data from the US because of the limited information on prenatally diagnosed NTD cases in the US (Mosley et al., 2009). Fig. 2 shows NTD prevalence rates pre-and post folic acid-fortification in 11 areas where mandatory fortification has been implemented; the data are from countries that have implemented fortification and have recorded the change in NTD rates. The greatest drop in prevalence has been apparent in countries with the highest indigenous NTD rate and the lowest rates achieved in most countries to date is 5–6 per 10,000 births. The totality of evidence, using data from both randomized trials and from pre- and post-fortification programs, indicates that not all NTDs are preventable via intervention with folic acid only.

These data contrast with countries in Europe where there has been no mandatory fortification program and no significant change in NTD rates over the past 25 years (Khoshnood et al., 2015). The European data suggests that failure to implement mandatory folic acid-fortification has caused and continues to cause NTDs to occur in almost 1000 pregnancies every year (Morris et al., 2021).

Fig. 2 NTD prevalence rates pre- and post-fortification of foods with folic acid in 11 areas where mandatory fortification has been implemented.

Notably, one recent study estimated that from 1998 to 2017, a total of 95,213 NTD pregnancies have occurred among 104 million births in 28 European countries; a prevalence of 0.92 per 1000 births (Morris et al., 2021). Ireland is recognized as having one of the highest rates of NTD-affected pregnancies in the world and there are concerns that the incidence of NTD is increasing in recent years. In 2016, following an extensive scientific review, the Food Safety Authority of Ireland published an updated report recommending mandatory fortification of bread or starch with folic acid (FSAI, 2016). Similarly, in 2017, The UK Scientific Advisory Committee on Nutrition confirmed its longstanding advice that mandatory fortification of cereal flours with folic acid should be introduced for the prevention of NTD (SACN, 2017). Subsequently, in 2021 the UK Government announced that it will introduce the mandatory fortification of non-wholemeal wheat flour with folic acid, but the legislation to enact the new policy has not yet been implemented.

### **Effects on other health outcomes**

Apart from preventing NTD, optimal maternal folate status prevents the development of megaloblastic anemia in mothers during pregnancy. There is also some evidence that folic acid can prevent other major birth defects. The Hungarian folic acid intervention trial found a 47% reduction in birth defects other than NTDs. Several studies reported decreasing trends in the prevalence of congenital heart defects and other rarer defects since folic acid-fortification began in the US and Canada and after implementation of folic acid intervention studies in China, but an association with increased folic acid intake was not established. There have also been reports of a decreased prevalence in several childhood cancers although the data are inconsistent. There is no convincing evidence of a protective effect of folic acid on the prevalence of orofacial clefts.

There may also be other beneficial effects of intervention to optimize folate status in pregnancy and throughout the lifecycle. Deficient maternal folate status (and/or elevated homocysteine) has been associated with an increased risk of adverse pregnancy outcomes including gestational hypertension, preeclampsia, placental abruption, pregnancy loss, low birth weight and intrauterine growth restriction (Psara et al., 2020). Although there is some evidence that folic acid supplementation in pregnancy can reduce the risk of gestational hypertension and pre-eclampsia (De Ocampo et al., 2018), this is conflicting.

In addition to protecting against the development of NTDs in the offspring, there is emerging evidence linking maternal folate throughout pregnancy with neurodevelopment and cognitive function in the child (Caffrey et al., 2019). The biological mechanism linking maternal folate with the offspring brain is unclear, but likely involves folate-mediated epigenetic changes related to brain development and function. Indeed, a wealth of literature supports the fetal origins of human disease throughout the lifecycle and emerging evidence implicates epigenetic modifications as the likely mechanism. DNA methylation, the most widely studied epigenetic mechanism for gene regulation, is dependent upon the supply of methyl donors provided by folate and related B-vitamins via S-adenosylmethionine. Folate deficiency could thus lead to aberrant gene expression leading to adverse health outcomes. Thus, the human *in utero* environment may influence offspring brain health in the longer term via folate-mediated DNA methylation, but this aspect requires further investigation (Caffrey et al., 2019).

Also, numerous studies have shown that elevated plasma homocysteine is independently associated with greater risk of cardiovascular disease. Because folic acid intervention lowers plasma homocysteine, mandatory food fortification with folic acid may have beneficial effects on the risk of cardiovascular disease, particularly in relation to the primary prevention of stroke where the evidence (from both randomized trials and population-based data) for a beneficial effect of folic acid is quite compelling.

### **Emerging folic acid policy: risk-benefit assessment**

High folate intakes are not associated with any adverse effects. However, there are concerns of potential adverse effects of excess intakes of folic acid, the synthetic vitamin form. Excessive folic acid intake constitutes exposure doses that exceed the Tolerable Upper Intake Level (UL) of 1000 µg/d for adults, as set by the US Institute of Medicine (IOM, 1998). The main safety concern with folic acid-fortification was that some sectors of the population, particularly older people, would be exposed to very high folic acid intakes because of concomitant fortification and supplement use.

Once ingested, folic acid is reduced by dihydrofolate reductase and after subsequent methylation, it is released in the systemic circulation as 5-methylTHF. However, the reduction of folic acid is a slow process that is influenced by individual variations in dihydrofolate reductase activity and thus exposure to high oral doses of folic acid can result in the appearance of unmetabolized folic acid in the circulation. The latter is not a normal constituent of plasma or other tissues. On this basis, concerns have been raised regarding potential (although unconfirmed) adverse health effects of unmetabolized folic acid arising in the circulation through high folic acid exposures from supplements and fortified foods. Unlike the case with 5-methylTHF (the normal folate form entering cells), the uptake of folic acid by cells does not require vitamin B<sub>12</sub>, therefore, folic acid entering a cell might initiate DNA synthesis in a vitamin B<sub>12</sub>-deficient person, thereby preventing the development of anemia and potentially delaying a diagnosis of B<sub>12</sub> deficiency, allowing the associated neurologic damage to progress and become irreversible. Although such an effect has not been demonstrated to date, concerns remain about the potential physiological impacts of the nutrient imbalance caused by high folic acid intakes together with low vitamin B<sub>12</sub> concentrations. Adding vitamin B<sub>12</sub> as well as folic acid to fortified food has been suggested as a solution, but more evidence on efficacy, dosage, and feasibility is required. Another concern is the possibility that, because of its role in DNA synthesis, high folic acid status will help to advance established cancers and promote malignant transformation of premalignant lesions. Other possible adverse effects of high folic acid intake have been suggested, including reports of decreased natural killer cell cytotoxicity, increased twinning rates, interference with the efficacy of anticonvulsant and antifolate drugs, and increased childhood asthma and autism rates. None of these reports have been substantiated but caution and vigilance remains an important public health position in relation to the food fortification strategy.

A recent report from a 2019 expert workshop, as convened by the US National Institutes of Health, tasked with reviewing the evidence in this area, concluded that there is an insufficient body of evidence to support adverse human health outcomes as a result of high intakes of folic acid. Nonetheless, these experts called for further high quality research to determine the safety of excess folic acid intake (Maruvada et al., 2020). Thus, the totality of the evidence at this time suggests that adverse effects associated with folic acid overexposure are unlikely at the generally low folic acid levels arising through mandatory food fortification. Nonetheless the risk-benefit debate surrounding food fortification with folic acid continues among policymakers and effective monitoring should remain a key aspect of policy in this area.

### Recommendations to prevent first occurrence and recurrence of NTDs

As a result of the conclusive evidence of the benefits of folic acid against NTD, public health authorities globally recommend women to take folic acid supplements from before conceiving until the 12th week of pregnancy. Internationally established recommendations distinguish between occurrent (first-time) and recurrent NTDs. Women with a previously affected pregnancy are advised to take the much higher dose of 4.0 mg of folic acid daily from at least four weeks before conception until the end of the third month of pregnancy. The 4.0 mg dose should be taken under the supervision of a doctor because giving high doses of folic acid can complicate the diagnosis of vitamin B12 deficiency. Women with epilepsy on anticonvulsant therapy require individual counseling before starting folic acid supplementation.

For the prevention of first occurrence of NTDs, most public health authorities recommend that all women capable of becoming pregnant consume 400 µg of folic acid per day and that total folic acid consumption should not be more than 1.0 mg/d to avoid the possible risks of high intakes. The only practical ways of achieving optimal red blood cell folate status associated with lowest risk of NTDs are by consuming folic acid supplements or folic acid fortified foods, rather than increasing intakes of foods naturally rich in folate. Irrespective of local fortification policy and availability of fortified foods, women should be advised to take supplements, from before and in early pregnancy to ensure optimal folate status. If multivitamins are used to provide folic acid, care should be taken not to exceed safe levels of other components, particularly vitamins A and D.

### Conclusions

Maternal folic acid supplementation taken periconceptionally is known to have beneficial effects in the prevention of NTDs. Mechanistically, the known role of folate in one-carbon metabolism provides a biological basis to link maternal folate status with NTD and other offspring health outcomes. Vitamin B12 and riboflavin, also involved in the one-carbon network, may have additional preventative roles in NTD, albeit unproven in randomized trials. Although there are clear recommendations in place worldwide for the prevention of NTD through folic acid supplementation before and during early pregnancy, for many women the very early stage when the neural tube is closing may have passed before supplementation is started. Thus, current public health measures that do not involve mandatory fortification of foods with folic acid, have been shown to be largely ineffective in reducing NTDs. Mandatory folic acid-fortification of food is proven to be a highly effective measure to prevent NTD, but policy in this area remains controversial owing to concerns—as yet unproven—related to potential adverse effects of over-exposure to folic acid. In the absence of population-wide fortification in many countries, optimizing folate status of mothers in early pregnancy to provide protection against NTDs remains challenging. This means that, despite the existence of robust scientific evidence for nearly three decades of the benefits of folic acid intervention, preventable NTDs are not being prevented in many countries worldwide, including in Europe.

### Glossary

**Congenital** Acquired during development in the uterus and not through heredity.

**Fetal alcohol spectrum disorders (FASD)** Describes the range of effects that can occur in an individual whose mother had a high alcohol intake during pregnancy. These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications.

**Fetoplacental unit** The fetus and the placenta as a single physiological unit.

**Hydrocephalus** An abnormal increase in the amount of cerebrospinal fluid within the cranial cavity that is accompanied by expansion of the cerebral ventricles, enlargement of the skull and especially the forehead, and atrophy of the brain.

**Intracranial** Affecting or involving intracranial structures.

**Intrauterine** Situated or occurring in the uterus.

**Isoretinoin** An oral retinoid (derivative of vitamin A).

**Neonate** An infant less than a month old.

**Retinochoroiditis** Inflammation of the retina and choroid.

**Teratogenic** Of, relating to, or causing malformations of an embryo or a fetus.

### Introduction

A balanced diet that contains adequate amounts of all the nutrients needed by a mother and her growing fetus is essential for a healthy pregnancy. Pregnant women also need to be advised about how to reduce their risk of exposure to substances that may be toxic to the fetus during development (teratogenic) and therefore associated with the production of physical defects in the developing embryo (e.g., alcohol and excess vitamin A), as well as other dietary and lifestyle behaviors that could optimize maternal health and reduce the risk of health problems in their children. The aim of this article is to describe evidence relating to food safety issues during pregnancy, including potential risks to the fetus as a result of prenatal exposure to food pathogens or toxic food components (e.g., heavy metals and dioxins) and the potentially harmful effects of high doses of alcohol, caffeine, and vitamin A.

### Food-Borne Infections during Pregnancy

For many years it has been recognized that food-borne antenatal infections may cause death or serious fetal damage. Women may be more susceptible to the effects of infection during pregnancy because of immunological changes leading to suppression of the

immune system (most commonly cell-mediated immunity), probably as a result of increases in pregnancy-associated sex steroids, such as oestradiol or progesterone. Among the most common causes of diarrhea during pregnancy are several food- or water-borne pathogens (bacteria, protozoa, or viruses), including salmonella species, *Helicobacter pylori*, *Shigella*, *Escherichia coli*, and *Cryptosporidium*. Hepatitis A is also a food- or water-borne pathogen of concern, particularly in countries where sanitation is poor. In pregnant women, severe vomiting and diarrhea may negatively affect the availability of important nutrients to the growing fetus. For example, impairment of the supply of folate (or the synthetic form, folic acid) during a critical stage of development could increase the risk of associated neural tube defects, such as spina bifida.

Although rare, infection with *Listeria* or *Toxoplasma* during pregnancy is of particular concern because even in a mild form these infections can prove fatal. Listeriosis caused by the consumption of food containing the bacterium *Listeria monocytogenes* leads to flu-like symptoms, such as fever, muscle aches, and sometimes nausea or diarrhea. If the infection spreads to the nervous system, it may also cause headaches, stiff neck, confusion, loss of balance, or convulsions. The bacterium has been found in a variety of raw foods, including unpasteurized (raw) milk and cheeses, uncooked meats, and vegetables, and in processed foods that become contaminated after processing, such as soft cheeses, pâtés, cold cuts of meat and smoked fish. According to the Centers for Disease Control and Prevention, pregnant women in the US are approximately 20 times more likely than other healthy adults to get listeriosis and approximately one-third of listeriosis cases occur during pregnancy. In the UK, the Health Protection Agency Centre for Infections reported approximately 30% of human cases to be pregnancy-associated (both mother and neonate affected) in England and Wales between 1983 and 2009. The fetus and newborn are at greatest risk of this infection and its consequences can be severe, leading to miscarriage, stillbirth, and premature delivery or to meningitis in the newborn infant. When infection occurs during pregnancy, antibiotics given promptly to the pregnant woman can often prevent infection of the fetus or newborn, and infants developing the infection can also be treated in the same way.

*Toxoplasma gondii* is a parasite that can be transmitted to the fetus *in utero* through transplacental transmission, causing stillbirth, miscarriage, or mental retardation (in immunocompetent people infection is asymptomatic or mild). The parasite has been found in raw, inadequately cooked or cured meat, cat feces, and unwashed raw fruit and vegetables. It has also occasionally been reported in unpasteurized goats' milk. In the UK, toxoplasmosis occurs in approximately 2.5–5.5 in 1000 pregnant women (1750–2850 cases per year), generally causing flu-like symptoms, swollen lymph glands, or muscle aches and pains that last for a few days to several weeks. If a pregnant woman contracts the infection, there is an approximately 30–40% chance of fetal infection (congenital toxoplasmosis). The incidence and risk of placental transmission is dependent on the trimester during which maternal infection is contracted. The risk of transmission in the first trimester is estimated to be 10–15% and the outcome if contracted at this stage can be severe or life-threatening to the fetus. Conversely, the risk rises to 70–80% in the third trimester but the clinical outcome is usually less severe, or may be asymptomatic. Congenital toxoplasmosis can cause hearing loss, hydrocephalus, eye and brain damage, epilepsy, growth retardation, intrauterine death, and other problems. Congenital toxoplasmosis affected 0.34 per 10 000 births in England and Wales in 2002–2004. Studies over the past 15 years have estimated between 1 and 10 per 10 000 births elsewhere in Europe, and similar rates for the US. The most common symptoms observed in newborns are retinochoroiditis (inflammation of the retina and choroid) and/or intracranial abnormalities (with or without developmental delay). In Europe, 1% or 2% of infected infants develop learning difficulties or die and 4–27% develop permanent loss of vision. Mothers can be tested to determine if they have developed an antibody to the infection. Fetal testing may include ultrasound and testing of amniotic fluid or cord blood. When toxoplasmosis is diagnosed during pregnancy, antibiotic treatment can often help reduce the severity of symptoms in the newborn.

The risk of food poisoning can be minimized by ensuring adequate attention to good hygienic practice when preparing, cooking, and storing foods (Table 1). Pregnant women should therefore be advised of the need for a high regard for food hygiene and personal cleanliness during this vulnerable time. In addition, there are a few foods that may pose a particular (although small) risk, which should be avoided during pregnancy where possible (Table 2).

## Alcohol

### Excessive Alcohol Consumption during Pregnancy

Chronic alcohol abuse may result in a wide spectrum of secondary disturbances of the absorption and utilization of many nutrients, including glucose, amino acids, fat, sodium, and some vitamins (especially thiamin, vitamin B<sub>12</sub>, and folate). The inhibition of folate absorption by alcohol is of particular concern because of the risk of neural tube defects associated with an inadequate supply of this vitamin to the fetus before conception and during the first trimester of pregnancy. Alcohol may also directly impair the placental transfer of nutrients essential for growth (e.g., amino acids), which at critical phases of fetal organogenesis could compound any direct fetotoxic effects of ethanol or acetaldehyde.

Both alcohol and its primary metabolite, acetaldehyde, are teratogenic. Excessive alcohol consumption (>80 g of ethanol or 10 units per day) during pregnancy can result in a child being born with a specific combination of physical and mental disabilities known as fetal alcohol syndrome (FAS). Such fetuses usually survive until birth but are growth retarded and display a characteristic range of clinical features, principally craniofacial abnormalities and neurological damage (Table 3). However, FAS is not the only outcome of prenatal alcohol exposure, and it has been suggested that it can present as a spectrum of disorders. Fetal alcohol spectrum disorder (FASD) is an umbrella term used to describe a range of effects that can occur due to the presence of alcohol during the prenatal stage. FASD is characterized by the presence of some of the criteria for FAS and is associated with lesser degrees of harm from maternal alcohol consumption.

**Table 1** General guidelines on good hygienic practices in the home

The risk of food poisoning can be minimized by adopting the following practices:

*Cleanliness in the kitchen*

- Keeping all work surfaces scrupulously clean
- Washing cooking utensils after coming into contact with raw meat, poultry or eggs to prevent cross contamination
- Using separate chopping boards for foods that are to be cooked (e.g., raw meat)
- Keeping kitchen cloths clean; rinsing crockery in hot water, leaving it to dry, then wiping it with a clean tea towel
- Using kitchen towels to mop up spills, rather than a dishcloth
- Ensuring waste bins are covered and away from food and keeping pets away from the kitchen.

*Hygienic food handling*

- Washing all equipment and work surfaces before and after touching raw food
- Washing all foods to be eaten raw thoroughly
- Cooking meat thoroughly to an internal temperature of at least 70 °C
- Keeping raw and cooked foods separated during preparation and storage
- Cooling cooked foods as quickly as possible if they are to be stored in a fridge or freezer
- Covering foods and not leaving them standing around in the kitchen
- Storing food at the correct temperature (less than 4 °C in the fridge or less than –18 °C in the freezer)
- Storing raw meat, well covered, at the bottom of the fridge
- Storing eggs in a fridge, if possible
- Never overloading the fridge as this can reduce the circulation of cool air
- Keeping foods for as short a time as possible (especially meat and fish) and following storage instructions (i.e., not using beyond the 'use by' or 'best before' date)
- Thawing frozen meat thoroughly before cooking
- Avoiding reheating and food more than once
- Reheating foods thoroughly (if this is done in a microwave, the standing times recommended by the manufacturer should be observed to ensure that food attains an even temperature before it is eaten).

*Personal hygiene*

- Washing hands thoroughly before preparing food, after visiting the toilet and after emptying the rubbish bin
- Never licking fingers or utensils and put them back into food
- Washing hands after blowing or touching the nose whilst handling food
- Keeping nails clean and hair out of food
- Wearing a clean apron
- Not handling food during periods of illness, e.g., heavy cold, sickness or diarrhea
- Covering all cuts, spots and pimples, particularly on the hands, with a waterproof dressing and replacing it often
- Wearing rubber gloves when emptying cat litter trays.

The extent of the damage from alcohol varies depending on the stage of development at which high doses are encountered. The fetus is most vulnerable to organ damage from the time the umbilical cord begins to function (5 weeks) to the completion of organ development (11 weeks). Inhibition of growth and neurobehavioral development occurs in the second and third trimester. Although the facial features of FAS become more subtle with age, growth deficits and central nervous system impairment may be permanent. The reported worldwide incidence of FAS is 0.97 in 1000 births; however, the incidence of FASD remains unclear largely due to the absence of robust and routine data collection. Nevertheless, it is clear that FASD is more common in some populations than others. For example, in Australian aboriginal populations the incidence of FASD is estimated at 5 per 1000 births, whereas in the Western Cape Province of South Africa the incidence of FASD exceeds 60 cases per 1000 births.

FAS is only seen in infants born to women who are excessive drinkers, but it is not an inevitable result of heavy drinking in pregnancy, and even children born to mothers who are active alcoholics may not show it. This differing susceptibility of fetuses to the syndrome is thought to reflect the interplay of genetic factors, social deprivation, nutritional deficiencies, and tobacco and other drug abuse, along with alcohol consumption.

### **Binge Drinking and Social Alcohol Consumption during Pregnancy**

Binge drinking is generally defined for women, as the consumption of four or more drinks in approximately 2 h (Centers for Disease Control and Prevention) or at least 6 units of alcohol (**Table 4**) per occasion (Strategy Unit, London) in the US and in the UK, respectively, and may be particularly harmful because it exposes the fetus to high blood alcohol concentrations over relatively short periods of time and may be associated with repeated withdrawal episodes. Animal studies have demonstrated binge-like exposure to alcohol to be as teratogenic as long-term exposure throughout gestation, even if the overall alcohol amount consumed by binge drinking is less than intake during more continuous drinking patterns. Human studies have found associations with binge drinking and neurodevelopment outcomes, such as an increase in 'disinhibited behavior,' a reduction in verbal IQ, an increase in delinquent

**Table 2** Foods to avoid during pregnancy

<i>Foods to avoid</i>	<i>Reason</i>
Some types of cheese <sup>a</sup> : <ul style="list-style-type: none"> <li>• Mould-ripened cheeses, e.g., Camembert, Brie</li> <li>• Some goats' cheeses</li> <li>• Soft blue cheeses, e.g., Stilton</li> </ul>	To minimize risk of listeriosis
All types of pâté (including vegetable)	To minimize risk of toxoplasmosis
Unwashed fruit and vegetables	
Raw or undercooked meat	
Cured meats, e.g., Parma ham and salami	
Unpasteurized goats' milk or goats' cheese	To minimize risk of food poisoning from Salmonella and Campylobacter
Raw or partially cooked eggs or foods made from them, e.g., homemade mayonnaise, soft- whip ice cream, cake mix, mousses, and hollandaise sauce (eggs should be cooked until both the white and yolk are solid.	
Raw or undercooked meat, poultry, shellfish (e.g., oysters) and fish (e.g., smoked salmon, trout, sushi)	
Undercooked ready meals and ready-to-eat poultry (unless they have been reheated to a very high temperature).	
Unpasteurized milk and milk products	To avoid excess vitamin A intake
Untreated water	
Liver products and supplements containing vitamin A or fish liver oils	
Some types of fish: shark, swordfish, king mackerel, tilefish, and marlin	To avoid high intakes of mercury and other contaminants
Limit intake of tuna, no more than two tuna steaks a week (approximately 140 g cooked or 170 g raw each) or four medium-size cans of tuna a week (approximately 140 g when drained)	
No more than two portions of oily fish per week, e.g., fresh tuna (not canned tuna, see above), salmon, mackerel, sardines and trout.	

<sup>a</sup>Foods containing these cheeses that have been properly cooked will be safe to eat.

behavior and learning problems. However, findings for other health outcomes have been inconsistent, possibly because of the notorious problems of recording binge drinking during pregnancy.

The question of whether moderate or occasional alcohol consumption is safe during pregnancy has been widely debated. Currently, there is little evidence that modest drinking (<10 units per week) has any harmful effects. In a systematic review of the evidence, reported in the National Institute of Health and Clinical Excellence (NICE) 2008 guidelines "Antenatal care: routine care for the healthy pregnant woman," the highest risk suggested was a three- to fourfold increase in the risk of miscarriage in women

**Table 3** Symptoms of fetal alcohol syndrome (FAS)<sup>a</sup>

The diagnosis of FAS requires signs in all of the three following categories: <ul style="list-style-type: none"> <li>• Prenatal and postnatal growth retardation</li> </ul>
Intrauterine growth retardation, including smaller than normal head circumference, continued growth below the 10th centile and failure to thrive. <ul style="list-style-type: none"> <li>• Central nervous system involvement</li> </ul>
Neurological abnormalities, developmental delay, intellectual impairment, brain malformation, hearing and visual disabilities. <ul style="list-style-type: none"> <li>• Physical anomalies</li> </ul>
Characteristic facial deformity including short upturned nose, receding forehead and chin, smaller than normal eye apertures, absent philtrum and asymmetrical ears.

<sup>a</sup>The diagnosis of FAS requires signs in all three of the categories.

**Table 4** Definition of a unit of alcohol

---

1 unit of alcohol approximately equals 8 g of absolute alcohol, which is equivalent to:
½ pint of ordinary strength beer, lager, or cider
¼ pint of strong beer or lager
1 small glass wine
1 single measure of spirits
1 small glass sherry

---

who consume approximately 10 units of alcohol per week compared to abstainers. For other health outcomes, the majority of the studies did not report a statistically significantly increased risk with low-to-moderate alcohol intake, but the evidence was not entirely consistent. Many studies are confounded by factors such as cigarette smoking, social class, drug abuse, very high levels of caffeine intake, and different cross country categorization of 'light,' 'moderate,' and 'heavy' drinking. Although there is general agreement that women should not drink alcohol excessively during pregnancy, a consensus opinion of a safe threshold level of alcohol consumption has not been established at any stage of pregnancy, and advice differs among countries.

Despite the lack of evidence of detrimental effects on any outcome at low-to-moderate maternal alcohol consumption, many professional bodies err on the side of caution. The Royal College of Obstetricians and Gynaecologists and NICE suggest that the only way to minimize any harmful effects to the fetus from alcohol is to not drink at all during pregnancy. The UK Department of Health advises that pregnant women or those planning to conceive to avoid alcohol completely and if they do choose to drink they should not consume more than 1 or 2 units once or twice a week (Table 4), and should avoid intoxication. Advice in North America (US and Canada) is that women should not consume alcohol at all during pregnancy, and there are warnings on products and advertisements. Anecdotally, many pregnant women develop a spontaneous aversion to the taste and/or smell of alcoholic beverages and so may limit their intakes anyway.

## Vitamin A

During the period of early development, the supply of preformed vitamin A (retinol) must be carefully managed to ensure that the developing fetus is exposed to neither too little nor too much of the nutrient because either condition can have teratogenic consequences. Adequate vitamin A is required for normal embryonic development, and an insufficient supply during pregnancy can result in malformations in the offspring as well as increased mortality and morbidity during early childhood from infectious diseases, such as diarrhea, measles, and respiratory infections.

Excess vitamin A intake has also been associated with teratogenicity in animals and may represent a risk in humans, particularly within the first trimester of pregnancy. Characteristic features include severe motor deficit and malformations of the heart, thymus, face, jaw, ears, palate, and brain. Although adverse effects from dietary sources are very rare, events have occurred with the ingestion of high-dose supplements and with isotretinoin treatment for severe acne; this medication is now only permitted under strong supervision in women of reproductive age. Therefore, as presented in the SACN report 'The influence of maternal, fetal and child nutrition on the development of chronic disease in later life,' pregnant women are advised to avoid taking preformed vitamin A (retinol) supplements and to also avoid consuming liver or liver products. This advice is based on the risk of teratogenesis associated with retinol consumption at doses higher than 3000 µg retinol equivalents (RE) per day.

In Western countries, where vitamin A deficiency is rare, women who are or might become pregnant are advised against taking vitamin A supplements (including cod liver oil), except on the advice of a doctor or antenatal clinic, and not to consume liver or liver products. In developing countries with a high prevalence of vitamin A deficiency, vitamin A supplementation programs have resulted in decreased pregnancy-related mortality and lower rates of childhood morbidity and mortality, with benefits clearly outweighing any potential risks. The initiation of such programs in any population should be carefully examined in each case according to the risk–benefit ratio, with the final decision taking into account the vitamin A status of the population, the availability of vitamin A-rich foods, and whether supplementation can be supervised. The World Health Organization recommends that high-dose vitamin A supplements for women be restricted to the first 6 weeks postpartum, before they are likely to become pregnant again.

## Fish and Pregnancy

Fish is a good source of protein, vitamins, and minerals. In particular, oil-rich fish (e.g., mackerel, salmon, kippers, herrings, trout, sardines, and fresh tuna) contain the long-chain *n*-3 fatty acids eicosapentenoic acid (EPA) and docosahexenoic acid (DHA), which may confer many health benefits to the developing fetus. For example, DHA is required for nerve and retinal development, and eating oily fish has been found to have a slight beneficial effect on birth weight and length of gestation. In the US and Canada, the position of the American Dietetic Association (ADA) and Dietitians of Canada, is that adults, including pregnant and lactating women, should consume a combined intake of 500 mg day<sup>-1</sup> of DHA and EPA. In the UK, 450 mg day<sup>-1</sup> of DHA and EPA

combined is recommended for adults and pregnant women, the equivalent of consuming two servings (one serving=140 g) of fish a week, one of which is oil-rich. However, consumption of oil-rich fish has been positively associated with intakes of certain contaminants, namely mercury, dioxins, and polychlorinated biphenyls (PCBs), and concern has been expressed about the consequences of prenatal exposure to these toxic chemicals on the risk of brain and nervous system abnormalities. As a result, pregnant women in the UK are advised not to consume more than two portions of oily fish a week.

## Mercury

Mercury is a metal that is present in the environment from natural and man-made sources (e.g., coalburning or other industrial pollution). It is converted primarily by microorganisms to a more toxic form, methylmercury, which is bioaccumulated in the aquatic food chain, reaching its highest levels in large, longer living predatory fish. Among humans, the sole source of exposure to methylmercury is the consumption of fish and sea mammals.

Methylmercury is neurotoxic and accumulates in the brain and central nervous system. It inhibits the division and migration of neuronal cells and disrupts the cytoarchitecture of the developing brain. Although a mother may show no signs of neurotoxicity, the developing fetus may be damaged following exposure to methylmercury. The concentration of methylmercury in fetal brain has been shown to be 5–7 times higher than that in maternal blood, and it has been estimated that the fetus is 5–10 times more sensitive to methylmercury exposure than an adult, although the reason for this is unknown.

Disasters in Minamata, Japan, in the 1950s and in Iraq in 1971–72 demonstrated that acute prenatal exposure may result in severe mental retardation, cerebral palsy, blindness, and deafness. However, whether exposure to lower chronic doses, which may occur if pregnant women consume large amounts of fish, can also lead to adverse neurodevelopmental consequences is less certain. Large, long-term prospective epidemiological studies of high fish-eating populations have not found a consistent pattern of association between exposure and neuropsychological outcomes. Although subtle neuropsychological changes were reported in a study of children in the Faroe Islands study, where exposure was mainly from whale consumption, a similar study in the Seychelles found no adverse effects from fish consumption alone.

The Joint FAO/WHO Committee on Food Additives revised its safety guideline for weekly intake of methylmercury, known as the provisional tolerable weekly intake (PTWI), to 1.6 mg kg<sup>-1</sup> body weight per week. The UK government's independent expert Committee on Toxicity of Chemicals in Food, Consumer Products, and the Environment (COT) has applied a lower PTWI limit of 0.7 mg kg<sup>-1</sup> body weight per week to women who are pregnant or those intending to become pregnant and to mothers who are breast-feeding.

Any public health recommendations to pregnant women regarding fish consumption must recognize the important role that it plays as part of a healthy, balanced diet. Most fish contain trace amounts of methylmercury, but high concentrations of the metal have only been found in large, predatory fish, such as shark, marlin, and swordfish (Table 5). If a pregnant or breast-feeding mother were to consume one portion of these predatory fish, she would exceed the lower PTWI set by COT and the EPA by 400%. Therefore, as a precaution, pregnant women, breast-feeding mothers, and those who intend to become pregnant within the next 12 months are advised to avoid consumption of these types of fish (in the US, this also includes king mackerel and tilefish). Some samples of tuna have also been found to have higher levels than other species. In the UK, pregnant women (and those who may become pregnant) are advised to restrict their weekly intake to two 140 g portions of fresh tuna or four 140 g portions of canned tuna.

**Table 5** Concentrations of methylmercury (mg kg<sup>-1</sup>) in surveyed fish in the UK

<i>Fish</i>	<i>Methylmercury mg kg<sup>-1</sup></i>
Shark	1.52
Swordfish	1.35
Marlin	1.09
Fresh Tuna	0.40
Canned Tuna	0.19
Herring	0.09
Pink Shrimps	0.09
Cod	0.07
Plaice	0.06
Mackerel	0.05
Haddock	0.04
Scallops	0.01

## Dioxins and Polychlorinated Biphenyls (PCBs)

Fish can also contain other organic pollutants, such as PCBs and dioxins. Whereas mercury accumulates in the muscles of larger predatory fish, PCBs and dioxins are found in the fatty tissues of fish. Most human exposure to PCBs and dioxins comes from dietary sources because they accumulate in the lipid fractions of meat, fish, milk and milk products, eggs, grains, and oils.

PCBs and dioxins have been linked with increased rates of some cancers in studies of individuals exposed to high amounts through either vocational exposure or accidental environmental contamination. Prenatal exposure to large amounts of these pollutants (e.g., through contaminated fish) has been associated with neurobehavioral alterations in newborn children. Some studies have also suggested that exposure to smaller quantities of PCBs and dioxins in utero may lead to more subtle cognitive and motor developmental delays, although a favorable home environment appears to counteract any effect. However, the difficulty of separating the effects of PCBs and dioxins from potentially confounding factors (e.g., exposure to other contaminants, breast-feeding, smoking, and maternal education) makes it difficult to reach firm conclusions. Further research is also needed to ascertain whether any cognitive changes are temporary or persist into later life.

The potency of dioxins is expressed as toxic equivalents (TEQs), which have been internationally accepted. In the UK, the tolerable daily intake (TDI) recommended by COT is 2 pg TEQ kg<sup>-1</sup> body weight, which is in line with recommendations of other international and European expert committees. In common with the US and the European Union, approximately one-third of the UK population may exceed the TDI in their daily diet. The TEQ, therefore, provides a target to reduce dioxins and PCBs in the environment internationally. Since the 1960s, following the prohibition of many dioxins and PCBs by governments, concentrations have been declining in breast milk, which is commonly used to determine exposure. For example, between 1982 and 1997, consumption of dioxins and PCBs in the UK decreased by 75% and between 1997 and 2001 fell by a further 50%, largely due to strict controls concerning production, use, and disposal of PCBs and dioxins: it is anticipated that intakes will continue to decrease.

## Caffeine

Caffeine is a methylated xanthine that acts as a mild central nervous system stimulant. It is the most widely consumed xenobiotic in pregnancy and is found in a number of foods and beverages (Table 6). The main sources are coffee, tea, cocoa, chocolate, and soft drinks, as well as prescription and nonprescription medicines, such as diet pills, headache treatments, and cold and flu medicines. Tea and cocoa also contain significant quantities of theophylline and theobromine, which are caffeine derivatives that have not been as widely researched.

Once caffeine and its derivatives are consumed, they are absorbed into the blood and body tissues and can cross the placenta to the fetus. Cytochrome P450 1A2 (CYP1A2), the principal enzyme involved in caffeine metabolism in the liver, is absent in the placenta and the fetus, therefore the exposure of the fetoplacental unit to caffeine depends on maternal caffeine metabolism, which is influenced by genetic and environmental factors. Typically the body metabolizes caffeine more slowly during pregnancy, especially in the last few months; the half-life of caffeine increases from approximately 5–18 h during the second and third trimesters. Blood caffeine concentrations are therefore raised during pregnancy with no change in intake. In contrast, smoking is known to increase caffeine metabolism appreciably.

Although very high doses of caffeine are teratogenic in animals, no link between consumption during pregnancy and birth defects has been demonstrated in humans. However, high maternal caffeine intakes (>500 mg day<sup>-1</sup>) have been associated with increased fetal heart rate and newborn cardiac arrhythmias. Maternal caffeine intake has been reported to be associated with low birth weight, but the safe threshold level remains unknown. A number of studies have found an association with caffeine intakes greater than 300 mg day<sup>-1</sup> and fetal growth restriction and some have also demonstrated increased risks at intakes as little as 141 mg day<sup>-1</sup>. In 2001, the Committee on Toxicology of Chemicals in Food, UK, conducted a thorough review of the literature and concluded that although caffeine consumption of more 300 mg day<sup>-1</sup> might be associated with spontaneous miscarriage and low birth weight, the evidence was inconclusive.

**Table 6** The caffeine content of beverages and foods

1 cup (190 ml) of instant coffee: ~75 mg
1 cup (190 ml) of brewed coffee (filter or percolated): ~100–115 mg
1 cup (190 ml) of decaffeinated coffee (brewed or instant): ~4 mg
1 cup (190 ml) of tea: ~50 mg
1 cup (200 ml – using manufacturers' instructions) of drinking chocolate: 1.1–8.2 mg
250 ml serving of energy drinks (containing either caffeine or guarana): 28–87 mg
330 ml serving of cola (regular and diet) – 11–70 mg
50 g bar of chocolate – 5.5–50 mg

**Table 7** 200 mg of caffeine is roughly equivalent to

3 average cups or 2 average size mugs of instant coffee
2 average cups of brewed coffee
4 average cups of tea or 2 mugs of tea
5 cans of regular cola drinks (e.g., 40 mg each)
2 cans of 'energy' drinks (e.g., 80 mg each)
200 g (4 standard 50 g bars) of milk chocolate (e.g., 50 mg each)

The lack of consistency between studies, particularly in relation to the dose at which an effect is reported, has made it very difficult to identify a threshold level of caffeine intake that presented an increased risk during pregnancy. However, in 2008 a large prospective observational study was conducted to reduce the uncertainties of previous evidence and provide a more robust basis on which to advise pregnant women on caffeine consumption. Results of the study, published in the *British Medical Journal*, linked maternal caffeine intake with increased risk of fetal growth restriction and concluded that sensible advice would be to reduce caffeine intake before conception and throughout pregnancy. Based on this evidence, guidance has changed in the UK on the consumption of caffeine for women trying to conceive and pregnant women, to limit their daily intake to 200 mg day<sup>-1</sup> (previous recommendation was a maximum daily intake of 300 mg day<sup>-1</sup>). This is the equivalent of approximately two mugs of coffee a day (Table 7).

The revised level in the UK of 200 mg day<sup>-1</sup> is endorsed by the March of Dimes in the USA, however, the ADA, in their 2008 Position Paper, suggest 300 mg day<sup>-1</sup> as a safe upper limit and this is in line with the advice given by the EU Scientific Committee on Foodstuffs. In practice, many pregnant women reduce their coffee intake as a result of a spontaneous aversion to the taste and smell, particularly in early pregnancy. For example, in the UK average daily caffeine consumption decreased from 238 to 139 mg day<sup>-1</sup> during the first trimester, and then increased to an average of 153 mg day<sup>-1</sup> by the third trimester of pregnancy, so most pregnant women are unlikely to be affected by the change in advice.

### Avoiding Foods to Prevent Allergy

Food allergy has been estimated to affect approximately 3–7% of infants and young children in Western Europe, although the majority of children outgrow food allergies by the time they start school. Prevalence is assumed to be increasing in line with other forms of atopic disease, although evidence to support this is limited. Some food allergies (e.g., peanut allergies) can persist into adulthood and in severe cases can be life threatening. Most confirmed food allergies are associated with a relatively limited range of foods, including cows' milk, eggs, tree nuts, peanuts, soybeans, wheat, fish, and shellfish.

The development of food allergy depends on several factors, including genetic factors and early exposure to allergenic proteins in the diet, food protein uptake and handling, and the development of tolerance. However, it remains uncertain whether sensitization occurs *in utero* and, if so, whether this occurrence is restricted to specific stages of gestation. There is little evidence to support any benefit of avoiding specific foods during pregnancy to reduce the risk of allergic disease in a genetically susceptible child. Indeed, such a strategy may be counterproductive because it has been suggested that exposure to foreign proteins that cross the placenta is important to establish a normal immune response that enables the infant to develop normal tolerance to the many foreign proteins in the environment. Because restrictive diets may limit the supply of essential nutrients, these should only be practiced under medical supervision. Inappropriate and unnecessary exclusion of foods could prevent both mother and infant from obtaining the nutrients they need, resulting in significantly reduced weight gain and a tendency toward lower birth weights.

Owing to the severity of reactions experienced from peanut allergy, some countries have issued specific advice around intake during pregnancy. In the UK, COT had previously issued cautionary advice that women may wish to avoid peanuts during pregnancy and breast-feeding and not introduce peanuts into their child's diet before three years of age, if their child has a family history of allergy. However, in 2009 the Government revised its advice based on a systematic review which indicated that there is no clear evidence that eating or not eating peanuts (or foods containing peanuts) during pregnancy, breast-feeding or early childhood has any effect on the chances of a child developing a peanut allergy. Pregnant women in the UK are now advised that they can choose to eat peanuts irrespective of whether their child has a family history of allergies. Similarly in the US, the American Academy of Pediatrics previously suggested that pregnant women avoid peanuts, until research from the Avon Longitudinal Study of Parents and Children (ALSPAC) reported no association between maternal consumption of peanuts during pregnancy and childhood peanut allergy. The March of Dimes in the US now advises that women who are not allergic to peanuts can safely eat peanuts during pregnancy.

## Food Additives and Herbal Supplements

Pregnant women often express concern about food additives. However, all additives have to be approved as safe for almost all but a small proportion of the population who may experience rare reactions to them before they can be used in foods. The presence of an 'E' number demonstrates that it has passed safety tests and been approved for use by the European Community. In the UK, COT sets an Acceptable Daily Intake for each additive, which is the amount that can be consumed daily with no risk to health. This may limit the amount of an additive used or restrict its use to certain food products. Even when an additive has been approved, new research is constantly reviewed and approval for any additive will be withdrawn if doubt is raised about its safety.

A number of herbal supplements and preparations may be used during pregnancy, most commonly to relieve gastrointestinal symptoms. Although the use of many herbal remedies is safe during pregnancy, this cannot be assumed simply because a product is described as 'natural.' Many plants, trees, fungi, and algae can be poisonous to humans, and several pharmaceuticals have been developed or derived from these sources because of the powerful compounds they contain. Very few randomized, clinical trials have examined the safety and efficacy of alternative therapies during pregnancy, and women should be warned to use any medicine, including herbal remedies, with care during pregnancy and with the advice of a doctor or pharmacist.

## Summary

In addition to the consumption of a healthy, balanced diet, there are food safety precautions that need to be followed to ensure a safe pregnancy. A summary of the evidence and current advice described in this article is given in **Table 8**. However, it is important to highlight that recommendations during pregnancy across the globe, continue to change from time to time as new evidence emerges and guidelines are published. A recent virtual issue report by *Maternal & Child Nutrition* and *Nutrition Bulletin* has been published which pulls together articles describing these recent changes in nutritional recommendations which are also summarized in the above article.

**Table 8** A summary of advice regarding dietary habits and foods safe during pregnancy

- Pregnant women should pay careful attention to food and personal hygiene so as not to expose themselves to any risk of food poisoning, which is not only highly unpleasant but also potentially very dangerous to the unborn child in some cases (e.g., with listeriosis and toxoplasmosis).
- Foods that have been linked with the bacteria *Listeria monocytogenes* should be avoided. These include pâtés and mould-ripened, soft cheeses (e.g., brie and camembert). Preprepared foods should be heated until they are piping hot and fruit and vegetables washed well, especially if they are to be eaten raw.
- To reduce the risk of toxoplasmosis, pregnant women should avoid eating raw or uncooked meat, unpasteurized goats' milk or goats' cheese, or unwashed fruit and vegetables. After handling raw meat, chopping boards, utensils and hands should be washed thoroughly. When gardening or emptying cat litter trays, rubber gloves should always be worn.
- Undercooked foods (e.g., meat, poultry, eggs), foods containing raw egg (e.g., mayonnaise, soft whip ice cream) and raw fish (e.g., sushi, smoked salmon) should also be avoided.
- Drinking alcohol heavily throughout pregnancy (>80 g or 10 units per day) is linked with fetal alcohol syndrome. Modest drinking (<10 units per week) does not appear to have harmful effects but most professional bodies err on the side of caution and recommend that pregnant women abstain from drinking alcohol or limit their consumption to no more than 1–2 units per day.
- Supplements containing high doses of preformed vitamin A and foods containing large amounts of this vitamin (liver and liver products) are best avoided in countries where intake from a well-balanced diet should be sufficient. In areas of endemic vitamin A deficiency, supplementation can reduce pregnancy-related mortality and reduce rates of childhood morbidity and mortality. However, most experts agree that preformed vitamin A supplements in doses of more than 3000 RE should not be taken by women who may become pregnant. Beta-carotene is safe for pregnant women.
- Although it is not presently clear if intakes of mercury and other contaminants such as PCBs and dioxins at levels that can be obtained from eating fish can influence children's neurological development, government organizations in a number of countries recommend that pregnant women avoid species of fish that have been found to contain high levels of these substances. This includes shark, marlin, swordfish, tilefish and king mackerel. Some countries have also recommended limiting tuna intake (e.g., in the UK pregnant women are encouraged to consume no more than two tuna steaks or four medium-size cans of tuna per week).
- Consumption of caffeinated beverages (e.g., coffee, tea and colas) has been associated with miscarriage and low birth weight, although many studies are confounded by high alcohol intakes, smoking, and drug and other substance abuse. In the UK, the recommendation is that pregnant women limit their caffeine intake to 200 mg day<sup>-1</sup> which is endorsed by the March of Dimes in the US, however, the ADA and EU Scientific Committee on Foodstuffs suggest a safe upper limit of 300 mg day<sup>-1</sup>.
- Avoiding specific foods during pregnancy is unlikely to reduce the risk of allergic disease in a susceptible child. In the UK, the Government recommends if women would like to eat peanuts or foods containing peanuts during pregnancy, they can choose to do so as part of a healthy, balanced diet. The March of Dimes in the US now advises that women who are not allergic to peanuts can safely eat peanuts during pregnancy.
- Additives permitted for use in foods undergo stringent safety tests over a long period of time before being approved and are safe for consumption during pregnancy by all but a small proportion of women who experience rare reactions to specific additives.
- Many pregnant women who would not consider taking over-the-counter medications often view herbal products as a safe and natural alternative. However, very few randomized, clinical trials have examined the safety and efficacy of alternative therapies during pregnancy. Pregnant women should be advised to seek advice from a doctor or pharmacist before taking any medication, including herbal supplements.

### Key points

- To review history and current pregnancy weight gain recommendations.
- To discuss consequences of excessive and inadequate weight gain for maternal and child health.
- To identify research gaps and opportunities.

### Glossary

**Body Mass Index** Weight (in kg) divided by height (in meters squared). Used as an indicator of undernutrition or overweight

**Gestational diabetes mellitus** Abnormal *glucose metabolism* accompanied by major alterations in the metabolism of fat and protein. Diagnosed by high *blood glucose* and/or *urinary glucose*. This is the most common medical disorder in pregnancy

**High birth weight (macrosomia)** >4500 g

**Low birth weight (LBW)** <2500 g

**Preeclampsia** A condition which can appear suddenly in *late pregnancy*, with symptoms of high blood pressure, edema, urinary protein, severe headache, and vision problems. This may turn into *eclampsia* (convulsions or coma) if not treated

**Preterm Birth (PTB)** <37 weeks from conception. A normal duration of gestation is 40 weeks

**Small for Gestational Age (SGA)** <10th percentile of birthweight for sex and gestational age

### Introduction

Maternal nutrition and adequate weight gain during pregnancy are essential for healthy birth outcomes. This article reviews historical and current pregnancy weight gain recommendations for optimal maternal and child health. There have been several advances in the last 50 years both domestically and globally that have enhanced our understanding of the impact of inadequate and excessive gestational weight gain. However, the majority of women fail to meet current recommendations. Further research is needed to help support women to enter pregnancy with a healthy BMI as well to gain within recommended amounts.

## Pregnancy weight gain recommendations

In 1970, the US National Academy of Sciences published guidelines for weight gain during pregnancy in the report “Maternal Nutrition and the Course of Pregnancy.” The recommended pregnancy gain was 24 lb (10.9 kg), with a range of 10–25 lb (9.1–11.4 kg). The report advised health care providers and pregnant women not to restrict weight gain—a practice that had been fairly widespread during the previous decade in order to reduce the perceived increased risk of *labor complications*, *preeclampsia*, and excess weight retention postpartum. In fact, many *obstetricians* had been recommending gains of only 15–20 lb (6.8–9.1 kg).

Even with the more generous recommendations set in 1970, by the 1980s it had become clear that average gain of women in the United States far exceeded these guidelines. An analysis of data from the National Natality Survey in 1980 showed the average *pregnancy weight gain* to be 29 lb (13.2 kg), and by the time of the National Maternal Infant Health Survey in 1988 the average had increased to 32 lb (14.5 kg). The range of gain among women was very wide, from no gain to more than 75 lb (34.1 kg).

Based on this realization, in 1990, the weight gain recommendations were revised completely by a committee established by the Institute of Medicine (IOM) of the National Academy of Sciences. Existing data from a national survey were analyzed to determine the weight gain that was compatible with a normal pregnancy outcome. The latter was defined as the infant being born full term and of normal birth weight, and the absence of *pregnancy or delivery complications*. It became apparent from these analyses that maternal weight-for-height at conception, expressed as *body mass index* (BMI) (weight in kilograms divided by height in meters squared), was an important predictor of actual weight gain. Women with a low BMI gained more weight than women with high BMIs. Different weight gain recommendations were therefore developed for women entering pregnancy with different BMIs.

The 1990 recommendations were revised again in 2009, the justification being that women were becoming pregnant at an older age and heavier weight, were more likely to have multiple pregnancies, and to gain excessive amounts of weight during pregnancy. The increasing prevalence of maternal overweight and obesity at conception is a global phenomenon, and associated with greater risk of *preeclampsia*, *gestational diabetes*, *cesarean delivery*, problems with breast-feeding, and subsequent overweight in the child. As in 1990, the known relationship between pregnancy weight gain and BMI formed the basis of the recommendations, but the BMI categories were changed to those used by the World Health Organization. The recommended gains in [Table 1](#) are consistent with the lowest risk of: cesarean delivery, giving birth to a premature infant, excessive weight retention after delivery, low or high birth weight, and subsequent *childhood obesity* in each BMI category.

For underweight women (BMI < 18.5), recommended gains are 12.5–18 kg (28–40 lb) or 0.51 kg (1 lb) per week; for women with a normal BMI (18.5–24.9), gain should be 11.5–16 kg (25–35 lb) or 0.42 kg (1 lb) per week; for overweight women (BMI > 25–29.9), gain should be at least 7 kg (15 lb) and not more than 11.5 kg (25 lb) or 0.28 kg (0.6 lb) per week; and obese women (BMI ≥ 30) should gain the least, namely 5–9 kg (11–20 lb) or 0.22 kg (0.5 lb) per week. New weight gain charts were constructed that show the recommended gains over the course of pregnancy for each BMI group ([Fig. 1](#)), enabling the adequacy of weight gain to be tracked for individual women. To use the chart, women’s height and weight should be measured as near to the time of conception as possible (because pregnancy causes a temporary reduction in height) and used to obtain their BMI from a table. Maternal recall of prepregnancy weight and height can be used as a practical alternative but may be substantially less reliable.

## Global weight gain standards

Global gestational weight gain standards were published in 2016 using prospective data from the Fetal Growth Longitudinal Study component of the INTERGROWTH-21st Project ([Cheikh Ismail et al., 2016](#)). Healthy, well-nourished and educated women were enrolled from eight geographically diverse settings (Brazil, China, India, Italy, Kenya, Oman, United Kingdom, and United States). All enrolled women had a BMI of 18.50–24.99 in the first trimester of pregnancy, height of > 153 cm and had a live singleton birth. Women in the study received quality antenatal care, had accurate measurements of gestational age, had low rates of adverse maternal, perinatal and neonatal outcomes and their children experienced normal growth and development through age 2 years ([Villar et al., 2013, 2019, 2018, 2014; Papageorgiou et al., 2014](#)). Prospectively collected data from this unique study were used to determine the 3rd, 10th, 25th, 50th, 75th, 90th, and 97th gestational weight gain centiles by exact week of gestation ([Fig. 2](#)).

**Table 1** Recommendations for pregnancy weight gain by BMI at conception.

BMI category	Recommended weight gain range, kg (lb)	Rate of weight gain in second and third trimester range, kg (lb)/week
Low (BMI < 18.5)	12.5–18 (28–40)	0.44–0.58 (1–1.3)
Normal (BMI 18.5–24.9)	11.5–16 (25–35)	0.35–0.50 (0.8–1)
Overweight (BMI > 25.0–29.9)	7–11.5 (15–25)	0.23–0.33 (0.5–0.7)
Obese (BMI ≥ 30.0)	5–9 (11–20)	0.17–0.27 (0.4–0.6)

### Excessive and inadequate weight gain

Most of the literature on *pregnancy weight gain* and maternal outcomes is observational making it difficult to infer causality on the relationship between high or low weight gain with poor outcomes. Inadequate maternal weight gain is associated with poor *fetal growth*. Birth weight in turn is an important determinant of child health and survival. Low weight-for-length at birth may also be a risk factor for chronic disease in later life. Likewise, excessive maternal weight gain may have adverse consequences for both the mother and child.

In a 2017 systematic review, including over a million women from the United States, Asia and Europe, 23% of women gained below IOM recommendations and 47% gained above recommendations ([Goldstein et al., 2017](#)). Excessive gestational weight gain was associated with lower risk of SGA and preterm birth but higher risk of large for gestational age, macrosomia and cesarean delivery. The data however were insufficient for evaluating gestational diabetes. On the other hand, inadequate gestational weight gain was associated with a higher risk of small for gestational age (SGA), preterm birth (PTB) and lower risk of larger for gestational age (LGA) and macrosomia. In addition, in a 2019 individual-level analysis across 33 trials of predominately Caucasian women, over two-thirds of women gained outside IOM recommendations ([Rogozinińska et al., 2019](#)). Gestational weight gain above IOM recommendations was associated with increased odds of cesarean section, LGA and reduced odds of SGA while weight gain below recommendations was associated with increased odds of PTB and low birth weight (LBW). The consequences of inadequate and excessive gestational weight gain remain consistent across diverse populations and settings ([Goldstein et al., 2018](#)).

A better understanding of demographic, behavioral, psychosocial and medical characteristics associated with inadequate or excessive gestational weight gain is important to help inform programs and policies to support optimal weight gain and health outcomes (Deputy et al., 2015). Maternal BMI at conception is inversely related to expected pregnancy weight gain, but, overweight and obese women still tend to deliver heavier infants and underweight women are more likely to have smaller infants. Among women with a low BMI, birth weight is more strongly related to pregnancy weight gain, so the greatest risk of LBW is for underweight women with a low pregnancy weight gain. It is crucial that underweight women gain adequate amounts of weight, while, excessive weight gain among obese and overweight individuals is a concern. Exercise during pregnancy may be a protective strategy for preventing excessive gestational weight gain and gestational diabetes (Barakat, 2019).

## Pattern of weight gain

Relatively little (1–2.5 kg) of the total weight gain during pregnancy occurs during the *first trimester*; gain in the *second trimester* is highest, followed by a slightly lower gain in the third. Nevertheless, it is important to pay attention to the quality of pregnant women's diets during the first trimester and to ensure that they do not restrict their intake during this time, when there is the strongest risk of nutrition-related *birth defects* and spontaneous abortions.

In a 2021 analysis of the Womens First Trial that included 2331 women in the Democratic Republic of Congo, Guatemala, India and Pakistan, women's preconception BMI, early gestational weight gain (from preconception to 12 weeks) and gestational weight gain from 12 to 32 weeks were all independently associated with birth length and weight (Bauserman et al., 2021). In addition, data from the PRECONCEPT prospective study of 5011 women who were followed from preconception through 6–7 years postpartum in Vietnam, provide evidence that maternal preconception nutritional status (height, weight and BMI) was associated with an increased risk of LBW and SGA births as well as stunting at 2 years (Young et al., 2015, 2017, 2018). There was a similar and independent association with maternal nutrition during preconception and pregnancy on birth outcomes implying that programs aimed only on pregnancy may have half the potential impact in this context. In addition, ultrasound data on fetal growth were used to identify critical periods for gestational weight gain that are most influential on child growth. Early weight gain in the first 20 weeks had 3 times the influence on birthweight compared to gain  $\geq 30$  weeks. Collectively, findings from these two large studies suggest programs will have the greatest impact on improving birth outcomes if they address maternal nutrition both before and during pregnancy and underscore the importance of understanding the patterns of weight gain across pregnancy. New global standards for gestational weight gain provide opportunities for better understanding the timing of weight gain across pregnancy and optimal total weight gain worldwide (Cheikh Ismail et al., 2016).

## Changes in body composition and maternal energy status

It used to be assumed that maternal *energy intake* during pregnancy was the main determinant of the amount of weight gained. Although our knowledge of this relationship is still inadequate, newer information indicates that other maternal factors, especially body composition, are important predictors.

The weight gained during pregnancy can be roughly divided into the weight of the fetus, placenta, and *amniotic fluid* (a total of approximately 5 kg), maternal gain in the uterus, breasts, blood, and fluid (approximately 4 kg), and maternal fat. The latter component is the most variable, accounting for approximately 70% of the variability in *pregnancy weight gain*. Although average fat gain in different studies is approximately 2–5 kg, and values for individual women range from a loss of several kilograms to a gain of approximately 12 kg. Even in a group of women with normal BMIs at conception, the range of fat gain was 0.5–9.5 kg. Women with greater fat mass at conception gained less fat during pregnancy, as would be expected from their lower weight gains. The greater fat gain among women low BMIs is a potential energy store for the fetus and would afford some protection against maternal malnutrition in *late pregnancy*—a situation that is not uncommon in some economically disadvantaged countries.

Maternal BMI at conception influences not only the amount of maternal weight and fat gained during pregnancy but also changes in maternal *basal metabolic rate* (BMR). In studies of well-nourished pregnant women, BMR has been reported to increase by approximately 20–30%. However, for undernourished women the increment in BMR may be decreased compared to those who are well nourished.

Overall, it is clear that heavier women gain less weight and fat during pregnancy and have a larger increase in BMR. However, few studies have body composition measures and ethnic differences may limit the use of BMI. It has not been determined how these differences translate into energy requirements for women in the different BMI groups used to predict weight gains. Therefore, the values for energy requirements, which vary by trimester, are used for all pregnant women regardless of their BMI at conception.

## Weight gain for special population groups

### Adolescents, short women, and ethnic groups

There is insufficient evidence for creating different weight gain guidelines for adolescents. To ensure adequate *nutrition* for those who are still growing special attention should be given to ensuring that the quality of their diets is good. The effects of this recommendation on weight retention postpartum have not been evaluated adequately.

Women who are less than 157 cm tall tend to give birth to infants who are large relative to maternal pelvic size, with a subsequently slightly greater risk of a more difficult delivery. However, pregnancy weight gain recommendations do not differ by maternal height.

The IOM, 2009 recommendations cite insufficient evidence to recommend different pregnancy weight gains for ethnic groups. Black women in the United States tend to gain less weight in pregnancy and to produce lower birth-weight infants. The reasons for this are not known, but it could not be explained by differences in gestational age or other factors. Adequate weight gain in this group is known to be especially important for the prevention of *fetal growth* restriction. In one study, 18% of nonobese black women who gained less than the IOM recommendations gave birth to low-birth-weight infants compared to 10% whose gain was in the ideal range and 4% who gained more than the recommendations. In obese black women, the LBW prevalence was approximately six times higher than that for those who gained less than the recommendations.

Most surveys indicate that Hispanics seem to gain approximately the same amount of weight as Anglo women. In the 1980 National Natality Survey, Hispanic and non-Hispanic white women gained a similar amount of pregnancy weight, but the risk of LBW was twice as high in Hispanics. Surveillance of a predominantly Hispanic population indicated that half of the underweight women and one-third of the normal weight women gained the recommended amount of weight, whereas more than half and three-fourths of overweight and obese women, respectively, had excessive gains. Inadequate weight gain during the *third trimester* was predictive of PTB. Underweight Hispanic women had nearly twice the risk of premature delivery.

New insights from the global gestational weight gain standards using the data from the INTERGROWTH-21st Project provide evidence of similar weight gain across eight populations in diverse settings and conclude that the observed differences by race/ethnicity reported in the literature are likely caused by socioeconomic, medical, cultural, and nutritional factors (Cheikh Ismail et al., 2016). Evidence from this study indicates that separate gestational weight gain charts are not required for different ethnic/racial groups.

### Substance abusers

Cigarette smokers tend to gain less weight during pregnancy and to produce smaller infants. This effect is not explained by a lower food intake. Alcohol and drug use have similar effects. Simply gaining more weight during pregnancy will not compensate for the adverse effects of these practices on *fetal outcome* or *pregnancy complications*.

### Multiple births

Relatively few data are available from national surveys on which to base weight gain recommendations for women with twins or multiple births. Recommendations by the recent IOM Committee are: normal weight at conception, 37–54 lb; overweight, 31–50 lb; and obese, 25–42 lb. There is insufficient information to make recommendations for underweight women.

### Obese and overweight women

Obesity during pregnancy is associated with higher morbidity for both the mother and the child. Higher prepregnancy weights have been shown to increase the risk of late (>28 weeks of gestation) *fetal deaths*. In addition, the prevalence of *gestational hypertension* increases threefold and there is a three to four times greater risk of *gestational diabetes* in obese pregnant women. However, in prolonged fasting, i.e., 16–18 h, there is more risk of blood *ketones* being elevated in pregnant women that may increase risk of poor intellectual development of their offspring, thus prolonged fasting and *weight loss* in pregnancy is not recommended. However data needed to inform obesity prevention and weight loss programs are lacking (Lassi et al., 2020; Furber et al., 2013).

### Exercising women

Women who are physically fit at conception are able to continue to *exercise during pregnancy* without harm to themselves or the fetus, as long as the activity is not too strenuous or prolonged. In several studies exercising women gained 2 or 3 kg less than those who were more sedentary.

## Pregnancy weight gain and postpartum risk of obesity

On average, well-nourished women retain relatively little weight a year after delivery (approximately 0.5–1.5 kg). Delivery is followed by a rapid loss of weight in the subsequent 2 weeks due to fluid loss then a slower rate of loss for the next 6 months, so a complete return to preconception weight should not be expected in less time than this. In general, weight still retained at 1 year postpartum is unlikely to be lost without lowering intake and/or increasing physical activity. If weight retention is substantial, it can add to the risk of obesity in the longer term, and obesity is a major public health concern in many countries.

The relatively low average weight retention postpartum obscures the fact that many women do retain an excessive amount of weight. Those who retain most are likely to have gained large amounts of weight during pregnancy. At 10–18 months postpartum, weight retention was 2.5 kg for women who gained more than the IOM recommendation compared to 0.7 kg for white women, and 3.2 kg for black women who gained the advised amount. These large racial differences in weight retention have not been explained and certainly may be a risk factor for the higher prevalence of later obesity in this group.

Most women breast-feed their infants exclusively or partially for a relatively short time. There is little difference in *weight loss* between women who breast-feed and those who do not for periods up to 6 months postpartum. This is presumably due to the greater appetite and *energy intake* of women who are breast-feeding and perhaps to dieting on the part of nonbreast-feeders. One study of women who breast-fed until 12 months postpartum did report 2 kg more weight loss compared to women who stopped breast-feeding before 3 months. Even more weight was lost by those who breast-fed more often and gave longer feeds.

Women with a high BMI at conception tend to either lose or gain more weight postpartum than those with a normal BMI; approximately one-third end up weighing less than at conception, and one-third weigh substantially more. The reasons for the highly variable weight retention in this group are not known.

Although inadequate intake of nutrients during lactation can lead to maternal nutrient depletion and lower breast milk content of some nutrients and especially vitamins, breast-feeding women who choose to lose weight can do so by exercising and/or reasonable restriction of energy intake. Exercising by jogging, biking, and aerobics for 45 min, four or five times per week for 12 weeks did not affect well-nourished mothers' ability to lactate or influence their milk composition. However, it is possible that severe energy deficit in lactation, especially of underweight women, will reduce breast milk volume.

## Impact of supplementation

Numerous investigators have explored the benefits of energy and/or protein supplementation for *pregnancy weight gain* and other outcomes. A 5-year controlled trial in The Gambia provided daily prenatal dietary supplements (two biscuits) that contained 4250 kJ (1000 kcal) energy and 22 g protein. This supplement increased pregnancy weight gain and birth weight during the hungry and harvest seasons. There was a significant but very small increase in head circumference and a significant reduction in *perinatal mortality*.

Supplementation of undernourished women in the *third trimester* is most likely to increase birth weight. In the Dutch famine during World War II, low food intakes during the third trimester rapidly reduced birth weight and length, and head circumference. These *adverse outcomes* did not occur a few months after the food supply improved. Low intakes in the *second trimester* had less effect, although insufficiency in the *first trimester* had no effect. An increase in LBW prevalence was also observed in The Gambia when third-trimester gestation overlapped with the hungry season. Nonetheless, *nutrition* interventions initiated earlier and continued throughout pregnancy will have the strongest effect on birth weight. There are enduring advantages to continued supplementation postpartum (during lactation) and into the ensuing pregnancy. A *longitudinal study* in Guatemala reported a significant increase (approximately 350 g) in birth weight in the second pregnancy when the mother was supplemented during the previous pregnancy and throughout subsequent lactation and the second pregnancy, compared to those who were not supplemented during the prior pregnancy. Overall, it is appropriate for supplementation of undernourished women to begin as early in the pregnancy as possible so that both mother and fetus receive the maximum benefits for optimal health and development.

In the 2021 Lancet Nutrition Series, maternal balanced energy protein supplements were recommended for undernourished women during pregnancy, especially in food insecure populations. Balanced energy protein supplementation was associated with a 40% reduction in LBW, 61% reduction in stillbirths and a 29% reduction in SGA (Keats et al., 2021; Lassi et al., 2020). There was however inadequate evidence on the effects of balanced energy protein supplements on maternal weight gain, morbidity or mortality. Evidence from five food distribution programs also indicated increased birth weight and length and reduced rates of SGA, stunting, and wasting (Lassi et al., 2020).

In addition, in the past 10 years there has also been a rapid expansion of research on the efficacy and effectiveness of prenatal lipid-based nutrient supplements (LNS) to improve birth outcomes (Das et al., 2018). In a systematic review of the literature, there was a slight, positive effect of LNS birth weight, birth length, SGA and stunting compared to iron and folic acid. Evidence on gestational weight gain is limited and requires further examination.

## Summary

Healthy weight gain during pregnancy can improve birth outcomes and maternal and child health. However, the majority of women fail to meet current recommendations. Women who gain inadequate weight during pregnancy are at greater risk for delivering a LBW, PTB, or SGA infant. Women who gain excessive weight during pregnancy on the other hand are at increased risk for macrosomia and giving birth to large for gestational age infant, having excessive postpartum weight retention and childhood obesity. The consequences of inadequate and excessive gestational weight gain remain consistent across diverse populations and settings. The new global weight gain standards provide new gestational age specific benchmarks for optimal weight gain. Increasing evidence suggests the importance of maternal nutrition both before and during pregnancy. Further research is needed to help support women to enter pregnancy with a healthy BMI as well to gain within recommended amounts.

## Key points

The objectives of this article are to describe:

- Origins and definition of the term ‘stunting’, and its use as an indicator of child health and nutrition
- Global and regional burden of stunting and secular trends
- Consequences of stunting in early childhood
- Risk factors for stunting
- Nutrition-specific and nutrition-sensitive interventions to reduce the burden of stunting

## Introduction

Stunting refers to a state of inadequate physical growth in stature (infant or toddler supine length, or standing height of an older child). The term was originally proposed by John Waterlow in 1972 to refer to “a reduction in final stature” that results from an abnormally slow rate of linear growth in childhood (Waterlow, 1972). From its early usage, stunting has been assumed to represent “nutritional growth failure” due to long-standing dietary deficiencies, in contrast to “acute” malnutrition, such as kwashiorkor or marasmus (Waterlow, 1973); however, it is now widely acknowledged that stunting should not be used to ascribe a specific cause to a child’s deficit in length or height (Raiten and Bremer, 2020). Stunting is usually applied to young children (under the age of 5 years), but it may also be used to refer to low heights of adolescents and adults.

Currently, stunting is defined in statistical terms, whereby a child is considered stunted if their crown-to-heel length or height z-score (HAZ) is less than  $-2$  (i.e., more than 2 standard deviations below the median of the distribution of normal lengths or heights for children of the same sex and age) and severe stunting may be defined as a z-score less than  $-3$  (de Onis and Branca, 2016). This definition of stunting is analogous to related forms of child undernutrition such as ‘underweight’ and ‘wasting’, which are similarly defined according to biologically arbitrary thresholds in the normative weight-for-age and weight-for-height distributions, respectively (WHO Multicentre Growth Reference Study Group, 2006). Since their publication in 2006, the World Health Organization (WHO) child growth standards (WHO-GS) have been the most widely used source of normative distributions to enable assessment of an individual child’s length or height value under five years of age (WHO Multicentre Growth Reference Study Group, 2006). The WHO-GS for length and height, which are applicable to children born at term, were recently complemented by the publication of the Intergrowth-21st standards for newborn length by gestational age and sex (Villar et al., 2014a,b), and postnatal growth references for preterm infants (Villar et al., 2015). The recommendation to use a common set of international growth standards/references to assess nutritional status is based on the well-supported notion that ethnicity or genetic factors play a minimal role in explaining the variance in the growth of young children, such that the distribution of individual child lengths/heights at a given age is expected to be similar around the world if environmental conditions and feeding practices are optimized (de Onis, 2006;

Villar et al., 2014a,b). As such, the WHO-GS and the Intergrowth-21st standards/references remain widely used in research and public health applications globally.

In pediatric medical practice, the terms ‘failure to thrive’ and ‘short stature’ are commonly used to describe children who are growing too slowly (i.e., gaining too little weight) or who are shorter than age-matched peers, respectively. Conversely, the label and concept of stunting is almost exclusively applied to infants and children in community and primary care settings in low- and middle-income countries (LMICs). ‘Linear growth faltering’ is a closely related concept to stunting, insofar as it refers to a child’s – or population of children’s – suboptimal rate of growth in length or height, which if prolonged or pronounced, can result in stunting. However, there are no standard quantitative definitions of linear growth faltering. Some authors have promoted the consideration of a “stunting syndrome” as a condition of vulnerable children in LMICs who, beyond their measured impairments in physical growth, suffer from a range of related adversities including other nutritional deficits (e.g., micronutrient deficiencies), enteric dysfunction, developmental and cognitive delays, immune dysfunction, and increased risks of chronic diseases in later life (Prendergast and Humphrey, 2014). However, when defined in statistical terms, stunting is not intended as a clinical diagnosis, as there is no biological basis for the nominal cut-points used to distinguish stunted from non-stunted children (Perumal et al., 2018).

## Stunting prevalence and global and regional trends

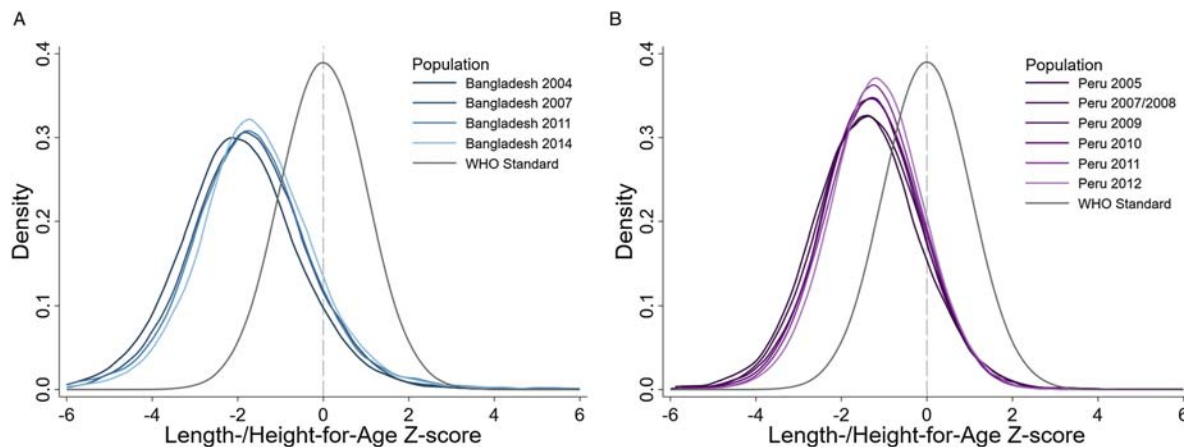

Stunting is most appropriately used as an indicator of the location and dispersion of the height-for-age distribution of a particular population relative to a normative reference or standard distribution such as the WHO-GS. The prevalence of stunting (i.e., proportion of children in a population with HAZ less than  $-2$ ) can be compared across populations or tracked over time to assess differences or changes in the population burden of undernutrition. The conventional statistical definition of stunting implies that 2–3% of healthy children would be classified as stunted (since a z-score of  $-2$  is equal to the 2.3<sup>rd</sup> percentile of a normal distribution). With this benchmark in mind, in 2018 the WHO adopted the following stunting prevalence thresholds to classify the level of severity of stunting at the country level: ‘very low’ ( $<2.5\%$ ), ‘low’ (2.5–10%), ‘medium’ (10 to  $<20\%$ ), ‘high’ (20 to  $<30\%$ ) and ‘very high’ ( $\geq 30\%$ ) (de Onis et al., 2019). Stunting prevalence has also been used as a component of composite indicators intended to convey the overall burden of child undernutrition in LMICs, including the ‘composite index of anthropometric failure’ (Nandy et al., 2005) and ‘child growth failure’ (Kinyoki et al., 2020).

Under-5 stunting prevalence is a robust indicator of the burden of growth faltering for comparisons across populations or within populations over time (i.e., secular trends). Stunting prevalence reflects the health status of the whole population rather than identifying a sub-group of growth-restricted children within the population (Perumal et al., 2018). In most populations in which stunting prevalence is elevated (above  $\sim 2.5\%$ ), mean HAZ and the distributions of heights are shifted down (Roth et al., 2017; Victora et al., 2021) (Fig. 1). Reductions in stunting prevalence in countries that have successfully improved child health and nutrition status have been accompanied by upward shifts in HAZ distributions (Bhutta et al., 2020). The downward-shifted height distributions of populations in many LMICs means that even the tallest children in such settings tend to be shorter than they would have been had they been living under conditions that were optimal for growth. In fact, only a very small proportion ( $\sim 0.1\%$ ) of children in population-representative survey samples in LMICs live under conditions that support normal growth (Karra et al., 2017). Therefore, an elevation in stunting prevalence (i.e., prevalence greater than  $\sim 2.5\%$ ) indicates a public health problem that is considerably more pervasive than suggested by counting the number of stunted children.

Tracking stunting prevalence or mean HAZ as a function of age within a cohort or survey population may provide additional insights into age-related dynamics of linear growth faltering (Rieger and Trommlerová, 2016); however, such analyses must be approached cautiously because the same stunting prevalence at two different ages implies different degrees of severity and duration of the linear growth faltering process. The later the age at which stunting is observed, the longer the time over which the children have been exposed to suboptimal growth conditions. And, because postnatal growth velocity is normally rapid in early infancy and then declines until the pubertal growth spurt, stunting at later ages is less likely to resolve, particularly given the progressively shortening window in which it remains possible for catch-up to occur before growth stops. Therefore, the implications of stunting for longer-term growth and health are affected by the duration of time over which faltering has occurred. As such, stunting prevalence estimates should generally only be used to compare populations (within countries over time, or between countries) based on samples of children of the same age or within the same age window (e.g., under-5 years).

The global prevalence of stunting among children under 5 years of age has declined by over 45% since 1990, by almost 35% in the last two decades for which data are available (from 32% in the year 2000 to 21% in 2019), and by 18% in the most recent decade (2010–2019) (UNICEF/WHO/World Bank Group, 2020) (Fig. 2). The international agencies that track malnutrition indicators (UNICEF, WHO and World Bank) report stunting prevalence as well as the estimated absolute number of children under five years who are affected by stunting. For example, in 2019, the estimated 21% global prevalence corresponded to at least 144 million stunted children worldwide (UNICEF/WHO/World Bank Group, 2020). The absolute number is used to track progress with respect to the WHO nutrition target of a 40% reduction in the number of stunted children from 2010 to 2025. Estimates in 2020 indicated that the pace of reductions in stunting have been inadequate to meet the WHO targets at a global level, although many individual countries are achieving target reductions (UNICEF/WHO/World Bank Group, 2020).

There is considerable regional variability in stunting prevalence. Based on 2019 estimates, prevalence of stunting was 33% in Sub-Saharan Africa and South Asia, 14% in the Middle East and North Africa, 11% in East Asian and Pacific Region, 9% in Latin

**Fig. 1** Density distributions of length/height-for-age z-scores (LAZ/HAZ) for children under 5 years of age in Bangladesh (panel A) and Peru (panel B) based on anthropometric data from population-representative Demographic and Health Surveys (DHS). Distributions in both countries demonstrate that an elevated prevalence of stunting (proportion with LAZ/HAZ < -2) is a result of a whole-population leftward shift in child height compared to the World Health Organization (WHO) growth standard. Secular improvements in child nutritional status in the past two decades in both countries are marked by declines in the prevalence of stunting (Bangladesh: 51% in 2004 to 36% in 2014; Peru: 29% in 2005 to 18% in 2012). Decline in stunting prevalence involves a rightward shift in the LAZ/HAZ distribution, but this effect may not be uniformly distributed across the population. For example, in Peru (Panel B), increases in height in more recent survey years were more apparent at the lower than the upper tail of the distribution.

**Fig. 2** Prevalence of stunting by World Bank Region (UNICEF, WHO, World Bank Group Joint Malnutrition Estimates, March 2020 Edition). Stunting prevalence 1990–2019).

America and the Caribbean and Eastern Europe and Central Asia, and 2.6% in North America (UNICEF/WHO/World Bank Group, 2020). The rates of decline have also varied across world regions, with the largest declines observed in Asia, followed by Africa and Latin America and the Caribbean. Against the global trend, Oceania (excluding Australia and New Zealand) has not experienced a decline in the prevalence of stunting over the last two decades (prevalence of 37% in 2000 vs. 38% in 2019). Nationally, the highest prevalence of stunting has been documented in Burundi (54%), Madagascar (50%), Timor-Leste (50%), Niger (48%), Guatemala (47%) and Yemen (45%) (Kinyoki et al., 2020). In 2019, 101 of the 134 countries for which recent malnutrition estimates were available had an estimated stunting prevalence higher than 10%, which the WHO considers to be at least a ‘medium’ level of severity (UNICEF, 2019).

Within countries, important between-district differences in stunting prevalence among children under 5 years of age highlight socioeconomic inequities. For example, in India, the national prevalence of stunting among children under 5 years of age was 36%

in 2015, yet the state-level prevalence ranged widely from 18% to 48% (Victora et al., 2021). Other sub-national estimates point to a concerning high prevalence of stunting in some communities. A prevalence as high as 60% has been observed in the Karuzi province in Burundi and in the Jigawa state in Nigeria, and over 58% in Laos' Houaphan province (Kinyoki et al., 2020). An increased prevalence of stunting has also been observed in settings of violent conflict, political instability and other settings with major disruptions in civil society. Yet, a recent analysis of data from DHS and MICS surveys from low- and middle-income countries, confirmed that while the distributions of height-for-age z-scores are still below the reference values in the WHO growth standards in both groups of countries, both groups are also slowly progressing towards the standard WHO distribution (Victora et al., 2021).

### Mortality and developmental outcomes associated with stunting

Beyond its role as an indicator of suboptimal nutritional status, stunting has also been interpreted more broadly as an indicator of elevated risks of adverse child health outcomes. A key reason that the global public health community has adopted stunting and wasting as core global child health indicators is their associations with short-term mortality. Stunted (HAZ between  $-3$  and  $<-2$ ) and severely stunted children (HAZ  $<-3$ ) have 2.3-fold and 5.5-fold higher mortality rates, respectively, compared to a reference group of children with HAZ  $\geq -1$ , although these associations for stunting are weaker than for wasting (Olofin et al., 2013). An important observation is that even children with HAZ from  $-2$  to  $<-1$  have a significantly elevated mortality rate, and there is no inflection point in the mortality-HAZ relationship at the stunting threshold of HAZ =  $-2$  (Olofin et al., 2013); therefore, while height reflects a child's relative risk of death in LMIC settings (primarily due to common infectious diseases such as pneumonia and diarrhea), there is no particular significance of the stunting classification at the individual level. Furthermore, there is no convincing evidence that short stature is itself a cause of death; rather, it is more likely that the underlying factors that constrain linear growth also exacerbate exposures to infectious pathogens or impair immune responses.

Stunting reflects a chronic state of deprivation with respect to the conditions and resources necessary for optimal child growth and development; as such, its associations with long-term developmental and human capital outcomes have been examined in numerous studies. An analysis of 5 low- and middle-income country cohort studies from Brazil, Guatemala, the Philippines, India and South Africa showed that for each unit reduction in z-scores by 2 years of age, there was, on average, a half-year reduction in years of schooling (a marker of educational attainment) (Victora et al., 2008). An analysis of data from Demographic and Health Surveys from 21 countries observed an average reduction of  $\sim 0.3$  school years per HAZ z-score reduction, but with marked variability in the effects, ranging from reductions as small as 0.1 years to as large as 1.2 years (Karra and Fink, 2019). Nevertheless, some studies have shown that although lower HAZ z-scores increased the probability of a child being in earlier than expected grades in school, this may be a consequence of delays in school entry (Crookston et al., 2011), lower probability of high school completion by adult age, and higher probability of failing and/or repeating grades (Daniels and Adair, 2004). Low HAZ and stunting have also been associated with lower indices of early childhood cognitive and motor development (Sudfeld et al., 2015a,b). However, as with associations between height and mortality (as described above), there is no clear inflection point at the stunting threshold of HAZ =  $-2$  in the relationships between HAZ and developmental measures (Sudfeld et al., 2015a,b).

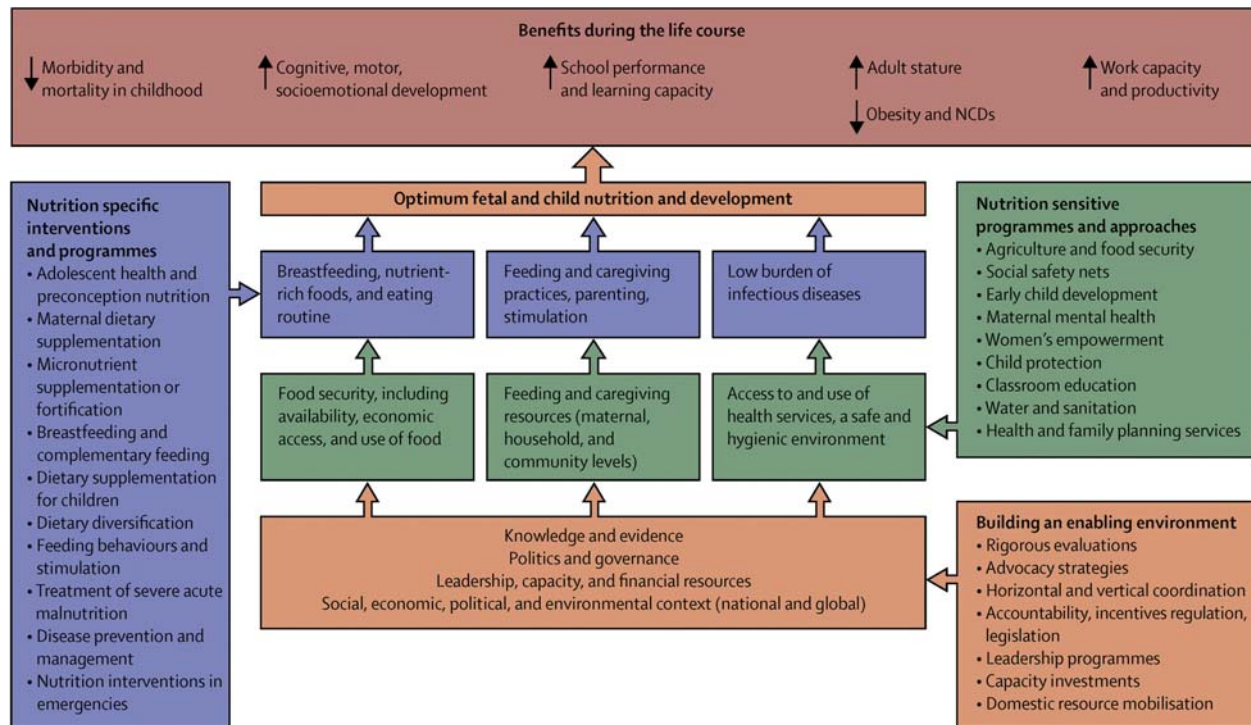

The relevance of associations between stunting and measures of cognitive outcomes in observational studies has been questioned. Cognitive development and linear growth have common determinants which may largely explain the observed associations (Leroy and Frongillo, 2019). Developmental indicators may improve even without any changes in anthropometric status, while interventions that mitigate linear growth faltering do not necessarily improve cognitive outcomes; moreover, the effect of interventions focused on nutrition seem to have a weaker effect on cognition compared to interventions that directly support infant and early childhood nurturing and stimulation (Prado et al., 2019). Stunting is generally not considered to be a direct cause of low schooling attendance and attainment, even though the associations continue to be observed even after adjustment for other socio-economic factors associated with stunting, such as parental education. Furthermore, parental behaviors and decisions about health care and feeding may be responsive to the length/height of their children, which may partly compensate for the adverse effects of undernutrition (Liu et al., 2009). Therefore, an elevated prevalence of stunting in a community is most appropriately viewed as a marker of suboptimal environmental conditions rather than a direct cause of adverse child health outcomes.

### Stunting risk factors

Stunting in LMICs is a consequence of adverse social, environmental and economic conditions that cause fetal and child growth to proceed more slowly than expected under ideal conditions (Victora et al., 2021) (Fig. 3). Conceptual frameworks to explain stunting and other forms of child undernutrition have emphasized a range of proximal household, maternal and infant care-related factors that affect child health, and which are assumed to primarily act as mediators of upstream societal and political influences (Black et al., 2013; Mosites et al., 2017; Bhutta et al., 2020). Nutritional deficiencies due to inadequate dietary intake or impaired nutrient absorption or utilization due to chronic inflammation or other stressors are believed to be the primary proximate factors that impair skeletal growth and development, thereby leading to stunting.

Innumerable studies of stunting risk factors in LMICs have sought to identify sources of between-child variation in height (or HAZ) within a particular population (e.g., cohort, community, or country). Yet, identifying specific remediable causes of linear growth faltering has proved challenging. Among the risk factors with the strongest and most consistent associations with stunting

**Fig. 3** Framework for actions to achieve optimum fetal and child nutrition. Source: Black R.E, Victora C.G, Walker S.P, Bhutta Z.A, Christian P, de Onis M, et al., Maternal and child undernutrition and overweight in low-income and middle-income countries, *Lancet*. 382 (9890), 2013, 427–451.

are maternal short stature (Kim and Subramanian, 2017; Mal-ed Network Investigators, 2017; Richter et al., 2018; Li et al., 2020) and adverse perinatal outcomes (i.e., preterm birth and fetal growth restriction measured as low birth weight or small-for-gestational age) (Christian et al., 2013; Danaei et al., 2016). The observation of neonatal stunting in many LMICs underscores the early timing of onset of linear growth faltering and has brought increased attention to the importance of maternal and fetal exposures as antecedents of infant and child stunting. Additional maternal characteristics that increase the risk of stunting include younger age, lack of education (Li et al., 2020), and short spacing between consecutive pregnancies (Fink et al., 2014). Observational epidemiologic studies conducted in LMICs suggest a positive association between longer birth interval (>36 months) and lower risk of stunting (~10%–50% relative reductions in prevalence), but this association was not consistently observed across all countries (Dewey and Cohen, 2007).

Low household socioeconomic status and low levels of parental education are widely recognized as important contextual factors associated with the risk of childhood stunting. However, even the wealthier segments of the populations in LMICs have negatively-shifted height distributions (Rieger and Trommlerová, 2016; Victora et al., 2021) and therefore an elevated prevalence of stunting (Black et al., 2013). Household characteristics that reflect deficiencies in sanitation (e.g., open defecation, lack of improved toilet or latrine facilities) and hygiene (e.g., lack of availability of soap and clean water next to a latrine) have also been associated with the risk of stunting (Danaei et al., 2016; Vilcins et al., 2018), but the association of stunting with unsafe drinking water has been less consistent (Owais et al., 2016; Kim and Subramanian, 2017; Li et al., 2020).

Stunting has been associated with several caregiver-reported factors that describe infant and early child dietary and feeding-related behaviors, such as low dietary diversity after the age of introduction of complementary foods (Kim and Subramanian, 2017; Mosites et al., 2017) or low proportion of total energy from protein (Mal-ed Network Investigators, 2017). However, breastfeeding practices in early infancy do not appear to influence the longer-term prevalence of stunting (Owais et al., 2016); in fact, stunting prevalence typically increases during the early postnatal period (Victora et al., 2021) when exclusive or predominant breastfeeding is relatively common in many LMICs. Early childhood zinc deficiency has long been linked to poor linear growth, but its contribution to the overall global stunting burden may be minor (Mosites et al., 2017). Enteropathogens (Mal-ed Network Investigators, 2017), environmental enteric dysfunction (i.e., intestinal wall injury, inflammation, and permeability), and intestinal dysbiosis have been of particular recent interest, but the extent to which they cause an elevated prevalence of stunting remains unclear (Harper et al., 2018; Budge et al., 2019). Mycotoxin exposures are associated with low HAZ, but there is less conclusive evidence to support associations of stunting with other environmental toxins or pollutants (e.g., pesticides, heavy metals, indoor air pollution) (Vilcins et al., 2018).

Social and biological factors that explain between-child variance in individual risks of stunting are similar or analogous to those that account for between-population variation in the stunting burden. For example, district-level stunting prevalence in India is associated with maternal health and education, average household wealth, and other measurements of socioeconomic

status (Karra et al., 2017). In addition, reductions in the prevalence of stunting in LMICs over time have been associated with policy and programmatic changes in the health and non-health sectors that improve women's access to health care, nutrition and education (Bhutta et al., 2020), household access to improved sanitation and water, and improvements in other related domains of early child health and nutrition (Argaw et al., 2019). However, recognition of stunting as an indicator of whole-population growth faltering highlights the critical importance of upstream community-level and ubiquitous factors that cause nearly all children in some communities to grow too slowly and thereby increase the prevalence of stunting in a population. Furthermore, the extent to which conventional stunting risk factors operate as causal determinants of growth faltering and stunting in LMICs is unclear because of the strong likelihood of confounding in observational studies in which nearly all individual- and household-level risk factors under consideration are strongly and broadly correlated with social disadvantage and economic deprivation.

## Preventive interventions for stunting

Over the past 20 years, the global development agenda has included major efforts to reduce undernutrition among young children in LMICs. In 2000, the United Nations General Assembly ratified eight Millennium Development Goals, which included halving the prevalence of underweight (weight-for-age z-scores  $<-2$  SD based on the World Health Organization Child Growth Standards) as the global target to reduce hunger (United Nations General Assembly, 2000). The 2015 Sustainable Development Goals further set out an ambitious target to "end all forms of malnutrition, including achieving, by 2025, the international agreed upon targets on stunting and wasting among children under 5 years of age" (United Nations, 2015). In 2012 the World Health Assembly endorsed a comprehensive implementation plan on maternal, infant, and young child nutrition, which included the six Global Nutrition Targets, including the target to "achieve a 40% reduction in the number of children under-5 who are stunted by 2025" (World Health Organization, 2018). As such, substantial investments have been made in global nutrition research to design and evaluate interventions and programs to reduce the prevalence of stunting.

## Frameworks addressing child undernutrition

In 1990, the United Nations Children's Fund (UNICEF) developed a seminal comprehensive conceptual framework on the causes of child undernutrition, highlighting the multifactorial nature of undernutrition (UNICEF, 1990). Subsequently, the Lancet 2013 Nutrition Series advanced this framework to identify pathways to optimal fetal and child growth and development (Black et al., 2013a,b) (Fig. 3). This renewed framework identified 'nutrition-specific' interventions and programs designed to address immediate causes of suboptimal growth in early life, such as poor breastfeeding practices, inadequate quality and quantity of foods, caregiving practices, and infectious disease burden, as well as 'nutrition-sensitive' interventions and programs that aimed to address the underlying determinants of undernutrition, including food security, feeding and caregiving resources, access and use of health services and a safe, hygienic environment (Black et al., 2013a,b) (Fig. 3). Whereas nutrition-specific interventions are expected to have a direct effect on nutritional outcomes, nutrition-sensitive interventions are expected to have an indirect effect through mediating pathways (Keats et al., 2021). Interventions to reduce stunting among young children are therefore often categorized as being nutrition-specific, nutrition-sensitive, or integrated solutions that include both nutrition-specific and nutrition-sensitive components.

## Nutrition-specific interventions to reduce the risk of stunting

### Maternal prenatal interventions

The period from conception to the first 2 years of life – the 'first 1000 days' – is widely recognized as a critical window in the life cycle in which linear growth faltering and stunting may be most amenable to prevention (Victora et al., 2010). Several interventions to prevent stunting have focused on meeting the higher nutritional needs of pregnant and lactating women to promote optimal fetal growth (Dewey, 2016), primarily through micronutrient and food supplementation (Bhutta et al., 2013; Keats et al., 2021). Daily iron-folic acid supplements (IFA) containing 30–60 mg of iron and 400 µg of folic acid, and multiple micronutrient supplements (MMS), which typically provide 15 essential vitamins and minerals, have been among the most extensively evaluated interventions for improving maternal prenatal nutrition (Keats et al., 2021). While these interventions improve maternal iron status and reduce the risk of low birthweight and small-for-gestational age, there has been no reported effect on stunting prevalence (Oh et al., 2020). Supplementing breastfeeding mothers with daily MMS during the first 6 months post-pregnancy also does not affect stunting in early infancy (Park et al., 2020a). Other single micronutrient supplementation studies, such as calcium supplements, iron supplements alone, or folic acid supplements alone, may improve some maternal and perinatal outcomes but have not been shown to affect newborn length or stunting prevalence (Keats et al., 2021). However, compared to IFA alone, provision of daily small-quantity lipid nutrient supplements (SQ-LNS), which consist of multiple micronutrients in a 20 g lipid-based vehicle providing 118 kcal/day, has been shown to improve mean length at birth and reduce the risk of stunting at birth in a meta-analysis of two studies (Das et al., 2018) (Table 1). Similarly, in a multi-country randomized trial of SQ-LNS per day provided to women starting at least 3 months or more preconceptionally and throughout pregnancy (two-doses for a subset of women who had a body mass index of  $<20$  kg/m<sup>2</sup>), compared to no preconception or antenatal supplementation, reduced the prevalence of stunting at birth (Hambidge et al., 2019). Balanced energy protein supplements (BEP), which are food supplements with protein content less than 25% of the total caloric

**Table 1** Effect of prenatal and postnatal nutrition-specific interventions on stunting among children <5 years of age.

<i>Interventions</i>	<i>Study type</i>	<i>Publication year</i>	<i>Sample size</i>	<i>Effect estimates for stunting</i>	<i>General conclusions and caveats</i>
<b>Prenatal maternal interventions</b>					
Daily small-quantity lipid nutrient supplements (SQ-LNSs) providing 118 kcal/day	Systematic review and meta-analysis (Das et al., 2018)	2018	2 trials, 4166 participants	RR 0.82 (95% CI: 0.71, 0.94)	Daily SQ-LNS during pregnancy reduced the risk of stunting at birth in geographically diverse settings, compared to standard iron-folic acid supplementation.
	Multi-country RCT (Guatemala, India, Pakistan, Democratic Republic of Congo) (Hambidge et al., 2019)	2019	1465 participants	Preconception to delivery: RR 0.69 (95% CI: 0.49, 0.98) Mid-pregnancy to delivery: RR 0.78 (95% CI: 0.57, 1.07)	Effect estimates for newborn stunting, for SQ-LNS compared to “no nutrition supplements”. Women who were underweight (body mass index <20 kg/m <sup>2</sup> ) were provided an additional daily dose of SQ-LNS.
<b>Postnatal infant and child interventions</b>					
Breastfeeding promotion	Systematic review and meta-analysis (Lassi and Rind, 2020)	2020	6 trials, 6518 participants	RR 1.00 (95% CI: 0.88, 1.14)	Intervention type and duration of breastfeeding promotion are highly variable.
Zinc supplementation	Systematic review and meta-analysis (Liu et al., 2018)	2018	9 trials, 9975 participants	RR 1.01 (95% CI: 0.96, 1.06)	Some zinc supplementation trials have reported positive effects on length but not on stunting, with some suggestions that benefits of the intervention may be greater for children >2 years.
<b>Lipid nutrient supplements (LNS)</b>					
Small quantity (SQ-LNS) providing ~120 kcal/day starting at 6 months of age	Individual participant meta-analysis (Dewey et al., 2021)	2021	17 trials, 36,795 participants	RR 0.88 (95% CI: 0.85, 0.91)	Robust evidence from individual meta-analysis of trials indicate a reduction in the relative risk of stunting with daily SQ-LNS supplements among children 6 to 18 or 24 months of age. Evidence from network meta-analysis suggests LNS with higher energy density (~220 kcal–285 kcal/day) may result in larger effects on the relative risk of stunting (RR 0.80 95% CI: 0.66, 0.97) (Park et al., 2020b)
<b>Complementary foods starting at 6 months of age</b>					
Animal source foods	Systematic review (Shapiro et al., 2019)	2019	19 studies	Pooled effect not estimated given heterogeneity of definitions and interventions regarding animal source foods	Trials evaluating animal source foods on stunting mostly showed null effects, with one or two small studies indicating a positive effect.
Eggs	Single RCT providing one egg/day for 6 months among children 6–9 months of age in Ecuador (Iannotti et al., 2017)	2017	163 participants	RR: 0.53 (95%CI: 0.37, 0.77)	Effect of daily egg consumption for 6 months on stunting observed in the Ecuador trial was not sustained two years after the intervention.

**Table 1** Effect of prenatal and postnatal nutrition-specific interventions on stunting among children <5 years of age.—cont'd

<i>Interventions</i>	<i>Study type</i>	<i>Publication year</i>	<i>Sample size</i>	<i>Effect estimates for stunting</i>	<i>General conclusions and caveats</i>
	Single RCT providing one egg/day for 6 months to infants 6–9 months of age in Malawi (Stewart et al., 2019)	2019	595 participants	RR: 0.98 (95%CI: 0.80, 1.19)	Similar trial in Malawi found no effect of an egg/day intervention on linear growth, though this was hypothesized to be due to high baseline consumption of animal source foods in the study population.
Complementary food provision, with or without education in food insecure environments	Systematic review and meta-analysis (Lassi and Rind, 2020)	2020	7 trials, 7894 participants	RR 0.64, (95% CI: 0.44, 0.92)	Pooled effect size based on seven trials of heterogeneous complementary feeding interventions, including the daily egg intervention in Ecuador. The quality of evidence however was rated as low.

RCT, randomized controlled trial; CI, confidence intervals.

content, reduced the risk of adverse birth outcomes including stillbirths among undernourished pregnant women, but effects on postnatal stunting prevalence have not been examined (Ota et al., 2015).

### Postnatal infant and young child interventions

Interventions designed to meet the nutritional requirements of exclusively breastfed infants (birth to 6 months of age) and infants and children during the complementary feeding period from 6 to 24 months of age have also been evaluated in terms of their effects on stunting (Dewey, 2016; Park et al., 2020a, 2020b). The World Health Organization recommends exclusive breastfeeding for the first 6 months (World Health Organization, 2002). Although maternal breastfeeding education and promotion interventions improve exclusive breastfeeding rates and reduce the risk of diarrheal diseases (Lassi and Rind, 2020), these interventions do not affect linear growth or stunting prevalence (Lassi and Rind, 2020; Park et al., 2020b). Providing MMS to children age 6–24 months during the complementary feeding period is associated with a reduced risk of anemia and marginal improvements in linear growth, but not stunting (Taylor-Robinson et al., 2015). However, evidence from a network meta-analysis of several nutrition-specific interventions provides some suggestion that MMS to children in the complementary feeding period may reduce the risk of stunting (Park et al., 2020b).

Daily SQ-LNS (providing approximately 120 kcal/day with recommended dietary allowance for multiple micronutrient supplements) to children also reduced the prevalence of stunting in an individual participant data analysis of 17 trials, and this association was not altered by differences in geographic regions, baseline prevalence of stunting or malaria, water quality, sanitation, or duration, frequency, and compliance of supplementation (Dewey et al., 2021). Although single micronutrient supplements, such as iron and zinc supplements, are effective in reducing the prevalence of anemia and diarrheal diseases, respectively, these interventions do not improve linear growth or reduce stunting (Liu et al., 2018; Keats et al., 2021). Interventions designed to improve dietary diversity and quality of complementary foods through the provision of animal source foods, including dairy, flesh foods (e.g., meat, fish, poultry), eggs, seafood and insects, have had little to no effect on stunting (Shapiro et al., 2019). Although one small randomized controlled trial of 163 infants in Ecuador showed a lower risk of stunting among children 6–9 months of age who received one egg per day for 6 months, compared to children who received no supplementation (Iannotti et al., 2017), the effect was not sustained two years after the intervention (Iannotti et al., 2020). In a similar trial in Malawi, providing one egg per day to infants 6–9 months for a duration of 6 months did not affect linear growth or stunting prevalence (Stewart et al., 2019). While complementary food education alone has not been found to improve linear growth in food-secure or -insecure settings, provision of complementary foods, with or without education, is associated with a lower risk of stunting in food insecure settings (Lassi and Rind, 2020). Among the few caregiving interventions evaluated in relation to child growth, kangaroo mother care (i.e., skin-to-skin contact) compared to control (i.e., placement under a warmer or incubator) for a period of 1–6 weeks after birth has been shown to yield higher linear growth velocity in high-risk newborns but there was no observed effect on stunting (Park et al., 2020b).

### Nutrition-sensitive interventions to reduce the risk of stunting

Nutrition-sensitive interventions aim to enhance maternal resources, including health and education, household wealth, access to and utilization of health services, or improve water, sanitation and hygiene (WASH) practices. Compared to nutrition-specific interventions, there is limited evidence related to the effects of nutrition-sensitive interventions on linear growth faltering and stunting (Keats et al., 2021). Interventions to promote sexual and reproductive health rights of women through education, delaying age at first pregnancy, and increasing school enrollment and retention among adolescents have been evaluated in relation to preventing unintended pregnancies and optimizing inter-pregnancy interval, but did not evaluate postnatal child outcomes (Lassi and Kedzior, 2020). Disease management through deworming with anthelmintics for soil-transmitted helminths during pregnancy to improve maternal health or among school-aged children have shown no effects on linear growth or stunting prevalence (Salam et al., 2015; Taylor-Robinson et al., 2015; Welch et al., 2017). However, in a meta-analysis, prenatal SQ-LNS food supplementation programs which additionally provided access to maternity and obstetric care or provided malaria treatment were found to reduce the risk of newborn stunting (RR 0.82, 95%CI: 0.71, 0.94) (Lassi and Padhani, 2020). Cash transfer programs, which provide supplemental income to low-income households either unconditionally (i.e. not tied to any obligations) or conditionally (i.e., requiring school enrollment, health check-ups, or attendance at health education sessions, among other behaviors) have been shown to improve a wide range of underlying determinants of undernutrition, including food security, dietary diversity, health care utilization, and maternal mental health (Leroy et al., 2009; de Groot et al., 2017). However, cash transfer programs vary substantially in the amount of basic cash transfer and the types of conditions that are associated with them, and therefore evidence for improving linear growth and reducing stunting is mixed (Leroy et al., 2009; de Groot et al., 2017). Nonetheless, a recent meta-analysis of studies on cash transfer programs restricted to high-quality studies, which included clear control groups for comparison, found a small but significant decrease in the absolute prevalence of stunting among children <5 years of age (−2.1%, 95%CI: −3.52, −0.69) (Manley et al., 2020).

Improvements in WASH practices have been hypothesized to promote growth and reduce stunting prevalence by reducing the incidence of diarrheal diseases and enteric dysfunction in young children in LMICs; however, in three large, high-quality cluster randomized trials conducted in Bangladesh, Kenya, and Zimbabwe, there were no effects of WASH interventions on child linear growth or risk of stunting (Luby et al., 2018; Null et al., 2018; Humphrey et al., 2019). These trials used various methods to improve drinking water (e.g., water chlorination), sanitation (e.g., improved pit latrines), and hygiene practices (e.g., handwashing with soap or handwashing stations) coupled with theory-based behavior change communication models to ensure intervention uptake (Pickering et al., 2019). All trials further provided nutrition counseling regarding infant and young child feeding practices and SQ-LNS per day from 6 to 18 or 24 months alone and in combination with WASH interventions to test the synergistic effect of improved nutrition and WASH practices (Pickering et al., 2019). Compared to the control arm, children who were in the nutrition counseling and SQ-LNS arm alone had higher mean length-for-age z-scores (0.13–0.25 SD across studies) and lower risks of stunting (Pickering et al., 2019); however, across all studies, WASH interventions had no effect on linear growth or the prevalence of stunting. Despite high intervention fidelity in implementation and high-compliance due to robust behavior change communication, the results of these trials suggest that modest improvements in WASH practices at the household-level, particularly those which are not tailored to the local etiologies of diarrheal diseases and enteropathogens, are unlikely to have a substantial impact on child stunting (Cumming et al., 2019); rather, community-level structural changes to improve environmental conditions, such as piped drinking water, sewage drains, and human waste treatment facilities are likely needed to positively shift the population distribution of HAZ and achieve substantial reductions in the prevalence of stunting.

### Conclusion

Childhood stunting reflects inadequate growth in stature (body length, height). In LMICs, stunting is usually a result of environmental and social conditions that are inadequate to support optimal fetal and child growth and development. The prevalence of stunting in a community is an important indicator of child health and nutrition that has been used to demonstrate and quantify inequities in childhood nutrition status between and within countries, globally. In many LMICs, stunting is evident at birth, underscoring the important contribution of maternal health and nutrition as well as social and environmental exposures in the prenatal period to the later risks of infant and child stunting. Despite reductions in under-5 stunting prevalence worldwide over the past several decades, stunting remains common in many LMICs, underscoring the persistence of adverse community-level and household conditions that impair child growth and development and increase the risk of child mortality. Identifying specific causes of stunting has been a long-standing challenge, and few specific interventions have been convincingly shown to improve child growth and reduce the risk of stunting in LMICs. As a result, over the last two decades, intervention research to support improvements in maternal and child nutrition has shifted from a focus on single-nutrient interventions to multi-component policies and programs that broadly span the domains of nutrition, health, economics, and the environment. For example, in five exemplar case-country studies (Peru, Kyrgyz Republic, Nepal, Ethiopia, and Senegal) that achieved larger than expected reductions in stunting prevalence in a 15-year period relative to their economic growth, relatively large investments in both nutrition-sensitive and -specific interventions and programs over a sustained duration of time were associated with substantial population-level reductions in stunting (Bhutta et al., 2020). Continued investments in broad-based multi-sectoral approaches to improving child and family health and nutrition will be needed to further reduce stunting prevalence in LMICs worldwide (Heidkamp et al., 2021).

## Key points

- Over the past two decades, many studies have examined the association between overall dietary patterns and coronary heart disease (CHD) risk, which represents a stark shift from studies of individual foods/nutrients in the previous decades.
- Strong evidence indicates that the Mediterranean diet, Dietary Approaches to Stop Hypertension, and healthy plant-based diets lower CHD risk.
- Several additional theoretical dietary indices consistently associate with lower CHD risk, including the Healthy Eating Index, the Alternative Healthy Eating Index, and indices capturing dietary inflammatory potential.
- Empirical dietary pattern analysis affirms results from theoretical dietary pattern analysis, where data-driven “healthy” or “prudent” dietary patterns consistently associate with lower CHD across many diverse population-based studies.
- Areas where more research is needed in relation to dietary patterns and CHD risk include: (1) global dietary indices; (2) machine learning techniques for empirical dietary pattern analysis; and (3) the use of omics, particularly multi-omics, to understand individual responses to dietary patterns and inform personalized dietary recommendations.

## Introduction

Cardiovascular diseases (CVD) are the leading cause of death globally, accounting for approximately 19.1 million deaths in 2020. CVD cost the US an estimated \$228.7 billion annually in direct and indirect costs in 2017–2018. A recent study found that poor diet quality is the top modifiable risk factor related to CVD-related morbidity and mortality, accounting for approximately half of CVD deaths annually. Importantly, <1% of US adults achieve dietary patterns associated with ideal cardiovascular health. Thus, improving diet quality worldwide has a high potential to reduce CVD burden, particularly CHD, which is the leading cause of CVD death. In this article, we provide a brief history of dietary guidance to reduce CHD with a major focus on recent evidence linking overall dietary patterns to CHD and CVD risk.

## A timeline of research on diet and CHD

Traditional dietary advice to prevent CHD has focused on single nutrients or foods, with a particular emphasis on types of dietary fat. The diet-heart hypothesis postulates that replacing dietary saturated fats with unsaturated fats reduces serum cholesterol, thereby lowering atherosclerosis and CHD risk. In the 1950s, Ancel Keys, an American physiologist, launched the Seven Countries Study and demonstrated that increases in dietary fat intake were positively linked to serum cholesterol and CHD risk. Consequently, in the

1980s–90s, limiting total dietary fat was a major focus of dietary recommendations to reduce CVD risk, particularly by reducing saturated fat and cholesterol intake. This led to the emergence of the low-fat diet era, which saw an explosion of many reduced-fat food products in the market that were often perceived as “healthy”. However, these foods were often high in refined carbohydrates and added sugars to improve flavor and palatability that was lost due to their lower fat content. In the early 2000s, the landmark Women’s Health Initiative Dietary Modification Trial showed that women who reduced their total fat intake by 8.2% of total energy had no significant benefit on incidence of CHD over 6 years (hazard ratio [HR] [95% confidence interval (CI)] 0.97 [0.90–1.06]) when compared to the control group. Since then, there has been a major shift to focus on the “quality” of fat rather than the “quantity” and dietary recommendations have shifted to recommend replacing saturated and *trans* fat with monounsaturated and polyunsaturated fatty acids to reduce CVD risk. Recently, using mathematical models, studies have examined the effect of substituting one food or nutrient with another on CHD risk since this closely mimics real-world food choices made by individuals. For example, one study demonstrated that substitution of saturated fat intake with carbohydrates from whole grains, but not carbohydrates from refined starches and/or added sugars, is associated with lower CHD risk.

As research continued to examine the role of diet, it became clear that dietary components other than fat were also important for lowering CHD risk. Many studies have now shown associations between an array of nutrients and foods and higher CHD risk and CHD-mortality, including higher intakes of added sugar, red/processed meat, sodium, and ultra-processed foods, along with lower intakes of fruits and vegetables, *n*-3 fatty acids/fish, polyunsaturated fatty acids, whole grains, dietary fiber, low- or non-fat dairy, nuts/seeds, and legumes.

Although evidence surrounding many of these foods has been replicated in large scale prospective studies and randomized clinical trials, some foods have remained controversial in their association with cardiometabolic risk. For example, eggs are often consumed in combination with processed meats and refined grains, making it difficult to extricate their individual effects from the effect of the overall dietary pattern. A detailed history of the wealth of research identifying which nutrients and foods associate most strongly with CHD is out of the scope of this article and has been described elsewhere (Bechthold et al., 2017; Bhupathiraju and Tucker, 2011).

## The emergence of dietary pattern research

Given the complexities of examining the individual effects of single foods or nutrients on disease risk, research in the last few decades has placed a greater emphasis on the overall *dietary pattern*. A dietary pattern is the combination of foods and beverages that constitutes an individual’s complete dietary intake over time. It is not surprising that the first diet scores examined in relation to CHD mortality continued their focus on types of dietary fat in “lipid-lowering” or “cholesterol lowering” dietary patterns. However, more recent studies have focused on the influence of all dietary components together on CHD risk. A theoretical *dietary pattern index* assigns scores according to individual intakes of certain foods to yield an overall score reflecting adherence to a dietary pattern of interest. We provide several examples of how different dietary pattern analysis techniques can be utilized in research as we describe the current state of the evidence linking dietary patterns to CHD risk below. **Table 1** summarizes results from systematic reviews and meta-analyses examining the association between dietary patterns and CVD and/or CHD.

## Dietary patterns associated with coronary heart disease risk

### Mediterranean diet

The *Mediterranean diet* pattern was one of the first dietary patterns recognized by epidemiologist Dr. Ancel Keys in the 1960s Seven Countries Study. Keys recognized the lower death rate from CHD among individuals living in the Mediterranean region compared to other parts of the world and hypothesized that their diet and lifestyle habits may be a key driver. Key components of the Mediterranean diet include high intakes of cereals, vegetables, fruits, beans, nuts, and olive oil as the primary fat, moderate intakes of potatoes, fish, poultry, eggs, and wine, and low intakes of red meat and sweets containing added sugars (see **Fig. 1** for additional information).

One of the first examples of a systematic exploration of diet quality was the development of a Mediterranean Diet Score (MDS) by Drs. Antonia Trichopoulou and Dimitrios Trichopoulos. In the MDS, individuals were assigned a score of 0 or 1 if their intakes were below or above the median for 8 components of the MDS: high ratio of monounsaturated: saturated fat intake; moderate alcohol intake; high legume intake; high cereal intake; high fruit intake; high vegetable intake; low meat intake; and low dairy intake. Since then, various modern adaptations of the MDS have emerged, all with similar guiding principles. In 1995, Drs. Walter Willet and Trichopoulos further described and popularized the Mediterranean diet pyramid as a healthy dietary pattern to reduce CVD risk.

Adherence to a Mediterranean diet pattern has been associated with lower CHD and CHD mortality not only in Mediterranean regions but also in many populations across the world. In a 2020 meta-analysis that included US and European cohorts, higher adherence to a Mediterranean diet pattern was associated with a 27% lower risk of CHD and a 17% lower risk of CHD mortality (Becerra-Tomás et al., 2020). A quasi-experimental study design using observational data showed that improving adherence to the Mediterranean diet over time has also been associated with lower CVD risk and CVD mortality among US

**Table 1** Summary of systematic reviews and meta-analyses of the effects of dietary patterns on coronary heart disease, cardiovascular disease, and CVD mortality.

<i>Study reference</i>	<i>Design</i>	<i>Exposure</i>	<i>Outcome</i>	<i>Results</i>
<b>Mediterranean diet</b>				
Sofi et al., 2008	Meta-analysis of 12 prospective cohort studies; 1,574,299 participants; follow-up ranging from 3 to 18 years	Adherence to MD: A two-point increase in adherence score for MD	CVD mortality	CVD death: RR 0.91; 95% CI: 0.87–0.95
Sofi et al., 2010	Systematic review and meta-analysis of 7 cohort studies; >2 million participants; follow-up ranging from 4.9 to 20 years	Adherence to MD: A two-point increase in adherence score for MD	CVD incidence or mortality	CVD incidence or mortality: RR 0.90; 95% CI: 0.87–0.93
Sofi et al., 2014	Meta-analysis of 18 studies; 4,172,412 participants	Adherence to MD: A two-point increase in adherence score for MD	CVD risk	CVD: RR 0.90; 95% CI: 0.87–0.92
Liyanage et al., 2016	Systematic review and meta-analysis of 6 studies; 10,950 participants; follow-up ranging from 6 months to 9 years	Adherence to MD: Highest vs. lowest category	CHD/CVD	CHD events: RR 0.65; 95% CI 0.50–0.85; no association with CVD death
Grosso et al., 2017	Meta-analysis of 20 studies; 888,257 participants; follow-up ranging from 2 to 20 years	MD adherence: highest quintile vs. lowest	CVD/CHD	CVD death: RR: 0.76; 95% CI: 0.68–0.83 CHD death: RR: 0.72; 95% CI: 0.60–0.86
Rosato et al., 2019	Systematic review and meta-analysis of 29 studies	Adherence to MD: Highest vs. lowest category	CHD	CHD events: RR 0.70; 95% CI 0.62–0.80
Becerra-Tomás et al., 2020	Systematic review and meta-analysis of 3 RCTs and 38 cohort studies; 1,154,443 participants; follow-up ranging from 2 to 26 years	MD adherence: Highest vs. lowest	CVD/CHD	CVD death: RR: 0.79; 95% CI: 0.77–0.82 CHD incidence: RR: 0.73; 95% CI: 0.62–0.86 CHD death: RR: 0.83; 95% CI: 0.75–0.92
Tang et al., 2021	Meta-analysis of 7 prospective cohort studies; 37,879 participants; follow-up ranging from 3.8 to 10.0 years	Highest versus lowest Adherence to MD	CVD mortality	Each 2-unit increment in a score of adherences to MD. CVD death: HR 0.91; 95% CI: 0.82–1.01
<b>Dietary approaches to stop hypertension</b>				
Salehi-Abargouei et al., 2013	Systematic review and meta-analysis of 6 studies; 259,984 participants; follow-up ranging from 7 to 24 years	Adherence to the DASH diet: Highest vs. lowest	CHD and CVD events or mortality	Highest vs. lowest: CVD death: RR 0.80; 95% CI: 0.74–0.86 and CHD death: RR 0.79; 95% CI: 0.71–0.88
Schwingshackl and Hoffmann, 2015	Systematic review and meta-analysis of 15 cohort studies; 1,020,642 participants; follow-up ranging from 5 to ≥24 years	DASH score: Highest vs. lowest	CVD incidence and mortality	CVD mortality or incidence: 0.82; 95% CI: 0.80–0.86
Chiavaroli et al., 2019	Umbrella review of 46 studies; 946,554 participants	Adherence to the DASH diet: Highest vs. lowest	CHD incidence	CHD incidence RR 0.79; 95% CI: 0.71–0.88
Yang et al., 2019	Systematic review and meta-analysis of 7 studies; 377,725 participants, follow-up ranging from 2.8 to 24 years	Adherence to the DASH diet: Highest vs. lowest	Coronary artery disease incidence	CAD RR 0.82; 95% CI: 0.78–0.87
Soltani et al., 2020	Systematic review and meta-analysis of 12 cohort studies; 1,314,675 participants; follow-up ranging from 6.5 to 19.2 years	Adherence to DASH score: Per each 5-point increment of adherence to the DASH diet score	CVD mortality	CVD death: HR 0.96; 95% CI: 0.95–0.98
Morze et al., 2020	Systematic review and meta-analysis of 113 studies; 3,277,684 participants; follow-up ranging from 2 to ≥24 years	DASH score: Highest vs. lowest	CVD incidence and mortality	CVD mortality or incidence: 0.80; 95% CI: 0.79–0.84
<b>Plant-based diets</b>				
Huang et al., 2012	Systematic review and meta-analysis of 7 studies; 124,706 participants	Vegetarian diet	CVD mortality	CVD death: RR 0.71; 95% CI: 0.56–0.87

men and women. Strengthening the case for potential causality, randomized controlled trials evaluating the effects of the Mediterranean diet on intermediate biomarkers related to the development of CHD show similar results. For example, the Mediterranean diet has been associated with improved blood lipids, blood pressure, body weight, endothelial function, and inflammatory biomarkers.

The largest study to date evaluating the effects of the Mediterranean diet pattern on primary prevention of cardiovascular diseases is the landmark Primary Prevention of Cardiovascular Disease with a Mediterranean Diet (PREDIMED) trial (Estruch et al., 2018). In the PREDIMED, participants were randomized to a Mediterranean diet supplemented with extra-virgin olive oil, a Mediterranean diet supplemented with mixed nuts, or a control diet including advice to reduce total dietary fat. After a median follow-up time of 4.8 years, participants in the Mediterranean diet with extra-virgin olive oil and Mediterranean diet with nuts arms were 31% and 28% less likely, respectively, to experience a cardiovascular event compared to participants following the control diet. Although the PREDIMED trial provides the strongest evidence to date supporting the adoption of the Mediterranean diet pattern to help reduce cardiovascular disease risk, prior randomized controlled trials (RCT) have echoed this sentiment.

Given the strength of the evidence, the 2015–2020 and 2020–2025 Dietary Guidelines for Americans recommend the Mediterranean dietary pattern as a healthy eating pattern to lower chronic disease risk. As highlighted at the end of this article (**Utility of omics in precision nutrition**), incorporation of omics data into existing and new observational and interventional studies of the Mediterranean diet may allow us to learn more about how personalized recommendations within the context of the overall Mediterranean dietary pattern may further improve CHD prevention throughout the lifespan.

### Dietary approaches to stop hypertension

A more recent success story began in the 1990s with the *Dietary Approaches to Stop Hypertension* (DASH) clinical trial (Appel et al., 1997; Sacks et al., 1995). In a seminal 8-week RCT, the DASH Collaborative Research Group demonstrated that following a dietary pattern rich in fruits, vegetables, low-fat dairy, whole grains, poultry, fish, and nuts/legumes and reduced saturated fat, cholesterol, red/processed meats, sweets, and sugar-sweetened beverages can substantially lower blood pressure (BP) compared to control diets aiming to increase fruit and vegetable intake alone (mean [97.5% CI] change in systolic BP: -2.7 [-4.6, -0.9] mmHg and diastolic BP -1.9 [-3.3, -0.6] mmHg) or reflecting the typical US diet (mean [97.5% CI] change in systolic BP: -5.5 [-7.4, -3.7] mmHg and diastolic BP -3.0 [-4.3, -1.6] mmHg). The DASH-Sodium Trial provided further evidence to support that the DASH diet is effective at several levels of sodium intake, with the greatest reduction in blood pressure occurring in individuals following the DASH dietary pattern and consuming <1500 mg/day of sodium. This landmark study has shaped guidelines for the prevention of hypertension and cardiovascular disease over the past 20 years and spurred several investigations into the DASH diet and a variety of health outcomes.

The benefits of the DASH diet extend to lower risk of CVD. In a meta-analysis of 47 studies, higher adherence to a DASH style dietary pattern (see Fig. 2 for additional information) was associated with a 20% lower risk of incident CVD and CVD mortality (Morze et al., 2020). These associations appear to be consistent across populations, including individuals across North America, Europe, and Asia, as well as individuals with type 2 diabetes. Improving adherence to the DASH diet over time has also been

**Fig. 2** Overview of the Dietary Approaches to Stop Hypertension (DASH) dietary pattern.

associated with lower CVD risk and CVD mortality among US men and women. Higher DASH diet adherence has been shown to be associated with several cardiometabolic risk factors, including lower low-density lipoprotein-cholesterol (LDL-C) and type 2 diabetes risk.

### Plant-based dietary patterns

The role of plant-based diets (PBDs) in preventing and managing chronic disease has long been of interest to researchers. Although the definition of PBDs can be diverse, they are primarily characterized by lower intakes of animal foods and higher intakes of plant-based food products, including fruits, vegetables, grains, and legumes. For instance, a vegetarian diet is mostly focused on plant-based products and excludes meat, poultry, and seafood with a low to moderate intake of dairy products or eggs. On the other hand, a vegan diet excludes all animal-based products, including dairy products, eggs, and honey. In the 1950s, Dr. Mervyn Hardinge first began investigations into how vegetarian diets influence health. Following these preliminary investigations, several studies investigated dietary patterns among the Seventh-day Adventists from California, a religious group that adheres to a lacto-ovo-vegetarian diet. These studies showed that Seventh-day Adventists following a non-vegetarian dietary pattern had approximately twice the rate of CHD mortality compared to vegetarian Adventists after adjusting for several important confounders. Building on these early studies, a large body of research has examined the relationship between PBDs and CHD.

To understand the mechanisms through which PBDs may be beneficial to cardiovascular health, several RCTs examined the effect of PBDs on intermediate cardiometabolic risk factors. A meta-analysis of 11 RCTs found that compared to non-vegetarian diets, vegetarian diets lowered LDL-C, but also lowered high-density lipoprotein cholesterol (HDL-C) and had no effect on triglyceride (TG) concentrations. In a meta-analysis that included 7 clinical trials and 32 observational studies, vegetarian diets significantly lowered blood pressure. Both observational and clinical data remain inconclusive about the associations between vegan dietary patterns and CHD outcomes and cardiometabolic risk factors. However, these studies were generally small and larger studies are needed to understand how vegan dietary patterns influence cardiometabolic disease risk.

When examining studies of plant-based diets and cardiometabolic health outcomes, it is vital to understand which foods are being replaced. For example, while replacing refined grains with healthy sources of animal protein, such as fatty fish, may be beneficial to cardiometabolic health, this may not be true when refined grains are replaced with processed meat. Likewise, it remains imperative to examine the quality of plant-based foods. Consistent evidence has shown that low quality carbohydrates, such as refined grains and sugar sweetened beverages, are adversely associated with cardiometabolic risk, while high quality carbohydrates, such as whole grains, and legumes, are associated with better cardiometabolic outcomes. To address these issues, Satija et al. developed the *plant-based diet index* (PDI), the healthy PDI, and the unhealthy PDI (Satija et al., 2017). In the overall PDI, all plant-based foods, regardless of quality, are scored positively while all animal foods are scored negatively. For the hPDI, all healthy plant-based foods (see Table 2 for additional information) are scored positively, while all animal foods and unhealthy plant-based foods are scored negatively. For the uPDI, all unhealthy plant-based foods are scored positively, while healthy plant-based foods and animal foods are scored negatively. To illustrate that quality of PBDs is important, an analysis by Satija et al. showed that participants with the greatest adherence to a hPDI had a 25% lower risk of CHD, while those with higher adherence to a uPDI had a 32% higher CHD risk. Similar associations have been observed in other studies as summarized in a recent meta-analysis of 5 cohorts, the hPDI was associated with a 13% lower risk of CVD and the uPDI was associated with a 5% higher risk of CVD-specific mortality. Further, a 10-point increase in the hPDI or uPDI was associated with a 9% lower or 8% higher risk of CVD mortality among US men and women, respectively.

Collectively, the beneficial effects of healthful PBDs on established cardiometabolic risk factors found in RCTs, and their inverse associations with CHD in prospective cohort studies provide evidence that healthful PBDs likely reduce CHD risk. In fact, the 2015–2020 and 2020–2025 Dietary Guidelines for Americans recommend a healthy vegetarian diet as an eating pattern to lower risk of chronic diseases. In addition to their health benefits, healthy PBDs are environmentally sustainable and fit within the food system's planetary boundaries. A more comprehensive discussion of the potential mechanisms through which healthy PBDs can influence cardiometabolic health is provided in **Omic signatures of dietary patterns and CHD** section.

### Dietary inflammatory potential

Inflammation is a biological response to injury that plays an important role in the initiation and progression of atherosclerosis. Chronic inflammation appears in conjunction with several chronic diseases and accumulating evidence suggests that it contributes to CVD pathogenesis. Dietary components exhibit pro- and anti-inflammatory properties and are a modifiable targets to reduce chronic inflammation and CVD risk. The *Dietary Inflammatory Index* (DII) and the *empirical dietary inflammatory pattern* (EDIP) are two tools that have been developed to capture the inflammatory potential of overall dietary patterns.

The DII is a literature-based dietary pattern developed to rank individuals' diets based on their inflammatory potential. The original scoring algorithm developed in 2009 was subsequently updated and improved in 2014. The current DII includes 45 foods, nutrients, or compounds with weights reflecting the number of research articles that have observed inflammatory or anti-inflammatory properties for each dietary component. Several studies have validated the DII, observing positive associations between the DII and inflammatory biomarkers, such as C-reactive protein (CRP), interleukin-6 (IL-6), and tumor necrosis factor alpha receptor 2 (TNF $\alpha$ -R2).

**Table 2** Examples of food items constituting the 18 food groups in the Plant-based Diet Index (PDI) from the 1984 Nurses' Health Study food frequency questionnaire.

	<i>Plant food groups</i>	<i>PDI</i>	<i>hPDI</i>	<i>uPDI</i>
<b>Healthy</b>				
Whole grains	Whole grain breakfast cereal, other cooked breakfast cereal, cooked oatmeal, dark bread, brown rice, other grains, bran, wheat germ, popcorn	Positive scores	Positive scores	Reverse scores
Fruits	Raisins or grapes, prunes, bananas, cantaloupe, watermelon, fresh apples or pears, oranges, grapefruit, strawberries, blueberries, peaches or apricots or plums	Positive scores	Positive scores	Reverse scores
Vegetables	Tomatoes, tomato juice, tomato sauce, broccoli, cabbage, cauliflower, brussels sprouts, carrots, mixed vegetables, yellow or winter squash, eggplant or zucchini, yams or sweet potatoes, spinach cooked, <b>spinach</b> raw, kale or mustard or chard greens, iceberg or head lettuce, romaine or leaf lettuce, celery, mushrooms, beets, alfalfa sprouts, garlic, corn	Positive scores	Positive scores	Reverse scores
Nuts	Nuts, peanut butter	Positive scores	Positive scores	Reverse scores
Legumes	String beans, tofu or soybeans, beans or lentils, peas or lima beans	Positive scores	Positive scores	Reverse scores
Vegetable oils	Oil-based salad dressing, vegetable oil used for cooking	Positive scores	Positive scores	Reverse scores
Tea and coffee	Tea, coffee, decaffeinated coffee	Positive scores	Positive scores	Reverse scores
<b>Less healthy</b>				
Fruit juices	Apple cider (nonalcoholic) or juice, orange juice, grapefruit juice, other fruit juice	Positive scores	Reverse scores	Positive scores
Refined grains	Refined grain breakfast cereal, white bread, English muffins or bagels or rolls, muffins or biscuits, white rice, pancakes or waffles, crackers, pasta	Positive scores	Reverse scores	Positive scores
Potatoes	French fries, baked or mashed potatoes, potato or corn chips	Positive scores	Reverse scores	Positive scores
Sugar sweetened beverages	Colas with caffeine and sugar, colas without caffeine but sugar, other carbonated beverages with sugar, noncarbonated fruit drinks with sugar	Positive scores	Reverse scores	Positive scores
Sweets and desserts	Chocolates, candy bars, candy without chocolate, cookies (home-baked and ready-made), brownies, donuts, cake (home-baked and ready-made), sweet roll (home-baked and ready-made), pie (home-baked and ready-made), jams or jellies or preserves or syrup or honey	Positive scores	Reverse scores	Positive scores
<i>Animal food groups</i>				
Animal fat	Butter added to food, butter or lard used for cooking	Reverse scores	Reverse scores	Reverse scores
Dairy	Skim low fat milk, whole milk, cream, sour cream, sherbet, ice cream, yogurt, cottage or ricotta cheese, cream cheese, other cheese	Reverse scores	Reverse scores	Reverse scores
Egg	Eggs	Reverse scores	Reverse scores	Reverse scores
Fish or seafood	Canned tuna, dark meat fish, other fish, shrimp or lobster or scallops	Reverse scores	Reverse scores	Reverse scores
Meat	Chicken or Turkey with skin, chicken or Turkey without skin, bacon, hot dogs, processed meats, liver, hamburger, beef or pork or lamb mixed dish, beef or pork or lamb main dish	Reverse scores	Reverse scores	Reverse scores
Miscellaneous animal-based foods	Pizza, chowder or cream soup, mayonnaise or other creamy salad dressing	Reverse scores	Reverse scores	Reverse scores

hPDI = Healthful Plant-Based Diet Index; PDI = Overall Plant-Diet Index; uPDI = Unhealthful Plant-Based Diet Index.

Consistent with the biomarker data, observational studies have observed a positive association between the DII and CVD risk. A meta-analysis of 6 cohort studies found that higher DII scores were associated with a 35% higher CVD risk (Namazi et al., 2018). A recent umbrella review of the DII and human health ranked the evidence for this positive association between the DII and myocardial infarction as “convincing” according to the AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews) quality assessment tool. However, the largest study to date (n = 15,693) included in these meta-analyses was a cross-sectional study examining the association between the DII and diagnosis of a previous circulatory disorder, which represents a lower quality of evidence than a prospective cohort study. A more recent meta-analysis examined the evidence for an association between the DII and

cardiometabolic diseases in cohort and non-cohort studies separately and estimated a 35% higher risk for cardiometabolic diseases prospective cohort studies (myocardial infarction, ischemic heart disease, stroke, congestive heart failure, and/or CHD). Thus, current evidence surrounding DII and cardiometabolic risk has been consistent, although larger studies in more diverse populations are warranted.

Unlike the DII, the EDIP is a data-driven food-based index that was developed using a combination of reduced-rank regression and step-wise linear regression based on circulating concentrations of CRP, IL-6, and TNF $\alpha$ -R2. A total of 18 foods groups that contribute either pro-inflammatory or anti-inflammatory properties in an overall dietary pattern were selected. A large prospective study among 210,145 individuals with 9794 CHD cases found that individuals with higher scores on the EDIP, reflecting a more pro-inflammatory diet, had a 46% higher risk of developing CHD. The EDIP was also associated with higher concentrations of pro-inflammatory markers (IL-6, soluble intercellular adhesion molecule-1 [sICAM-1], TNF $\alpha$ -R1, TNF $\alpha$ -R2, CRP, and leptin) and lower concentrations of an anti-inflammatory marker (adiponectin). Other studies have demonstrated positive associations between the EDIP and cardiometabolic risk factors, including weight gain, type 2 diabetes, and metabolic syndrome.

The overall body of literature indicates that a higher inflammatory potential of diet is associated with a higher risk of CHD. The DII and EDIP are two separate tools that can be used to characterize the inflammatory potential of diet. Further studies and refinement of these tools may lead to more consistent recommendations about the food components that best reflect the inflammatory potential of diet and CHD risk.

### Other theoretical dietary indices to capture “healthy” dietary patterns

Theoretical dietary indices offer the distinct advantage of measuring adherence to dietary guidelines released by government institutes, academic institutions, foundations, and other non-profit organizations aiming to improve overall health or reduce the risk for specific diseases. These indices score participants based on how well their intakes align with the recommended intakes. The nutrient- and/or food-based targets within these indices change over time as recommendations are updated to reflect the latest scientific evidence.

One example is the *Healthy Eating Index* (HEI), which was first developed by Dr. Eileen Kennedy and colleagues in 1995 to capture adherence to the US Dietary Guidelines for Americans. Several iterations of the HEI have followed this original version and have been updated every 5 years with the release of the Dietary Guidelines for Americans. Adherence to the 2015–2020 Dietary Guidelines, which was quantified using the HEI-2015, was associated with a lower risk of CHD (HR [95% CI] 0.78 [0.74–0.82]) among 209,133 US men and women followed for up to 32 years. A recent meta-analysis of 13 studies estimated an approximately 19% lower incidence of CVD or CVD mortality among participants in the highest quartile of adherence to various versions of the HEI compared to those in the lowest quartile (Morze et al., 2020).

The *Alternative Healthy Eating Index* (AHEI) is a dietary index first developed in 2002 to capture a dietary pattern predictive of reduced chronic disease risk. It was created to improve upon an earlier dietary index, the Recommended Food Score, which was a simpler summary of diet quality. An updated version of the AHEI was created in 2010 to reflect that latest scientific evidence. The AHEI-2010 has been extensively studied and better adherence to the AHEI-2010 was associated with a nearly 23% lower risk of CVD or CVD mortality (Morze et al., 2020). Improved diet quality as measured by changes in the AHEI-2010 over time has also been associated with lower CVD risk (greatest vs. least improvement HR% [95% CI]: 0.92 [0.87–0.99] in each 4-year period) and CVD mortality (greatest vs. least improvement HR [95% CI]: 0.85 [0.78–0.91] over 12 years) among US men and women. While a significant proportion of diet indices have been developed in the US, research in other countries have also utilized dietary indices to quantify adherence to country-specific dietary recommendations. For example, the *Healthy Nordic Diet Index* was created to reflect adherence to Nordic nutrition recommendations, which include consumption of whole grains, berries, fruits, vegetables, unsaturated oils, low-fat dairy, fish, and poultry, and avoidance of sugar-sweetened beverages. Consistent data has shown that higher adherence to the healthy Nordic Diet was associated with a 20% lower risk for myocardial infarction after adjusting for several risk factors and confounders among 82,116 participants from Germany and Denmark.

The *American Heart Association Diet Score* (AHA-DS) is a dietary index first developed in 2013 as a means to capture adherence to the dietary guidelines released by the American Heart Association. The scoring criteria have subsequently been updated and are used in the American Heart Association’s annual heart disease and stroke statistics report to monitor dietary targets to reduce CVD risk. Although many of the criteria in the AHA-DS are similar to those in the AHEI, HEI, DASH, and Mediterranean diet, more studies are needed to understand how the AHA-DS index associates with incident CHD risk in both epidemiological and interventional studies.

Most of the diet quality indices described thus far were developed and validated in high-income countries and are often country-specific. Recent studies have aimed to create diet quality indices that are optimized for application in low- and middle-income countries. Given the double burden of malnutrition in many developing countries, there have been concerted efforts to develop diet quality metrics that can capture both risk of nutrient inadequacy and risk of chronic disease, while also monitoring diet quality in populations and population subgroups. These efforts led to the development of the *Global Diet Quality Score* (GDQS), which was based on the prime diet quality score. The GDQS was developed using data from women in 10 African countries, China, India, Mexico, and the US. A major difference between the GDQS and other diet scores is that it is entirely food-based, which removes the need for investigators to rely on nutrient databases in resource poor settings. The GDQS has been associated with several cardiometabolic risk factors in these countries, but its association with CHD risk is yet to be evaluated. These internationally optimized diet quality scores will be crucial for monitoring dietary intakes around the world to identify individuals at high risk for CHD.

## Empirical dietary patterns

Data-driven or empirical approaches are complementary approaches to dietary indices and can yield unique insights about dietary patterns and health outcomes. The two most common empirical dietary pattern approaches include *cluster analysis* and *principal components analysis* (PCA). These approaches, when utilized in different settings and populations, have often identified a “prudent” and a “Western-style” dietary pattern. The prudent or “healthy” dietary pattern is often defined by higher intakes of fruits, vegetables, fish and lean meats, legumes/nuts, whole grains, olive oil, soy, poultry, and low-fat dairy. The Western or “unhealthy” dietary pattern, on the other hand, reflects high consumption of red/processed meat, refined grains, high-fat dairy, added sugars, butter, and potatoes, and low intakes of fruits and vegetables. In several meta-analyses that included participants from Asia, North America, and Europe, the prudent/healthy dietary pattern was repeatedly associated with a lower CHD risk. On the other hand, associations of greater adherence to a “Western-style” dietary pattern with higher CHD risk were less consistent. This may be because empirical “unhealthy” dietary patterns derived in individual studies may include different combinations of foods that display differential associations with CHD.

Because empirical dietary pattern analyses are data-driven, they have often identified unique patterns that reflect traditional diets of various cultural groups that has allowed investigators to examine the healthfulness of a “traditional” diet. For example, in the Reasons for Geographic and Racial Differences in Stroke (REGARDS) study, a US Southern-style dietary pattern characterized by added fats, fried foods, eggs, organ meats, processed meats, and sugar-sweetened beverages was identified that was associated with a higher incidence of CHD (comparing quartile 4 [Q4] with quartile 1 [Q1], (HR [95% CI]: 1.37 [1.01, 1.85])). Likewise, a PCA-derived traditional Dutch dietary pattern, characterized by high intakes of potatoes, red/processed meat, eggs, coffee, and boiled vegetables/legumes and a low intake of fast food, sugar/sweets, savory sauces, French fries, soy products, and cereals, was also associated with a higher risk of coronary artery disease (HR [95% CI]: 1.25 [1.07, 1.47])). Empirical dietary patterns present a promising methodology to generate hypotheses that may inform future dietary indices reflecting traditional dietary patterns. In addition to the Mediterranean diet, which has been extensively studied, larger studies are needed that explore the associations of traditional dietary patterns with CHD risk.

Although cluster analysis and PCA are the most popular types of empirical dietary pattern analyses explored in the CHD literature, *reduced rank regression* (RRR) and *machine learning* techniques have also proved to be successful approaches in identifying dietary patterns. RRR is similar to PCA, except the method selects dietary patterns that maximize the variability in a chosen set of response variables instead of maximizing variability in the food groups. These response variables can either be intermediate risk factors or nutrient variables. Because RRR involves both a priori decisions about intermediate variables and a data-driven component, RRR is considered a supervised data-driven or hybrid method to derive dietary patterns. The EDIP, which was discussed in the **Dietary inflammatory potential** section, was generated using RRR to identify foods that were most predictive of various inflammatory biomarkers. Likewise, empirical dietary indices for hyperinsulinemia (EDIH) and insulin resistance (EDIR) represent indices that are most predictive of C-peptide concentrations and TG:HDL-C ratio, respectively. The EDIH and EDIR separately developed in two studies included similar food groups. Diets with higher insulinemic potential included higher amounts of red/processed meat, butter, refined grains, fried foods, and potatoes, along with lower amounts of wine, coffee, whole fruit, and leafy green vegetables. Among 40,074 participants with 4904 deaths over a median of 7.8 years in the US National Health and Nutrition Examination Survey (NHANES), the EDIH (Q4 vs. Q1 HR [95% CI]: 1.41 [1.15, 1.75]) and EDIR (Q4 vs. Q1 HR [95% CI]: 1.35 [1.09, 1.67]) were both associated with higher risk of CVD mortality.

In addition to intermediate biomarkers of insulin resistance and inflammation, other studies have utilized RRR to identify dietary patterns predictive of lipid biomarkers that associate with CHD risk. Foods predictive of lipid concentrations in the Whitehall II study included white bread, fried potatoes, sugary drinks, burgers, and sausages, and low consumption of French dressing and vegetables. Not surprisingly, this pattern was associated with a higher CHD risk (Q4 vs. Q1 HR [95% CI]: 1.57 [1.08, 2.27])). Given that certain fatty acids can be cardioprotective, a study of individuals from Singapore identified a dietary pattern that associated with 9 different circulating fatty acids (n-3 polyunsaturated fatty acids [18:3n-3, 20:3n-3, 20:5n-3], odd-chain fatty acids [15:0, 17:0], 18:2n-6 and 20:1, and lower 20:4n-6 and 16:1). This pattern was characterized by high intakes of soy, vegetables, fruits, tea, tomato products, bread, fish, margarine, and dairy, and low intakes of rice, red meat, coffee, alcohol, sugar-sweetened beverages, and eggs and was associated with a 24% lower risk of CHD-related mortality.

*Random forest methods* are an example of a supervised machine learning approach to dietary pattern derivation. Using random forest with tree classification (RF-TCA) analysis, researchers identified 7 dietary patterns in the European Prospective Investigation into Cancer (EPIC)-Netherlands cohort that could be classified as “Western-like”, “prudent-like,” or “traditional-like.” They observed a higher risk of CHD among individuals following a “traditional-like” pattern compared to those following a “prudent-like” pattern (HR [95% CI]: 1.36 [1.12, 1.65])). In the Framingham Heart Study, random forest model selection identified 7 dietary components (whole milk, red meat, eggs, alcohol, cheese, coffee, and decaffeinated coffee) that ranked in the top 20% of important features for prediction of either CHD, heart failure, or stroke out of 204 potential diet and lifestyle variables. Random forest methods and other machine learning models have proved useful in recent studies of dietary patterns and cardiometabolic risk factors, as well as other disease applications. Thus, further use of machine learning methods examining the influence of dietary patterns on CHD in large epidemiological studies is warranted.

## Novel omics approaches for precision nutrition in CVD prevention

### Utility of omics in precision nutrition

Dietary indices and empirical dietary patterns derived from self-reported intakes have allowed us to gain deep insights into how dietary patterns influence CHD risk. However, accurately assessing diet in free-living individuals remains among the most challenging aspects of nutrition research. Because diet is a complex pattern of inter-related exposures, both of known and unknown constituents, coupled with relatively large within-person day-to-day variability, accurately quantifying dietary exposures remains an ongoing challenge in nutrition research (Maruvada et al., 2020). Recent advances in omics profiling technologies have allowed for new opportunities for biomarker discovery, while also providing a more detailed phenotyping of individuals. Several omics measurements exist that may be altered by dietary intakes, including the gut microbiome, proteome, lipidome, metabolome, epigenome, and transcriptome. The genome also influences dietary preferences and changes how dietary intakes influence health. Therefore, a comprehensive understanding of “nutritional omics” will not only allow for identification of objective measures of diet, but will also uncover biological pathways through which diet can influence cardiometabolic disease risk. A better understanding of these mechanisms will provide a foundation for both personal decision-making and regulatory policies that influence dietary patterns, paving the path for “personalized nutrition”. Although our knowledge of individual responses to diet is still very limited, personalized nutrition will encompass individualized dietary recommendations that are based on individual preferences and predicted responses to dietary intakes. The field of biomarker discovery of dietary intakes using systems epidemiology approaches is exploding given the 2020–2030 Strategic Plan for US National Institutes of Health Nutrition Research’s focus on “Precision Nutrition”. While a comprehensive overview of existing biomarkers of foods and dietary patterns is beyond the scope of this article, in this section, we discuss cutting-edge research that has utilized omic technologies to understand diet-disease mechanisms.

### Omic signatures of dietary patterns and CHD

Several recent studies have integrated omic biomarkers of dietary pattern analyses into epidemiological studies of CVD and CVD risk factors. These include studies of the microbiome, epigenome, proteome and metabolome.

Given the strong evidence linking the Mediterranean diet and CHD, several recent studies have aimed to identify omic profiles of the Mediterranean diet and cardiometabolic disease risk. Given the large number of features present in omic data, machine learning techniques have proved useful to select potentially important features for discriminating between individuals with different dietary intakes. Data reduction using machine learning and related network analysis techniques can even allow us to make inferences from data that contains more features than participants. One study utilized one such machine learning technique, an elastic net regression model, to develop and validate a metabolite profile of 67 metabolites that reflected adherence to a Mediterranean diet in data from the PREDIMED study and two US cohorts. Several of the metabolites that were included in the Mediterranean diet “metabolomic signature” were previously associated with intakes of individual foods. These included long chain *n*-3 fatty acids that reflect fish intake and anti-oxidative polyphenols that may reflect extra-virgin olive oil or wine intake. The integrated 67 metabolite signature of the Mediterranean diet was significantly associated with lower CVD incidence in both the PREDIMED study (Q4 vs. Q1 HR [95% CI]: 0.73 [0.59, 0.91], *n*=1,012, 227 CVD cases) and the two US cohorts (Q4 vs. Q1 HR [95% CI]: 0.85 [0.77, 0.95], *n* = 6,868, 351 CVD cases), even after adjusting for self-reported measures of the MDS. This implies that a comprehensive metabolomic signature of a diet pattern can capture metabolic variation that cannot be captured by self-reported measures of diet and are, thereby, more powerful at detecting diet-disease associations. Another study conducted in the United Kingdom identified a metabolite score, which was derived from 66 metabolites that were significantly associated with the MDS, that also associated with several cardiometabolic risk factors among 10,806 adults without type 2 diabetes. Among the MDS food groups, they observed that fruits were associated with amino acids and biogenic amines, meat with acylcarnitines, and fish with phospholipids.

In addition to the Mediterranean diet, it will be useful to explore omic biomarkers of additional dietary patterns highlighted in the **Dietary patterns associated with coronary heart disease risk** section and their relation to CHD risk. Similar machine learning techniques referenced above have already been utilized to identify metabolomic signatures of dietary patterns and evaluate their associations with cardiometabolic risk factors. A recent study among >10,000 US men and women identified three distinct metabolomic signatures of the PDI, hPDI, and uPDI. The PDI (Q4 vs. Q1 HR [95% CI]: 0.86 [0.79, 0.93]) and hPDI (Q4 vs. Q1 HR [95% CI]: 0.79 [0.72, 0.86]) metabolomic signatures were both inversely associated with type 2 diabetes risk, while the uPDI was not associated with type 2 diabetes risk. Another study among individuals of Puerto Rican descent identified an AHA-DS-associated metabolomic signature of 58 metabolites, primarily lipids and amino acids. This signature was associated with higher HDL-C and LDL-C concentrations and lower waist circumference. The results from these studies strongly indicate the usefulness of combining various metabolites to comprise a composite marker of diet quality, and indicate that further investigation of metabolite profiles of diet quality and CHD risk will be fruitful to reveal mechanisms underlying diet-CHD relationships.

While individual omics profiling technologies are each important parts of systems biology data pipelines, the largest benefit for a systems view of chronic disease risk is achieved when combining data from multiple omics types. Multi-omics approaches

have been highlighted as promising approaches to improve our understanding of how diet contributes to complex chronic disease etiology and have proved successful for other chronic disease outcomes. However, few studies to date have leveraged multiple layers of omics to drive novel precision nutrition approaches. One study demonstrated that a Mediterranean diet pattern was significantly associated with changes in gut microbiome profiles, including changes in pathways related to plant-derived polysaccharide degradation, dietary fiber metabolism, short-chain fatty acid production, and secondary bile acid production among 307 male participants in the Health Professionals Follow-up Study. Integrating genetics and microbiome measures, the authors observed an association between the Mediterranean diet and cardiometabolic disease risk only among individuals without *Prevotella copri* present in their microbiome, providing an example where personalized nutrition advice could be useful. A recent cross-sectional study among US individuals of Hispanic/Latino descent integrated gut microbiome and serum metabolites to improve our understanding of the mechanisms by which serum trimethylamine-*N*-oxide (TMAO) associates with cardiometabolic risk. In this study, they demonstrated that serum TMAO concentrations may be a potential biomarker of fish, red meat, and egg intake and that higher serum TMAO is associated with changes in the microbiome and higher odds of prevalent CVD. Another group of researchers examined cross-sectional associations between metabolites and proteins and dietary pattern indices among 2208 participants from the Framingham Heart Study. Lipids, amino acids, bile acids and derivatives, nucleotide, metabolism, and tricarboxylic acid and derivatives were found to be shared among three dietary pattern indices measured: the AHEI, DASH and Mediterranean diet. As multi-omics data becomes available within more and more nutrition studies, investigation of multi-omics biomarkers of dietary intakes is a promising avenue for future research.

## Conclusions

Poor diet quality across the world results in a substantial proportion of CHD events and deaths each year. Thus, public health strategies to improve diet quality should be prioritized to reduce the global burden of CHD. Dietary pattern research over the past few decades has identified many dietary patterns that associate with lower CHD risk, including Mediterranean, DASH, and healthy plant-based dietary patterns. Achieving these healthy dietary patterns will require significant shifts in individual choices and behaviors, which could be promoted through policy and infrastructure changes to create a food environment that encourages healthy dietary choices. Although advancements in nutrition science have led to some consensus on the components of a “healthy” dietary pattern, controversy still exists for some foods/nutrients and most studies of CHD endpoints rely on self-reported dietary intakes. Studies utilizing novel omics profiling techniques, particularly multi-omics approaches, present an opportunity to identify objective biomarkers of diet and unveil novel mechanisms by which diet contributes to CHD risk. An improved understanding of how to modulate biomarkers of diet and predict individual responses to diet will help us move toward personalized approaches to dietary recommendations for CHD prevention. The wealth of omics data currently being generated in nutrition studies of cardiometabolic risk suggests a bright future of discoveries that will advance precision nutrition in CHD prevention.

### Key points

- Coronary heart disease (CHD) is the most important cause of deaths and disease burden globally. It is rapidly increasing in developing countries of Asia and Africa, in contrast to developed countries where it is declining.
- Nutrition transition from unhealthy to healthy nutrients and foods has been important in prevention and control of CHD in developed countries. In developing countries an unhealthy food transition is currently evolving.
- Cardioprotective foods include omega-3 fats, unrefined carbohydrates, fiber, low sodium, high potassium, fruits, vegetables, nuts and fish.
- Composite dietary patterns are important, and consumption of the Mediterranean type, DASH-type and other prudent diets is recommended.

## Introduction

Coronary heart disease (CHD) is the leading cause of death in the world. It is well established as the foremost contributor to mortality and morbidity in most developed countries and has now emerged as the leading cause of death and disability in most developing countries. The global health transitions, which have seen substantial changes in age-specific coronary mortality rates across the world, have also been associated with nutrition transitions, which explain a large part of the rise or fall of CHD-related death rates ([Global Burden of Disease Study 2019 Viewpoint Collaborators, 2020](#)).

Diet and nutrition have been extensively investigated as risk factors for CHD ([Gupta and Wood, 2019](#)). Many dietary factors have been linked directly to an increased or decreased risk of CHD or to major established risk factors of CHD such as high blood pressure (BP), disordered blood fats- raised low density lipoprotein (LDL) cholesterol and triglycerides and low high density lipoprotein (HDL) cholesterol, diabetes and metabolic syndrome, overweight and obesity, and also to emerging risk factors like inflammatory markers and homocysteine. Nutrition influences atherogenesis, thrombosis, and inflammation, all of which are interconnected pathways that lead to CHD ([Gupta and Wood, 2019](#)). Observational epidemiological studies and clinical trials have contributed to a wide body of knowledge on the role that some nutrients (like saturated and trans-fats, salt, and refined carbohydrates) play important role in increasing risk of CHD and of protective effect of other nutrients (such as fruit and vegetables, polyunsaturated fats, nuts, and fish) against CHD. This knowledge has been successfully applied both in public health and in clinical practice, to reduce the risk of CHD, in populations as well as in individuals. This article summarizes the present state of that knowledge, as relevant to prevention of CHD.

## Global trends in CHD as a reflection of nutrition transition

CHD affects about 126 million individuals (1655/100,000) globally and led more than 9 million deaths in 2020 and are large fraction of not only the total number of deaths world-wide due to cardiovascular diseases but also of the global total of deaths from any cause ([Global Burden of Disease Study 2019 Viewpoint Collaborators, 2020](#)). Although age-specific coronary mortality rates have declined in the developed countries, over the past few decades, the absolute burdens of CHD continue to be high ([Global Burden of Disease Study 2019 Viewpoint Collaborators, 2020](#)). Notably, CHD death rates are rising in the developing countries, where about half of these deaths occur below the age of 70 years, entailing high loss in potential productive years of life as well as in national incomes. In the INTERHEART study, which examined risk factors for myocardial infarction (MI) in 52 nations worldwide, the mean age for first MI in South Asia was 53 years compared to 58 years in other parts of the world. In Eastern and Central Europe CHD mortality rates rose sharply in the 1980s and 1990s but have declined in the recent decades.

These changes in CHD mortality rates have accompanied well documented or clearly discernible shifts in the nutritional state of the populations ([World Health Organization, 2003](#)). The decline of CHD mortality in Western and Northern Europe was linked to a reduction in the consumption of unhealthy fats (saturated fats and trans-fats) and salt as well as an increased consumption of fruits and vegetables. Similarly, the decline of CHD mortality in Poland was explained by the increase in fruit and vegetable consumption and growing substitution of vegetable fats for animal fats. Similar evidence of a favorable nutrition transition preceding the decline in CHD mortality rates is available from other developed countries like USA, UK, Canada, Australia, and New Zealand ([World Health Organization, 2003](#)).

The developing countries have, on the other hand, witnessed a nutrition transition in the opposite direction ([World Health Organization, 2003](#)). China and India, for example, experienced a large increase in fat consumption over the past two decades, accompanied by a progressive rise in the mean plasma cholesterol levels of the population as well as in the CHD mortality rates. Other developing countries too are increasingly adopting unhealthy dietary patterns, which augment the risk of CHD. In India, there has been a progressive increase in the consumption of unhealthy dairy products, refined sugars, and hydrogenated edible oils, most of which are very high in saturated and trans-fats ([Gupta and Wood, 2019](#)).

## Understanding the links between nutrition and CHD

The pathogenesis of CHD is mediated through the interconnected pathways of atherogenesis (fat deposition in the walls of the coronary arteries to form plaques), thrombosis (blood clotting over disrupted plaques), and inflammation (which initially damages the blood vessel walls and continues to destabilize the plaques) ([Lawler et al., 2021](#)). Nutrition has a major role in influencing each of these pathways and often provides the connecting link between them.

Major coronary risk factors include an abnormal blood lipid profile (especially plasma cholesterol and its subfractions), high BP, and diabetes. Overweight and obesity (both the general and central patterns) are also associated with an increased risk of CHD ([Gupta and Wood, 2019](#)). Nutrition has a powerful influence on all of these risk factors, with an unhealthy diet pattern tending to elevate them and a healthy diet pattern reducing the levels of risk ([Table 1](#)). Diet becomes especially important in the context of the metabolic syndrome (a complex of central obesity, high BP, dyslipidemia, and glucose intolerance), an entity, which has been identified as a major risk factor for CHD. Nutrition is also linked to the propensity to develop cardiac arrhythmias, and is an important predictor of sudden cardiac death. These links between dietary patterns and several specific nutrients not only manifest as fat deposition in the arteries, plaque growth, plaque instability, and thrombosis but are also evident much earlier in the natural history of CHD, as endothelial dysfunction (inability of the arteries to dilate normally), elevated levels of inflammatory markers

**Table 1** Dietary nutrients and composite diets with evidence of prevention, harm and equivocal impact on CHD incidence.

	<i>Preventive effect</i>	<i>Evidence of harm</i>	<i>Equivocal evidence</i>
Nutrients	<ul style="list-style-type: none"> <li>• N-3 fatty polyunsaturated fats</li> <li>• Monounsaturated fats</li> <li>• Unrefined carbohydrates</li> <li>• Fiber</li> <li>• Low to moderate sodium</li> <li>• High potassium</li> <li>• Fruits and vegetables</li> <li>• Nuts</li> <li>• Fish (fatty)</li> <li>• Unrefined cereals</li> </ul>	<ul style="list-style-type: none"> <li>• High cholesterol</li> <li>• Saturated fats</li> <li>• Trans fats</li> <li>• Refined carbohydrates</li> <li>• Very high sodium</li> <li>• Antioxidant vitamins</li> <li>• Heavy alcohol and binge drinking</li> </ul>	<ul style="list-style-type: none"> <li>• N-6 polyunsaturated fats</li> <li>• Vitamin D</li> <li>• Multi-vitamins</li> <li>• Calcium</li> <li>• Flavonoids</li> <li>• Phytochemicals</li> <li>• Dairy and dairy-products</li> </ul>

(such as C-reactive protein), and increased intimal medial thickness of arterial walls. These precede and predict the clinical manifestation of CHD.

## Nutrients and coronary heart disease

### Saturated fatty acids (SFA)

The relationship between dietary fats and cardiovascular disease (CVD), especially CHD has been extensively investigated, with strong and consistent associations emerging from a wide body of evidence accrued from animal experiments, as well as observational studies, clinical trials, and metabolic studies conducted in diverse human populations (Mozaffarian, 2016). This relationship was initially considered to be mediated mainly through the atherogenic effects of plasma lipids (total cholesterol, lipoprotein fractions such as LDL and HDL cholesterol, and triglycerides). The effects of dietary fats on thrombosis and endothelial function as well as the relationship of plasma and tissue lipids to the pathways of inflammation have been more recently understood.

The relationship of dietary saturated fat to plasma cholesterol levels and to CHD was graphically demonstrated by the Seven Countries Study involving 16 cohorts, in which saturated fat intake explained up to 73% of the total variance in CHD across these cohorts (World Health Organization, 2003). The most effective replacement for SFAs, in terms of CHD prevention, is by polyunsaturated fatty acids (PUFAs) and monounsaturated fatty acids (MUFAs). This agrees with the outcome of large randomized clinical trials, in which replacement of saturated and trans-fats by polyunsaturated vegetable oils effectively lowered CHD risk (Mozaffarian, 2016). Replacement of SFA with either polyunsaturated or mono-unsaturated fat was shown to lower both LDL and HDL cholesterol. But substitution of SFAs with higher carbohydrate intake especially refined carbohydrates increased the risk for atherogenic dyslipidemia associated with insulin resistance and obesity (Sacks et al., 2017).

According to the American Heart Association, an important thing to remember is the overall dietary picture. Saturated fats are just one piece of the puzzle. In general eating more fruits, vegetables and whole grains and taking fewer calories is a better approach to diet. The large UK Biobank study found no clear associations between total saturated fat and cardiovascular disease outcomes. However, consuming 5% higher total energy from saturated fat from meat was associated with 19% and 21% elevated risks of total cardiovascular disease and heart disease, respectively—but these associations did not remain significant after adjusting for the body mass index (BMI). Associations of SFA from dairy with heart disease went in the opposite direction, but this association was not clear after adjusting for BMI. Similar outcomes have been reported by the Prospective Urban Rural epidemiology (PURE) study conducted in 17 countries. There was a weak positive association of SFA with CHD incidence and mortality and inverse association with all-cause mortality. The current evidence still points to more harm than good of saturated fats and the intake should be balanced (Mozaffarian, 2016; Sacks et al., 2017).

### Trans-fatty acids (TFA)

Trans fatty acids are geometrical isomers of unsaturated fatty acids that assume SFA-like configuration. Partial hydrogenation, the process used to create TFA, also removes essential fatty acids such as linoleic acid (LA) and alpha linolenic acid (ALNA). Evidence that intake of TFA increases the risk of CHD initially became available from large population-based cohort studies in USA and in an elderly Dutch population (Mozaffarian et al., 2006). Metabolic studies have demonstrated that TFA render the plasma lipid profile even more atherogenic than SFA, by not only elevating LDL cholesterol to similar levels but also decreasing HDL cholesterol. As a result, the ratio of LDL cholesterol to HDL cholesterol is significantly higher with a TFA rich diet (2.58) than with a SFA diet (2.34) or an oleic acid diet (2.02). This greatly enhances the risk of CHD. In controlled trials, each 1% energy replacement of TFA with SFA, MUFA, or PUFA, respectively, decreased the total cholesterol/HDL cholesterol ratio by 0.31, 0.54, and 0.67.

Controlled and observational studies have reported that for every 2% increase in energy from TFA, there was a 32% higher risk of MI or CHD death (Mozaffarian et al., 2006). In prospective cohort studies, each 2% energy replacements of TFA with SFA, MUFA, or PUFA lowered CHD risk by 17%, 21%, and 24%, respectively. Therefore, risk of developing CHD depends on the TFA content of the oil or food and also on the fatty acid composition of the substituted oil or fat (Sacks et al., 2017; Mozaffarian et al., 2006).

Eliminating TFA from the diet is an important public health strategy to prevent CHD (Gupta and Wood, 2019). Since these are commercially introduced agents into the diet, policy measures related to the food industry practices would be required along with public education. TFA have been eliminated from retail fats and spreads in many parts of the world, but deep-fat fried fast foods and baked goods are a major and increasing source (World Health Organization, 2003). In the USA, New York City has an ongoing successful program to phase out TFA in restaurant foods. Other US states and most European countries have successfully implemented ban on TFA containing processed foods to help their citizens reduce CHD risk (Mozaffarian, 2016). All packaged foods have a nutrition label that includes fat content. Food makers are required to label trans fats on nutrition and food supplements. Reading of the food labels can help keep track of how much TFA is consumed. Some manufacturers have bypassed this guidance by using the words-partially hydrogenated-in the ingredient list. It is best to avoid food with trans fats completely hence its prudent to limit intake of ultra-processed, packaged and fried foods.

### Polyunsaturated fatty acids (PUFA)

PUFA are categorized as n-6 PUFA (mainly derived from linoleic acid) and n-3 PUFA (mainly present in fatty fish and also derived from alpha-linoleic acid). Clinical trials, in which n-6 PUFA (containing linoleic acid) were substituted for SFA showed a greater impact on reduction of both plasma cholesterol and CHD risk, in contrast to trials where low-fat diets, were employed (Mozaffarian, 2016). Much of the epidemiological evidence related to n-3 PUFA is derived from the study of fish consumption in populations or interventions involving fish diets in clinical trials. Fish oils were, however, used in a large clinical trial of 11,300 survivors of MI. After 3.5 years of follow-up, the fish oil group (1 g per day) had a statistically significant 20% reduction in total mortality, 30% reduction in cardiovascular death, and 45% decrease in sudden death (Mozaffarian, 2016; Sacks et al., 2017). However, results of recent randomized clinical trials have failed to demonstrate that consumption of 1–2 g per day of n-3 fatty acids eicosapentanoic acid (EPA) and docosahexanoic acid (DHA) is protective for CHD (Gupta and Wood, 2019). On the other hand, a clinical trial using higher doses of highly purified EPA decreased plasma triacylglycerols, blood pressure, platelet aggregation, and inflammation and significantly reduced CHD risk (Arnett et al., 2019). The balance of omega-6/omega-3 fatty acids has been found to be an important determinant in reducing the risk for CHD. The proportions of SFA, MUFA, and PFA as constituents of total fat intake and total energy consumption have engaged active attention, in view of the strong relationship of these fatty acids to the risk of CHD (Gupta and Wood, 2019).

### Monounsaturated fatty acids (MUFA)

The only nutritionally important MUFA is oleic acid, which is abundant in olive and canola oils and in nuts. The epidemiological evidence related to MUFA and CHD is derived from studies on the Mediterranean diet (detailed below), as well as from multiple observational studies around the world (Visseren et al., 2021). A number of clinical trials and their meta-analyses have confirmed the importance of MUFA in diet (Mozaffarian, 2016). The current recommendation of 10–15% calorie intake from MUFA could be further revised in view of the ongoing debate on harms of high carbohydrate diets and avoidance of very high intake of SFA or PUFA (Arnett et al., 2019; Visseren et al., 2021).

Reduction of SFA in the diet has been widely recommended, but its replacement has been an area of debate, as to whether the place of reduced SFAs should be taken by MUFA, PUFA, or carbohydrate (Gupta and Wood, 2019; Sacks et al., 2017). Both MUFA and PUFA improve the lipoprotein profile, although PUFAs are somewhat more effective. In view of this, almost all dietary guidelines suggest that SFA should be kept below 10% of daily energy intake (preferably reduced to 7–8%), MUFA should be increased to 13–15%, and PUFA raised to 7–10% of daily energy, with the total fat contributing to less than 30% of all calories consumed (Arnett et al., 2019; Visseren et al., 2021). These may need to be adjusted for populations who consume less quantities of total fat, so as to ensure an adequate intake of MUFA and PUFA even under those circumstances. The emphasis is now shifting from the quantity of fat to the quality of fat, with growing evidence that even diets with 30–35% fat intake may be protective if the type of fats consumed is mostly from the MUFA and PUFA categories (Mozaffarian, 2016; Visseren et al., 2021). Enhancing the nutritional quality of dietary fat consumption, to provide greater cardiovascular protection, may be attempted by decreasing the sources of saturated fats and eliminating TFA in the diet and increasing the consumption of foods containing unsaturated fatty acids (both MUFA and PUFA).

### Dietary cholesterol

Cholesterol in the blood and tissues is derived from two sources: diet and endogenous synthesis. Dairy fat and meat are major dietary sources. Dietary cholesterol only raises plasma cholesterol levels by a small degree (Arnett et al., 2019). Although both high density lipoprotein (HDL) and LDL fractions increase, the effect on the total/HDL ratio is still unfavorable, but small. Evidence from observational studies conducted in several countries generally does not indicate a significant association with cardiovascular disease risk. Although meta-analyses of intervention studies differ in their findings, most associate intakes of cholesterol that exceed current average levels with elevated total or LDL cholesterol. The current literature does not support the notion that dietary

cholesterol increases the risk of heart disease in healthy individuals. The upper limit for dietary cholesterol intake has been prescribed, in most guidelines, to be less than 300 mg per day in healthy individuals and less than 200 mg per day in those with CHD, but this is a moving target as exemplified by the recent US dietary guidelines (Arnett et al., 2019). However, as endogenous synthesis is sufficient to meet the physiological needs, there is limited requirement for dietary cholesterol, and it is advisable to keep the intake as low as possible. If intake of dairy fat and meat are controlled, then there needs to be no severe restriction of egg yolk, although some limitation remains prudent. Eggs are affordable, rich in protein and micronutrients, nutrient-dense and low in saturated fatty acids. The healthy eating pattern can incorporate nutrient-dense, calorie-controlled meals with balanced nutrients and a variety of colorful vegetables and fruits (Arnett et al., 2019; Visseren et al., 2021). A recommendation that gives a specific dietary cholesterol target within the context of food-based advice is challenging for clinicians and consumers to implement; hence, guidance focused on dietary patterns is more likely to improve diet quality and to promote cardiovascular health.

### Carbohydrates

High-carbohydrate diets appear to reduce HDL cholesterol levels and increase the fraction of small dense LDL, both of which may impact adversely on vascular disease (Mozaffarian, 2016). This dyslipidemic pattern is consistent with the elevation of plasma triglycerides and is typical of the metabolic syndrome (Gupta and Wood, 2019). Carbohydrate diets with high-glycemic index adversely impact glucose control, with associated changes in plasma lipids, and have been linked to an increased risk of CHD. However, a diet with moderately restricted carbohydrate intake but rich in vegetable fat and vegetable protein improves lipid profile and may lower CHD risk. WHO has advised that restriction of sugars and carbohydrates having high glycemic index are important for overall CHD risk reduction (World Health Organization, 2003). The nature of carbohydrate is of utmost importance in relation to the reduction of CHD. Non-starch polysaccharides present in intact fruits, legumes, and whole grains reduce total and LDL cholesterol and also help to improve glycemic control.

### Fiber

Most soluble fibers reduce plasma total and LDL cholesterol concentrations, as reported by several trials (Mozaffarian, 2016). Fiber consumption strongly predicts insulin levels, weight gain, and cardiovascular risk factors like blood pressure, plasma triglycerides, LDL and HDL cholesterol, and fibrinogen. Several large cohort studies in the USA, Finland, and Norway have reported that subjects consuming relatively large amounts of whole grain cereals have significantly lower rates of CHD (World Health Organization, 2003). Review and meta-analyses of trials have indicated that consumption of soluble fibers reduces blood cholesterol as well as the postprandial blood glucose response (World Health Organization, 2003). It has been found that consumption of insoluble fiber from whole grains such as nuts, legumes and other edible seeds are associated with reduced risk of developing CHD.

### Antioxidants

Observational studies have reported inverse associations between the frequency of CHD and dietary intake of antioxidant vitamins (Mozaffarian, 2016). Vitamin E and vitamin C in combination have shown a long-term antiatherogenic effects but these are beneficial only for people who have antioxidant deficiency or are exposed to high levels of oxidative stress such as smokers, diabetics, and elderly patients. Though several cohort studies showed significant reductions in the incidence of cardiac events in men and women taking high-dose vitamin E supplements, large clinical trials failed to demonstrate a cardioprotective effect of vitamin E (Mozaffarian, 2016). Beta-carotene supplements too did not provide protection against CHD and, in some trials, appeared to increase the risk. Foods containing high amounts of antioxidants are protective and the focus should be on increased consumption of high antioxidant containing fruits, vegetables, and nuts to reduce CHD risk (Arnett et al., 2019; Visseren et al., 2021).

### Folate

The relationship of folate to CVD has been mostly explored through its effect on homocysteine, which has been incriminated as an independent risk factor for CHD. Reduced plasma folate has been strongly associated with elevated homocysteine levels and folate supplementation has been demonstrated to decrease those levels. Data from the Nurses' Health Study, in USA, showed that folate and vitamin B6, from diet and supplements, conferred protection against CHD (fatal and nonfatal events combined) and suggested a role for their increased intake as an intervention for primary prevention of CHD (Mozaffarian, 2016). Large randomized clinical trials have failed to show benefit of folic acid supplementation on incidence of cardiovascular events- CHD and stroke. Therefore, recommendations related to folate supplementation cannot be currently advocated as the results from clinical trials so far provide insufficient evidence. Meanwhile, dietary intake of folate through natural food sources may be encouraged, especially in individuals at a high risk of arterial or venous thrombosis and elevated plasma homocysteine levels.

### Flavonoids and other phytochemicals

Flavonoids are polyphenolic antioxidants, which occur in a variety of foods of vegetable origin, such as tea, onions, many colored vegetables, fruits and nuts (World Health Organization, 2003; Lawler et al., 2021). Data from several prospective studies indicate an

inverse association of dietary flavonoids with CHD. The role of these and other phytochemicals (such as plant stanols and sterols), in relation to CHD, needs to be elucidated further. Recent evidence indicates that consumption of foods rich in sterols and stanols help reduce the LDL cholesterol levels with beneficial effects on apolipoprotein B/A<sub>1</sub> ratio, HDL cholesterol, and triglycerides. Randomized clinical studies are needed to confirm importance in CHD prevention but high intake of foods containing these substances is recommended (Arnett et al., 2019).

### Sodium and potassium

High blood pressure is a major risk factor for CHD, accounting for a third of all CHD events (Gupta and Wood, 2019). The relative risk of CHD, for both systolic and diastolic BP, operates in a continuum of increasing risk for rising pressure but the absolute risk of CHD is considerably modified by coexisting risk factors (such as blood lipids and diabetes), many of which are also influenced by diet. There is a large body of epidemiological and clinical trial evidence to support reducing sodium intake to less than 2–2.5 g/day (World Health Organization, 2003). Controversy exists regarding importance of lowering salt intake to very low levels of sodium and some studies have shown increased CVD risk with very low sodium diets (<3–5 g sodium) (Gupta and Wood, 2019). Therefore, it is prudent to recommend low sodium diet with intake varying from 3 to 5 g sodium to CVD risk.

The benefits of dietary potassium, in lowering BP and reducing cardiovascular risk is undisputed. However, the specific effects on CHD risk have not been well studied. A recent Chinese study reported that replacement of dietary sodium with potassium significantly reduced incidence of stroke but benefit on CHD risk was unequivocal (Neal et al., 2021). Keeping the dietary sodium-potassium ratio low is essential, to avoid hypertension and stroke. Including enough fresh fruits and vegetables can take care of potassium intake.

### Calcium

Although protective against osteoporosis, calcium supplements accelerate vascular calcification and increase mortality in patients with renal failure. The Women's Health Initiative is the largest trial of vitamin D supplementation to date and has shown no effect of vitamin D plus calcium supplementation on the risk of CHD events (Mozaffarian, 2016; Arnett et al., 2019). The pooled analysis of randomized trials has reported that calcium supplements (without co-administered Vitamin D) were associated with approximately 30% increase in the incidence of myocardial infarction whereas, there was smaller and nonsignificant association with stroke and mortality.

## Specific foods

### Fruits and vegetables

A systematic review reported that nine of 10 ecological studies, two of three cases–control studies and six of 16 cohort studies found a significant protective association for CHD with consumption of fruit and vegetables or surrogate nutrients (Mozaffarian, 2016). In a 12-year follow-up of 15,220 male physicians in US, men who consumed at least 2.5 servings of vegetables per day were observed to have a 33% lower risk for CHD, compared with men in the lowest category (1 serving/day). A follow-up study of NHANES, the large national survey of USA, also reported a coronary protective effect of regular fruit and vegetable intake. Persons who consumed fruits and vegetables three or more times a day were at 24% lower risk than those who consumed less than once a day. The INTERHEART and PURE studies also reported low consumption of fruit and vegetables to be a major risk factor for CHD, across all the global regions (Gupta and Wood, 2019). All the major prevention guidelines recommend intake of 300–500/day of fruits and green vegetables to reduce CHD risk (World Health Organization, 2003; Arnett et al., 2019; Visseren et al., 2021).

### Fish

Multiple meta-analyses of cohort studies have suggested a CHD protective effect of fish intake (Mozaffarian, 2016; Arnett et al., 2019; Visseren et al., 2021). Compared with those who never consumed fish or did so less than once a month, persons who ate fish had a lower risk of CHD (38% lower for five or more times a week; 23% lower for two to four times a week; 15% lower for once a week; 11% lower for one to three times a month) (World Health Organization, 2003). Each 20 g per day increase in fish consumption was related to a 7% lower risk of CHD. However, the Diet and Angina Randomized Trial-2 demonstrated that advice to those with stable angina to eat fatty fish did not reduce mortality, and taking fish oil capsules was associated with debatable risk of cardiac or sudden death (Arnett et al., 2019). The apparently conflicting results of the two trials was attributed to the differential actions of n-3 fatty acids in acute and chronic conditions, and different effects of consuming fish and taking fish oil capsules (Mozaffarian, 2016; Arnett et al., 2019).

### Nuts

Several large epidemiological studies have demonstrated that frequent consumption of nuts was associated with decreased risk of CHD, the best known among them being the Adventist Health Study and PREDIMED study (Visseren et al., 2021). The extent of risk

reduction ranged from 18% to 57%, for subjects who consumed nuts more than five times per week compared to those who never consumed nuts. An inverse dose-response relationship has been demonstrated between frequency of nut consumption and the risk of CHD, in men as well as in women. Most of these studies considered nuts as a group, combining many types of nuts (tree nuts-walnuts, almonds, pistachio, pecans, macadamia nuts- and peanuts). A meta-analysis reported that consumption of 50–100 g (1.5–3.5 servings) of nuts five times/week as part of a heart healthy diet with total fat content (high in mono- and poly-unsaturated fatty acids) of 35% of energy, significantly decreased LDL cholesterol levels and it is now universally recommended (Gupta and Wood, 2019; Arnett et al., 2019; Visseren et al., 2021).

### Dairy products

Dairy consumption has been correlated positively, in ecological studies, with blood total cholesterol, however the influence on CHD mortality is equivocal (World Health Organization, 2003). Earlier reports from observational cohort studies have suggested that milk consumption correlates positively with coronary mortality in 43 countries and with myocardial infarction in 19 regions of Europe. On the other hand, data from Swedish population-based cohort studies and EPIC Study in Europe have reported beneficial effects of milk in reducing CHD events and mortality (Visseren et al., 2021). Milk is an important nutrient in low and lower-middle income countries and the PURE study have reported beneficial effects in reducing cardiovascular risk (Gupta and Wood, 2019). There is need for more scientific evidence as milk and its products form an important source of protein in low and lower-middle income countries and cannot be ignored.

### Alcohol

The relationship of alcohol to overall mortality and cardiovascular mortality has generally been J-shaped, when studied in western populations in whom the rates of atherothrombotic vascular disorders are high (Global Burden of Disease Study 2019 Viewpoint Collaborators, 2020). The protective effect of moderate ethanol consumption is primarily mediated through its effect on the risk of CHD, as supported by more than 60 prospective studies (Mozaffarian, 2016). A consistent coronary protective effect has been observed for consumption of one to two drinks per day of an alcohol-containing beverage but heavy drinkers or binge-drinking have higher total and cardiovascular mortality than moderate drinkers or abstainers.

## Composite diets

### Mediterranean diet

The traditional Mediterranean diet has been described to have eight components: (1) high monounsaturated-to-saturated fat ratio, (2) moderate ethanol (wine) consumption, (3) high consumption of legumes, (4) high consumption of cereals (including bread), (5) high consumption of fruits, (6) high consumption of vegetables, (7) low consumption of meat and meat products, and (8) moderate consumption of milk and dairy products (Visseren et al., 2021). Most of these features are found in many diets in that region. The characteristic component is olive oil, and many equate a Mediterranean diet with consumption of olive oil. A secondary prevention trial of dietary intervention in survivors of a first recent MI (the Lyon Heart study), which aimed to study the cardioprotective effects of a Mediterranean-type of diet, actually left out its most characteristic component, olive oil. The main fat source was rapeseed oil. Vegetables and fruits were also increased in the diet. On a 4- year follow-up, the study reported a 72% reduction in cardiac death and nonfatal MI. The risk of overall mortality was lowered by 56% (World Health Organization, 2003).

Large cohort studies in Greece and in several elderly European population groups have also reported a protective effect against CHD and better overall survival in persons consuming a Mediterranean type of diet (Visseren et al., 2021). The protection was afforded by the composite diet rather than by any single component. Improvement in metabolic syndrome and reduction of inflammatory markers has also been observed with this diet, which may explain part of the protection against CHD (Gupta and Wood, 2019). Primary prevention PREDIMED randomized trial conducted in Spain and other Mediterranean countries has conclusively demonstrated benefits of this type of diet in prevention of CHD (Visseren et al., 2021).

### Dietary Approaches to Stop Hypertension (DASH)

A composite diet, employed in the DASH (Dietary Approaches to Stop Hypertension) trials, has been found to be very effective in reducing BP in persons with clinical hypertension as well as in people with BP levels below that threshold (Mozaffarian, 2016). This diet combines fruits and vegetables with food products, which are low in saturated fats. Notably, the addition of exercise and weight loss to the DASH diet results in additional blood pressure lowering beyond the DASH diet alone, greater improvements in vascular and autonomic function, and reduced left ventricular mass. Prevention of CHD was evaluated in secondary analyses of DASH diet studies but remain inconclusive (Visseren et al., 2021).

### Vegetarian diets

A reduced risk of cardiovascular disease has been reported in populations of vegetarians living in affluent countries and in case-control comparisons in developing countries ([World Health Organization, 2003](#)). Long-term vegetarians have also been shown to have better antioxidant status (as measured by the plasma ascorbic acid status) and CHD risk profile than do apparently healthy omnivores. Reduced consumption of animal fat and increased consumption of fruit, vegetables, nuts, and cereals may underlie such a protective effect. However, typical vegetarian or vegan diets per se need not be healthful. If not well planned, they can contain a large amount of refined carbohydrates and TFA, and are at times deficient in the required levels of vegetable and fruits. The composition of the vegetarian diet should, therefore, be defined in terms of its cardio protective constituents utilizing components of Mediterranean and DASH diets.

### Prudent diets

In the Prudent versus Western Patterns diet study in the Health Professionals Follow-up Study in USA, a prudent diet pattern was characterized by higher intake of vegetables, fruit, legumes, whole grains, fish, and poultry whereas the western pattern was defined by higher intake of red meat, processed meat, refined grains, sweets and dessert, fries and high-fat dairy products ([Mozaffarian, 2016](#)). After adjustment for age and other coronary risk factors, relative risks, from the lowest to the highest quintiles of the prudent pattern score, were 1.0, 0.87, 0.79, 0.75, and 0.70, indicating a high level of protection. In contrast, the relative risks, across increasing quintiles of the western pattern, were 1.0, 1.21, 1.36, 1.40, and 1.64, indicating a mounting level of excess risk. These associations persisted in subgroup analyses according to cigarette smoking, body mass index, and parental history of MI. In the INTERHEART study, consumption of a prudent diet (high in fruits and vegetables) was associated with up to 30% reduced risk of MI worldwide ([Gupta and Wood, 2019](#)). PURE study also reported benefits of a healthy diet pattern consisting of unrefined cereals, fruits, vegetables, nuts and unsaturated fats ([Gupta and Wood, 2019](#)).

### Japanese diet

The traditional Japanese diet has attracted much attention because of the high life expectancy and low CHD mortality rates among the Japanese. This diet is low in fat and sugar and includes soy, seaweeds, raw fish, and a predominant use of rice. Traditionally it has been high in salt, but salt consumption has recently been declining in response to Japanese Health Ministry guidelines ([World Health Organization, 2003](#)). The Okinawa diet (a prefecture of Japan renowned for high life expectancy) when compared to the Mediterranean and DASH diets was found to have the lowest fat, particularly saturated fats, which may likely be a contributing factor to the low CHD mortality rates in Japan ([World Health Organization, 2003](#)).

### Comprehensive prevention

The powerful relationship of specific nutrients, food items, and dietary patterns to CHD has been persuasively suggested by observational epidemiological studies (which indicate the potential for primary prevention in populations) and conclusively demonstrated by clinical trials (which demonstrate the impact on both primary and secondary prevention among individuals). Atherosclerotic vascular diseases (especially CHD) are multifactorial in origin. Each of the risk factors operates in a continuous manner, rather than across an arbitrary threshold. When multiple risk factors coexist, the overall risk becomes multiplicative. As a result of these two phenomena, the majority of CHD events occurring in any population arise from any individuals with modest elevations of multiple risk factors rather than from the few individuals with marked elevation of a single risk factor ([Gupta and Wood, 2019](#)).

These phenomena have two major implications for CHD prevention. First, it must be recognized that a successful prevention strategy must combine population-wide interventions (through policy measures and public education) with individual risk reduction approaches (usually involving counseling and clinical interventions) ([Gupta and Wood, 2019](#)). Second, diet is a major pathway for CHD prevention, as it influences many of the risk factors for CHD, and can have a widespread impact on populations and substantially reduce the risk in high-risk individuals ([Arnett et al., 2019](#); [Visseren et al., 2021](#)). Even small changes in blood pressure, blood lipids, body weight, central obesity, blood sugar, inflammatory markers, etc., can significantly alter the CHD rates, if the changes are widespread across the population ([Gupta and Wood, 2019](#)). Modest population-wide dietary changes can accomplish this, as demonstrated initially in Finland and now across the globe ([World Health Organization, 2003](#); [Mozaffarian, 2016](#)). At the same time, diet remains a powerful intervention to substantially reduce the risk of a CHD-related event in individuals who are at high risk due to multiple risk factors, prior vascular disease, or diabetes.

### Conclusions

A diet, which is protective against CHD, should integrate: plenty of fruits and vegetables (300–500 g per day); a moderate amount of fish (two to three times a week); a small quantity of nuts; adequate amounts of PUFA and MUFA (together constituting

approximately 75% of the daily fat intake); low levels of SFA (less than 25% of the daily fat intake); complete elimination of TFA; limited salt intake (preferably 5–7 g salt for 3–5 g of sodium per day) and restricted use of sugar and refined carbohydrates. Such diets should be culturally appropriate, economically affordable and based on locally available foods. National policies and international trade practices must be shaped to facilitate the wide availability and uptake of such diets. Nutrition counseling, of individuals at high risk, too must adopt these principles while customizing dietary advice to specific needs of the person. CHD is eminently preventable, as evident from research and demonstrated in practice across the world. Appropriate nutrition is a major pathway for CHD prevention and must be used more widely to make CHD prevention even more effective at the global level.

### Key points

- Cultural history and societal traditions that are deeply embedded in beliefs about food and health based largely on deduction and causal inference from unverified assumptions remain powerful determinants of eating practices today
- Beliefs in food culture about the associations between food and health are often more persuasive than evidence-based nutrition science information
- Most discrepancies between food culture and evidence based on nutrition science should be reconciled but those that adversely affect health must be resisted and resolved

### Glossary

**Food culture** Integrated patterns of human knowledge, beliefs, and behaviors about food that are learned shared and transmitted across generations

**Foodways** Customary habits and practices related to food and eating of groups of people, regions, or historical periods

**Food patterns** Quantities, proportions, variety, or combinations of different foods and drinks in diets and the frequency with which they are consumed

**Food folklore** Traditional beliefs, customs and tales about food that are preserved and shared widely among people of a culture

**Food guides and recommendations** Recommendations about foods, food groups, or their suggested proportions in overall diets that today are largely based on scientific evidence about the relationship between food intakes and health outcomes

## Introduction

Food is an important part of human culture as well as being biologically essential. The anthropology of food is a sub-discipline that connects an ethnographic and historical perspective, including the material and symbolic importance of food, and how these concepts intersect with contemporary social issues in food production and consumption systems. Social scientists address the societal and cultural aspects of food and nutrition while biological scientists study the physical properties of foods and physiological chemistry. Food culture therefore falls at the nexus of these disciplines (Grivetti, 2003).

Food culture refers to the integrated patterns of human knowledge, beliefs, and behaviors about food that are learned, shared, and transmitted across generations. These beliefs include habitual foodways, food patterns, food folklore, and subjective psychological, social, and political world views that are constantly changing but at different rates. They coexist in society along with food guides or recommendations based on current biological knowledge of the relationships between food and health outcomes. It is not surprising that science-based recommendations about eating and health are often rejected when they fly in the face of older and larger traditional beliefs.

This article defines terms used to describe food culture, eating habits and culinary practices. It summarizes the cultural elements related to food and other factors that historically have determined what is eaten, and how they have changed over the centuries. The dynamic tension between them and eating recommendations based on induction from scientific discoveries in food and nutrition science that seek to shape eating habits today is summarized. The discrepancies between these different types of knowledge must be reckoned with by those who wish to change consumer behavior in more healthy directions, and to conclude a framework is presented for examining causal inference and reconciling food culture, food folklore with science-based food recommendations for health.

## Food in cultural history

Food is physiologically necessary to sustain life by providing essential nutrients. But it also plays a larger and equally essential role in culture. Food plays potent symbolic roles in religion and cultural traditions. For example, rice has been associated with fertility in many cultures for millennia and even today rice is thrown on newly married couples. Similarly, bread has been a symbol of divinity and has played an important role in many religious services and observances.

Food choice is determined largely by human factors other than nutrient need, such as the senses, personal preferences, psychological and social attitudes toward eating and health, social structures, economics, and politics. But geographical and environmental availability, technology, and economics are also potent influences. Geography, environment, and technologies available have predominated in shaping the staple foods that are the basis of the great cuisines of the world (Grivetti, 1992, 2003, 2000). Each cuisine and dietary pattern has its preferred foods and customs (Albala, 2011). For example, in East Asia, the Japanese and many Chinese patterns that are distinct, including Szechuan, Cantonese, Mandarin, Shandong, and others. South Asian cuisines in India differ by region and are heavily influenced by religious beliefs. Western Asian Middle Eastern cuisines are also influenced by the different foods available and religion. Oceania draws on traditional foods grown in the region. Diets of the Western hemisphere include geographically available traditional foods as well as European imports. The evidence that traditional diets consumed in different regions of the world and among different ethnic groups have allowed populations to thrive and survive suggests that there are many different forms of a reasonably healthy diets.

Economics has always been a potent force on foodways and food culture. As the science of food and nutrition expanded in the late 19th and early 20th century, the seminal study of H. Seebohm Rowntree on the poor in England made it clear that their earnings were insufficient to obtain adequate diets, and that age, unemployment and illness were often the root causes of poverty, not vice-versa (Rowntree, 1901; Freeman, 2008).

Food culture is no longer limited to influences from the immediate geographical environment as it was years ago (Dwyer and Drewnowski, 2017). European eating patterns have expanded globally, and these and American variations of them now often coexist with more traditional cuisines in many countries. In affluent countries during the 20th century traditional, largely plant-based diets produced locally by the eaters themselves were increasingly replaced by diets of commercially produced prepared and processed foods. The spread and mixing of cuisines between countries has not been without controversy, and there are calls for going back to traditional locally produced diets of whole foods, older “slow food” eating customs, and foodways. Others advocate for economic, esthetic, economic, technological, environmental, sustainability and other changes in food production as well as focusing on enhance health.

## Food beliefs, diet, and health across the centuries

The connection between diet and health has been known for ages, although the precise constituents that led to good health proved elusive. Views of “healthy” diets have altered over time as food availability, food prices, income, and as the various preordained organizing principles to explain associations between diet and health changed. Many elaborate theories have been used to explain diet-health associations and produce dietary recommendations. For example, the ancient Greeks believed that the body was composed of four humors: blood (hot and moist), phlegm (cold and moist), yellow bile (hot and dry) and black bile (cold and dry). Health was thought to result from a balance of these humors, and illness from an imbalance. To counteract imbalances and restore health, physicians often prescribed specific foods, based on their perceived degree of heat and moisture. For example, fever, regarded as a hot and dry condition, was attributed to an excess of yellow bile. Cool and moist foods, such as cucumbers, were prescribed to treat it. In contrast, edema, a cool and moist condition, was treated with foods that were viewed as warm and dry.

Curative properties ascribed to foods and their prescription as medicines was based on these early medical theories and not on scientific evidence. In ancient Rome, cabbage was considered the perfect medicinal plant and was prescribed frequently for a wide range of ailments, including wars, deafness, and drunkenness. Many other foods were also highly regarded in ancient cultures for their therapeutic qualities, including apples, herbs, garlic, honey, milk, peppers, and others.

The hot, cold, moist, and dry properties of food were regarded as important in other ancient societies, including China, where achieving a balance between the opposing forces of yin (cold/moist) and yang (hot/dry) has guided traditional Chinese medical practice for centuries, and continues to be popular today.

Another theory used to dictate traditional dietary recommendations, The Doctrine of Signatures, based on the notion that “like cures like” was popular in the nineteenth century in many countries. Therapies were chosen by deduction and based on similarities of color, aroma, shape, and other characteristics. For example, beet juice, which is deep red, was thought to be an effective cure for blood diseases, whereas yellow plants were believed to alleviate jaundice and other liver ailments. The pungent odors of onions and garlic were thought to ward off disease, stimulate strength and bravery, arouse the libido, and banish evil spirits. Walnuts, which resemble the brain, were eaten to improve the intellect. The ginseng root, with its resemblance to the human torso, was used by the Chinese as a panacea. The common names of many herbs and botanicals reflect folklore about their curative properties (Table 1). For example, the word ginseng is derived from the root words gin, meaning man, and sing, meaning essence.

## Influence of food and nutrition science on food culture and recommendations

The advent of the sciences of food and nutrition in the early 20th century led to a greater understanding of the associations between individual foods, diets, health. For many decades, the primary focus of nutrition scientists was on how the constituents of foods prevented disease. Using chemistry, experiments in animals, observations of humans and an inductive approach they identified nutrients, individual constituents of foods that caused deficiency disease when they were not present. Using this knowledge, they constructed dietary recommendations from the “bottom up” which included combinations of foods that contained enough of the beneficial constituents and little of those with negative effects (such as alcohol). The inductive approach was effective and while a view of food solely through a nutrient lens was reductionistic, it did permit progress to be made in conquering dietary deficiency diseases, which were due to lack of only one or a few constituents (nutrients such as vitamin D, thiamine, riboflavin, niacin, calcium, and iron) that were often present only in certain foods or food groups. More recently the same approach has been useful in detecting allergen ingredient related reactions to foods.

In Western countries this “nutrient centric” view sometimes became myopic (Fardet and Rock, 2018). It led to overly simplistic focus on “good” foods and food groups with a similar profile of essential “positive” nutrient constituents such as vitamins, minerals, protein and sufficient energy. The concept later expanded to include avoidance of “bad” foods or foods high in ingredients with “negative or unhealthy” ingredients such as fat, cholesterol, saturated fat, and added sugars that were linked to poor health

**Table 1** Food names related to food folklore.

<i>Herb (common name)</i>	<i>Botanical name</i>	<i>Folklore</i>
Blackeye root	<i>Tamus communis</i>	Heals bruises, removes discoloration
Bloodroot	<i>Sanguinaria canadensis</i>	Cures blood disorders and heart disease
Birthwort	<i>Aristolochia longa</i>	Alleviates complications associated with childbirth
Eyebright	<i>Euphrasia officinalis</i>	Cures eye disorders
Ginseng	<i>Panax quinquefolium</i>	General panacea for humans
Heartsease	<i>Viola tricolor</i>	Relieves heart ailments
Liverwort	<i>Anemone hepatica</i>	Relieves liver disorders
Lungwort	<i>Sticta pulmonaria</i>	Cures pulmonary diseases
Maidenhair fern	<i>Asplenium trichomanes</i>	Promotes hair growth and prevents balding
Snakeroot	<i>Aristolochia serpentaria</i>	Antidote for snake bites
Spleenwort	<i>Asplenium</i>	Remedy for disorders of the spleen

outcomes in epidemiological studies. Groups of foods with similar nutritional characteristics were judged “good” or “bad”. However, reductionist explanations like these run the danger of oversimplifying complex food health relationships, and are limited by contemporary scientific understanding, while science constantly changes. For example, in the 1960s and 1970s eggs, a low-cost source of high-quality protein, were regarded as “unhealthy” foods because they contained cholesterol, which scientists incorrectly assumed to be the major cause of increased serum cholesterol and coronary artery disease risk. Recently, sugar sweetened beverages and added sugars have been incorrectly assumed to have constituents with particularly obesogenic properties rather than the true causes, their high calorie content, high amounts consumed and high frequency with which they are consumed.

As the chronic degenerative diseases rose in prevalence, causal inference about diet became more difficult, because the deficiency disease hypothesis no longer applied. Many nutrients and other food constituents alter risk, but so do many other environmental and genetic factors. As for obesity, the causative component (food energy) is in many foods. Inductive approaches to tackling these diseases are more complicated. These realities have moved nutritional thinking from single nutrients or foods toward comprehensive characterizations of dietary patterns consisting of many foods in various amounts and their associations with health.

## Modeling dietary patterns

Human beings require nutrients and not specific foods, food groups or dietary patterns to be healthy, but they must eat foods to obtain these nutrients. For this reason, they need guidance on food selection and overall intakes since it is the quality of the total diet rather than the nutrient content of individuals foods that determine associations with health (Tapsell et al., 2016). Overall dietary patterns explain more of the impact of diet on non-communicable disease risk than single nutrients, dietary ingredients, foods, or food groups, as they include the synergistic, interacting influences of nutrients non-nutrient bioactive constituents and energy intakes. Foods must be acceptable if they are to be consumed and different foods are usually consumed together. Therefore, dietary patterns are important. Food pattern modeling is a method for evaluating the impact of specific changes in amounts or types of foods and beverages in a dietary pattern. The ideal result is the healthiest acceptable dietary pattern that is consistent with nutrient recommendations.

Modeling studies to develop dietary patterns use either an a priori or an a posteriori approach to describe foods and dietary patterns associated with health outcomes. The a priori method, determines how food selections fit in meeting preexisting recommendations. This approach begins with the nutrient recommendations (e.g., Dietary Reference Intakes) or types and amounts of various foods or groups of foods that are declared by authorities to be associated with good health outcomes (such as the Healthy Eating Index [HEI] or the Dietary Approaches to Stop Hypertension [DASH] diet). Recommendations to modify existing eating patterns in more healthful directions are then made by adding foods that are sources of missing nutrients (protein, vitamins, fiber), and decreasing those with ingredients known to be associated with ill effects (high calories, alcohol, sugar, saturated and trans-fat, salt) while also meeting human nutrient needs.

A second modeling approach is a posteriori. It separates out the components in epidemiological datasets that include dietary intakes and health outcomes by use of mathematical techniques (such as linear programming, principal components analysis or cluster analysis) to disaggregate the effects of different foods and to optimize combinations of foods that show strong health associations.

The results of such modeling are usually presented as groups of foods found to be and labeled as beneficial or prejudicial to health. Patterns associated with beneficial health outcomes are given names such as healthy, prudent, plant-based, Mediterranean-like, Healthy Eating Index pattern [HEI], healthy vegetarian and Dietary Approach to Stop Hypertension [DASH] and have particularly “healthy halos” presently, but they are heterogeneous in the foods they contain. Some of the labels are not new; various vegetarian and Mediterranean diets have been described since antiquity (Grivetti, 2001). Groups of foods associated with poor outcomes are often referred to as “Western”, “Standard American diet” “unhealthy” “ultra-processed” “high fat, low fiber high sugar”, or “junk food” patterns. However, descriptions of the unhealthy “Western” diet are quite disparate, for example: “contain high amounts of processed foods, red meat, high-fat dairy products, high-sugar foods, and pre-packaged foods”; “high saturated fat, red meat, empty carbohydrate, junk food, low fresh fruit and vegetable, low whole grain, seafood and poultry”, “inadequate fruits, vegetables, whole grains, legumes, fish, low fat dairy and excessive refined and processed food, alcohol, salt, red meat, sugary drinks, snacks, eggs, and butter”, and “low potassium, high sodium, high fat and simple carbohydrate foods”.

Although the groups of beneficial and prejudicial foods to health are often given similar labels, the foods comprising the groups are confusing, as they are often inconsistent, rather than constituting a standard set of foods from study to study (Boushey et al., 2017). This makes aggregation of studies and generation of recommendations for consumers on what should be eaten or avoided difficult. Efforts are now being made to obtain more agreement on what exactly they consist of (Sotos-Prieto et al., 2021).

A third, mixed, approach is to engineer entirely new dietary patterns from the bottom up by modifying existing patterns to include nutrients and other constituents known to be associated with good health (or some other desirable characteristic, such as sustainability); or by recommending entirely new patterns associated with the most positive health outcomes found in epidemiological studies, while ensuring that nutrient needs are covered. Food acceptability is often inferred from food consumption surveys and, to make the recommended dietary pattern more realistic, more modeling may be needed to minimize the changes from current consumption. Modelers may also add other factors they regard as desirable, such as cost, sustainability, acceptable types of food (plant only), food production (organic) or processing (non or lightly processed). However, each additional factor further constrains

the number of foods that are deemed appropriate, potentially limiting the acceptability of the pattern. It then remains to be seen if the entirely new recommended patterns are translatable.

Care must be taken in interpreting results, especially when most studies upon which findings are based are observational in nature and residual confounding by other factors influencing outcomes cannot totally be removed. It is often difficult to identify what the most important food groups, foods or nutrient are in the “healthy” dietary pattern that are associated with favorable health outcomes. Some foods may be more important to health than others, and others may have no relationship whatsoever, and yet their relative effects may be unknown. Also, recommended dietary patterns might not have the same results in populations eating very different diets and living in radically different circumstances than those in the populations studied. Rather, dietary patterns may be time and place dependent.

### Association of dietary patterns with health outcomes

A recent systematic review of dietary patterns for developing the Dietary Guidelines for Americans 2020–25 illustrates the utility of dietary pattern modeling in crafting dietary recommendations. It examined a single randomized clinical trial and 152 observational studies of dietary patterns consumed for their effects on all-cause mortality ([English et al., 2021](#)). Similarities and differences in diets eaten were described by the foods and beverages eaten rather than by subjective labels. The results were examined a priori (e.g., based on scientific consensus of what a healthy pattern was, such as the HEI) and a posteriori (by what factors explained variation in patterns or aggregated individuals into nonoverlapping groups). Dietary patterns characterized by greater consumption of vegetables, fruits, legumes, nuts, whole grains, unsaturated vegetable oils, fish, and lean meat or poultry were associated with lower risk of all-cause mortality in adults and older adults. Groups with greater adherence to the “healthier” patterns also had lower all-cause mortality.

After taking confounders into account, the “healthier” patterns continued to show beneficial effects. The study populations were from countries with a high Human Development Index. In the systematic review, further analysis showed that, with respect to individual food groups, healthy patterns included relatively low intakes of red and processed meat, high fat dairy, or refined carbohydrates or sweets ([English et al., 2021](#)).

### Food culture in the USA

As the distinguished food anthropologist Louis Grivetti pointed out years ago, the patterns of food that people eat depend on availability, familiarity, and selection, or “AFS”. US Dietary recommendations focus particularly on guiding eaters to selecting foods in accordance with them. Human beings differ in the ways in which they fulfill their common nutrient needs through the foods they eat, how they eat them, and what reasons they give for doing so. Therefore, each population’s preferences must be considered as unique, and what is acceptable in one society may not be in another. This section focuses on food culture as it stands today in the USA, although some of the same forces may also be operating in other countries.

### From nutrients to food patterns

In early 1900s the concern was largely about getting enough food to eat, with less attention to what was eaten. Food availability data in the USA show that, over the past century, profiles of dietary intakes in essential nutrients are probably healthier than ever before. However, the amounts of food eaten are greater and, in the sedentary US population, overweight and obesity have resulted. Starting in the early 20th century, American nutrition scientists began providing dietary recommendations based on what was known about nutrients that fit consumers’ economic resources, with additional advice about avoiding food waste, particularly during World War I (WWI). Food guides focused mainly on getting enough nutrients to prevent deficiency disease, and stressed commodities that were good sources of certain nutrients like milk, meat, grains, fruits, and vegetables while the remaining items in the diet to fill energy needs were left up to individual preferences. Carbohydrates, especially sugar and starchy foods were regarded as fattening and not included in advice. A relatively high fat low fiber diet was common. At the federal level food plans for citizens on different budgets were developed by the US Department of Agriculture.

During WWII there was continuing emphasis on both animal and plant foods high in protein, milk, and vegetables, fruits, and grains. By the 1950s and 1960s the notion of a “heart healthy” diet had emerged with the endorsement of the American Heart Association that stressed a low saturated fat, low cholesterol diet, with limits on meats and eggs high in these constituents. By the 1970s, federal food guidance gradually changed from giving recommendations solely on what foods to include (the Basic Four food groups) to limiting food energy intakes, with more emphasis on total diets.

The first edition of the Dietary Guidelines for Americans focused on ingredients to avoid (saturated and later trans fats, sugar, salt) as well as on foods to include. Over time, there was increasing emphasis on controlling how much food was consumed, and various icons were used to illustrate the concepts of variety, balance, and moderation ([Dwyer, 2019](#)). Starting in the 1990s US federal policies began to present dietary recommendations as food patterns rather than emphasizing nutrients or “basic” foods. With the advent of the internet, federal food guidance that included applications which could generate eating plans personalized to one’s own calorie and nutrient needs became available. The 2015–20 Dietary Guidelines Advisory Committee focused on 3 food patterns (the Healthy US-Style, Healthy Mediterranean-Style, and Healthy Vegetarian Eating Patterns) as well as emphasizing

a variety of foods high in nutrient (but not caloric) density, in reasonable amounts, and tools to help consumers follow a healthy eating pattern. The committee also emphasized the need for physically active lifestyles, food safety and food sustainability. Sustainability, defined as evaluating the environmental impacts of food sources was later deemed to be out of scope by the administration and so recommendations were not presented in the final guidelines. The latest version of the Dietary Guidelines for Americans 2020–25 provides the same three examples healthy eating patterns. In addition, consumers are urged to meet food group needs with nutrient-dense foods and beverages and to stay within calorie limits. Limiting foods and beverages higher in added sugars, saturated fat, and sodium, and limiting alcoholic beverages is also stressed.

### New views of healthy and unhealthy foods

As in the past, there is much consumer interest today on “healthy” and “unhealthy” foods. Defining what is meant by healthy and unhealthy continues to be highly culturally determined and controversial. Traditionally, government guidance has singled out specific food groups such as fruits and vegetables or whole grains as “healthy” because they are rich in essential nutrients and low in ingredients like salt, sugar, or saturated fat that are in excess in population diets. At present, the Food and Drug Administration estimates that about 15% of the foods on the market would be eligible for a voluntary “healthy” label under existing regulations, although only about 5% of products use the label. Federal guidelines are more selective in labeling foods as “unhealthy” and tend to use the term sparingly, only when the entire population is at risk, as when foods known to be contaminated by food borne pathogens. Definitions of “unhealthy” in government regulations assume that the foods themselves are neither inherently healthy nor unhealthy but that they may become so in particular contexts or for particular people, such as when foods are high in constituents like salt and they are consumed in excess, especially by those at risk of cardiovascular disease. Today advocates of healthy eating are increasingly assigning “bad” as well as “good” labels to individual foods, based on their content of salt, saturated fat, cholesterol, added sugars or others which they view as associated as having adverse effects on population health. However, unlike the lack of nutrients or the presence of food borne pathogens that always pose risks of ill effects, individual food ingredients are more time and context specific in their health effects, as lifestyles and eating patterns change. For example, a food such as butter (high in saturated fat) is associated with coronary heart disease in the USA whereas ghee (also high in saturated fat) is not, but the reverse might be true in India, where ghee consumption is high and butter consumption is lower. Similarly sugar sweetened beverages are highly associated with obesity in the USA’s sedentary population whereas the same amounts might not be in a lean, physically active population in a low-income country with low energy intakes. Therefore, special care needs to be taken in labeling of foods as “unhealthy” because they are highly population and time context specific.

### Advent of broader concerns influencing food guidance

Some nutrition scientists and other biological and social scientists advocate for dietary recommendations that go beyond nutrition science’s traditional domain in providing recommendations about foods to eat and diets based primarily on nutrient needs.

Current recommendations include the food’s environmental sustainability, food security, degree of food processing, location of food production and general concerns and causes. There is growing pressure to include some of these broader concerns in recommendations. For example, the United Nations’ sustainable development goals emphasize improvements in health, society, economics, and the environment. These goals have led to recommendations for sustainable healthy diets and foods systems to integrate these social dimensions into food and nutrition patterns, beyond most current recommendations. One example is the recently published *Eat Lancet* report, the first full scientific review of what constitutes a healthy diet from a sustainable food system, and which actions can support and speed up food system transformation (Willet et al., 2019). Meat consumption has received much attention as a negative force (Godfray et al., 2018), although it is not likely to be easy to change preferences for it (Ruckert-John, 2017). A companion Lancet Commission report on obesity and undernutrition also stresses the need for changes in dietary patterns and lifestyle toward more sustainable food systems (Swinburn et al., 2019). They are useful beginnings at a more holistic view of the role of food and nutrition in planetary health. However, the devil in the details includes ensuring that all the assumptions from the various disciplines are based on sound evidence, and that there are ways to operationalize these various dimensions into culturally acceptable eating patterns in free societies (Nicholls and Drewnowski, 2021).

### Food folklore continues

Scientific concepts about food and nutrition that have developed over the past two centuries are relative newcomers to human thought about food and health. Therefore, although some folk beliefs about food have been discarded over the years, it should come as no surprise that other aspects of food folk beliefs continue to be passed down from generation to generation, and new ones have been introduced. In the USA, there have been ebbs and flows in specific foods or ingredients that were considered healthy or unhealthy. Commonly held food cultural beliefs today are a mélange of traditional beliefs, folklore, partially understood nutrition science concepts, food advertising, marketing efforts and public health campaigns (Table 2). Traditional food culture beliefs continue. Many of the highly touted “healthy foods” of today like chocolate have long and storied pasts (Dillinger et al., 2000). For example, great emphasis is placed on the qualities of protein foods and supplements, just as was the case over 100 years ago (O’Hagan, 2021). Athletes have always had their special foods and dietary regimes (Grivetti and Applegate, 1997; Applegate and Grivetti, 1997).

**Table 2** Food culture: traditional and new folklore and beliefs about specific foods.

<i>Food</i>	<i>Some traditional beliefs</i>
<b>Fruits</b>	
Apple	Preventive: “an apple a day keeps the doctor away”. Also thought to prevent caries and tooth decay
Blueberries	Cures kidney and urinary-tract ailments, improves memory and vision
Citrus fruits	Prevent scurvy, cure common cold
Cranberries	Prevent or cure urinary tract infections
Grapefruits	Burns calories, dissolves fat, aids in weight loss, avoid when taking medications
Raspberries	Raspberry leaf tea promotes labor contractions and aids in childbirth
<b>Vegetables</b>	
Beets	Cure for anemia, helps build iron rich blood
Carrots	Good eyesight
Celery	Promotes weight loss
Garlic	Stimulates digestion, inhibits germs, lowers cholesterol and blood pressure
Lettuce	Induces sterility
Onions	Cooked onions cure the common cold, “good for the heart”
Peppers	Cure heartaches
Potatoes	Cure for impotence scurvy and soothe and soften the skin, but are fattening
Spinach	Builds strong muscles
<b>Grains</b>	
Bread	Fattening
Flaxseed	Cures constipation, prevents cancer, lowers cholesterol
Oats	Oatmeal and oat bran prevent heart disease
<b>Dairy</b>	
Milk	Raw milk helps the immune system, milk causes mucus and phlegm, mothers who drink a lot of milk and dairy have colicky babies, calcium in milk causes kidney stones
Yoghurt	Prevents vaginal yeast infection, cures vaginitis, constipation, and diarrhea
<b>Meat</b>	
Beef	Beef protein makes muscles stronger, red foods like beef cause high blood pressure
Chicken soup	Cures the common cold
Eggs	Raw eggs build muscle, brown eggs are healthier than white eggs, eggs cause heart disease
Legumes	Beans are laxative
Seafood	Fish is brain food, is good for the heart and prevents heart attacks, oysters increase sexual potency
<b>Fats, sweets and alcohol</b>	
Olive oil	Protects against breast cancer and heart disease
Cod liver oil	Relieves rheumatism, aching muscles, stiff joints and prevents rickets
Sugar	Causes hyperactivity, excess causes diabetes and heart disease
Honey	Natural and does not raise blood sugar, mixed with water cures colic
Chocolate	Causes acne, prevents heart disease
Salt	Sea salt is healthier than table salt, salt tablets prevent muscle cramps, and a no salt diet will protect against high blood sugar
Alcohol	Helps warm the body in cold weather, is a sleep aid if consumed before bedtime, red wine is good for the heart, brandy cures a cold, drinking alcohol with raw oysters makes them safe and free of food borne infection
<b>Other</b>	
Processed and ultra processed foods	Cause many chronic diseases and obesity
Organic foods	Healthier than conventionally grown foods
Natural foods	Healthier than processed foods
Additive free foods	Healthier than foods with additives

Complementary and alternative medicine of the 21st century includes foods with special properties, now called functional foods, nutraceuticals, and dietary supplements. Food folklore today also involves views about the healthfulness of the new alternatives for milk, meat, and other animal foods, dietary supplements, organic products, functional foods, “unprocessed foods” as well as larger societal issues related to climate change, international trade, sustainability, and the environment. At the same time, new demons are emerging. For example, it has been urged that many or most “ultra-processed” foods be abandoned, including advice in some documents published by the United Nations (Vidal et al., 2021). Some critics in the media, humanities and social sciences regard the food system as irrelevant, and their views have a large following (Bittman, 2021; Moss, 2021). Food cultural beliefs today are not only spread from one generation to another by word of mouth, but by the mass media, the Internet, Twitter, and other outlets. These influences are reflected as dietary recommendations. Some of the beliefs have a scientific basis, but many are unsupported by, or opposed to, current scientific findings. Pseudoscience, rather than sound, verifiable, and reproducible evidence, still provides the basis for much of today’s food culture. Food, nutrition, and biomedical professionals must be knowledgeable about current beliefs, as these influence popular views about diet-health relationships and eating habits.

## Evaluating food culture and nutrition science

### Types of evidence and utility in establishing causal inference

Although the combined historical experience of various cultures on the optimal relationship between food, diets, and health is helpful by itself, it is insufficient to determine whether relationships are valid or not. Single studies are inadequate to demonstrate cause-effect relationships and it is important to consider not only the strength of studies, but the type and quality of the research available. When many different types of evidence are supportive of a causal relationship, the weaknesses of individual studies are mitigated and causal inference is strengthened. In determining the validity of food folklore or traditional and complementary medicine, not only the totality of the evidence but also the type and quality of available evidence are important. The strength of the association between eating a food (the cause) and a health outcome (the effect) can be ranked according to the type of evidence presented (Table 4). The best evidence comes from studies that have the most control over the treatment being evaluated while eliminating other factors that may suggest an effect was present, when really it was not.

### Randomized double blind placebo controlled clinical trials

When several randomized double-blind placebo-controlled trials show a relationship between a specific food and a health effect, the evidence of a cause-effect relationship is considered to be very good. These studies exert rigorous control over the claims or treatment being evaluated and over the people who are subjected to it (by randomization) and the assumptions of both the experimenters and study participants (by placebos and blinding). Other types of evidence and studies are lower in the hierarchy because they are not as definitive. Although randomized double-blind placebo controlled clinical trials are considered “the gold standard” for determining diet-health relationships, such studies are rarely available for many nutrition questions. Lesser levels of evidence must usually be used. Also, randomized, double-blind clinical trials are usually too small to assess all potential adverse effects—observational studies are better at doing this, as was the case in demonstrating the adverse effects of ephedra for weight loss.

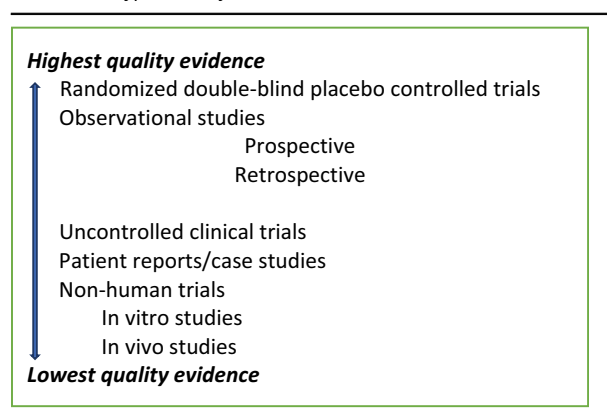

### Observational studies

Human studies that involve observation rather than direct intervention provide evidence that is satisfactory but less conclusive than randomized, controlled double blind clinical trials. These studies are designed to test a relationship between an exposure of interest and a health outcome. They include both cohort studies (prospective) and case-control studies (retrospective). In a prospective study, a group exposed to the treatment of interest and an unexposed group are followed forward in time. The health outcomes in both groups are observed and evaluated after controlling for confounding factors with the use of statistics. In contrast, retrospective studies compare individuals who have already developed an outcome of interest (case) against those who have not (control). Factors contributing to the development of the outcome are then determined by looking backward in time. Because observational studies cannot be precisely controlled, it is more difficult to establish cause and effect. However, when confounding factors can be

**Table 3** Food culture: separating food culture lore and food and nutrition science.

		<i>Scientific evidence</i>	
		<i>Strong</i>	<i>Weak</i>
Food culture lore	Strong	Fact	Undetermined
	Weak	Emerging science	Untruth (fiction, “alternative fact”)

**Table 4** Ranking the quality of scientific evidence about food by type of study.

adequately controlled for these studies provide suitable evidence to support diet health relationships. They are useful for discovering adverse events or beneficial effects that are attributable to the treatment.

### ***Uncontrolled clinical trials***

Clinical studies in which everyone is treated, in which only those who ask for the treatment are treated, or in which some are treated based on unsubstantiated clinical convictions are suspect. In such studies, no randomization occurs and neither the researcher nor the participant is blinded to the treatment. Therefore, it cannot be determined whether the treatment is actually the cause of the observed results or whether biased convictions of either or both the experimenter and study participants are falsely contributing to the results. Better evidence is needed before it can be stated with assurance that folklore based on such observations is true.

### ***Patient reports, case studies and folklore***

Even weaker is human evidence purporting to show cause and effect that comes from single medical case reports or anecdotal evidence. This type of evidence is also biased because those who experience success from the treatment are much more likely to report their stories than those who do not.

### ***Animal studies and laboratory experiments***

Nonhuman studies involving living animals (in vivo studies) or tissue culture (in vivo studies) are useful in providing information on the possible mechanisms of action, biological plausibility, dose response and action of a treatment. However, their ability to predict outcomes in humans is poor. Therefore, these studies are unconvincing, by themselves, of effects in humans and should be used only to support other types of evidence.

## **Tensions persist between traditional food culture and nutrition science**

There is a dynamic tension between folklore from food cultural traditions and evidence-based nutrition science conclusions about the associations between food and health. Food cultural beliefs cannot be taken as fact without evidence to support them. It is important to review the types and quality of the various studies used to establish causal inference between a food or food constituents and health (Table 4). Ideally, the best way to evaluate whether there is a health effect is to perform a systematic evidence-based review of many randomized double-blind placebo controlled clinical trials, and to examine the results of meta-analyses and other studies when all such reviews produce comparable conclusions of an effect, the hypothesized connection is likely to be justified. Comprehensive reviews of observational studies are also useful but causal inference is weaker because many residual factors associated with the effect cannot be controlled.

Comprehensive evidence-based reviews of food cultural beliefs are needed when they have strong health implications for large populations, especially when they involve questions of life or death, and might lead to very large costs. Because they are time consuming and require much expertise and expense, they have been done only for a few important questions. For example, the National Institutes of Health (NIH) sponsored reviews of obesity treatments. The Agency for Health Policy Research on Quality sponsored reviews of several dietary constituents. The American Institute of Cancer Research has conducted many studies of dietary constituents and their relationship to cancer to substantiate their dietary recommendations, the Cochrane Collaborative has carried out reviews of many diet-disease associations, and the American Academy of Nutrition and Dietetics has done reviews of various dietary treatments. However, few of these reviews deal with food cultural beliefs.

## **Evaluating folklore and food culture in clinical situations**

### ***Need to focus and prioritize beliefs most likely to affect safety and health***

It is impossible to amass evidence that refutes all possible food culture beliefs that may be false. Thus, prioritization is necessary to focus on the beliefs that, if followed, are likely to be serious threats to the health not only of a few individuals but to the health of the public. Most folk beliefs are harmless and scientifically unsupported, but some could endanger health (Tables 2 and 3). When food cultural belief and scientific evidence are both strong and agree, eating behavior will be in line with the science. For example, consider the advice to “eat for two” given to pregnant women (note: not eat for two *adults*, however!). Similarly, when both the food folklore is strong (“chamomile tea helps you sleep”) but the scientific evidence opposed to it indicates that there is likely little effect on health, few problems are likely to arise. However, when strongly held folklore (“raw milk is healthier than pasteurized milk and improves immune function”) is opposed by extensive scientific evidence, action is necessary because otherwise health may be harmed. A recent example was that vitamin supplements could prevent COVID 19 and make vaccination unnecessary. The situation is more complicated when there is strongly held belief about the health connection of a food or diet, but the scientific evidence is weak, uncertain, legally unconvincing, or “emerging”, that is, requiring more research before an association can be established or rejected.

**Examples** The following examples illustrate how important it is to consider the safety of substances, to conduct investigations, and to act upon them.

### ***Ephedra for enhanced athletic performance and weight reduction***

One recent example of a dangerous belief in food culture was that ephedrine alkaloids in dietary supplements were safe and effective performance enhancers useful for promoting rapid weight loss. In the late 1990s the prevalence of use was high, and major adverse events, including death, were reported. A randomized clinical trial would be unethical, given the likelihood of harm, and a massive effort was undertaken, instead, to evaluate the evidence linking the supplements with health effects in a timely fashion. The findings resulted in a ban on ephedra in dietary supplements by the US Department of Health and Human Services (Shekelle et al., 2003). However, the costs of such a review were large. From a public health standpoint, only beliefs likely to have major and negative impacts on public health are worth tackling by engaging in such an elaborate systematic evidence review process.

### ***Low fat, calcium/vitamin D supplements and post-menopausal hormone replacement therapy to prevent chronic degenerative disease (The Women's Health Initiative)***

Testing a belief with a well-designed randomized clinical trial is very expensive, and results are often nuanced, but benefit to the public's health can be large. For example, popular beliefs in the early 1990s included that post-menopausal estrogen replacement therapy prevented heart disease, that low fat diets prevented cancer, and that calcium-vitamin D supplements prevented osteoporosis. These assertions were all tested in the Women's Health Initiative (WHI). Results showed that the use of estrogen plus progestin hormone therapy after menopause increased (not decreased) risk for heart disease, stroke, blood clots, breast cancer, and dementia. It is now apparent that hormone therapy—estrogen plus progestin or estrogen alone—should not be used in postmenopausal women to prevent heart disease or to lower cholesterol levels (Rossouw et al., 2002). Hormone therapy is still an option for some women to help relieve moderate to severe symptoms that occur early in menopause, but effects continue to be mixed, depending on age, and may include increased risk of breast cancer in older women (El Khoudary et al., 2020, Vinogradova et al., 2020). The WHI dietary modification trial found that a low-fat diet did not significantly reduce the risk of breast cancer, heart disease, or stroke, nor did it reduce the risk of colorectal cancer. However, the low-fat diet did reduce the risk of ovarian cancer. The WHI calcium/vitamin D trial showed that calcium and vitamin D supplements provided modest benefit in preserving bone mass and preventing hip fractures in older women and certain other groups, but did not prevent other types of fractures or colorectal cancer. Long term follow-up suggests mainly positive effects of the dietary portions of the clinical trial (Prentice et al., 2021).

## **Guide for dealing with important folk beliefs that adversely affect health**

When food folklore in a culture is such that it poses a potential risk to patient health, it is important for health professionals to evaluate the evidence, but to also use their clinical judgment and communications skills to relate their findings to clients and patients. The clinical realities require the same intellectual elements involved in evaluating causal inference in biological research but the approach must be tailored to engage the patient in the dialog and stimulate action and understanding. One method for evaluating and resolving the issues is the “6Rs” method, provided below:

**Report** It is important that the clinician relate to the patient and establish two way communications to learn more about the folk belief, the strength of the individual's conviction about it, and whether it is likely to jeopardize the patient's treatment and health. Active listening on the part of the health professional will make it more likely that the patient will listen, understand, accept, and follow recommendations.

**Review** It is also important for the health professional to review all the evidence surrounding the food belief and safety, in particular. This is important because folk remedies and alternative medicines are often self-administered, without the assistance of physicians. If there is evidence that implementation of the belief will be hazardous to the patient's health, it must be discouraged.

**Recall** The next step is to collate the evidence that is available.

**Relate** The evidence must be communicated to the patient. Common sense is vital to fit the information to the patient's realities.

**Recommend** In crafting recommendations, it is important to consider the importance, feasibility, and effectiveness for the patient. The information must be individualized to fit the patient's problem and needs.

**Revise and Re-evaluate** Finally, the clinician's recommendation is not the last word. Although a relatively rapid response is usually required in a clinical situation, the ongoing relationship with the patient permits follow up after the initial encounter. Also, science itself constantly changes, so re-evaluation is often necessary.

## **Conclusion**

Food culture and food traditions vary widely throughout the world. People connect with their cultural or ethnic groups through similar food patterns, and food is often a means of retaining cultural identity. Food is represented, viewed, and perceived differently throughout the world and in each country eating and diet have different psychological and social rationales and meanings. Food culture in the future will continue to change and may evolve to be more science based. As the constraints of geography, environment and economics lessen, the influence of other forces, including information about food and nutrition science may come to play a larger role in everyday food related decisions (Crivetti, 2000). However, it is certain that people will continue to select the foods

to eat, and their diets based on many cultural influences. The ultimate verdict of what people regard as acceptable food choices will continue to be dynamic, negotiated, and changeable compromises among religious and philosophical prescriptions, social pressures, personal predilections and many other factors (Herzfeld, 2021). Food and nutrition scientists and clinicians can hope that their recommendations for healthy eating will eventually become part of the larger food culture. However, they should not be surprised if other beliefs and influences also continue to play a role in determining what people decide to eat. Biologists and social scientists alike should also remember that even what they regard as their most objective and evidence based recommendations may also include subjective judgements derived from their own interpretations of food culture.

### Key points

- The food environment is the interface where people interact with the wider food system to both acquire and consume foods
- The food environment is associated with dietary intake; however, the evidence of its impact on obesity is still to be fully understood
- Improving our knowledge and understanding about food environments is key to addressing overweight, obesity, and diet-related non-communicable diseases
- Achieving large-scale and sustainable prevention of diet-related health outcomes requires multi-component and multi-level interventions on the food environment

### Introduction

If you look around your home or workplace, what kind of foods would you find most easily available and affordable to you? Would you buy at whatever outlet that is closest? These issues highlight some of the most important elements of food environments.

Globally, diet-related noncommunicable diseases and obesity are the leading contributors to poor health. At the same time, we know that eating is a complex social behavior where availability, accessibility, affordability, and cultural acceptability of different foods and rituals play a key role. Accordingly, the role of food environments in shaping our diets is increasingly gaining policy attention.

In this article, we review definitions and concepts, evidence, and examples of the influence of food environments on the distribution of dietary risk factors and associated non-communicable diseases. Finally, we also provide insight into policies and interventions that can create, enable, and sustain healthier food environments for a better population health.

### Population determinants of diet

Globally, unhealthy diets are the main modifiable risk factor for chronic diseases ([Murray et al., 2020](#)). As such, the current global burden of disease of malnutrition, including childhood and adult overweight and obesity, has been attributed, at least partially, to large shifts in population diets over time ([Swinburn et al., 2011](#)). At the same time, eating is a complex social behavior where availability, accessibility, affordability, and cultural acceptability of different foods and rituals play key roles.

As stated by Geoffrey Rose, one can differentiate between two types of causes: the causes of individual disease cases and the determinants of disease incidence rates in our populations ([Rose, 1985](#)). The first, in this case, would look at why two individuals in the same population have different dietary patterns and try to discover which individual factors are different between them. The second type of cause would look at two different populations with different dietary patterns or at large changes of dietary patterns in the same population over time ([Franco et al., 2013](#)). The determinants of incidence rates are the ones we will need to study if we want to understand why dietary patterns have changed and worsened over time and why specific populations have higher rates of obesity or diabetes due to unhealthier dietary patterns. These population determinants are what Rose called mass influences on dietary patterns.

Mass influences on population diets include all components of the food system: from production and agriculture policies, processing, and transportation to food environments, marketing, retailing, and servicing. These components of the food system may differ across countries/regions and have changed over time within populations. Therefore, if we were able to understand these social determinants of population diets, we might be able to tackle the decreasing healthfulness of population diets and the associated

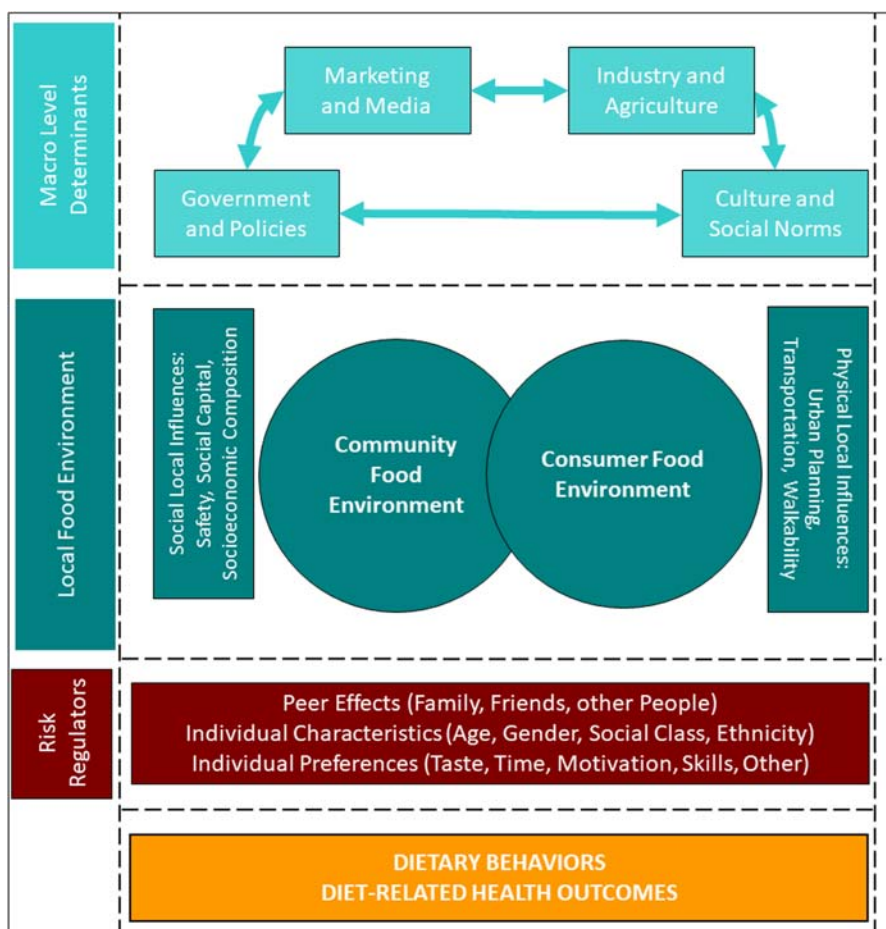

increases in obesity and other related chronic diseases like diabetes. Diabetes is currently one of the most important chronic diseases for the global economic and disease burden that diabetes means for people with diabetes but also for health systems and health expenditure.

Effective policies to combat unhealthy diets go beyond the individual and need to target the drivers of unhealthy diets (Roberto et al., 2015). One aspect of the food system that may be amenable to policies and more proximal interventions are the local food environments. The places where we buy food and eat do exert great influences over individual and population dietary behaviors. Considering the large differences in food environments within the same region or country and the shifting patterns over time in food availability, accessibility or affordability, local food environments represent a good example of a mass influence on population diets.

### Defining and conceptualizing food environments

As defined by Swinburn et al. food environments encompass “the collective physical, economic, policy, and sociocultural surroundings, opportunities, and conditions that mediate food systems and shape individual diets” (Swinburn et al., 1999). Furthermore, Glanz et al. described the food environment at the local scale and divided it into the community food environment—defined as the exposure to (un)healthy food retailers around home, schools, workplaces, and beyond; and the consumer food environment—defined as attributes experienced by consumers within these food retailers, like the availability, price, or placement of foods (Glanz et al., 2005). A further elaboration of this model, including macro-level determinants is shown in Fig. 1.

Government policies can have enormous impacts on what type of foods are available and at what price. Industrial and agricultural practices are also of utmost importance, and they are interconnected with government policies. Food culture and other social norms that determine what type of foods are acceptable also steer dietary behaviors with great strength. The interplay between industry pressures, government policies, and cultural aspects of food results in the food environments we live in nowadays. Factors modeling the effects of the food environment (like gender, age, and country of origin for example) are also of great importance.

**Fig. 1** Framework to study the food environment and its effects on diet. Adapted from Glanz, K., Sallis, J.F., Saelens, B.E., Frank, L.D., 2005. Healthy nutrition environments: concepts and measures. *Am. J. Health Promot.* 19(5), 330–333; Story, M., Kaphingst, K.M., Robinson-O'Brien, R., Glanz, K., 2008. Creating healthy food and eating environments: policy and environmental approaches. *Annu. Rev. Publ. Health* 29, 253–272.

Some of these factors are shaped more upstream from the food environment and relate closely to cultural and societal norms, while others are more proximal, like peer effects that have been shown to be a potent determinant of diet.

### Measuring the food environment

Over the last decades, researchers have applied more complex measures to assess the food environment (Lytle and Sokol, 2017; Bivoltis et al., 2018; Thornton et al., 2020). Yet, there is no clear consensus on the most appropriate operational definitions and measures. For example, Fleischhacker et al. showed that 20 (out of the 40 articles included) provided their own definition of a fast-food outlet (Fleischhacker et al., 2013). This use of diverse definitions has been identified as a key limitation of food environment research.

In terms of measures, most research has focused on characterizing the community food environment using objective measures like Geographic Information Systems (Lytle and Sokol, 2017) that are created around individual households or activity spaces (Thornton et al., 2020). In these studies, the food environment is measured as the availability, density of, or distance to certain types of food stores which are assumed to carry healthier foods or to be inherently unhealthy (e.g., fast-food restaurants) (Pinho et al., 2019).

As such, supermarkets have been considered as “healthy” or “low-BMI,” whereas other retailers (e.g., convenience stores) have been targeted as “unhealthy” or “high-BMI” stores. Yet, the same type of store may carry a widely different balance of healthy and unhealthy foods. For example, studies in Latin America reveal that supermarkets carry a much unhealthier balance of food compared to autochthonous stores (Perez-Ferrer et al., 2019).

An example to illustrate this can be found in Fig. 2, which depicts the availability of healthy food stores in two geographically and socioeconomically diverse cities Baltimore, the United States, and Madrid, Spain (Diez et al., 2016).

As the figure shows, the food environment in Madrid is richer and has a greater variety of food stores, while several areas of the comparable neighborhood in Baltimore are underserved in terms of food stores. This highlights the intricate interconnections between the community and the consumer food environment, but also with other aspects of the food system like transportation networks or use of cars. The bottom part of Fig. 2 highlights the two most common types of food stores in Baltimore and Madrid, respectively. Fruit and vegetable stores are widely available in Madrid and carry mostly fresh produce, compared with Baltimore’s corner stores carrying mostly processed foods.

Moreover, many studies conducted in the United States have focused on food deserts—socioeconomically disadvantaged urban areas with very limited and poor healthy food access. Yet, there is no evidence of food deserts in European countries (Helbich et al., 2017) and insights for many low- and middle-income countries is still lacking. On the other hand, the term food swamps refer to local food environments in which healthy and fresh food options are available, but where ultra-processed foods are also ubiquitous (Bridle-Fitzpatrick, 2015). The latter, as Cooksey-Stowers et al. reported, may play an even larger role than food deserts on diet-related health outcomes (Cooksey-Stowers et al., 2017).

Measures of the consumer environment, which capture the actual foods available within a store, tend to be more expensive and resource consuming. Studies have reported that financial actions (e.g., price discounts) increase the purchase of healthier food options. Yet, more evidence is needed on their effect on other foods because discounts may not hinder consumers from buying non-discounted, unhealthy foods. Regarding food labeling, research suggests that solely providing information (e.g., traffic light labels) does not affect shoppers’ purchasing behaviors. Yet, these features of the consumer food environment remain understudied and might be particularly context relevant.

As such, there is a need to conduct more studies combining both community and consumer nutrition environments. Ideally, these should apply valid and reliable measures, like the Nutrition Environment Measures Survey for Stores and Restaurants (NEMS-S/R), which can be adapted to particular contexts (Glanz et al., 2007; Martínez-García et al., 2020).

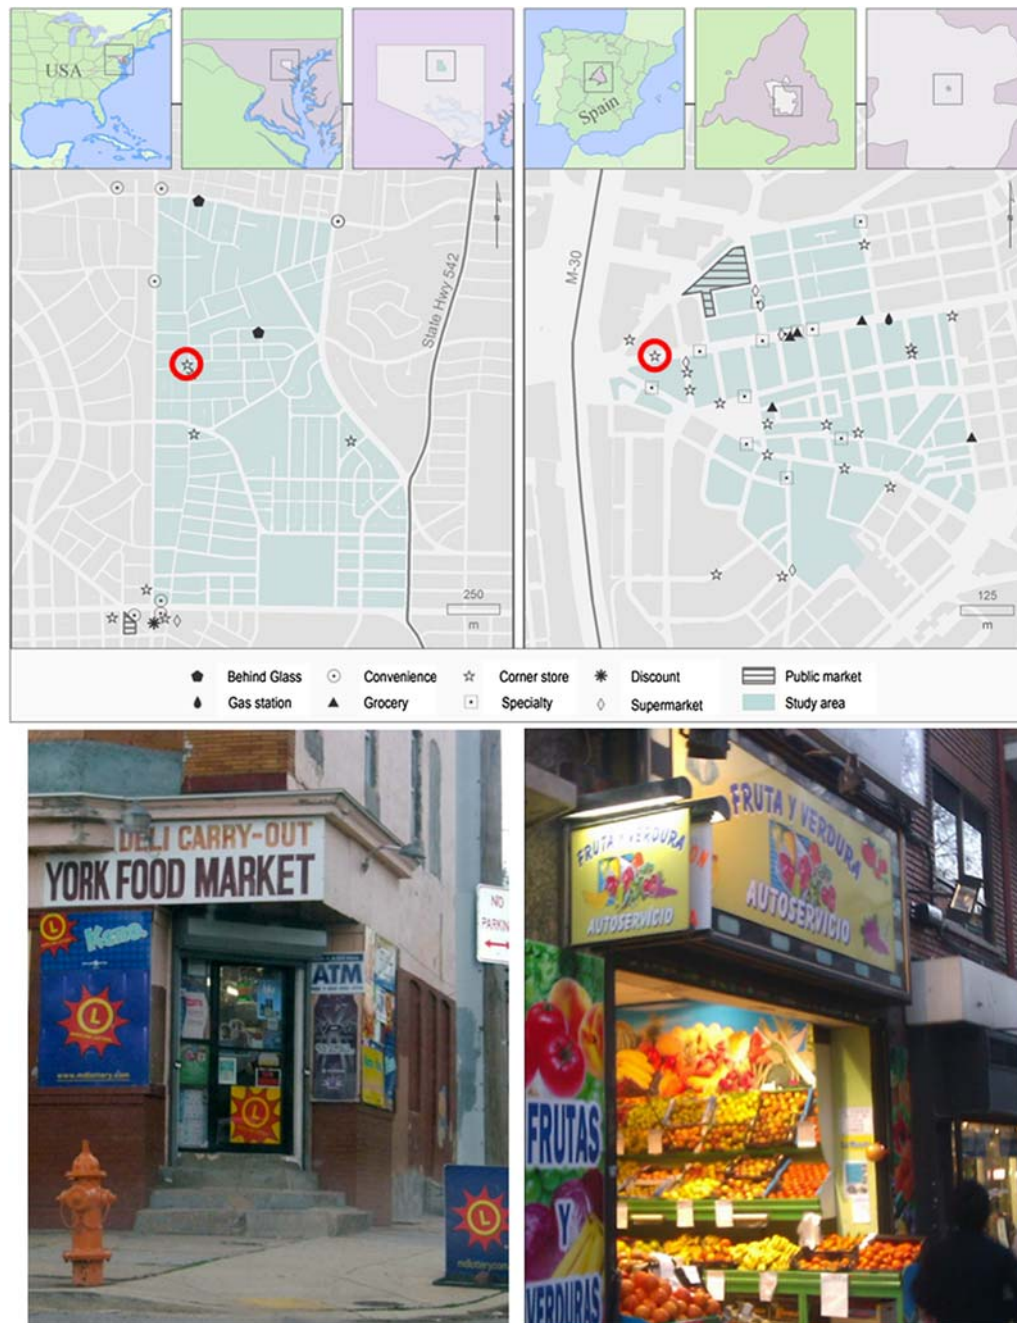

In addition, standardized and validated measures to capture the perceived food environment are needed. Although the body of literature using qualitative methodologies is growing, there are major gaps to be filled (e.g., research capturing children’s perceived food environment) (Pitt et al., 2017).

### Food environment, dietary behaviors, and diet-related health outcomes

There is growing evidence of the impact of the food environment on dietary intake; however, the evidence of its impact on obesity remains not well understood. As such, most studies have found the community food environment to be significantly related to food intake but not with body mass index. For example, fast-food access has been associated with fast-food consumption in most studies targeting children and adolescents (Jia et al., 2021). Yet, most studies have found mixed results between fast-food access and childhood obesity (Cobb et al., 2015).

On the other hand, studies conducted in Latin America have shown that living in a food environment with higher densities of convenience stores was significantly associated with a higher body mass index (Pineda et al., 2021). A recent systematic review also found that access to fast-food restaurants and convenience stores was positively associated with body weight status in China (An et al., 2020). Despite these examples, most studies examining the influence of the food environment on diet/obesity have exclusively focused on high-income populations. As such, more research on mid- and low-income countries is needed.

Studies on the impact of the consumer food environment have also indicated mixed results (Gustafson et al., 2012). Despite the large number of studies on this topic, a great variability in their measurement of the consumer nutrition environment and of the

**Fig. 2** Comparison of food stores present in two neighborhoods of similar number of inhabitants of similar relative socioeconomic status in Baltimore (the United States) and Madrid (Spain). Below, two stores (marked in map) in each neighborhood.

dietary assessment still exists. Assessing dietary behaviors is both expensive and challenging and often relies on self-reported measures.

A growing body of literature is also examining the association between the food environment and type 2 diabetes. Kanchi et al. have found that among US veterans in multiple community types, neighborhood food environment was associated with type 2 diabetes risk (Kanchi et al., 2021). In South Asia, Kusuma et al. also reported that both density and proximity to fast-food restaurants was associated with an increased risk of type 2 diabetes, especially among women (Kusuma et al., 2022). Results from another study conducted in the Netherlands confirm the evidence that the fast-food outlet environment is a diabetes risk factor (Ntarladima et al., 2022).

When assessing socioeconomic inequalities, research has shown that the food environment has a stronger impact, in terms of dietary behaviors, in most socioeconomically disadvantaged population groups. This is particularly the case for the school food

environment (Mackenbach et al., 2019). To illustrate, a recent study measured the availability of unhealthy foods within a 400 m walking distance of all schools present in the city of Madrid, Spain (Díez et al., 2019). The authors concluded that 95% of schools were surrounded by unhealthy food stores. Furthermore, schools located in most socioeconomically disadvantaged neighborhoods showed 62% more unhealthy retailers compared with schools located in middle-income areas.

### Interventions in the food environment

Governments need to promote, enable, and sustain healthy food environments (Mozaffarian et al., 2018). Therefore, and following the experience with tobacco control, recent policies such as zoning laws banning the opening of new fast-food outlets are being adopted (Mah et al., 2019). Other regulations include restricting the marketing of unhealthy foods to children, improving health-related food labeling, or implementing fiscal policies to (dis)incentivize consumption of (un)healthier foods and beverages (Mah et al., 2019). Although a substantial heterogeneity among interventions still exists, to date, most countries have implemented policies aiming at reducing the purchase and consumption of ultra-processed foods and sugar-sweetened beverages (Backholer et al., 2016).

The International Network for Food and Obesity/NCDs Research, Monitoring and Action Support (INFORMAS) has provided standardized methods to evaluate policies and actions through benchmarking (Sacks et al., 2021). The Food System Dashboard is a new monitoring initiative that applies this for the area of food and nutrition and which comprises several indicators related to the food system at each country (Fanzo et al., 2020).

Yet, the most important limitation is that policy assumptions are typically too narrow in scope and do not adequately consider the interplay between the food environment and the economic and sociocultural context of people's lives. Previous research has shown that structural conditions influence both food access but also the meaning of that food and the role it plays (Díez et al., 2017; Daniel, 2020). Therefore, interventions solely focusing on improving dietary behaviors will not be sufficient to reduce dietary inequalities. To illustrate this, Isaacs et al. suggest a shift in current interventions so that they focus on (1) greater engagement between national government and local authorities; (2) co-designing these policies with local communities and businesses serving these communities, while recognizing and managing the conflict of interest; and (3) place-based approaches tailored to the context of local communities (Isaacs et al., 2022).

Refining interventions on food environment will require a continued evaluation of policies and actions. Also, the complexity of the food environment makes it difficult to assess the contribution of an individual intervention. As stressed by the INFORMAS initiative, food environment research needs to (1) document stories of both success and failure; (2) engage with policy makers to understand how best to intervene in policy processes to support recommended policy implementation; (3) focus on strengthening accountability mechanisms; and (4) build consensus so that collective voices are amplified (Sacks et al., 2021).

### Conclusions

Diet is a complex social behavior where availability, accessibility, affordability and acceptability of different foods play key roles. The places where we buy food and eat can exert great influences over individual dietary behaviors, so that local food environments represent a good example of mass influences on population diets. Features of the food environment can be measured both objectively and subjectively. There is a current lack of comparability due to a large heterogeneity in the use of operational definitions and methodologies. More standardized and reliable methods are therefore needed to fully understand the relationship between the food environment, dietary behaviors, and diet-related health outcomes. Multicomponent interventions, as compared to single component interventions, have shown stronger evidence for improving food environments. Moreover, interventions need to consider the interplay between the food environment and the economic and sociocultural context.

## Key points

- The purpose of this article is to share publicly available information on maize flour, oil, rice, salt, and wheat flour fortification programs globally.
- Several documents are developed by country stakeholders to shape and guide fortification programs. Three were reviewed: legislation, standards, and regulatory monitoring protocols.
- There are many aspects of fortification programs that can be evaluated to determine if they are operating optimally or as planned. Four were reviewed: fortification compliance, proportion of people consuming fortified food (population coverage), potential nutrient contribution, and health status before and after fortification.
- Fortification may be a feasible intervention in countries without such programs that have a demonstrated nutritional need. A few criteria that can help identify whether fortification of a particular food should be explored to fill nutrient gaps in the diet were reviewed: the percentage of the food in the country that is industrially processed, the amount of the food that is consumed, and the percentage of people who eat this food.

## Introduction

Food fortification “is the practice of deliberately increasing the content of an essential micronutrient, i.e., vitamins and minerals (including trace elements) in a food, to improve the nutritional quality of the food supply and to provide a public health benefit with minimal risk to health” (WHO and FAO, 2006). Also known as enrichment (WHO and FAO, 2006), fortification adds needed nutrients to foods while they are being processed. In theory, most foods can be fortified with most nutrients. In practice, a limited number of foods are fortified with a limited number of nutrients.

Fortification contributes to the public health goal of reducing the prevalence of a nutrient deficiency or adverse functional outcome. For example, fortification of salt with iodine reduces iodine deficiency, goiter, cretinism, and low intelligence (Aburto et al., 2014; Keats et al., 2019). Similarly, wheat flour fortification with vitamin B9 (folic acid) reduces folate deficiency and neural tube defects (Keats et al., 2019; Rosenthal et al., 2014).

This article will focus on the large-scale (mass) fortification of foods with vitamins and minerals to serve a public health purpose. Specifically, the status of maize flour, oil, rice, salt, and wheat flour fortification programs will be described with respect to foundational documents and fortification performance. This will be followed by an assessment of the feasibility of fortifying these foods in countries that do not require or allow enrichment—an important exercise in countries that have a demonstrated nutritional need and are exploring the best interventions to meet those needs.

## Status of food fortification programs

The Global Fortification Data Exchange, or GFDx for short, is a website that compiles and visualizes information for up to 196 countries and five fortified foods: maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a). Other foods are also fortified at large scale to have a public health impact, such as sugar (Greene et al., 2017) and milk (López de Romaña, 2018). Because no websites consolidate information on sugar, milk or other mass-fortified foods, this article will focus on maize flour, oil, rice, salt, and wheat flour fortification programs.

The GFDx summarizes information for three topical areas: foundational fortification documents, fortification program performance, and fortification potential (GFDx, 2021a). This information is gathered in one of two ways: an on-line search for publicly available documents that contain fortification metrics, or a periodic survey sent to country stakeholders requesting fortification statistics or documents that contain them.

### Foundational fortification documents

Several documents are developed by country stakeholders to shape and guide fortification programs; they include legislation, standards, and regulatory monitoring protocols.

#### Legislation

Country-issued legislation documents typically stipulate whether fortification of a particular food is required (e.g., mandatory) or allowed (e.g., voluntary) (WHO and FAO, 2006). As of June 2021, most countries require or allow the fortification of salt, followed by wheat flour (Table 1).

Foundational documents go on to describe more details about the fortification of foods. For example, some countries with mandatory wheat flour fortification specify that all flour for human consumption must be fortified, whereas others indicate that only particular types of flour for human consumption must be fortified (Table 2) (GFDx, 2021a). For most salt fortification programs, all salt produced for human consumption must be fortified, whereas in a minority of countries, only certain salt types must be fortified (e.g., table salt).

Legislative documents specify that domestically produced and imported food must be fortified for most countries across the five foods (Table 2). It is unusual that some countries specify that exported foods must be fortified to the exporting countries' specifications (instead of the importing countries' standards).

Across five foods, most countries specify in their fortification foundational documents that foods for household use and that are used as ingredients for producing processed food must be fortified (Table 2). In contrast, salt is the only food where, if it is destined for animal use, it must be fortified. Few countries specify that donated foods (e.g., for humanitarian crises or social protection programs) must be fortified. Including the latter in countries' fortification documents may provide beneficiaries of social protection programs that provide food, with added vitamins and minerals through fortification.

#### Standards

Standards documents tend to describe the nutrients, nutrient levels and fortification compounds that are required or allowed to fortify foods in a country (Marks et al., 2018). Salt is generally a delivery vehicle for iodine, and oil for lipid-soluble vitamins (Table 3). In comparison, a greater variety of nutrients are required or allowed to be added to fortified grains (i.e., maize flour, rice, and wheat flour).

The World Health Organization (WHO) has guidelines for the fortification of maize flour (WHO, 2016), rice (WHO, 2018), salt (WHO, 2014), and wheat flour (WHO et al., 2009). For all of these except rice, WHO includes guidelines on the fortification compounds and levels to be used for 10 nutrients for maize flour, one nutrient for salt, and five nutrients for wheat flour fortification

**Table 1** The number of countries with mandatory or voluntary fortification of maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

<i>Food</i>	<i>Mandatory<sup>a</sup> (n)</i>	<i>Voluntary<sup>b</sup> (n)</i>	<i>Total (n)</i>
Maize flour	17	2	19
Oil	27	11	38
Rice	7	7	14
Salt	124	21	145
Wheat flour	85	14	99

<sup>a</sup>The country has legal documentation that has the effect of currently mandating fortification of the food vehicle in question with one or more vitamins or minerals i.e., the documentation indicates that fortification of all or some of the food is compulsory or required" (GFDx, 2021a).

<sup>b</sup>The country has official documentation and/or a food standard that provides guidance or conditions for fortification, but does not have the effect of mandating or requiring fortification. If a country has mandatory fortification for that food vehicle, it will be categorized by GFDx as not having voluntary fortification, even if some types of the food vehicle or some nutrients may be fortified on a voluntary basis" (GFDx, 2021a).

**Table 2** The number of countries with mandatory fortification of maize flour, oil, rice, salt, and wheat flour that specify which food types, their origins, destinations and uses must be fortified (GFDx, 2021a).

Food	Mandatory (n)	Food types <sup>a</sup> (n)		Food origins and destination <sup>b</sup> (n)			Food uses <sup>c</sup> (n)			
		All food types	Only certain food types	Domestically produced	Imports	Exports	Household use	Processed food use	Animal feed	Donated
Maize flour	17	8	9	17	17	0	17	16	1	2
Oil <sup>d</sup>	27	17	10	26	25	1	26	24	6	2
Rice <sup>e</sup>	6	3	3	6	5	0	6	6	0	1
Salt <sup>e</sup>	123	88	35	115	121	1	120	113	71	0
Wheat flour	85	42	43	85	79	6	85	85	2	7

<sup>a</sup>The food type categories are mutually exclusive. "All food types" means that all foods for human consumption are required to be fortified. "Only certain food types" means that only a subset of foods for human consumption are required to be fortified. If neither was expressly stipulated in a country's foundational documents, then "all food types" was assumed.

<sup>b</sup>The categories under food origins and destinations are not mutually exclusive. "Domestically produced" means that foods produced in the country must be fortified. "Imports" means that foods imported into the country must be fortified. "Exports" means that foods exported from the country must be fortified. If none was expressly stipulated in a country's foundational documents, then "domestically produced" and "imports" were assumed to apply.

<sup>c</sup>The food use categories are not mutually exclusive. "Household use" means that foods for use in a household must be fortified. "Processed food use" means that foods intended to be ingredients in another food must be fortified. "Animal feed" means that foods used to feed animals must be fortified. "Donated" means that donated foods (e.g., for social protection programs) must be fortified. If none was expressly stipulated in a country's foundational documents, then "household use" and "processed food use" were assumed to apply. If the foundational documents stipulate that "edible food" must be fortified, then "animal feed" was also assumed to apply.

<sup>d</sup>For food origins and destinations and food uses, the number of countries with data is 26.

<sup>e</sup>For one country with mandatory fortification, there is no documentation to determine the legislative scope.

**Table 3** The nutrients included in standards for fortified maize flour, oil, rice, salt, and wheat flour where fortification is mandatory or voluntary (GFDx, 2021a).

Food	Countries (n)	Nutrients
Maize flour	19	Calcium; iron; vitamins A, B1 (thiamin), B2 (riboflavin), B3 (niacin), B6 (pyridoxine), B9 (folate), B12 (cobalamin), D; zinc
Oil	36	Vitamins A, D, E
Rice	14	Calcium; iron; vitamins A, B1, B2, B3, B6, B9, B12, D, E; selenium; zinc
Salt	137	Fluoride, iodine, iron
Wheat flour	93	Calcium; iron; vitamins A, B1, B2, B3, B6, B9, B12, D; selenium; zinc

(Table 4). As WHO guidelines are evidence-informed (Peña-Rosas et al., 2012), it is reasonable to assume that fortification standards that align with WHO guidelines are more likely to lead to public health impact than those that are least aligned.

Iron is included in most countries' standards for maize flour and wheat flour fortification; the same is true for iodine in salt fortification (Table 5). Analyses for all nutrients in WHO guidelines for maize and wheat flour and for salt are available elsewhere (Bobrek et al., 2021; Greenwald, 2020).

Fortification compounds can differ in bioavailability, cost, whether and how they interact with other nutrients added through fortification, and sensory changes provoked in fortified foods (Hurrell et al., 2004; WHO, 2016). The ideal compound has the highest possible bioavailability, lowest cost, does not negatively interact with other nutrients and does not cause sensory changes to the fortified food.

Fortification compounds used to add iodine to salt specified in country standards were those recommended by WHO in the majority of countries (Table 5). This was also the trend for iron-fortification compounds in maize flour fortification standards. For wheat flour, one-quarter of country standards did not specify the name of the compound(s) that should be used to add iron to the flour. Without such guidance, less expensive and less bioavailable iron compounds may be used to fortify flour, reducing its potential impact for improving iron status among consumers (Hurrell et al., 2010).

For every nutrient in a fortification standard, two items are usually noted: the compound and the nutrient levels to be used in fortification. For maize flour, salt, and wheat flour, WHO offers recommended nutrient levels depending on the (1) amount of these foods that are consumed in a country and (2) fortification compound used (Table 4).

Across all publicly available standards for salt fortification, there are 182 instances of recommended potassium iodate and potassium iodide compounds listed (Table 6). For most of the compounds, iodine levels exceed WHO's recommended levels. The same was observed for iron levels reported for maize flour fortification. For wheat flour, there was an equal distribution across those iron compounds that are less than, exactly meet, or exceed WHO guidelines.

Nutrient levels may be lower than WHO recommendations if multiple foods are fortified with that nutrient in a country. For maize flour, the analysis considered the contribution of iron from fortified wheat flour (and vice versa). For countries where nutrient levels were below WHO guidelines, it may be worthwhile to review standards to determine if they are adequate to meet the nutrient

**Table 4** WHO guidelines for maize flour (WHO, 2016), salt (WHO, 2014), and wheat flour (WHO et al., 2009) fortification.

Maize flour

**TABLE 1.** Levels of nutrients to consider for adding to fortified maize flour and corn meal, when it is the only micronutrient intervention, based on extraction rate, chemical form and estimated per capita consumption<sup>a</sup>

Nutrient <sup>b</sup>	Flour-extraction rate <sup>c</sup>	Compound	Nutrient concentration to be added by estimated availability/consumption (mg nutrient/kg maize flour) <sup>d</sup>		
			<75 g/day <sup>e</sup>	75–149 g/day	150–300 g/day
Iron <sup>f</sup>	Low	NaFe-EDTA	40	40	20
		Ferrous sulfate	60	60	30
		Ferrous fumarate	60	60	30
		Electrolytic iron	NR	NR	60
	High	NaFe-EDTA	40	40	40
		Ferrous sulfate	60	60	60
		Ferrous fumarate	60	60	60
		Electrolytic iron	NR	NR	NR
Folic acid	Low or high	Folic acid	5.0	2.6	1.3
Vitamin A	Low or high	Vitamin A palmitate	6.0	3.0	1.5
Zinc	Low	Zinc sulfate/zinc oxide <sup>g</sup>	95	55	40
	High	Zinc sulfate/zinc oxide	100	100	80
Vitamin B <sub>12</sub> <sup>h</sup>	Low or high	Cyanocobalamin	0.04	0.02	0.01
For restitution of content lost during milling <sup>i</sup>					
Thiamine	Low or high	Thiamine hydrochloride	3.9	3.9	3.9
Riboflavin	Low or high	Riboflavin	2.0	2.0	2.0
Niacin	Low or high	Niacinamide	36	36	36
Pyridoxine	Low or high	Pyridoxine hydrochloride	6.2	6.2	6.2
Pantothenic acid	Low or high	Calcium pantothenate	4.2	4.2	4.2

NaFeEDTA: ferric sodium ethylenediaminetetraacetate; NR: not recommended

<sup>a</sup> This is a table to be used as a general guidance, and the number and amounts of nutrients should be adapted according to the needs of the country. These estimated levels consider only maize flour or corn meal as the main fortification vehicle in a public health programme. If other fortification programmes with other food vehicles and other micronutrient interventions are jointly implemented effectively, these suggested fortification levels need to be adjusted downwards as necessary.

<sup>b</sup> Nutrient levels were adapted from reference (18). In studies with maize flour, NaFeEDTA, encapsulated iron salts and ferrous bisglycinate have shown high bioavailability with high-extraction flours (15, 50, 51). Other iron compounds for use with high-extraction flour are included for increasing the variety of choices during the decision-making process. The addition of iron compounds at low levels of maize-flour or corn-meal consumption will depend on the organoleptic characteristics of the final product, after testing if feasible at industrial level (21).

<sup>c</sup> High-extraction flour (>80%) is also known as whole flour. It retains high levels of natural maize phytates, which inhibit the body's ability to absorb iron and zinc (4). For maize flour, nixtamalization is a process that yields high-extraction flour, while degermination and precooking produce low-extraction flour (7).

<sup>d</sup> Consumption of maize flour and corn meal varies widely in different countries, ranging from around 50 g/person/day in Ghana, Haiti and Uganda, to 300 g/person/day in Lesotho and Malawi (7).

<sup>e</sup> Estimated per capita consumption of <75 g/day does not allow for the addition of sufficient amounts of fortificant to cover the micronutrient needs for women of childbearing age. Fortification of additional food vehicles and other interventions may need to be considered.

<sup>f</sup> The amounts of iron presented here are in milligrams of elemental iron. The amount of a particular iron compound should be calculated depending on the molecular weight of the compound.

<sup>g</sup> Both zinc sulfate and zinc oxide could be used for maize fortification, although zinc oxide is cheaper (52, 53). As with iron, the phytate concentration (high flour-extraction rate) will affect the bioavailability of zinc (53, 54). These amounts of zinc fortification assume 5 mg zinc intake and no additional phytate intake from other dietary sources (18).

<sup>h</sup> The prevalence of vitamin B<sub>12</sub> depletion and deficiency is high in all age groups, reaching 50% in some countries (55, 56). Also, inclusion of vitamin B<sub>12</sub> is recommended when flour is fortified with folic acid (56, 57).

<sup>i</sup> Restitution of some B-complex vitamins should be achieved as a regular practice in all settings. The content in flour from white maize is: thiamine 3.9 mg/kg, riboflavin 2.0 mg/kg, niacin 36 mg/kg, pyridoxine 6.2 mg/kg and pantothenic acid 4.2 mg/kg (7).

Food

Table

Footnotes

Salt

Table 1. Suggested concentrations for the fortification of food-grade salt with iodine.

Estimated salt consumption <sup>a</sup> , g/day	Average amount of iodine to add, mg/kg salt (RNI + losses <sup>b</sup> )
3	65
4	49
5	39
6	33
7	28
8	24
9	22
10	20
11	18
12	16
13	15
14	14

<sup>a</sup> This includes consumption as table salt as well as salt from processed foods.

<sup>b</sup> This fortification concentration was calculated based on the mean recommended nutrient intake of 150 µg iodine/day + 30% losses from production to household level before consumption, and a 92% iodine bioavailability. Losses depend on the iodization process, the quality of salt and packaging materials and the climatic conditions. Losses could vary widely<sup>1</sup> and this table presents the value considering 30% losses. The monitoring of urinary iodine concentrations will allow adjustment of the selected fortification concentrations.

RNI: recommended nutrient intake, is the daily intake, set at the estimated average requirement plus 2 standard deviations, which meets the nutrient requirements of almost all apparently healthy individuals in an age- and sex-specific population group.

Although iodate is more stable, either potassium iodate (KIO<sub>3</sub>) or iodide (KI) can be used. Iodide may be used for dry, low crystal size and washed or refined salts. While iodate can be used alone and in any type of salt quality, iodide is used in very good quality salt and cannot be added alone. Therefore, some salt producers add sodium carbonate or sodium bicarbonate when they iodize salt, to increase alkalinity, and sodium thiosulfate or dextrose to stabilize potassium iodide. Without a stabilizer, potassium iodide may be oxidized to iodine and lost by volatilization from the product.<sup>2</sup>

An estimated additional variability of ±10% during iodization procedures could be considered at the production site for use in quality control and assurance procedures. This variability depends on the iodization methods used and quality assurance system in place.

Shaded areas correspond to the WHO salt reduction guideline.

Wheat flour

Table 1. Average levels of nutrients to consider adding to fortified wheat flour based on extraction, fortificant compound, and estimated *per capita* flour availability

Nutrient	Flour Extraction Rate	Compound	Level of nutrient to be added in parts per million (ppm) by estimated average per capita wheat flour availability (g/day) <sup>1</sup>			
			<75 <sup>2</sup> g/day	75-149 g/day	150-300 g/day	>300 g/day
Iron	Low	NaFeEDTA	40	40	20	15
		Ferrous Sulfate	60	60	30	20
		Ferrous Fumarate	60	60	30	20
		Electrolytic Iron	NR <sup>3</sup>	NR <sup>3</sup>	60	40
	High	NaFeEDTA	40	40	20	15
Folic Acid	Low or High	Folic Acid	5.0	2.6	1.3	1.0
Vitamin B <sub>12</sub>	Low or High	Cyanocobalamin	0.04	0.02	0.01	0.008
Vitamin A	Low or High	Vitamin A Palmitate	5.9	3	1.5	1
Zinc <sup>4</sup>	Low	Zinc Oxide	95	55	40	30
	High	Zinc Oxide	100	100	80	70

<sup>1</sup> These estimated levels consider only wheat flour as main fortification vehicle in a public health program. If other mass-fortification programs with other food vehicles are implemented effectively, these suggested fortification levels may need to be adjusted downwards as needed.

<sup>2</sup> Estimated per capita consumption of <75 g/day does not allow for addition of sufficient level of fortificant to cover micronutrients needs for women of childbearing age. Fortification of additional food vehicles and other interventions should be considered.

<sup>3</sup> NR = Not Recommended because very high levels of electrolytic iron needed could negatively affect sensory properties of fortified flour.

<sup>4</sup> These amounts of zinc fortification assume 5 mg zinc intake and no additional phytate intake from other dietary sources.

**Table 5** Comparison to WHO guidelines of fortification compounds listed in country standards: one illustrative nutrient each for maize flour, salt, and wheat flour where fortification is mandatory or voluntary (GFDx, 2021a).

Food	Nutrient <sup>a</sup>	Countries <sup>b</sup> (n)	All compounds are WHO-recommended <sup>c</sup> (n)	None of the compounds are WHO-recommended <sup>d</sup> (n)	Both recommended and non-recommended compounds <sup>e</sup> (n)	Compounds not specified <sup>f</sup> (n)
Maize flour	Iron	19	14	2	1	2
Salt	Iodine	137	88	1	36	12
Wheat flour	Iron	91	44	6	17	24

<sup>a</sup>According to the Global Fortification Data Exchange, this is the nutrient that the largest number of countries include in their fortification standards for this food (GFDx, 2021a).

<sup>b</sup>Countries for which the Global Fortification Data Exchange has a copy of the fortification standard for the food.

<sup>c</sup>Countries where every fortification compound listed in the fortification standard is recommended by WHO for fortification of maize flour (WHO, 2016), salt (WHO, 2014), and wheat flour (WHO et al., 2009).

<sup>d</sup>Countries where none of the fortification compounds listed in the fortification standard is recommended by WHO for fortification of the food.

<sup>e</sup>Countries where the fortification compounds listed in the fortification standard are a mix of those recommended by WHO and not recommended by WHO for fortification of the food.

<sup>f</sup>Countries where the fortification compound is not listed in the fortification standard for the food.

**Table 6** Percentage of WHO guidelines met by country standards for fortification levels: one illustrative nutrient for maize flour, salt, and wheat flour where fortification is mandatory or voluntary (GFDx, 2021a).

Food	Nutrient <sup>a</sup>	Fortification compounds <sup>b</sup> (n)	Meet < 100% of WHO guidelines <sup>c</sup> (n)	Meet 100% of WHO guidelines <sup>c</sup> (n)	Meet > 100% of WHO guidelines <sup>c</sup> (n)	Range of WHO guidelines met <sup>d</sup> (%)
Maize flour	Iron	16	5	0	11	47–251
Salt	Iodine	182	25	0	157	68–350
Wheat flour	Iron	90	33	29	28	33–251

<sup>a</sup>The nutrient that is included in the standards for the most number of countries with maize flour, salt, and wheat flour fortification (GFDx, 2021a).

<sup>b</sup>The number of WHO-recommended fortification compounds specified in countries' standards to fortify the food with the specific nutrient, i.e., electrolytic iron, ferrous fumarate, ferrous sulfate and NaFeEDTA for iron in maize flour and wheat flour, and potassium iodate and potassium iodide for iodine in salt (WHO et al., 2009; WHO, 2014, 2016). One country can have two or more WHO-recommended fortification compounds specified in their fortification standards.

<sup>c</sup>For each nutrient, country fortification standards specify fortification compounds and nutrient levels to be added to the food. For each compound, the nutrient level could be less than, equal to, or greater than nutrient levels in WHO guidelines issued for maize flour, salt, and wheat flour (WHO et al., 2009; WHO, 2014, 2016).

<sup>d</sup>The nutrient levels specified in country standards were compared to nutrient levels in WHO guidelines and a percentage was calculated of the WHO recommendations met. The minimum and maximum percentage of WHO recommendations met are listed.

needs of the population—taking into account other interventions that are delivering the same nutrients. A review is also merited for countries where nutrient levels are above WHO guidelines. Are the high levels warranted based on nutritional need? Is there a risk of providing too much of a nutrient to the population when other interventions are taken into account?

### Regulatory monitoring

Regulatory monitoring documents guide governments' enforcement activities for food fortification (Nathan, 1999). These documents state how government inspectors will monitor domestic facilities where fortified foods are produced (i.e., external monitoring) and imported foods that should be fortified (i.e., import monitoring) (WHO and FAO, 2006). For example, external monitoring protocols can stipulate with what frequency inspectors will visit plants that produce fortified food and what information they will collect during those visits, while import monitoring protocols specify how different agencies, including Customs officials, will coordinate to audit imported foods that should be fortified.

Protocols guide the monitoring activities carried out by government officials. Most countries with mandatory fortification of maize flour, oil, and wheat flour have publicly available protocols for external monitoring (Table 7). The same is true for maize flour, oil, and rice for import monitoring protocols. It would be of concern if these documents do not exist for some countries and if government inspectors have little written guidance on the monitoring work they are expected to carry out.

Best practices suggest the minimum information that foundational documents should contain about fortification monitoring (Marks et al., 2018). Country documentation was reviewed for the presence of two illustrative elements for external and import monitoring each (Table 8); information extracted from foundational documents for 27 other elements can be viewed elsewhere (Stern, 2021).

Relatively few documents reviewed for maize flour, oil, salt, and wheat flour stated which government agency was responsible for external or import monitoring (Table 8). Even fewer documents stipulated the frequency of government inspections for the five foods. These results are concerning if, in fact, the agency responsible for fortification or the frequency with which they should monitor is unknown. It is possible that this information is known and stated in documents that are not publicly available.

**Table 7** Number of countries with external monitoring and import monitoring documents for the regulatory monitoring of mandatory maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	Mandatory <sup>a</sup> (n)	External monitoring <sup>b</sup>		Import monitoring <sup>c</sup>	
		Protocol applicable <sup>d</sup> (n)	Protocol available <sup>e</sup> (n)	Protocol applicable <sup>d</sup> (n)	Protocol available <sup>e</sup> (n)
Maize flour	17	17	10	17	9
Oil	27	26	16	18	15
Rice	7	7	2	7	4
Salt	124	82	10	119	16
Wheat flour	85	71	48	85	26

<sup>a</sup>Number of countries with mandatory food fortification.<sup>b</sup>Government monitoring in domestic facilities where fortified foods are produced.<sup>c</sup>Government monitoring of imported foods that should be fortified.<sup>d</sup>External monitoring is applicable in countries where foods are domestically produced and import monitoring is applicable in countries where foods are imported into the country. In countries that exclusively import the food, for example, external monitoring protocols are not expected or applicable.<sup>e</sup>The monitoring protocol is publicly available.**Table 8** Number of countries with two best-practice monitoring elements included in their monitoring documents for maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	External monitoring <sup>a</sup>			Import monitoring <sup>b</sup>		
	Applicable <sup>c</sup> (n)	States which government agency is responsible for monitoring <sup>d,f</sup> (n)	Describes the frequency of inspection <sup>e,f</sup> (n)	Applicable <sup>c</sup> (n)	States which government agency is responsible for monitoring <sup>d,f</sup> (n)	Describes the frequency of inspection <sup>e,f</sup> (n)
Maize flour	17	6	3	17	8	5
Oil	26	10	4	18	5	2
Rice	7	4	1	7	6	2
Salt	82	37	1	119	37	10
Wheat flour	71	32	15	85	25	12

<sup>a</sup>Government monitoring in domestic facilities where fortified foods are produced.<sup>b</sup>Government monitoring of imported foods that should be fortified.<sup>c</sup>External monitoring is applicable in countries where foods are domestically produced and import monitoring is applicable in countries where foods are imported into the country. In countries that exclusively import the food, for example, external monitoring protocols are not expected or applicable.<sup>d</sup>Publicly available country documentation states which government agency(ies) is(are) responsible for monitoring.<sup>e</sup>Publicly available country documentation states the frequency with which government agency(ies) conduct(s) inspections.<sup>f</sup>The number may be greater than the number of countries with the protocol available, per the previous table. This means that a foundational document other than the external monitoring protocol (e.g., legislation, standards) has this information registered in it.

## Fortification program performance

Many aspects of fortification programs can be evaluated to determine if they are operating optimally or as planned. This article will review four: fortification compliance, proportion of people consuming fortified food (population coverage), potential nutrient contribution, and health status before and after fortification.

### Fortification compliance

A fundamental premise for fortified foods to have nutritional impact is that they must be fortified according to the country-defined standards. Broadly speaking, fortification compliance can be assessed in two non-mutually exclusive ways (GAIN and PHC, 2018). One, fortification processes in production facilities are audited by government inspectors to identify if best practices are being followed, such as calculations relating the amount of fortified food produced to the amounts of vitamins and minerals used in their production (i.e., premix reconciliation). Two, government inspectors gather samples of food that should be fortified from production facilities and send them to laboratories to determine if they contain the correct amounts of vitamins and minerals, as outlined in the country's fortification standards. With both methods, criteria are developed to classify production facilities and samples for compliance.

Few countries produce publicly available reports with compliance estimates (Table 9). Among these, the proportions of foods that are fortified according to country standards range from as low as 33% to as high as 100%.

**Table 9** Among countries with mandatory or voluntary fortification, those with publicly available fortification compliance data and the range of compliance for fortified maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	Mandatory or voluntary <sup>a</sup> (n)	Report compliance data <sup>b</sup> (n)	Percent compliance <sup>c</sup> (minimum-maximum)
Maize flour	19	2	33–33
Oil	38	0	Not applicable
Rice	14	1	100
Salt	145	7	59–96.6
Wheat flour	99	5	76–100

<sup>a</sup>Countries that require or allow fortification.<sup>b</sup>Countries that report the percentage of food that meets fortification standards for at least one year between 1995 and the present.<sup>c</sup>When compliance is available, the minimum and maximum percentages reported. If a country had multiple years of compliance data, only the latest year is included.

### Proportion of people consuming fortified food

The greater the proportion of individuals—especially those from the target population group—who consume fortified foods (i.e., population coverage), the greater the health impact of fortification. **Table 10** reports the percentage of people who consume foods that have been fortified (i.e., these are not necessarily foods that have been fortified to meet nutrient levels in fortification standards). Except for salt, few countries report population coverage (**Table 10**). Among those that do report these figures, the range is large (2.5–99.9%).

### Potential nutrient contribution

The potential nutrient contribution of fortified foods can be gleaned from standards information coupled with estimates of dietary intake of fortified foods. Specifically, the nutrient amounts added to food through fortification according to standards (in mg kg<sup>-1</sup>) multiplied by the daily amount of fortified food consumed (in g d<sup>-1</sup>) divided by 1000 yields the potential nutrient intake (in mg d<sup>-1</sup>) for each fortified food (Pachón et al., 2021).

The potential nutrient contribution was modeled under two scenarios (**Fig. 1**) (GFDx, 2021b). In the maximum scenario, it was assumed that (1) 100% of the food consumed in the country is industrially processed (and therefore easier to fortify and monitor) and (2) 100% of the food consumed in the country is fortified according to the country's standard (i.e., is compliant with national regulations). In the realistic scenario, actual data were used for the (1) percent of the food that is industrially processed in the country and (2) percent of food that is fortified according to the country's regulations.

Country-level nutrient intakes were compared to nutrient-specific Estimated Average Requirements (EARs) and Tolerable Upper Intake Levels (ULs) for women of childbearing age. EARs, when calculated for individuals, represent the amount of the nutrient required to meet the needs of 50% of the population. ULs represent the highest, daily safe amount that individuals can consume. The percent of nutrient-specific EARs (**Fig. 2**) and ULs (**Fig. 3**) potentially met through the consumption of fortified foods is summarized for up to 153 countries.

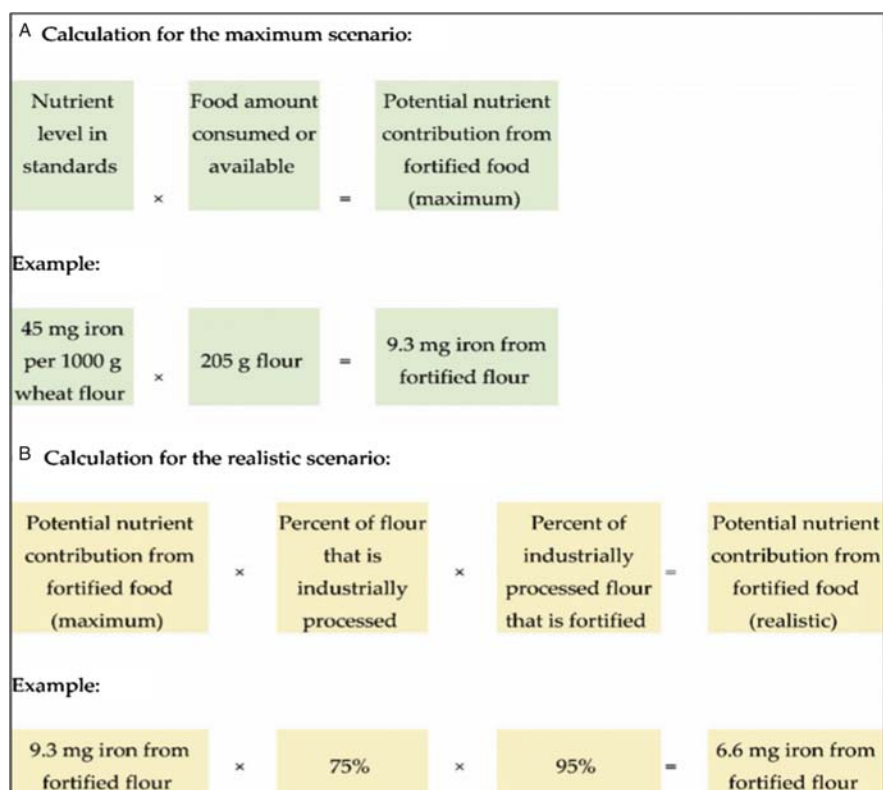

The analyses suggest that if 100% of maize flour, oil, rice, salt, and wheat flour in each country is industrially processed and all are fortified according to country standards (i.e., 100% compliance), these fortified foods can make a meaningful contribution to nutrient requirements (EARs) (**Fig. 2**). In practice, the actual contribution is lower because few countries have foods that are both 100% industrially processed and 100% compliant with fortification standards.

These findings point to two ways in which fortification programs can be modified so that the nutrients intended to be provided through fortification (i.e., based on country fortification standards) are delivered (Pachón et al., 2021). One is to consider alternative food vehicles for fortification that are mostly produced in industrial-scale facilities. The second is for industry to increase compliance with fortification standards.

**Table 10** Among countries with mandatory or voluntary fortification, those with publicly available population coverage data and the range of coverage for fortified maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	Mandatory or voluntary <sup>a</sup> (n)	Report coverage data <sup>b</sup> (n)	Percent coverage <sup>c</sup> (minimum-maximum)
Maize flour	19	2	2.5–6.5
Oil	38	3	34.1–54.4
Rice	14	0	Not applicable
Salt	145	89	6.9–99.9
Wheat flour	99	6	8.5–98.0

<sup>a</sup>Countries that require or allow fortification.<sup>b</sup>Countries that report the percentage of individuals who consume fortified foods for at least one year between 1995 and the present. The foods are fortified any amount.<sup>c</sup>When coverage is available, the minimum and maximum percentages reported. If a country had multiple years of coverage data, only the latest year is included.

**Fig. 1** Calculation of potential nutrient contribution (in  $\text{mg capita}^{-1} \text{day}^{-1}$ ) (A) under the maximum scenario where 100% of the food is assumed to be industrially processed and 100% is assumed to be fortified and (B) under the realistic scenario where the amount of the food that is industrially processed and fortified is known for a country (Pachón et al., 2021).

The median unadjusted and adjusted %EAR across all countries with available data across all five food vehicles: maize flour, oil, rice, salt, and wheat flour.

**Fig. 2** Maximum and realistic estimates of the combined nutrient contribution of maize flour, oil, rice, salt, and wheat flour fortified according to standards: comparison to Estimated Average Requirements (EARs) for women (GFDx, 2021b). In the unadjusted (maximum) scenario, it was assumed that (1) 100% of the food consumed in the country is industrially processed (and therefore easier to fortify and monitor) and (2) 100% of the food consumed in the country is fortified according to the country's standard (i.e., is compliant with national regulations). In the adjusted (realistic) scenario, actual data were used for the (1) percent of the food that is industrially processed in the country and (2) percent of food that is fortified according to the country's regulations.

The median unadjusted and adjusted %UL across all countries with available data across all five food vehicles: maize flour, oil, rice, salt, and wheat flour.

**Fig. 3** Maximum and realistic estimates of the combined nutrient contribution of maize flour, oil, rice, salt, and wheat flour fortified according to standards: comparison to Tolerable Upper Intake Levels (ULs) for women (GFDx, 2021b). In the unadjusted (maximum) scenario, it was assumed that (1) 100% of the food consumed in the country is industrially processed (and therefore easier to fortify and monitor) and (2) 100% of the food consumed in the country is fortified according to the country's standard (i.e., is compliant with national regulations). In the adjusted (realistic) scenario, actual data were used for the (1) percent of the food that is industrially processed in the country and (2) percent of food that is fortified according to the country's regulations.

The risk of exceeding ULs is low for most nutrients (Fig. 3). In countries where other interventions deliver micronutrients, it is prudent to review all programs to determine if any should be adjusted to minimize the risk of providing excess nutrients to the population.

### Health status before and after fortification

Ultimately, the purpose of food fortification is to effect a positive change on population health. This is assessed by measuring different indicators of nutrition and health status before and after fortification initiation.

Salt is the food for which the highest number of countries report the results of a health assessment (Table 11). While many nutrients are added to fortified food (e.g., vitamins A, D and E in oil), the status of only a few nutrients were evaluated in individuals who had access to these foods (e.g., vitamin A in oil). For most nutrients, multiple outcomes were measured (e.g., serum zinc and the prevalence of zinc deficiency for zinc).

For maize flour, rice, salt, and wheat flour, most of the outcomes assessed after fortification implementation were positive, meaning that there were improvements in health and nutritional status (Table 12). Salt showed the most negative changes, where median urinary iodine concentration decreased between the pre-fortification and the post-fortification periods. Oil was a notable exception, where there were no changes in any of the outcomes assessed, suggesting that fortification led to no health improvement.

**Table 11** Health outcomes reported after fortification implementation in countries with mandatory fortification of maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	Mandatory <sup>a</sup> (n)	Report at least 1 outcome <sup>b</sup> (n)	Nutrients assessed <sup>c</sup> (n)	Outcomes reported <sup>d</sup> (n)
Maize flour	17	5	2	7
Oil	27	1	1	2
Rice	7	2	1	4
Salt	124	79	1	1
Wheat flour	85	15	4	10

<sup>a</sup>Number of countries with mandatory food fortification.

<sup>b</sup>Number of countries that report the results of at least one health outcome after fortification implementation.

<sup>c</sup>In the studies completed, the number of nutrients that were assessed. The nutrients assessed were iron and vitamin B9 for maize flour, vitamin A for oil, vitamin B9 for rice, iodine for salt, and iron, vitamin B9, vitamin B12 and zinc for wheat flour.

<sup>d</sup>In the studies completed, the number of unique health outcomes that were assessed; each could be assessed in multiple population groups. The outcomes assessed included median urinary iodine concentration for iodine; plasma or serum ferritin, prevalence of iron deficiency, and the prevalence of iron-deficiency anemia for iron; plasma or serum retinol binding protein, breastmilk retinol and the prevalence of vitamin A deficiency for vitamin A; plasma or serum folate, red blood cell folate, prevalence of folate deficiency and the birth prevalence of neural tube defects for vitamin B9; plasma or serum cobalamin for vitamin B12; and plasma or serum zinc and prevalence of zinc deficiency for zinc.

**Table 12** Results of health outcomes assessed after countries mandate the fortification of maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	Total outcomes assessed <sup>a</sup> (n)	Positive change <sup>b</sup> (n)	No change <sup>c</sup> (n)	Negative change <sup>d</sup> (n)	Could not be determined <sup>e</sup> (n)
Maize flour	40	31	5	1	3
Oil	14	0	14	0	0
Rice	22	17	2	0	3
Salt	83	73	0	10	0
Wheat flour	91	76	10	1	4

<sup>a</sup>The total number of health outcomes assessed in any studies that assessed the impact of fortification. The types of health outcomes are noted in the footnotes for Table 11.

<sup>b</sup>The number of health outcomes that showed a positive health change from the pre to the post-fortification periods; this change was statistically tested. For example, if the prevalence of zinc deficiency statistically decreased from pre-to post-fortification, that outcome would be coded as a positive change. If serum ferritin statistically increased from pre-to post-fortification, that outcome would be coded as a positive change.

<sup>c</sup>The number of health outcomes that showed no change from the pre to the post-fortification periods; this lack of change was statistically confirmed. For example, if the prevalence of iron deficiency did not statistically change between the pre-to post-fortification, that outcome would be coded as no change.

<sup>d</sup>The number of health outcomes that showed a negative health change from the pre to the post-fortification periods; this change was statistically tested. For example, if the prevalence of folate deficiency statistically increased from pre-to post-fortification, that outcome would be coded as a negative change. If serum retinol statistically decreased from pre-to post-fortification, that outcome would be coded as a negative change.

<sup>e</sup>The number of health outcomes that were not statistically tested by the study authors. Without the statistics, whether the health outcome improved, worsened, or stayed the same between the pre- and post-fortification periods could not be determined.

However, all of the oil outcomes were evaluated in one study from one country. Results from other studies with oil fortification are welcome to understand the trends observed from large-scale fortification of this food.

### Fortification potential

Fortification may be a feasible intervention in countries without such programs that have a demonstrated nutritional need. A few criteria can help identify whether fortification of a particular food should be explored to fill nutrient gaps in the diet. If there is no nutritional need in a country, then this exercise is not needed.

Feasibility criteria include the percentage of the food in the country that is industrially processed, the amount of the food that is consumed, and the percentage of people who eat this food. Together with other insights, such as the food industry structure, the consumption habits of the population group with the most need, and other interventions already in place in the country, a decision can be made whether to pursue food fortification in the country.

### Proportion of food that is industrially processed

Foods can be fortified in small- or in large-scale facilities. However, government enforcement of fortification is easier when there are fewer large-scale facilities than many small-scale facilities (WHO and FAO, 2006). Further, food produced in large-scale facilities has a greater geographic scope than food produced in small-scale facilities.

For these and other reasons, the higher the proportion of food that is industrially processed, the greater the feasibility that it can be fortified at large-scale to have a public health impact in the country. There are dozens of countries where more than 75% of maize flour, rice and wheat flour produced is estimated to be industrially processed (Table 13). A handful of countries have such data for oil, and fortification is feasible in all of them.

**Table 13** Number of countries without mandatory or voluntary fortification and the percent of maize flour, oil, rice, salt, and wheat flour that is industrially processed (GFDx, 2021a).

Food	Have industrial processing data <sup>a</sup> (n)	Percent industrially processed <sup>b</sup> (minimum-maximum)	> 75% is industrially processed <sup>c</sup> (n)
Maize flour	73	1–100	65
Oil	3	80–100	3
Rice	107	1–100	80
Salt	0	Not applicable	Not applicable
Wheat flour	92	60–100	86

<sup>a</sup>Countries without mandatory or voluntary fortification of the food that have information in the Global Fortification Data Exchange about the percent of the food that is industrially processed in the country.

<sup>b</sup>For countries that have information on the percent of the food that is industrially processed, the minimum and maximum values in the range.

<sup>c</sup>Among countries with information on the percent of the food that is industrially processed, the number of countries where more than 75% of the food is industrially processed. The 75% cutoff value is an arbitrary designation.

The selection of 75% as a cutoff is arbitrary. Within each country, policy makers should decide what percentage is most appropriate. For example, there may be some cases where a lower percentage of industrially processed food may still warrant fortification, due to the number of people who consume the food.

### Amount of food consumed

Potential food vehicles for fortification are those consumed in “large” amounts by the target population (e.g., women of reproductive age). If there is only one viable food vehicle for fortification in a country, ideally the amount consumed is large enough that all needed nutrients can be added in amounts that do not cause sensory changes to the food. If there are two or more viable food vehicles in a country, the amount consumed of each individual food is less important.

For maize flour, rice, and wheat flour, “large” is defined as greater than 75 g daily, based on WHO guidance. Specifically, where flour intake is less than 75 g per capita per day, the amount of iron required to be added to have a positive health impact would likely cause sensory changes to the flour (WHO et al., 2009). Sensory changes will have the unintended effect of causing fewer people to eat and benefit from the fortified food. Thus, grain intake greater than 75 g per capita per day is arbitrarily used to define the minimum amount of food that should be consumed by the target population, if it is the only food that will be mass fortified in a country.

For grains, between 36 and 62 countries show food availability greater than 75 g per capita per day (Table 14). If there is nutritional need in these countries, fortification of one of these foods is potentially feasible.

### Proportion of population consuming the food

The ideal food vehicle is consumed by a large proportion of the target population. This information is available for a few countries in the Global Fortification Data Exchange. For a handful of countries, the population coverage of oil is high enough that fortification is feasible (Table 15).

## Conclusions

- The purpose of this article was to share publicly available information on maize flour, oil, rice, salt, and wheat flour fortification programs.
- Several documents are developed by country stakeholders to shape and guide fortification programs; they include legislation, standards, and regulatory monitoring protocols. These documents can be strengthened by including “best practice” information that they lack and more closely aligning them with international recommendations.
- Many aspects of fortification programs can be evaluated to determine if they are operating optimally or as planned. While there is great potential to contribute nutrients to the diet through fortification, there is surprisingly little public information available on food fortification compliance in countries, how many people consume fortified foods, and what health impact fortification is having on the population.
- Fortification may be a feasible intervention in countries without such programs that have a demonstrated nutritional need. Data can be used to help identify whether fortification of a particular food should be explored to fill nutrient gaps in a country’s diet. This minimum information should be coupled with conversations with key actors in a country from the public, private and civic sectors.

**Table 14** Estimates of the amount of maize flour, rice, and wheat flour available for human consumption in countries without mandatory or voluntary fortification (GFDx, 2021a).

Food	With food availability data <sup>a</sup> (n)	Food availability in grams per capita per day <sup>b</sup> (minimum-maximum)	Food availability > 75 g per capita per day <sup>c</sup> (n)
Maize flour	144	0–415	36
Rice	155	2–733	59
Wheat flour	73	6–549	62

<sup>a</sup>Countries without mandatory or voluntary fortification of the food that have information on the amount of the food available for human consumptions, as estimated by FAO in food balance sheets (FAO, 2021).

<sup>b</sup>Among countries with food availability data, the minimum and maximum range of food availability expressed in grams per capita per day, as estimated by FAO in food balance sheets (FAO, 2021).

<sup>c</sup>Among countries with food availability data, those where availability is greater than 75 g per capita per day. The cutoff was proposed by WHO for maize flour and wheat flour (WHO et al., 2009); here it is also applied to another grain that is fortified: rice.

**Table 15** Number of countries without mandatory or voluntary fortification that have coverage data for the consumption of any maize flour, oil, rice, salt, and wheat flour (GFDx, 2021a).

Food	With coverage data <sup>a</sup> (n)	Percent coverage <sup>b</sup> (minimum-maximum)	Coverage > 80% <sup>c</sup> (n)
Maize flour	0	Not applicable	Not applicable
Oil	3	0–95	2
Rice	0	Not applicable	Not applicable
Salt	Not recorded <sup>d</sup>	Not applicable	Not applicable
Wheat flour	0	Not applicable	Not applicable

<sup>a</sup>Countries without mandatory or voluntary fortification of the food that have information on the percent of population consuming the food.

<sup>b</sup>Among countries with coverage data, the minimum and maximum percent of people who consume the food.

<sup>c</sup>Among countries with coverage data, those where coverage is greater than 80%. The 80% cutoff value is an arbitrary designation.

<sup>d</sup>Salt intake is assumed to be universal; however, not all dietary surveys capture it's consumption. Therefore, information on population coverage is not visualized on the Global Fortification Data Exchange.

## Key points

- Food labeling is categorized as mandatory information or voluntary information and all labeling must be truthful and not misleading. Food labeling on prepackaged foods should be designed to inform the consumer about the appropriate use of the food in their overall diet, including the nutritional attributes of the food. Labeling that includes nutrition information is important for assisting consumers in understanding what foods to limit and what foods to get enough of for a healthful dietary pattern.

## Glossary

**Daily Value (or DV)** The term for NRVs used in Nutrition Facts on packaged food in the United States

**FOPL** Front of package labeling refers to nutrition information that is placed on the principal display panel of a food product

**NRV** Nutrient reference values developed by *Codex Alimentarius* for use in labeling food products. The reference values can be used to estimate the contribution of the food to meeting the recommended intake of the nutrient. NRVs have been developed for essential nutrients as well as for nutrients or food components whose intake should be limited

**Nutrition-related claims** Nutrition claims used on food packages can be based on the nutrient profile of a product (nutrient content claim), the role of a food, food component, or nutrient in reducing risk for disease (health claims or disease risk reduction claims) or the role of a food, nutrient, or food component in maintaining the structure or function of the body. Different terminology is used in different countries

**PDP** Principal display panel is the portion of the package label most likely to be seen by the consumer at the time of purchase and contains required label information such as the identity of the food and net quantity statements. The PDP may also contain promotional material about the product. The information panel is adjacent to the PDP with additional information such as nutrient and ingredient declarations

## Introduction

The labeling of prepackaged foods provides information that assists consumers in the purchase and use of the product. Certain elements of food labeling are considered mandatory for most prepackaged foods in many countries and must appear in a format and style specified by government regulations or standards. Several elements of food labels are considered voluntary and used at the discretion of the manufacturer but are still governed by regulations or standards. The regulations of most countries, including the standards and guidelines developed by the *Codex Alimentarius* Commission, specify that all labeling, whether mandatory or voluntary, should be truthful and not misleading and presented in a manner that is not deceptive to the consumer.

## Mandatory and voluntary labeling

The Codex standards and guidelines are useful to examine because they are adopted by many countries and reflect common practices among countries for the labeling of pre-packaged foods. This section discusses mandatory and voluntary labeling as established by Codex and the next section describes approaches to nutrition labeling, which is mandatory in some countries but in many countries is voluntary, unless a nutrition claim is made on the product.

Mandatory labeling refers to the information that should appear on all packaged foods unless a specific exemption is provided. Such mandatory elements, specified by the Codex General Standard for the Labeling of Prepackaged Foods, include the name of the food, a list of ingredients, net contents and drained weight, name and address of the manufacturer or distributor, country of origin, identification of the lot, date marking and storage instructions, and instructions for use (Codex General). Each of these elements requires additional specification at the national level to provide information that is relevant to the population. For example, the name of the food should include a common or usual name not just a fanciful or trade name for the product; ingredients are listed in decreasing order by weight; and guidelines are needed for the size and placement of font for these mandatory elements so that the information is legible for the consumer. Additional details can be found in the *Codex Alimentarius* General Standard for Labeling (Codex General) or in guidelines published by various government authorities (e.g. A Food Labeling Guide from the US FDA<sup>1</sup> (Guidance for Industry, 2013) or The Food Labeling Rules from the European Union (Food Labeling)).

Certain claims or representations about the food may result in additional mandatory declarations. For example, emphasis on a particular ingredient in a food may require a quantitative declaration of the ingredient. Treatment of the food with ionizing radiation requires inclusion of a written statement. For many countries, nutrient declaration in labeling is voluntary; however, for most countries nutrient declaration becomes mandatory if a nutrition claim is used in labeling and in several countries nutrient declaration is mandatory for most prepackaged foods.

## Approaches to nutrition labeling

There are 3 main approaches for providing nutrition-related information: nutrient declaration, nutrition-related claims, and supplemental nutrition information (Schneeman, 2020). Nutrient declaration became mandatory on most packaged foods in the United States with enactment of the Nutritional Labeling and Education Act (NLEA) of 1990. Such labeling was viewed as important to address the increasing prevalence of obesity and diet-related chronic diseases, such as diabetes and cardiovascular disease (U.S. Department of Health and Human Services, 1988). In addition to making nutrition information on food packages available to help consumers make better food choices, requiring nutrient declaration also provides an incentive to manufacturers to improve the nutritional profile of their products. The impact of nutrition labeling on product formulation was demonstrated when *trans* fatty acids was added to the list of mandatory nutrients for inclusion in Nutrition Facts. In the time frame between proposing and finalizing this requirement and the initiation of enforcement, the *trans* fatty acid levels were reduced substantially in the USA food supply (Doell et al., 2012).

## Nutrient declaration

Nutrient declaration is intended to address food and nutrition public health issues in the population and thus help consumers make better choices at the point of purchase. The nutrients to be included in the declaration are specified in regulations or standards. For example, the Codex standard for nutrient declaration was updated in 2013 to require declaration of energy value, the amounts of protein, available carbohydrates, total fat, saturated fats, sodium, and total sugars. In addition, the Codex standard mandates declaration of any nutrient for which a nutrition or health claim is made and allows for declaration of the amount of any nutrient considered relevant for maintaining nutritional status in a country or region (Codex Alimentarius, 2013). Although the Codex guideline encourages that nutrient declaration be mandatory on all packaged foods, it is considered voluntary information, unless a nutrition or health claim is made. Several countries have mandated nutrient declaration on most packaged foods and some countries, such as the USA and Canada, also mandate the format to be used for this declaration. Countries that mandate nutrient declaration often include certain nutrients or food components in addition to what is specified in the Codex standard because the information is relevant to national public health issues. For example, in the USA, in addition to the declaration in the Codex standard, *trans* fat, cholesterol, dietary fiber, added sugars, vitamin D, calcium, iron, and potassium are also included in the updated nutrient declaration (Code of Federal Regulations).

To be useful for consumers, the nutrient declaration should be presented in context. One way of providing context is to declare the amount of the nutrient or food component per the amount of food that is customarily consumed (i.e. a standard serving of the food). Knowing the amount of nutrient or food component per serving can be used to put that amount in context as a percentage of the recommended amount for daily consumption (e.g. referred to as the % Daily Value on the Nutrition Facts used in the USA). Another approach for providing context is to report the amount of the nutrient per 100 g of food (or 100 mL of beverage). Both

<sup>1</sup>The FDA Food Labeling Guide has not yet been updated to include the updates to Nutrition Facts that are now part of the Code of Federal Regulations, 21 CFR 101.9 <https://www.govinfo.gov/content/pkg/CFR-2021-title21-vol2/pdf/CFR-2021-title21-vol2-part101.pdf>. 2021 edition.

approaches can be used to compare products, either based on the standardized serving size or the common metric of 100 g or mL (even when this is not the amount of the food that is customarily consumed).

Jurisdictions that mandate nutrition labeling typically consider situations that might exempt a product from bearing a nutrition label (e.g. a package size may be too small to bear a label). A product with limited nutritional content may be allowed to use a more minimal format that indicates it is not a source of certain nutrients.

### Nutrient-related claims

The use of nutrition claims in food labeling is considered voluntary and used at the manufacturer's discretion; however, regulations and standards govern how and where they can be used on prepackaged foods. Codex provides guidelines for 4 types of nutrition claims: nutrient content claims, nutrient comparative claims, maintaining health claims (referred to as structure-function claims in the USA), and disease-risk reduction claims (typically referred to as health claims in the USA) (*Codex Alimentarius*, 2009).

Nutrient content claims characterize the nutrient profile of the food and, such characterization typically depends on the amount per serving compared to an established reference value for the nutrient. Such reference values are referred to as Nutrient Reference Values (NRV) by Codex or as Daily Values (DV) in the USA. For example, according to the Codex guidelines on the use of nutrition and health claims, a serving should provide 15% of the NRV to claim that the food is a source of a specific vitamin or mineral and to be high in the nutrient would require twice the amount (*Codex Alimentarius*, 2009). The % of NRV to qualify for a nutrient content claim varies among governments. NRVs and DVs have been established for essential nutrients as well as for certain food components associated with chronic disease risk (e.g. saturated fatty acids or dietary fiber). The information on the % of the Daily Value is useful to understand the contribution of a food to the total daily value set for the nutrient or food component. Education programs in the USA emphasize that 20% or more of the DV is considered a lot of the nutrient or food component, whereas 5% or less of the DV is considered a small amount. For nutrients or food components to limit (e.g. sodium, added sugars, saturated fats), the selection of foods with a high DV should be limited.

A comparative claim compares the nutrient content of 2 or more foods. As an example, in the USA a product that claims to have a reduced sodium content should have its sodium content reduced by 25% of the relevant comparison product. Because nutrient content claims and comparative claims are profiling foods in relation to recommended intakes, such claims should be authorized for use in labeling so that consumers are provided with reliable, consistent information when such claims are made. In addition, to establishing appropriate reference values, regulations for nutrient content claims can also require certain disclosure statements regarding the overall nutrient profile of the product. For example, a dairy product that is high in calcium may need to refer consumers to Nutrition Facts if the product is also high in total fat or saturated fats.

Claims about maintaining health or the structure and function of the body characterize the role of the nutrient in metabolism, growth and development, or typical functions of the body. The European Food Safety Authority (EFSA) in the European Union reviews such claims before they can be used in food labeling (*Health and Nutrition Claims*); however, in the USA manufacturers can use such claims without prior approval but all statements must be truthful, not misleading, and be substantiated. In addition, such claims cannot imply a role in reducing risk for disease.

Disease-risk reduction claims characterize the relationship between a substance, which can be a food, nutrient, or food component, and the reduced risk of developing a disease or health-related condition. Such claims are not intended for curing, treating, mitigating, managing, or preventing disease but about reducing risk. In countries that allow the use of disease-risk reduction claims, such claims are authorized after a scientific review of relevant evidence and conditions, including the food's nutrient profile, may be set on the type of products that can use the claim in labeling (*US Food and Drug Administration*, 2009).

### Supplemental nutrition information

In recent years, several government authorities have developed nutrition information schemes that are used on the principal display panel (PDP) of food packages and are referred to as front-of-pack labeling (FOPL). The rationale for labeling on the PDP is to make certain types of information quick to find and balance other types of promotional information on the PDP. Generally, this type of labeling is most useful when it is used to supplement the nutrient declaration, which provides a more complete summary of the nutritional profile of a product and can be used to verify information on the PDP (*Schneeman*, 2020).

The schemes for FOPL fall into several categories, which include interpretive systems that are nutrient-specific such as traffic lights or stop signs; declaration of nutrients, including the % DV on the PDP such as the Facts-up-Front system developed by industry groups; summary indicator systems such as Nutri-score that is based on both nutrients to limit and foods and nutrients to encourage; hybrid systems such as the Health star rating that combines a summary score with nutrient declaration on the PDP; and endorsement logos such as the Keyhole symbol developed by Nordic countries or the Heart Tick from Heart Associations/Foundations in several countries. The nutrient-specific systems typically were developed to provide warnings about excess amount of nutrients or food components to limit such as added sugars, sodium, *trans* fatty acids, and saturated fats. Examples of these systems include the traffic lights developed in the UK, the stop sign symbol used in Chile (*Reyes et al.*, 2019), or the Canadian food package symbol for saturated fats, sodium and/or sugars. Other systems are designed to provide an overall score or profile of the food product that reflects nutrients and food components to limit as well as nutrients and food groups that are recommended to get enough of. Examples of these systems include the Healthy Star rating developed by Australia and New Zealand or the Nutri-score developed by France. Endorsement schemes are used to indicate that the product conforms to a specific nutrient profile to bear

the logo, such as the Nordic keyhole system. A challenge for these systems is to determine the approach for calculating the content of nutrients or food components within the food to enable meaningful comparisons among products. Some systems are based on a typical serving size, while other systems calculate the content per 100 g. For typical serving size to provide an accurate estimate for labeling purposes, standards for the amount customarily consumed need to be available. Presenting information per 100 g has the potential to be misleading if actual amounts of the food consumed are much smaller than 100 g (Visioli et al., 2022).

Because supplemental nutrition labeling systems have different purposes, effort is needed to design and implement an approach that is most useful within the targeted audience. In addition, education is useful so that consumers understand how to identify the supplemental labeling system as distinct from promotional material on the PDP and interpret the symbols appropriately. Many of these systems are useful when consumers are trying to compare the nutritional qualities within a category of products (e.g. comparing breakfast cereals) and some systems are used to indicate foods that should be limited in the overall dietary pattern (e.g. sugar-sweetened beverages). For additional details see the websites provided below, Schneeman (2020) and Institute of Medicine of the National Academies (2012).

## Conclusion/outlook

The regulation and standardization of labeling requirements provides valuable tools for consumers to make more informed decisions on the purchase and appropriate use of prepackaged foods. Nutrition labeling is an example of information that consumers generally cannot obtain unless it is provided by the manufacturer or distributor of the product and is essential for consumers to manage the healthfulness of their food choices. The labeling of food products has been expanding and now includes additional information that relates to various consumer preferences such as sustainability, use of genetically engineered ingredients, agricultural practices (organic), the concept of “natural” as well as practices such as kosher, halal, or vegan. In all cases such labeling must be truthful and not misleading and conform to government standards or regulations, where they have been promulgated. The promulgation of regulations specific to a certain representation or claims in labeling is more likely to occur when a framework is needed to provide clear, well-defined standards for use of terms to avoid misuse that becomes misleading for consumers. For example, in the USA, regulations now exist for designating a product as organic and or when a declaration on the use of genetically engineered ingredients is required.

Nutrition labeling has primarily focused on information related to the content of nutrients and food components that are essential or related to risk of chronic diseases. However, food-based dietary guidelines emphasize the importance of dietary patterns and food groups to meet these nutritional needs. Certain supplemental nutrition labeling schemes incorporate recommendations for food groups into their scoring algorithms (e.g. Healthy Star or Nutri-Score); however an overall score may not provide specific information on how the product contributes to food group recommendations at the point of purchase. Developing a labeling system to communicate the contribution of a product to meeting food group recommendation in dietary patterns could assist consumers in matching product information with food-based dietary guidelines.

### Key points

- Food insecurity affects hundreds of millions of households across world regions
- Poverty and social injustice are the main underlying factors driving the food insecurity pandemic
- Food insecurity has a strong negative impact on the physical and mental health of people
- Food insecurity has a strong negative impact on planetary health
- Household food insecurity is strongly linked with household water insecurity
- Addressing food insecurity is central to the ability of nations to meet the Sustainable Development Goals by 2030
- Experience-based food insecurity scales should be used more to track food insecurity globally

### Glossary

**Cost of the diet** A linear programming tool that estimates the lowest cost diet that meets all nutrient requirements of individuals of a household, using data on which foods are locally available, their nutrient content and their price. This cost estimate can be compared to income or expenditure data to determine which proportion of the population would be able to afford an adequately nutritious diet.

**Dietary diversity** Extent to which the diet includes foods from different food groups. The greater the diversity, the more likely the diet meets nutrient requirements

**Food security** When all people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life.

**Livelihood** A livelihood comprises the capabilities, assets (stores, resources, claims and access), and activities required for a means of living

**Malnutrition** Malnutrition is a broad term commonly used as an alternative to undernutrition but technically it also refers to “overnutrition”. Please refer to definition of undernutrition below. People are also malnourished if they are overweight or obese as a result of consuming too many calories, while intake of vitamins and minerals may still be inadequate. Overweight and obesity increase the risk of cardiovascular disease and diabetes

**Undernourishment** The number of undernourished people is estimated at national level, and aggregated at global level, and represents the number of people that have to survive on less than 2100 kcal day<sup>-1</sup>, which is estimated from food balance sheets (food production minus export plus import)

**Undernutrition** Undernutrition is defined as the outcome of insufficient food intake and repeated infectious diseases. It includes being underweight for one's age, too short for one's age (stunted), thin for one's height (wasted) and deficient in vitamins and minerals (micronutrient malnutrition)

**Window of opportunity** The first 1000 days of a child's life, from conception until 24 months of age, during which ensuring appropriate nutrition is essential to enable the child to have the best start in life and develop to its full potential

## Introduction

Food security is a very important determinant of whether people can lead an active and healthy life, because it determines their access to foods required to meet nutrient needs. This article reviews the definition of food security, the consequences of food insecurity, the indicators used to measure food security depending on the level at which it is studied, how it links to nutrition and health as well as to livelihoods, what it is affected by, the consequences of food insecurity, and measures that are taken to mitigate these causes and consequences. Special attention will be paid to why it is important that food security assessments also include an estimate of the extent to which nutrient needs are being met, and the approaches and indicators, which can be used for that purpose.

## Framework and definitions

### Food security

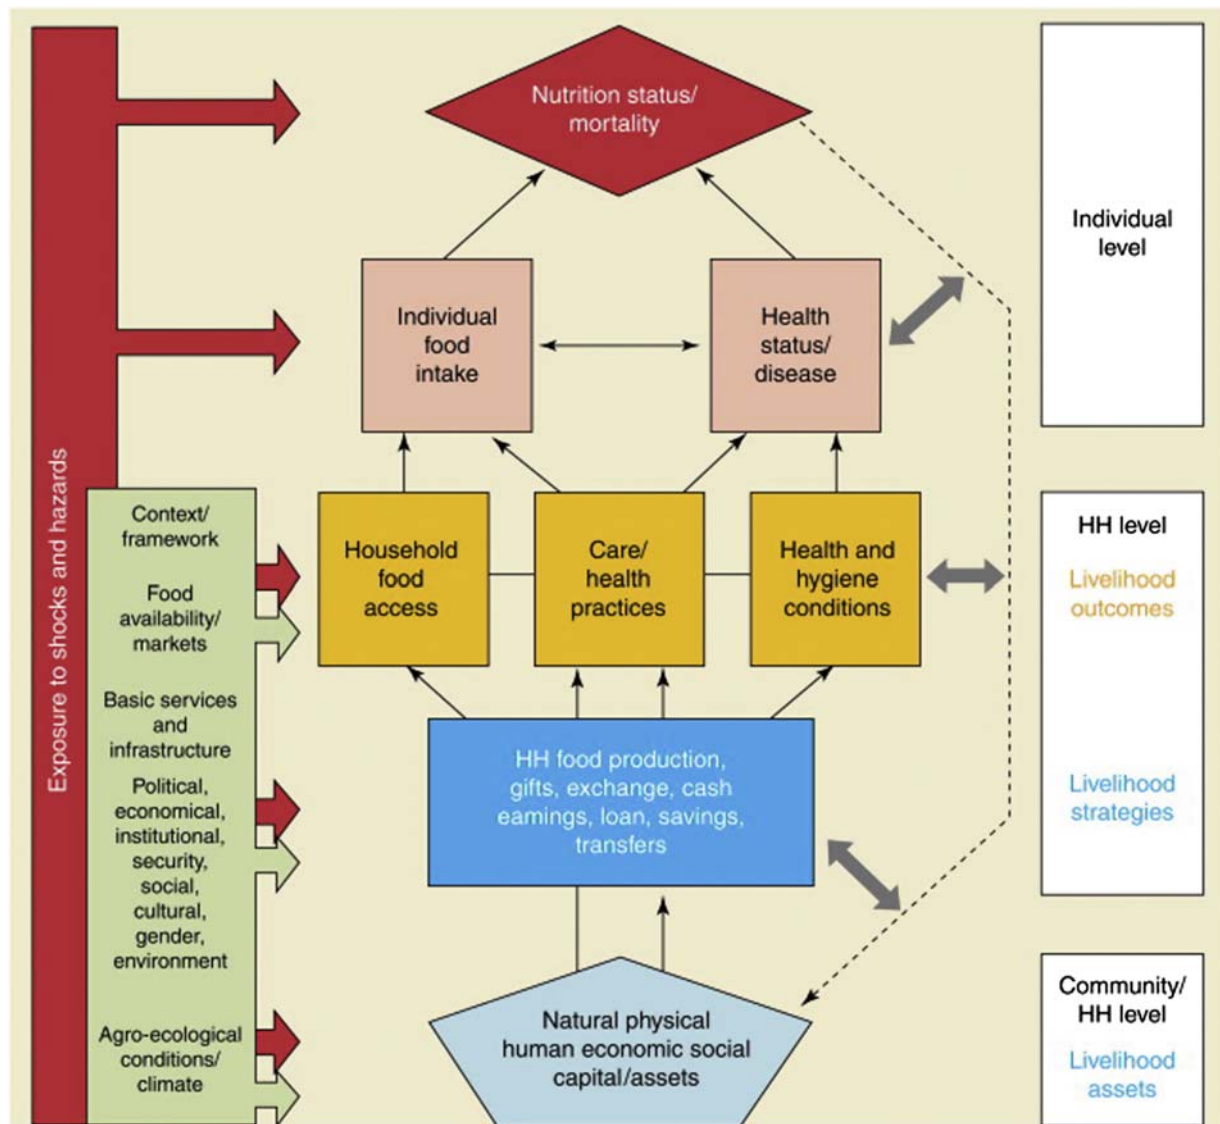

Food security was defined, at the World Food Summit in 1996, as “when all people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life”.

Food insecurity affects hundreds of millions of households across world regions. Poverty and social injustice are the main underlying factors driving the food insecurity pandemic Food insecurity has a strong negative impact on the physical and mental health of people and of the planet (Pérez-Escamilla, 2017; Pérez-Escamilla et al., 2020b).

Food security has many dimensions and can be studied at different levels. The different dimensions include food availability, access to, and utilization of food. Recognizing the fact that food security is not constant the stability of the food supply is also an important dimension of food security. The utilization of food refers to what happens with food at the household level, i.e., allocation among different members, preparation, and utilization by the body, i.e., digestion, bioavailability, etc., which is closely linked to health status as well as age and physiological status. The different levels at which food security can be studied include individual, household, community, district, province, country, and region. Depending on the level of focus, different dimensions, aspects, and indicators can be used.

### Meeting nutrient needs

It is important to note that the definition makes explicit reference to safe and nutritious food to meet dietary needs, i.e., meeting every individual's nutrient requirements for leading an active and healthy life. Whether an individual's nutrient requirements are met depends on food consumption as well as on disease, as the latter increases nutrient needs and also affects the way nutrients are metabolized and used by the body.

**Fig. 1** WFP Food and Nutrition Security Conceptual Framework (based on UNICEF conceptual framework for causes of malnutrition and DFID sustainable livelihoods framework). Reprinted with permission from WFP (2009).

The United Nations Children's Fund (UNICEF) framework for causes of malnutrition is focused on the individual level (see Fig. 1 in which it has been integrated). It specifies that direct causes of malnutrition are food consumption and health or disease; underlying causes are access to food, caring practices, hygiene conditions, and health-care services; basic causes are human, economic, and organizational resources and controls, including education, governance, etc. Whereas access to food determines food consumption and thus nutrient intake, and hygiene conditions and health-care services determine health and disease and thus nutrient needs and utilization, caring practices affect how accessible food is used, i.e., food distribution among household members, food preparation, feeding frequency, breastfeeding practices, and how health-care services are utilized. Simply put, caring practices reflect the choices made from among the options available to the individual or the household, and are also influenced by knowledge and empowerment.

### Food security as a component of livelihood security

The United Nations World Food Program (WFP) Food and Nutrition Security Conceptual Framework proposed in 2009 (see Fig. 1) combines the UNICEF framework and the United Kingdom Department for International Development (DFID) Sustainable Livelihoods Framework, because food security is closely linked to household livelihood security, which can be described as the ability of a household to meet the basic needs of its members. Livelihood can be described as comprising the capabilities, assets (stores, resources, claims, and access), and activities required for a means of living. A livelihood is sustainable when it can cope with

and recover from stress and shocks, maintain or enhance its capabilities and assets, and provide sustainable livelihood opportunities for the next generation; when it contributes net benefits to other livelihoods at the local and global levels in the long and short term. The livelihood unit is usually the household. Household livelihood security is defined as adequate and sustainable access to income and resources to meet basic needs. Basic needs include food, proper nutrition, clean water, health and health facilities, economic and educational opportunities, housing, physical safety, and time for community participation and social integration. Households use six main tangible and intangible forms of capital, i.e., human (skills, knowledge, health, and nutritional status), financial (income, credits, savings, and liquid assets), natural (crops grown), physical (assets and land), social (support networks), and political (participation in community decisions, power).

As shown in the framework, we distinguish livelihood assets, strategies and outcomes, and the outcomes that affect an individual's food consumption (i.e., nutrient intake), health or disease state (i.e., nutrient needs and nutrient utilization), and care and health practices (i.e., choices from among available options).

Policies, institutions, and organizations affect livelihood assets and strategies. Policies can be split into the following categories: macroeconomic policies, i.e., measures aimed at stabilizing an economy; social policies, which aim to protect and improve health, nutrition, education of the disadvantaged; sectoral policies that focus on specific areas within an economy, such as agriculture, health, water, sanitation, and environment. At the interface between these policies and households are the institutions and organizations that implement or affect the policies, i.e., the state, formal civil society, informal civil society, and the private sector.

Shocks and hazards, which can range from death of a family member to increased food prices, droughts, floods or armed conflict, can affect different and multiple dimensions of the framework, with different intensity and for a variable period of time.

Thus, the Food and Nutrition Security Conceptual Framework shows how many different factors affect food availability, food access, food utilization and stability of food supplies, which together determine food security, and how food security in turn is a component and function of livelihood security, which is a function of livelihood assets and strategies and is affected by both macro- and microlevel factors. It is also important to note the rich multidisciplinary nature of the topic of food security.

## Indicators and classification of food security status

The level at which food security is of interest, i.e., household, community, district, or country, determines which factors should be assessed.

### International food security phase classification (IPC) for countries

For example, the IPC provides guidance to countries for classifying a country's regions and subregions. It emphasizes that as much as possible existing and relevant information should be used, and that there is no fixed set of indicators and methods to refer to.

**Table 1** shows the five stages of food security that are distinguished in this IPC classification together with proposed indicators and their cut-offs for the different stages. Some indicators reflect context and livelihood assets, such as civil security, "structural" (underlying hindrances to food security), livelihood assets/capital; some reflect vulnerability, such as hazards, destitution/displacement; others reflect underlying causes of malnutrition such as water access/availability, food access/availability, dietary diversity; the top ones reflect outcome, i.e., crude mortality rate ( $\times/10,000 \text{ day}^{-1}$ ), disease, acute malnutrition (wasting), and stunting. Some of these apply to the national or subnational situation (civil security, hazards, and structural hindrances), whereas others have to be collected from individuals (nutritional status) or households (food and water access). This means that information from different sources needs to be gathered, reviewed, and classified in order to arrive at a food security classification of a country's regions or subregions.

The IPC partners have substantial experience with the collection and interpretation of these indicators and their classification. Here, we will focus on the aspects of food security that are most directly linked to food intake and nutrient adequacy, because these are most closely linked to the outcomes, nutritional status, and health.

### Indicators of nutrient intake at the national, household, and individual level

Nutritional status and health are the ultimate outcomes of food security that are very much of interest because they determine human capital at present and in the future. It is very important to recognize the fact that foods are a source of nutrients and that the human body requires approximately 40 different nutrients for growth, development, and health. Reaching an adequate intake for each of these nutrients requires consumption of a diverse diet, including plant and animal source foods as well as fortified foods. Also different groups in the population require these nutrients in different amounts, depending on their age (growth spurts), physiological status (pregnancy and menstruation), health, and physical activity.

The indicators of food intake in the IPC classification are food access/availability, expressed as  $\text{kcal capita}^{-1} \text{ day}^{-1}$ , and dietary diversity, expressed as deficient or sufficient. These two specific indicators are usually collected either at the household level or, in the case of  $\text{kcal capita}^{-1} \text{ day}^{-1}$ , estimated at the national level. The latter indicator is also used for Millennium Development Goal no. 1, i.e., the proportion of the population that is undernourished, which presents the proportion of the population that has to survive on less than  $2100 \text{ kcal capita}^{-1} \text{ day}^{-1}$  and is estimated from food balance sheet data (i.e., total kcal available from food production and

**Table 1** International food security phase classification reference table.

Phase classification		Key reference outcomes current or imminent outcomes on lives and livelihoods. Based on convergence of direct and indirect evidence rather than absolute thresholds. Not all indicators must be present for classification.	
1	Generally food secure	Crude mortality rate	<0.5/10,000/day
		Acute malnutrition	<3% (w/h < -2 z-scores)
		Stunting	<20% (h/age < -2 z-scores)
		Food access/availability	Usually adequate (>2100 kcal ppp day), stable
		Dietary diversity	Consistent quality and quantity of diversity
		Water access/avail.	Usually adequate (>15 L ppp day), stable
		Hazards	Moderate to low probability and vulnerability
		Civil security	Prevailing and structural peace
		Livelihood assets	Generally sustainable utilization (of 6 capitals)
2	Moderately/borderline food insecure	Crude mortality rate	<0.5/10,000/day; U5MR < 1/10,000/day
		Acute malnutrition	<3% but <10% (w/h < -2 z-scores), usual range, stable
		Stunting	<20% (h/age < -2 z-score)
		Food access/availability	Borderline adequate (2100 kcal ppp day); unstable
		Dietary diversity	Chronic dietary diversity deficit
		Water access/avail.	Borderline adequate (15 L ppp day); unstable
		Hazards	Recurrent, with high livelihood vulnerability
		Civil security	Unstable; disruptive tension
		Coping	"Insurance strategies"
		Livelihood assets	Stressed and unsustainable utilization (of 6 capitals)
		Structural	Pronounced underlying hindrances to food security
3	Acute food and livelihood crisis	Crude mortality rate	0.5–1/10,000/day, U5MR1–2/10,000/day
		Acute malnutrition	10–15% (w/h < -2 z-score), >than usual, increasing
		Disease	Epidemic; increasing
		Food access/availability	Lack of entitlement; 2100 kcal ppp day via asset stripping
		Dietary diversity	Acute dietary diversity deficit
		Water access/avail.	7.5–15 L ppp day, accessed via asset stripping
		Destitution/displacement	Emerging; diffuse
		Civil security	Limited spread, low intensity conflict
		Coping	"Crisis strategies"; CSI > than reference; increasing
		Livelihood assets	Accelerated and critical depletion or loss of access
4	Humanitarian emergency	Crude mortality rate	1–2/10,000/day, >2x reference rate, increasing; U5MR > 2/10,000/day
		Acute malnutrition	>15% (w/h < -2-z score), >than usual, increasing
		Disease	Pandemic
		Food access/availability	Severe entitlement gap; unable to meet 2100 kcal ppp day
		Dietary diversity	Regularly 3 or fewer main food groups consumed
		Water access/avail.	<7.5 L ppp day (human usage only)
		Destitution/displacement	Concentrated; increasing
		Civil security	Widespread, high intensity conflict
		Coping	"Distress strategies"; CSI significantly > than reference
		Livelihood assets	Near complete and irreversible depletion or loss of access
5	Famine/humanitarian catastrophe	Crude mortality rate	>2/10,000/day (example: 6000/1,000,000/30 days)
		Acute malnutrition	>30% (w/h < -2 z-score)
		Disease	Pandemic
		Food access/availability	Extreme entitlement gap; much below 2100 kcal ppp day
		Water access/avail.	<4 L ppp day (human usage only)
		Destitution/displacement	Large scale, concentrated
		Civil security	Widespread, high intensity conflict
		Livelihood assets	Effectively complete loss; collapse

Reprinted with permission from Integrated Food Security Phase Classification, 2008. IPC User Guide, Version 1.0. The IPC in the Central and Eastern Africa Region Project. Nairobi, FAO. Available from [www.ipcinfo.org](http://www.ipcinfo.org) (accessed on January 17, 2011).

net import or export) compared to total population size. (The other indicator for MDG1 is underweight, i.e., the proportion of children aged 0–59 months that have a weight that is too low for their age (<–2 SD of the median of the reference population)).

However, nutrient needs are different for different individuals. For that reason, adequacy of food intake, in terms of energy (kcal), dietary diversity, and if possible also specific nutrients (such as micronutrients, protein, and fat), are best collected at the individual level and expressed per population group, in order to identify which groups are most at-risk from a nutritional point of view. However, collecting these data at the individual level is very labor intensive and requires detailed food composition

data. Furthermore, there are several ways of collecting and interpreting these data. Therefore, very often outcome indicators are collected at the individual level, i.e., nutritional status and health, together with one or more household level indicators of access to food and possibly dietary diversity.

### Experience-based food insecurity scales

Experienced-based food insecurity scales have been found to be helpful for policy making (Pérez-Escamilla, 2012; Pérez-Escamilla et al., 2020a). The first scale of this nature, the US Household Food Security Survey Module (USHFSSM) was developed and applied by the US Government for the first time in 1995 (Wunderlich and Norwood, 2006) and since then it has been continuously used to monitor household food insecurity in the country. This module is based on an experience-based scale that asks a person that is knowledgeable of the food insecurity situation in the household responds to 18 questions (USDA, 2012). The issues addressed through these questions range from household members being worried about running out of food, to household members sacrificing dietary quality all the way to experiencing over hunger (i.e., going for a whole day without eating) as a result of lack of economic access to foods. Questions are asked in reference to a time period such as the 4 weeks, 3 months or 12 months preceding the survey and some of them are specific to the minors in the household. The successful experience with the USHFSSM led to its adaptation and validation across countries resulting in the Household Food Insecurity Access Scale (HFIAS) (Coates et al., 2007), Brazilian Food Insecurity Scale (EBIA) (Pérez-Escamilla et al., 2004), The Latin American and Caribbean Food Security Scale (ELCSA) (Comité Científico de la ELCSA, 2012), and the Food Insecurity Experience Scale (FIES) (Ballard et al., 2013), among others. In the next section the HFIAS is described in detail as an example of how experience-based scales look like.

### Household Food Insecurity Access Scale

Food and Nutrition Technical Assistance (FANTA) has developed a Household Food Insecurity Access Scale (HFIAS) that builds on the experience with the US Household Food Security Module and the Radimer/Cornell scale. It has been well validated and is increasingly being used. Table 2 shows the nine questions asked of households, which range from having experienced a small degree of food insecurity, i.e., worrying about not having enough food, to not having had any food for a consecutive 24 h period. The reference period is the past 4 weeks and each question is followed by a question about how frequently this specific experience occurred in the previous 4 weeks. This scale thus assesses access to food, mainly in terms of meeting self-perceived adequacy of quantity and whether there was deterioration from what the household is used to. It has recently evolved to a smaller subset of questions that are used to define the severity of household hunger (Household Hunger Scale). It is important to note that neither of the scales inquire about dietary diversity or individual foods consumed, nor do they estimate individual nutrient intake.

**Table 2** Questions of the FANTA Household Food Insecurity Access Scale.

No.	Question
1	In the past 4 weeks, did you worry that your household would not have enough food?
2	In the past 4 weeks, were you or any household member not able to eat the kinds of foods you preferred because of a lack of resources?
3	In the past 4 weeks, did you or any household member have to eat a limited variety of foods due to a lack of resources?
4	In the past 4 weeks, did you or any household member have to eat some foods that you really did not want to eat because of a lack of resources to obtain other types of food?
5	In the past 4 weeks, did you or any household member have to eat a smaller meal than you felt you needed because there was not enough food?
6	In the past 4 weeks, did you or any household member have to eat fewer meals in a day because there was not enough food?
7	In the past 4 weeks, was there ever no food to eat of any kind in your household because of a lack of resources to get food?
8	In the past 4 weeks, did you or any household member go to sleep at night hungry because there was not enough food?
9	In the past 4 weeks, did you or any household member go a whole day and night without eating anything because there was not enough food?

### Dietary diversity

Dietary diversity provides an indication of the potential adequacy of nutrient intake, because a diet that is sourced from a greater variety of food groups provides a wider range of nutrients (e.g., carbohydrates, fat, protein, fat soluble vitamins, water soluble vitamins, minerals, essential fatty acids, sulfur containing amino acids, etc.).

Methods for assessing dietary diversity ask how frequently, usually during the previous 7 day or 24 h, foods from different food groups were consumed. The number of food groups can range from 7 to 15, for example staples, lentils and legumes, oils and fats, leafy vegetables, colored vegetables, fruits, dairy products, eggs, meat and poultry, fish, and sugary foods and drinks.

These answers can be processed and used in different ways. For example, when the questions refer to a 7 day period, the total number of days that different food groups are consumed can be added together, thus if there are nine food groups, the total score would be  $9 \times 7 = 63$ , and households that consumed three foods every day would have a score of 21. One can also decide to count the food groups that provide more nutrients than just energy (i.e., in the above example leave out staples, oils and fats, and sugary foods and drinks), or calculate a score that reflects just the frequency of consumption of particular food groups, such as animal source foods. For categorizing the obtained scores into different levels of dietary diversity, knowledge of the local situation is required and preferably a relationship should have previously been demonstrated between differently derived scores and nutritional status, for example of children under 5 years, so that the best cut-offs can be chosen.

Whereas good correlations have been shown between household dietary diversity and household expenditure on different food categories as well as between household dietary diversity and children's nutritional status (stunting and micronutrient deficiencies), this relationship has not been established for every population from which dietary diversity data are being collected. This means that part of the use and interpretation of dietary diversity data has to refer to findings in other settings and be based on knowledge and judgment of the local situation.

### Common pitfalls of analyzing causes of malnutrition

As shown above, food security is generally assessed at the household level or higher, i.e., at the community, subregion or country level, whereas its main outcome, nutritional status, is assessed at the individual level. Depending on which indicators are used to assess food security, the conclusion that food security is not a problem whereas stunting, for example, affects 30% of the children under five, is very common. In these cases, the cause of malnutrition is then often sought in the nonfood-related factors of the framework for causes of malnutrition, i.e., hygiene, health and caring practices, rather than in a deficient intake of specific nutrients. This reasoning fails to recognize that as long as the food security indicator does not assess adequacy of nutrient intake, but just focuses on access to food, which can be any food, "food" may still be the main problem causing malnutrition.

For this reason it is very important to include dietary diversity as an indicator of food security, and preferably not only at household level, but also for specific groups such as children under five, and to analyze the data in such a way that it is a good proxy for nutrient adequacy of the population group of interest. For example, in the case of under fives, they require animal source foods, including dairy foods, as well as fortified foods in their diet in order to meet their nutrient requirements, especially of bioavailable minerals and type II nutrients that are important for growth. The intake of foods from these groups should thus be specifically assessed and reported.

Another way of assessing whether food consumption could possibly meet nutrient requirements is through linear programming. Based on availability of foods, their nutrient composition and their price, the lowest cost diet that would meet all nutrient requirements of a family composed of different members, e.g., a child younger than 24 months, a school-age child, a lactating mother, a father and a grandparent, can be calculated. This price can then be compared to income or food expenditure data in order to determine what proportion of the population could in theory afford a diet that meets all nutrient requirements. It is important to note that in practice, it is likely that a larger proportion does not meet all the nutrient requirements, because food choices are also affected by cultural practices and taste preferences that may not necessarily concur with best choice from a nutrient content point of view. This method, which is also known as the Cost of the Diet tool, has been developed by Save the Children UK and is known as the Cost of the Diet tool.

Knowing the causes of malnutrition is a must for being able to address it. Thus, when the prevalence of malnutrition is high, it is important to assess the level of food insecurity, including dietary diversity, and possibly also whether households could in theory afford a diet that could meet the nutrient requirements of all its members at the lowest cost. In addition to these factors that largely determine food consumption and hence nutrient intake, factors that affect nutrient needs, i.e., health or disease, as well as caring practices, which affect the choices made from among the possibilities available, are also important.

### Factors affecting food security

The conceptual framework shows that many different factors can affect livelihoods and food security, as well as the degree of vulnerability to changes thereof. Factors that affect food availability generally have to do with climate change, seasonality affecting crop production, or large-scale political changes such as wars. Food access is to a large extent determined by purchasing power, which is a function of income and food prices as well as of prices of other commodities such as fuel (for cooking and transport). The stability of food supplies is usually the first aspect of food security that changes and can be regarded as an early warning sign that livelihoods

and food security status are likely to deteriorate. Last but not least, food utilization is affected by household dynamics (intra-household distribution), behavioral factors, and health or disease (utilization by the body), both of which are less likely to change unless household structure and livelihood change substantially.

Relatively new and emerging challenges for food security include climate change and increasing natural disasters (affecting food availability) as well as high and fluctuating food prices and the global financial crisis (affecting access to food) and rapid urbanization (reliance on cash economy, smaller social networks to assist in coping with shocks, etc.).

With the food price increase in 2008, the global economic crisis in 2009, and the rising food prices in 2011, it is important to determine in which countries the population is at greatest risk of suffering from food insecurity, and to identify measures for mitigating the causes and consequences in the best possible way. It has been found that countries that were more linked to the global economy, more dependent on import and where a large proportion of the population were net-buyers of food, were more at-risk.

It is now clear that household food insecurity is strongly linked with household water insecurity and that both need to be addressed through better coordinated efforts (Young et al., 2021).

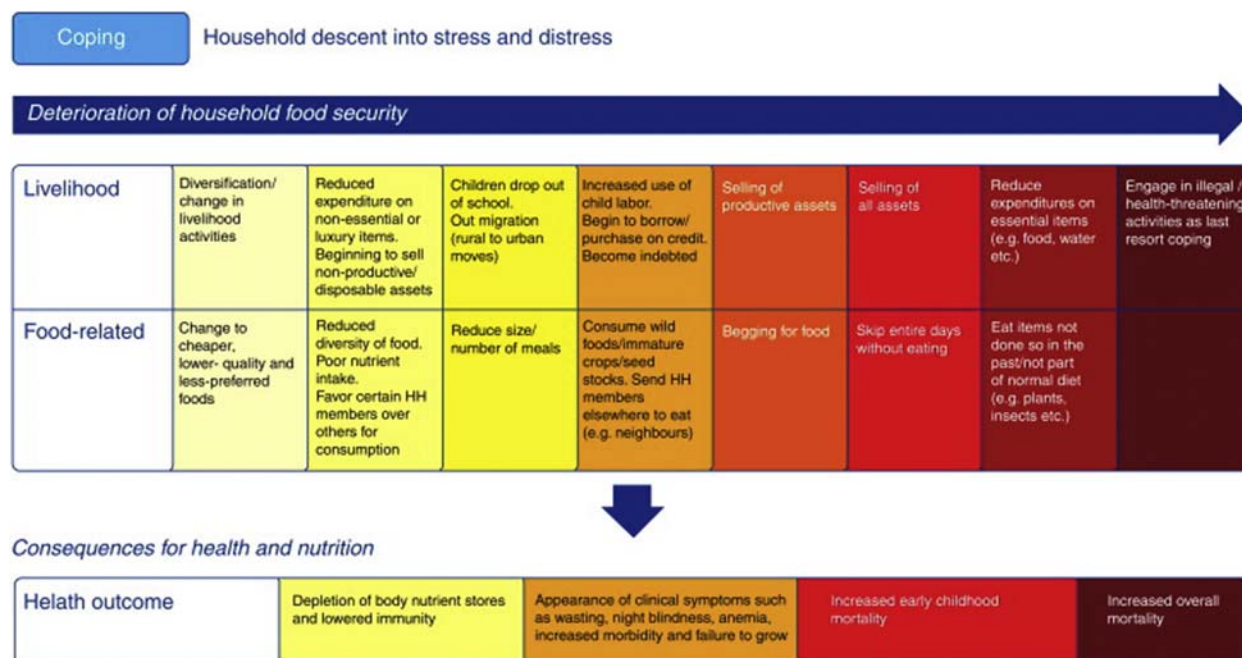

## Consequences of food insecurity

The consequences of food insecurity are several as it has a strong negative impact on and is affected by the physical and mental health of people and of the planet (Pérez-Escamilla, 2017). The Covid-19 pandemic clearly illustrated the complex syndemic that food insecurity is a part of (Pérez-Escamilla et al., 2020b).

Very importantly, due to decreased dietary diversity and also quantity, meeting nutrient needs becomes more and more difficult and therefore nutritional status and health deteriorate. This has short-term consequences, such as increased morbidity and mortality, as well as long-term consequences because an entire generation of young children can be affected for the rest of their lives.

The latter is due to the fact that the window of opportunity for optimal development of a young child is concentrated within its first 1000 days of life, starting from conception until 24 months of age. When the child is undernourished in this period of his or her life, he or she is at increased risk of morbidity and mortality, and later in life of delayed school enrollment, poorer school performance including earlier drop-out, lower income earning potential, and higher risk of obesity and chronic disease including diabetes, cardiovascular disease, and obesity.

Food insecurity also has consequences for other livelihood priorities, such as education of children, health-care seeking behavior, asset ownership, etc., which in-turn also relates to vulnerability to shocks. Fig. 2 shows consequences for livelihood and food consumption when households descend into stress and distress, and the concurrent health consequences.

**Fig. 2** Changes in livelihood, food selection and consumption, and nutritional status and health outcome when households descend into stress and distress. Reprinted with permission from Klotz, C., de Pee, S., Thorne-Lyman, A., Kraemer, K., Bloem, M.W., 2008. Nutrition in a perfect storm: why micronutrient malnutrition will be a widespread health consequence of high food prices. *Sight Life Mag.* 2, 6–13.

Health-care seeking and treatment adherence behaviors that are particularly affected by food insecurity are those of HIV/AIDS and tuberculosis, as populations affected by both overlap geographically. Firstly, these diseases are likely to increase food insecurity as household members fall ill and are hence not able to contribute to food production or earn an income. Secondly, their food insecurity affects diagnosis, treatment uptake and treatment adherence because that incurs costs, for example for transport, which hence competes with other priorities such as buying food for the family. Thirdly, some side effects of treatment such as nausea can be overcome by consumption of more palatable foods, which requires access to a variety of foods. Fourthly, recovery from malnutrition, which is what many people present with as they seek a diagnosis and enroll for treatment, requires treatment of the HIV and opportunistic infections as well as consumption of nutritious foods that need to be acquired.

### Mitigating the consequences of food insecurity

Measures to mitigate food insecurity can be several and depend on the causes, on who is affected and how, and on what changes can be realized in the particular context. Depending on whether the deterioration of food security is related to food availability, access, utilization or stability of supplies, different measures can be taken.

The main underlying driver for food insecurity is poverty and social injustice (Pérez-Escamilla, 2017) through diverse mediating factors (WFP, 2009). If the problem is related to food production, i.e., food availability, large-scale multiyear agricultural measures may be required, for example to mitigate impact of climate change, increase yields, improve irrigation, develop storage, transport and markets for produce, etc. Although this is often focused on staple crops, there can also be a component focused on dietary diversity and household level food production including vegetables, fruits, small livestock, community fish ponds, etc. These types of interventions are, in addition to being income-generating, also more nutrition-oriented, especially when combined with an education component to emphasize the importance of consuming a diverse diet.

Food access problems are typically experienced by households that largely depend on cash purchases, and are thus vulnerable to changes in income and changes in food prices. Urban households as well as rural households that are net-buyers because they do not produce enough food throughout the year were hit hardest by the recent high food prices and the global financial crisis. They faced lower or loss of income, increased food prices, lower subsidies or higher taxes on food and fuel, and also reduced public spending on health, water and sanitation.

Mitigating these kinds of consequences can either be at the “blanket” level, i.e., by reducing prices, or removing tax, for specific staple foods (bread and maize), which apply to everyone, or they can target the most vulnerable, for example through safety-net programs that provide free or subsidized foods to households that are identified to be most in need. Such identification can for example be done through self-selection, i.e., participation in public work programs in return for which a basic food supply is provided, or through applying specific selection criteria such as female- or child-headed households, income below a percentage of the minimum wage, etc. The assistance provided can be in the form of food, vouchers for food, fuel or transport, or cash. Depending on the context, one or the other may be more suitable.

However, because of the far-reaching consequences of food insecurity and poor dietary diversity on nutrition and health, food assistance for such households should not only focus on meeting caloric needs and having enough meals per day, but also on meeting nutrient needs, especially of the most vulnerable, i.e., young children and pregnant and lactating women. This may require making specific products available that can increase their diet’s content of specific nutrients. Such products can be in paste or powder form and if their aim is to improve intake of specific nutrients in addition to the prevailing, and affordable, home diet, an amount of 1–20 g day<sup>-1</sup> (i.e., up to 125 kcal day<sup>-1</sup>) should generally be sufficient.

Moving forward it is also key to ensure that household food and water security are examined together as they are strongly intertwined with each other (Young et al., 2021).

### Conclusions

In summary, food security is achieved when all people, at all times, have physical and economic access to sufficient, safe and nutritious food to meet their dietary needs and food preferences for an active and healthy life. Food security has many different dimensions, i.e., food availability, food access, food utilization and stability of food supply, and is closely linked to livelihood security, i.e., the ability to provide for the basic needs of the family such as food, shelter, clean water, education, etc. The main underlying driver of food insecurity is poverty and social injustice. The fact that food security can be studied at many different levels, from the national to household or individual level, means that the outcome of food security, i.e., nutritional status and health, and food availability and access to food are often the areas of focus. However, when a population is affected by malnutrition, and access to food seems to be in order, it is very important to determine whether nutrient needs are actually being met. This can be done by including measures of dietary diversity, nutrient intake, food expenditure and ability to afford a lowest cost diet that could meet all nutrient requirements. It would be most appropriate to refer to “Food and Nutrient Security”. Moving forward household food and water insecurity will need to be addressed simultaneously through well coordinated governance and actions.

### Key points

- Although methods for deriving intake values have progressed, they have not been implemented consistently across countries or regions; and critical data and resources needed to set intake values are not universally available, particularly to low- and middle-income countries.
- A harmonized approach to setting core intakes will enhance the availability of resources that are critical to the process and provide a consistent scientific basis for setting NRVs globally.
- A risk assessment framework is used to identify and assess indicators of nutrient adequacy or toxicity across age- and sex groups in the population.
- Nutrient intake requirements are based on a range of intake that is high enough to maintain nutritional adequacy but low enough to avoid risk of adverse health effects.
- The characteristics of chronic disease development are a primary challenge to identifying a causal relationship between exposure, and an adverse health outcome.
- Recent advances in the DRI framework provide an underpinning for harmonizing the methodological approach to deriving NRVs across population groups.
- Commitment of stakeholders to a harmonized process for deriving NRVs is essential in order to generate NRVs that are aligned to support nutrition policy, programs, and education globally.
- A harmonized approach to setting core intake values will enhance the availability of resources that are critical to the process, particularly for low- and middle-income countries, and provide a consistent science-based approach for setting NRVs globally.

### Glossary

**Lowest-Observed-Adverse-Effect-Level** The lowest level of exposure to a dietary component at which there is an adverse health effect

**No-Observed-Adverse-Effect-Level** A level of exposure to a dietary component at which there is no biologically or statistically significant increase in the frequency or severity of any adverse health effects

**Nutrient Reference Value** Nutrient-based dietary intake standards used by health professionals in planning and assessing diets for individuals and groups

**Risk assessment framework** The process used to determine nutrient intake amounts for both adequate and excessive intakes. There are four steps in the process: (1) hazard identification; (2) dose-response assessment; (3) intake assessment; and (4) risk characterization

**Uncertainty factor** A numeric factor that is applied to avoid underestimating risk due to uncertainties by introducing a margin of safety

## Introduction and historical background

In the late 1930s and early 1940s the Canadian Council of Nutrition and the US Committee on Foods and Nutrition, subsequently renamed the Food and Nutrition Board, initiated the process of developing recommendations for single nutrient intake values as a benchmark for meeting nutrient requirements to prevent deficiency diseases in the general population (McHenry, 1941; Roberts, 1940). The efforts of these two groups resulted in publication of the Canadian Dietary Standards (McHenry, 1941) and the Recommended Dietary Allowances (RDAs), respectively (NRC, 1941). Over the next several decades, the recommended nutrient intake values were revised and refined, and new values added as previously unknown nutrients were discovered. Beginning in the 1990s single nutrient values were revised to include a range of uses and applications, as well as address evolving health concerns, such as chronic disease, across population groups (IOM, 1994).

Specifically, this meant considering nutrient functioning beyond the prevention of deficiency states to include a broader role in maintaining health, and reducing risk of adverse health outcomes. Since the first nutrient reference values (NRVs) were developed, the process for deriving them has evolved to include more rigorous, transparent, and reproducible methodologies. However, while the methods for deriving intake values have progressed, they have not been implemented consistently across countries or regions; and critical data and resources needed to set intake values are not universally available, particularly to low- and middle-income countries, resulting in inconsistencies in nutrition policies, as well as across guidelines and nutrient intake recommendations across the world. A harmonized approach to setting core intake values will enhance the availability of resources that are critical to the process, particularly for low- and middle-income countries; and provide a consistent scientific basis for setting NRVs globally.

## Conceptual basis for nutrient reference values

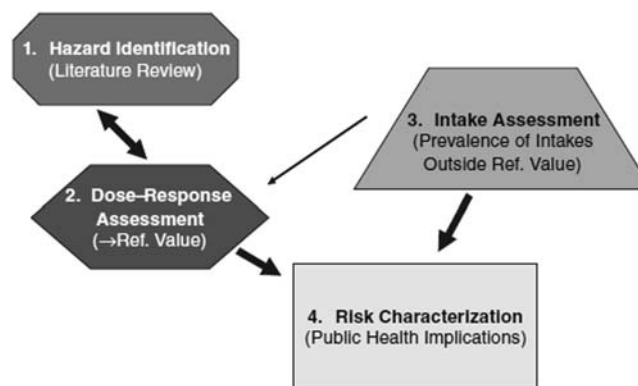

### Overview

Nutrient-based dietary intake standards, or NRVs, serve as a set of dietary intake values that are used by health professionals in planning and assessing the diets of individuals and groups. Nutrient intake standards and guidelines are a primary resource for a number of public and private institutions. Health professionals in hospitals, prisons, schools, and educational institutions use them to assist in planning healthy diets for both groups and individuals. The military uses NRVs to plan meals on- and off the field, and in procurement of food and military rations. Nutrition researchers use NRVs as a frame of reference to study association of intakes with disease states, and the food industry uses them to develop healthier products. Federal agencies at the national, state, and local levels use NRVs in the formulation of food and nutrition policy including establishing international regulatory and trade requirements, product labeling, food fortification standards, nutrition monitoring, and dietary guidance (IOM, 2003).

In the US, in the process of setting the original single-nutrient intake recommendations, the RDAs, initial consideration was given to meeting physiologic needs to prevent deficiency disease. The resulting recommendations defined intake levels for individual nutrients on the basis of essentiality. Specifically, the recommended intake levels for a given nutrient would cover requirements for a given age/sex group and also provide a margin of safety over the minimum requirements needed to prevent deficiency. Adequacy of intake was determined on the basis of amounts needed to support physiologic functioning and to support energy, maintain tissue integrity, and in the case of pregnant women, infants, and children, support growth and development (IOM, 1994; Harper, 1987). Over time, a more robust model for determining intake requirements emerged that was based on a risk assessment and intake distribution approach (IOM, 2008; Russel et al., 2009).

### Risk assessment framework

The risk assessment framework, shown in Fig. 1, indicates the steps in the process used to determine nutrient intake amounts for both adequate and excessive intakes (IOM, 2011). The first step, hazard identification, is used to identify and assess indicators of nutrient adequacy or harmfulness across age- and sex groups in the population. This step includes a review and synthesis of the evidence related to relevant health outcomes. The strength and quality of the evidence base is critical. In the synthesis of the first Dietary Reference Intakes (DRIs), NRVs developed jointly by the US and Canada, the evidence to support the derivation of intake values was based on narrative evidence reviews. Subsequent updates, however used systematic reviews as the evidence base (IOM, 2011; NASEM, 2019).

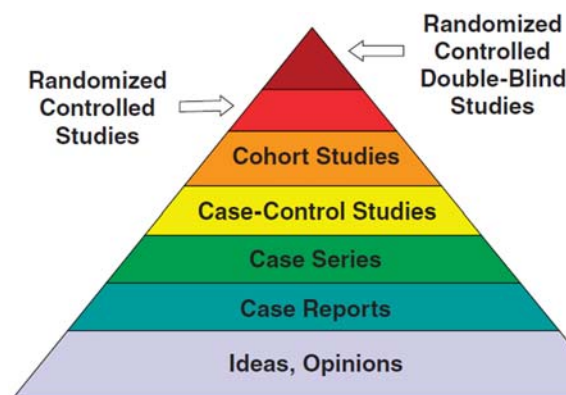

**Fig. 1** Risk assessment framework for deriving core nutrient reference values. Source: IOM (2008). Reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.

Fig. 2 shows a hierarchy of evidence, with the highest quality of evidence at the top of the pyramid. The type of evidence needed to identify and assess nutrient adequacy and harmfulness, or risk of adverse health effects, for a nutrient review, ideally, is the randomized controlled double-blind and randomized controlled trial and high-quality observational studies such as prospective cohort studies (IOM, 2008). Other observational studies, including other cohort and case-control studies can be used, although the quality of this type of evidence generally does not support development of a recommended intake, e.g. RDA. Rather, in the absence of adequate high-quality evidence, such evidence may be used to derive an estimated intake value, e.g. Adequate Intake (AI).

Systematic evidence reviews were introduced into the DRI process in the first update for calcium and vitamin D. This approach provided a more robust evidence base that allowed the calcium and vitamin D review panel to set an intake values for vitamin D for all age groups except infants. The derivation of the RDA in this case was based on new evidence for bone health (IOM, 2011). A subsequent update to the DRIs for sodium and potassium incorporated a more rigorous, transparent, and reproducible systematic review process with the application of the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) system to the evidence assessment stage. In this system, five domains: risk of bias, imprecision, inconsistency, indirectness, and publication bias, are used to rate the certainty of a given body of evidence in order to assess the level of confidence about the causality of an association between nutrient intake level and a health outcome (NASEM, 2017).

The second step in the risk assessment framework is dose-response assessment. At this step dietary intake levels needed to support derivation of core reference values, the Estimated Average Requirement (EAR) and Tolerable Upper Intake Level (UL), are determined. In some cases, however, dose-response assessment does not reflect actual nutrient levels. Calcium and iron, for example, cannot be metabolized, thus quantification of losses via blood, urine, feces, etc. is used to estimate the physiological requirement in order to derive an EAR (IOM, 2001, 1997).

When dose-response data is not available for example, in the determining the UL, a No-Observed-Adverse-Effect-Level (NOAEL) or a Lowest-Observed-Adverse-Effect-Level (LOAEL) serves as the basis for the derivation. An uncertainty factor and adjustment factor is applied to the NAOEL/LOAEL to identify the threshold for an adverse health effect. Uncertainty assessments are not precise however, and therefore an element in toxicity assessment that must be considered very carefully, a calculated uncertainty factor, could lower either the threshold for toxicity used to derive the UL or the intake level estimated to avoid a deficiency (Renwick, 2006). Uncertainty factors are usually set at 1 log unit or 0.5 log units from the NOAEL/LOAEL (IOM, 1998).

**Fig. 2** Hierarchy of evidence in systematic reviews to support the derivation of nutrient reference values. Source: IOM (2008). Reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.

The third step in the framework is intake assessment. In this step, population-based intake data and/or biomarkers of nutrient status are used to assess intake adequacy or excessive exposure levels for a nutrient. National surveys or other large population databases are generally used to obtain population-based intake data. Assuring that intake levels are sufficient requires knowledge of the dietary components that can affect nutrient bioavailability for a given population group. This is particularly important for age/sex groups with specific nutrient requirements, such as during pregnancy, infancy, and childhood. In some cases nutrient bioavailability is affected by the composition of the food source. Phytate in grains, for example, can impair mineral absorption (Gibson et al., 2010; Kim et al., 2009). Thus accurate data sources, i.e. food composition databases and population intake surveys are essential to estimating intake adequacy or excess.

The last step in the framework considers the public health consequences of not meeting an EAR/RDA or AI, and exceeding a UL. This includes determining how characteristics unique to a population age/sex group, such as body size, lifestyle, environment, or other factors, could influence nutrient requirements for that group. The risk assessment framework is advantageous in that it offers a systematic approach to the decision steps that take place over the process of deriving NRVs. Further, it supports documentation of the strength and sufficiency of the evidence and enhances transparency; and it allows for the incorporation of new and emerging scientific tools into the process (Yetley et al., 2017; Joint FAO/WHO Technical Workshop, 2005). The risk assessment framework laid the groundwork for future consideration of chronic disease endpoints in the process of deriving NRVs.

### Nutrient intake distribution model

Nutrient intake requirements are grounded in a model based on a distribution of intake levels that are high enough to maintain nutritional adequacy but low enough to avoid risk of adverse health effects. The DRIs are based on a distribution curve of observed levels of intake, represented graphically in Fig. 3 (IOM, 2000). In this model, the EAR, an estimate of the intake requirement that is adequate for 50% of a population age/sex group, is derived from evidence gathered and assessed in the risk assessment process described above. On the distribution curve, the RDA is set at 2 standard deviations above the EAR. This is an amount presumed to provide sufficient intake to cover at least 97.8% of the intake requirements for a given age/sex group in the population. When sufficient data to set an EAR is not available, an AI can be set instead. Estimated safe and adequate intake levels are bounded on one end of the intake curve by the RDA and on the other by the UL. This range of safe and adequate intake in the model predicts a low probability of either inadequate or excessive intake for a given nutrient (IOM, 2007).

## Nutrient intake and consideration of risk of chronic disease

### Inferring diet-disease relationships in chronic disease

NRVs are designed to cover a diverse population, deemed “apparently healthy”. In setting NRVs for a population, individuals who have a disease that requires therapeutic management, are malnourished or undernourished, have diseases resulting in malabsorption or requiring dialysis, or have severely altered energy needs, e.g. due to disability or altered mobility, are not included in the healthy population. However, within the overarching population, there is a wide range of health conditions, including overweight and obesity, which includes many individuals who have or are at risk for one or more chronic diseases. While risk of diet-related chronic disease has been recognized as a public health concern for many decades, a framework for considering chronic disease endpoints in deriving NRVs was not in place across developed countries, including in North America and Europe.

Prior to 2010 the DRIs lacked a specified reference value for nutrients associated with chronic disease endpoints. In the derivation of the first DRIs between 1997 and 2005, six nutrients were considered for a quantifiable relationship with chronic disease endpoints. These were: calcium and vitamin D and risk of osteoporosis and bone fracture; fluoride and dental caries; fiber and coronary heart disease; and sodium and potassium and hypertension (IOM, 1997, 2003, 2002/2005, 2005). The DRI study panels that

**Fig. 3** Distribution of intake levels with corresponding NRVs. Low risk of intake adequacy and adverse effects is between the RDA and the UL. NOTE: EAR = Estimated Average Requirement; RDA = Recommended Dietary Allowance; UL = Tolerable Upper Intake Level. Source: IOM (2000). Reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.

reviewed these nutrients were challenged by the paucity of and limitations in the evidence, including evidence to support a dose-response relationship relative to chronic disease health outcomes. Thus they were unable to find sufficient evidence to support a conclusion that the nutrients under consideration acted as modifiers of risk for chronic disease.

In the absence of sufficient evidence to derive an EAR and set an RDA in the first DRI reviews for calcium, vitamin D, fluoride, fiber, and potassium, AIs were set at levels considered adequate to avoid deficiency. Sodium deficiency however is not a health outcome of concern among US and Canadian populations; thus an AI was set based on presumed adequacy of intake and allowing for excess sodium loss in sweat by non-acclimatized individuals who are exposed to high temperatures or are moderately physically active (IOM, 2002/2005). Although the UL was originally intended as a threshold for a safe intake level to reduce risk of toxicity from excessive intake of a nutrient, in the case of sodium for example, a UL was set at a threshold intake level consistent with evidence available at the time to support primary prevention of hypertension, stroke, and coronary heart disease. In the dose-response assessment step of the risk assessment framework, blood pressure was used as a surrogate endpoint, based on both dose-response and prospective observational evidence that strongly correlated with dietary intake (IOM, 2005). In the case of fiber, the available evidence led the DRI panel to conclude that health outcomes associated with fiber intake were more strongly correlated with the amount of food consumed than age or body weight. Thus an AI was set based on grams of fiber intake per 1000 calories (IOM, 2002/2005).

### Challenges to consideration of chronic disease endpoints

The characteristics of chronic disease development are a primary challenge to identifying a causal relationship between exposure, as either a deficiency or excess of a nutrient or other bioactive food component and an adverse health outcome. Foremost among these challenges is the time frame in development of a chronic disease, which can take decades. Obtaining sufficient temporal evidence needed to establish a causal relationship, i.e. a randomized controlled trial or prospective cohort study, is generally infeasible in most instances. Further, the consistency of associations among different study types can be problematic. This has been seen in a number of studies on diet-disease relationships in which the outcome of a randomized controlled trial and an observational study on the same nutrient show different outcomes (Yaktine and Ross, 2019).

Another significant challenge is demonstrating a link between a single potential causal factor and disease risk. Diet is one of many factors that can influence risk of chronic disease and although there are numerous association studies on diet and disease risk, evidence of sufficient rigor and quality to demonstrate causality as defined in the risk assessment framework is lacking. Dose-response relationships are difficult to demonstrate in relating intake level to disease risk. Not only is time a factor in dose-response, a direct action of a nutrient or bioactive food component is difficult to establish. Most nutrients act in a concerted fashion rather than in isolation, as might be expected in, for example, a drug trial.

### Updating the DRI framework for chronic disease endpoints

In the US and Canada, two reports set the stage for expanding the DRI framework to include consideration of chronic disease endpoints in DRI development. First, Yetley et al. (2017) published a set of options for considering chronic disease endpoints in the derivation of DRIs, including the scientific and policy context for carrying out the work. The report considered: (1) the range of evidentiary challenges in selecting and using chronic disease endpoints in the DRI process; (2) intake-response models potentially relevant to chronic disease endpoints; and (3) justification for including chronic disease endpoints in the DRI process (Yetley et al., 2017).

Subsequently, the National Academies of Sciences, Engineering, and Medicine (NASEM) convened a study panel to assess the options put forward by Yetley et al. and establish a set of guiding principles for including chronic disease endpoints in future DRI reviews (NASEM, 2018a). Conceptually, the NASEM (2018a) report distinguished among the differences in the type and strength of evidence designed for determining adequacy, risk of adverse health outcomes, or chronic disease outcomes. The report recommendations were therefore based on characterizing the strength of the evidence for a chronic disease outcome, e.g. through an appropriate biomarker; and establishing a level of confidence in assessing the evidence for setting an intake level sufficient to reduce risk of the chronic disease. The report recommendations addressed extrapolating intake-response data on chronic disease risk across population groups; structuring intake recommendations as ranges as opposed to single values; and applying the existing DRI framework to assessment of chronic disease endpoints (NASEM, 2018a).

A DRI study panel was subsequently convened to undertake the task of applying the recommendations from both reports to assessing chronic disease endpoints related to sodium and potassium intake. The outcome was a new DRI value, the chronic disease risk reduction value (CDRR), designed as a range of intake that is beneficial to reducing the risk of a given chronic disease outcome, and based on moderate to high strength evidence for both causality and intake-response (NASEM, 2019). Significantly, the new CDRR differentiated risk of chronic disease from risk of adverse health effects from excess intake as defined by the UL, thus providing an alternate approach for considering health outcomes associated with high sodium intake. These recent advances in the DRI framework provided an underpinning for harmonizing the methodological approach to deriving NRVs across population groups.

## Harmonizing the derivation of nutrient reference values

### Origin of the harmonization effort

In response to an acknowledged need to address variability in the derivation of NRVs, a group of nutrition scientists met in Florence, Italy in 2005. The goal was to develop a harmonized framework for deriving NRVs. An important outcome of the 2005 meeting was a rationale for a conceptual framework to harmonize the methodological approach to deriving NRVs. The rationale stated four core reasons for harmonization. These are to:

1. “Improve the objectivity and transparency of values derived by diverse national, regional, and international groups;
2. Provide a common methodological basis for experts to consider in deriving NRVs;
3. Improve access to scientific and other resources used in the derivation of NRVs, particularly among low- and middle-income countries; and
4. Provide a common basis for uses and applications of NRVs across countries and regions globally” (King and Garza, 2007).

A significant accomplishment of the Florence meeting was the development of an organizing framework based on distributions of nutrient intakes required to achieve a given health outcome in the target population. The framework is built around two core NRVs, the average nutrient requirement (ANR) and the UL. Similar to the DRI framework, the ANR is used to derive an individual nutrient level (INL), which is the recommended nutrient intake level for the population. The UL, the highest level of normal intake that does not incur risk of adverse health effects, is derived from toxicity data on the nutrient under consideration (King and Garza, 2007).

These NRVs and their methodological derivation correlate with the DRI framework and the derivation of the EAR, RDA, and UL. While the description of the core NRVs varies across high-income countries and regions, the methodological approach to their derivation is similar and thus they are key concepts to harmonization. Also central to harmonization is developing a common terminology. **Table 1** shows examples of different terms currently used to describe reference values across countries and regions. The set of published monographs that came from the discussions in Florence captured these and other significant concepts and laid the groundwork for the effort to develop and implement a globally harmonized NRV process (King et al., 2007).

In 2009, the Department of Nutrition for Health and Development of the World Health Organization (WHO) established a new process for developing and updating nutrition guidelines in agreement with the WHO Handbook for Guideline Development (Global Programme on Evidence for Health Policy, 2003). In response, a WHO Nutrition Guidance Expert Group was formed (WHO, 2010). The charge to this group was to strengthen WHO’s part in communicating science-based advice, evidence-informed policy, and program guidance in support of the WHO Nutrition Program. At the same time, the Global Network of Institutions for Scientific Advice on Nutrition was formed to gather organizations from around the world who were responsible for providing scientific advice used to develop nutrition recommendations and guidelines (WHO, 2010). The group met to exchange information about nutrition guidance and to investigate opportunities to collaborate as a step toward harmonizing nutrition recommendations and guidelines. The meeting gave rise to recognition of the need for synergizing efforts aimed at developing nutrition guidance, including the harmonization of approaches for developing NRVs and guidance in support of national and international policy development.

### Current efforts to realize the goal of harmonization

In response to these efforts, NASEM undertook a series of steps to move the effort to harmonize the derivation of NRVs forward into the next phase of development and implementation. The first step was an international workshop that explored questions about the frameworks used to develop NRVs, the status of NRVs globally, and experiences and knowledge about harmonizing approaches to

**Table 1** Comparison of exemplar terms for nutrient reference values currently in use.

NRV designation	Country, regional, or global entity			
	United States and Canada	UK	European Union/EFSA	WHO/FAO
Overarching term	DRI	DRV	DRV	
Average requirement	EAR	EAR	AR	
Recommended intake level	RDA	RNI	PRI	RNI
Lower reference intake		LRNI	LTI	
Adequate intake	AI		AI	
Safe upper level of intake	UL	SUL	UL	UL
Appropriate macronutrient distribution range	AMDR	AMDR	RI	Population mean intake goals

NOTE: NRV = Nutrient Reference Value; UK = United Kingdom; EFSA = European Food Safety Authority; WHO = World Health Organization; FAO = Food and Agriculture Organization of the United Nations; DRI = Dietary Reference Intake; DRV = dietary reference value; EAR = estimated average requirement; AR = average requirement; RDA = recommended dietary allowance; RNI = reference nutrient intake; PRI = population reference intake; LRNI = lower reference nutrient intake; LTI = lower threshold intake; UL = tolerable upper intake level; SUL = safe upper intake level; RI = reference intake range for macronutrients.

derive intake standards (NASEM, 2018a). The workshop was planned and implemented in partnership with the WHO and the Food and Agriculture Organization of the United Nations (FAO), and with support from the Bill & Melinda Gates Foundation. The workshop took place at the FAO headquarters in Rome, Italy in 2017. Workshop discussions ranged from exploration of frameworks to support harmonization on a global scale; approaches for assessing evidence; contextual factors relevant to population groups across regions and countries; sharing of resources and expertise to facilitate the adoption of a harmonized approach; and possible barriers and challenges to achieving harmonization.

Three overarching strategic messages emerged from the workshop discussions. First, is the need for standardization of the methodology for deriving core NRVs. Specific actions needed include creating a centralized collaborative consultative group that would serve as a global resource for countries revising existing or developing new NRVs. Also needed are nutrition-specific tools, including consistent NRV terminology, or consistent definitions for NRV terms. Second is recognition of the specific needs of regions or countries with regard to food composition data, collection of data from dietary surveys, variables affecting nutrient bioavailability, and variation in health status among population groups needed to harmonize methodologies, particularly across low- and middle-income countries. Lastly, is the need to be mindful of research gaps and support developing the science from which intake requirements are derived (NASEM, 2018a).

The second action taken by NASEM toward harmonizing the derivation of NRVs was a consensus study to assess the methodological approach to deriving NRVs for specific population sub-groups, women of reproductive age and children from birth to 2 years of age (NASEM, 2018b). The study panel was charged to develop a framework to demonstrate the application of a harmonized approach and recommend ways to achieve a harmonized basis for deriving the core NRVs, the average requirement and the upper intake level, for these population sub-groups. The study panel's assessment of the NRV derivation process led to the initial finding that a harmonized approach to deriving NRVs would assure that the majority of a target population could achieve nutrient intake levels sufficient to avoid both deficiency and adverse health outcomes related to excessive intake, including toxicity and reduced risk of chronic disease.

The study panel's conclusions aligned closely with the strategic messages from the Rome workshop. Foremost, the panel concluded that the need for nutritional benchmarks is critical all over the world. This shared need, combined with the considerable effort and cost of deriving NRVs, is a sound justification in support of international cooperation (NASEM, 2018b). Additionally, in agreement with the workshop discussion, the need for a global expert consultative group would be the most appropriate model for promoting a harmonized NRV process. Finally, the study panel determined that in order to achieve a globally harmonized approach, the process for deriving NRVs must focus on two core values, the EAR and the UL (NASEM, 2018b).

The consensus study panel identified essential steps needed in deriving the core values that should be consistent across countries and regions (Fig. 4). These steps are based on the concept that selecting a methodological approach for a nutrient review is linked to identifying the role of the nutrient in meeting physiological needs, and understanding intake patterns, bioavailability of the nutrient, and the presence of infection and other local factors that influence the requirement for the population under consideration. Further, when updating an existing NRV or deriving a new value, an in-depth understanding of the uncertainties that affect the nutrient review process is vital to the credibility of the process, including the accuracy of the recommended intakes, and in enabling decision makers to use NRVs in nutrition policy (NASEM, 2018b). The recommended framework for deriving NRVs, shown in Fig. 5, provides a platform for deriving NRVs globally and across population groups. There are four steps in the process. These are: "(1) choose the appropriate tools, (2) collect relevant data from the tools; (3) identify the best approach or method of derivation; and (4) derive the core reference values, the AR and UL" (NASEM, 2018b).

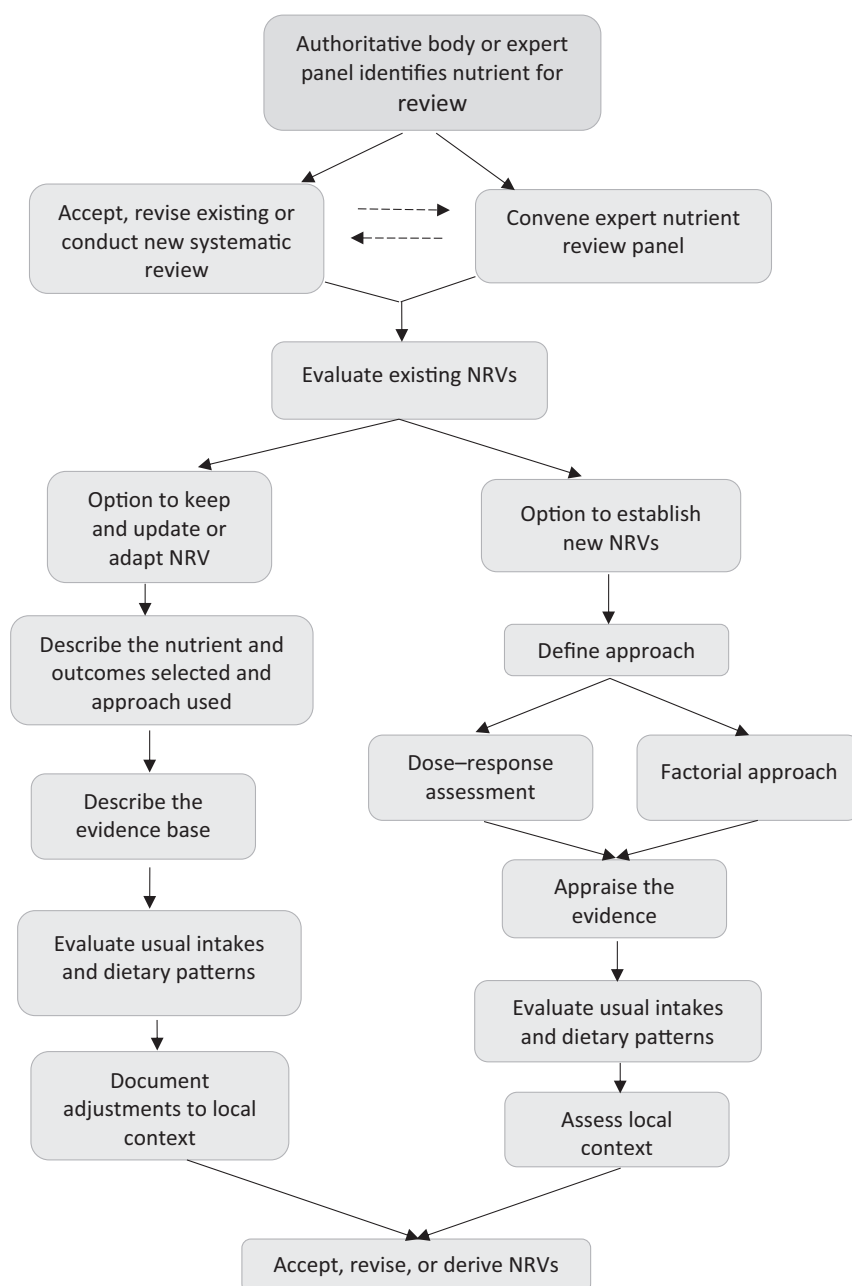

In the first step, selecting tools and data resources, the framework identifies three key tools and resources. These are systematic reviews, databases, and regional or local factors. Systematic reviews provide a wide-ranging, objective assessment of available evidence. As noted in NASEM (2018b), systematic reviews must be of sufficient quality and rigor to support assessment of intake requirements for the age/gender groups under consideration as well as establish findings and conclusions about the nutrient under review. This includes providing information about the search criteria, inclusion and exclusion criteria, study quality and data summaries, and consistency with the proposed methodology. Additionally, the heterogeneity inherent in any systematic review should be assessed for uncertainty (NASEM, 2018b).

The report concluded that the application of meta-analysis criteria will reduce uncertainty and bias due to variations across study designs, differences in populations, or the source of data. Additionally, the GRADE tool provides a qualitative approach to evaluating factors that may affect study quality and risk of bias. The GRADE approach stipulates that the certainty of evidence should be set at the lowest detectable level for all critical outcomes (Guyatt et al., 2011). This means that in general, randomized controlled trials receive a "high" rating for study quality and certainty, but may be rated lower; and observational studies general begin with a "low" certainty of evidence, but may be rated higher (see Fig. 2).

Food intake and food composition databases provide contextual information and other data, and are used to estimate factors that affect nutrient bioavailability (Gibson, 2007). Food intake data is also used to calculate prevalence of inadequate or excess intake.

In the second step, data collected from the tools and resources enables identification and selection of biomarkers, health outcomes, and dietary factors that affect nutrient requirements for various age/sex groups. Data that would be useful, particularly for low- and middle-income countries includes biomarkers of nutrient status, such as measures of a nutrient or its metabolite in biological fluids or tissues, anthropometric measures, or data from medical histories or physical exams.

In the third step, determining the best approach for deriving NRVs, dose response modeling is used when the relationship between nutrient intake and functional outcome is known. In the case of minerals, in which there is no known biomarker for

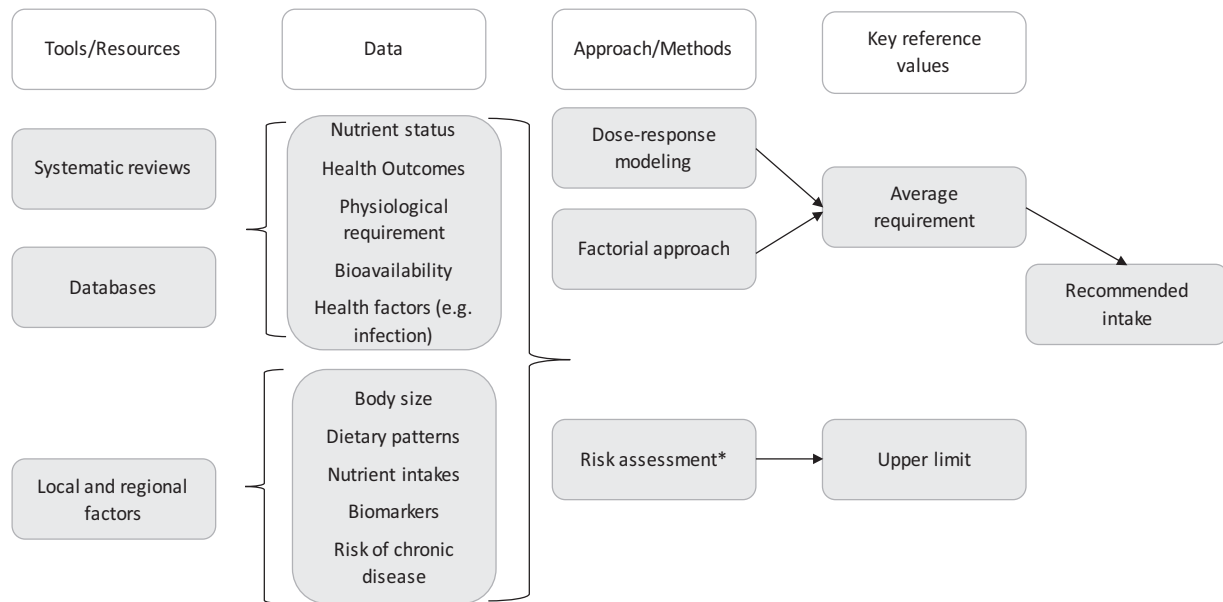

**Fig. 4** Flow diagram for deriving nutrient reference values. Source: [NASEM \(2018b\)](#). Reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.

adequacy, the factorial method is used. In this method, the amount of absorbed nutrient to replace basal losses from excretion, sweat, or exfoliation, or to account for menstrual loss or accretion due to growth is estimated. In the case of iron and zinc, for example algorithms to predict bioavailability are available to predict absorption, transport, and metabolism. Assessment of measures of physical activity are also included when evaluating energy intake.

In the last step, the AR is derived from dose-response or factorial modeling and the UL is determined from a risk assessment analysis. The nutrient intake distribution model described above and shown in [Fig. 3](#) illustrates the application of the risk assessment process to achieve a low risk of inadequacy or harmfulness from excess intake. Under this process, the AR will likely differ somewhat across countries or regions, depending on the criterion used in deriving the estimate.

The AR is not based on nutrient intake, rather it is determined from methodologies as described in the risk assessment framework to estimate physiologic need for a given age/sex group. Differences in physiological determinants, limitations in the available data, differences in bioavailability or absorption factors, and varying requirements for different age/sex groups are all influences that can affect the derivation of an AR ([NASEM, 2020](#)). The AR then becomes the basis for setting the recommended intake level. Thus, the

**Fig. 5** Framework for harmonizing the process for deriving nutrient reference values. Source: [NASEM \(2018b\)](#). Reproduced with permission from the National Academy of Sciences, Courtesy of the National Academies Press, Washington, D.C.

AR should: (1) be established from the amount of nutrient to meet the needs of 50% of the population; (2) be established, whenever possible, for all nutrients and food substances with public health relevance; (3) include appropriate designations for macro-nutrients, particularly when chronic disease endpoints are considered; (4) consider relevant nutrient-nutrient interactions; and (5) consider relevant subpopulations within the general population ([NASEM, 2018b](#)).

The UL is not a recommended intake and its derivation in the future will be influenced by inclusion of chronic disease endpoints in the analysis. The “Guiding Principles” report ([NASEM, 2017](#)) recommended that forthcoming nutrient reviews “characterize the health status of the population in terms of who is included and excluded for each DRI value” ([NASEM, 2017](#), p. 30). Hence, as new data becomes available, the UL will no longer be used as an intake value for chronic disease risk.

The process for deriving harmonized intake standards, described by the four major steps in the harmonization framework is based on six core principles. They are that:

1. NRVs are regularly updated;
2. The process is clear and transparent;
3. The methods are rigorous and relevant;
4. Factors influencing the NRV are documented;
5. The strength of the evidence is determined and
6. The review is complete and efficient.

The third action taken by NASEM was development of a tool kit ([NASEM, 2020](#)). The tool kit was created to support implementation of the recommendations from the NASEM consensus study ([NASEM, 2018b](#)). The goal of the tool kit is to share core principles, practices, and recommendations with key stakeholders, and to engage them in moving forward with practical steps that will facilitate harmonization globally. Further, the tool kit will serve as a first step in providing both guidance and resources for low- and middle-income countries to develop a harmonized approach to deriving NRVs for those populations. The tool kit resources are intended to facilitate the NRV process for low- and middle-income countries. Commitment from stakeholders to a harmonized process for deriving NRVs is essential in order to generate core intake values that are globally aligned and supportive of nutrition policies, programs, and education.

## Outlook

### Rationale for moving forward

Collectively, the three NASEM activities demonstrated that a harmonized approach to setting NRVs is essential for:

1. Resolving dissimilarities across countries in establishing nutrition standards;
2. Promoting consistent population health objectives;
3. Providing a means for creating food and nutrition policies that are aligned across countries and regions; and
4. Enhancing transparency in developing trade and regulatory policies with economic, health, and safety implications ([NASEM, 2020](#)).

Among low- and middle-income countries in particular, NRVs are key to formulating food and nutrition policy; developing food assistance programs, nutrition education, and monitoring population health. A number of actions can be taken in support of harmonizing the approaches to deriving NRVs. A future global dialog to gather support for harmonization as well as to identify a pathway for implementing the actions identified in the three NASEM reports will move the process forward. A collective effort among these groups is needed to describe the harmonization approach, as well as advocate for its implementation.

### Next steps

The need for harmonization of the NRV process is clear, as is the need for all users to have access to adequate resources for deriving the core (AR and UL) values. Implementing a harmonized approach to deriving NRVs will require discourse at the local, regional, and country levels in order to gain support, stimulate engagement, and foster investment from the groups and organizations to whom the effort will be entrusted. The costs of revising or establishing new NRVs will be high, and thus providing options for building on existing work and databases will reduce both time and cost. National, regional, and international leadership will move the harmonization process forward.

## Key points

The objectives of this article are to:

- Describe the epidemiology of nutrition and health inequities
- Describe Food insecurity inequities
- Present a Socio-ecological framework based on the social determinants of health to address inequities
- Describe specific programs that can facilitate access to healthy foods and physical activity environments among the most vulnerable
- Explain why addressing health inequities is crucial for countries to meet the United Nations Sustainable Development Goals

## Glossary

**Conditional cash transfer programs** Government programs that provide a small monthly stipend to low-income families as long as they meet certain conditions

**Food security** Access by all people at all times to enough food for an active, healthy life

**Health disparities** Differences in health outcomes and risk factors among population subgroups

**Health inequities** Differences in health which are not only unnecessary and avoidable but, in addition, are considered unfair and unjust

**Social determinants of health** The conditions in which people are born, grow, live, work, and age, including the health system

## Introduction

Health disparities refer to differences in health outcomes and risk factors among population subgroups (Carter-Pokras and Baquet, 2002; LaVeist, 2005). When deemed avoidable and unjust, these differences represent health inequities (The Marmot Review,

2021). The root cause of health inequities is social injustice (Marmot, 2005; Gravelle, 2009; Marmot et al., 2008; Williams et al., 2019). Health inequities are more prevalent among vulnerable sub-groups at social disadvantage. Health inequities follow a social gradient and can be a function of ethnicity/race, immigration status, gender, sexual preferences, religion, or disability status.

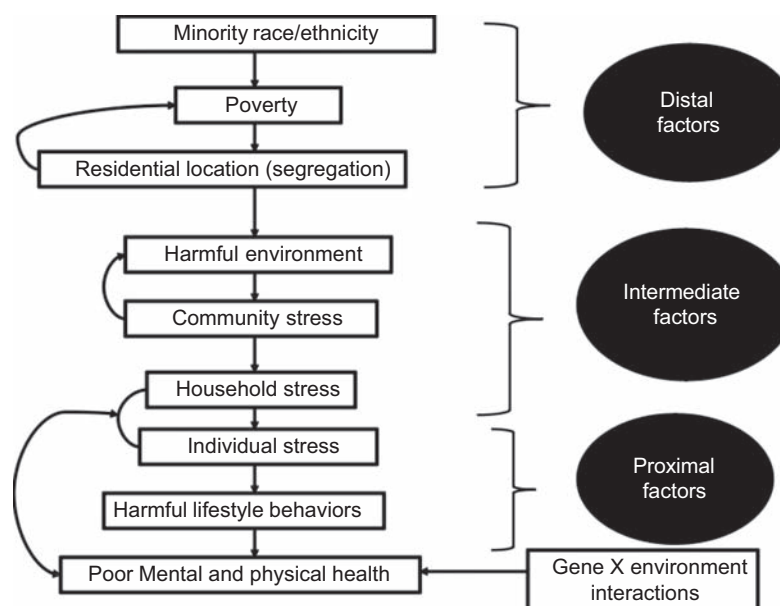

The social determinants of health (SDH) are key for understanding the distribution of health inequities within and across countries. These refer to the physical and social conditions of the environments where individuals are born, grow, go to school, work, socialize, and age (Institute of Medicine, 2002; Marmot et al., 2008; Marmot, 2005). Thus, efforts toward addressing health inequities must go above and beyond disease control and antipoverty measures, and must improve the psycho-social environments where socially disadvantaged groups live and work. Fully addressing health inequities requires making the basic resources needed to improve quality of life accessible to the most vulnerable. For example, improving the availability of nutritious foods, clean water and health care in a community does not guarantee that the most vulnerable within that community will have access to them, as the control of access to these resources has been shown to be socially determined (Fanzo and Davies, 2021; King et al., 2021; Young et al., 2021).

## Nutrition and health inequities epidemiology

Health and nutrition inequities have been well documented not only in developing, but also in developed countries (Perez-Escamilla et al., 2018). Even in the USA, which is considered to be the wealthiest nation on earth, low-income groups (overrepresented by ethnic/racial minorities) are substantially more likely to be food insecure, overweight or obese, to have type 2 diabetes, and to lack health insurance (Pérez-Escamilla, 2010; Reid, 2009) (Fig. 1).

## Malnutrition inequities

Decades of research have conclusively shown that under-nutrition, even in its relatively mild form, has negative consequences for human physical and intellectual development. Indeed, malnutrition explains over half of deaths among children under 5 y of age living in developing countries. Because human development is the basis for social capital, which, in turn, is the engine that drives national development, the problem of undernutrition is now recognized by key decision-making bodies and stakeholders as a top priority. The Food and Agricultural Organization (FAO) estimates that close to 800 million individuals worldwide experience energy undernutrition. The problem is more severe in the poorest regions of the world including sub-Saharan Africa, and South and Southeast Asia. Epidemiological data clearly show that, within countries, socio-economic position is a powerful determinant of risk of under-nutrition, including risk of stunting in children. In addition, hundreds of millions of individuals may have access to sufficient or even excessive amounts of energy, but do not have access to diets of adequate nutritional quality. As a result, low socio-economic groups are now facing a “double burden” of malnutrition (i.e., excessive rates of both under- and overnutrition) often-times coexisting within the same household and accompanied by micronutrient deficiencies. The problem of malnutrition has its roots in the SDH and is largely explained by major inequities in the distribution of wealth, power, and resources. In addition, two of

**Fig. 1** Socio-ecological model of health and disease. Original illustration prepared by author.

**Table 1** Key concepts and definitions.

Health inequities	Differences in health which are not only unnecessary and avoidable but, in addition, are considered unfair and unjust.
Social gradient in health	Health outcomes, including life expectancy, improve as a function of the position of individuals along the socio-economic continuum.
Social determinants of health	The conditions in which people are born, grow, live, work, and age, including the health system. These circumstances are shaped by the distribution of money, power, and resources at global, national, and local levels, which are themselves influenced by policy choices. The social determinants of health are mostly responsible for health inequities.
Socio-ecological model of health	Individual's health and nutrition outcomes are the result of multilevel distal, meso, and proximal factors and the interactions among them. This model recognizes that individual lifestyle choices are strongly shaped by the environments where people grow and live (i.e., the social determinants of health).
Social capital	Quality of social relationships, sense of trust, belonging, and reciprocity in wider society.
Developmental origins of health and disease hypothesis	Early life conditions, including nutritional and hormonal milieu to which individuals are exposed <i>in utero</i> and early childhood, impact longer-term health outcomes including obesity and chronic disease risk.
Food security	Access by all people at all times to enough food for an active, healthy life, and includes, at a minimum: (1) the ready availability of nutritionally adequate and safe foods and (2) an assured availability to acquire acceptable foods in socially acceptable ways (e.g., without resorting to emergency food supplies, scavenging, stealing, or other coping strategies).
Conditional cash transfer programs	Government programs that provide a small monthly stipend to low-income families as long as they meet certain conditions. These have included keeping children in school, bringing them to get immunized and receive other primary health care services, and in some instances participation of their caregivers.

Original table prepared by author.

the key proximal determinants of malnutrition are lack of access to nutritious diets and inadequate health care. Thus, nutrition inequities go hand in hand with inequities related to access to food, health care, and other basic human needs (**Tables 1–3**).

**Table 2** Sustainable development goals principles.

1. The 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015, provides a shared blueprint for peace and prosperity for people and the planet, now and into the future.
2. The 17 Sustainable Development Goals (SDGs) included in the agenda, are framed in the context of an urgent call for action by all countries—higher and lower income—through global partnerships.
3. The SDGs recognize that ending poverty and other deprivations must go hand-in-hand with strategies that improve health and education, reduce inequality, and spur economic growth—all while tackling climate change and working to preserve our oceans and forests.

Original table prepared by author.

**Table 3** Addressing key distal, meso, and proximal determinants of health: policy goals.

<i>Issues</i>	<i>Policy goals</i>
The social gradient	More equity in income and wealth distribution through better access to adequate education, employment opportunities, housing, health care, and food security.
Stress	Improve neighborhood safety, built and social environment. Universal access to good-quality schools and health care (physical, mental, and dental).
Early life	Universal access to prenatal care, breastfeeding promotion and support, high-quality child care and education infant, toddler and preschool programs, that include adequate nutrition in the context of nurturing care. Home visiting programs to support development of better infant feeding, parenting skills, and psycho-emotional health of the caregiver.
Social exclusion	Strong and enforceable civil rights laws that prevent discrimination based on individual's ethnicity/race, religion, gender, sexual orientation, age, disability status, and immigration status including being an internally displaced person or refugee, among others.
Work	Develop good skills for job market through good-quality vocational, college, and postgraduate educational opportunities. Establish minimum wages based on reasonable estimates of what families need to have a quality of life compatible with the principles of human rights and dignity. Provide reasonable paid parental leave policies that protect the job security of parents and their ability to provide nurturing care to their infants. Improve safety of work environments by reducing occupational hazards. Global trade policies should be restructured to allow the less powerful to have a chance to fairly compete in local and global markets. Increase credit access to small producers and businesses.
Unemployment	Safety net with reasonable unemployment benefits and retraining opportunities.
Social support	Increase social capital in deprived neighborhoods/communities.
Addiction	Increase social capital in deprived neighborhoods/communities. Provide access to effective primary prevention and substance-abuse treatment programs. Limit advertisement of alcohol and tobacco products in low-income neighborhoods. Use effective taxation (pricing) policies to limit abuse of substances.
Food	Restructure food price policies so that healthy nutrient-dense foods become more economically accessible to low-income groups. Restructure food systems in low-income areas to improve community access to healthy and nutritious foods, including fresh fruits and vegetables, legumes/pulses, minimally processed grains, and healthy and sustainable animal protein sources. Limit advertisement of foods high in saturated/transfats, sodium, and refined sugars in low-income neighborhoods and through mass media marketing targeting children. Ensure that food assistance programs provide services and benefits that are consistent with evidence-based dietary guidelines across the life cycle. Provide effective instrumental nutrition and food safety education, including healthy cooking, in schools and diverse community settings.

**Table 3** Addressing key distal, meso, and proximal determinants of health: policy goals.—cont'd

<i>Issues</i>	<i>Policy goals</i>
Physical activity and transport	Increase community access to safe green areas. Improve use of public open spaces for families to walk, exercise, and interact socially with other community members. Redesign urban areas traffic systems to facilitate the routine use of bicycles when going to school or work. Provide access to safe, clean, and efficient public transportation for individuals to be able to transport to work, school, and public open spaces.
Health care	Health care access for all. Must emphasize primary prevention, screenings, and referrals and cover physical, mental, and dental health care needs. Screenings should be conducted to identify SDH needs including household food and water insecurity, housing, and transportation.

Original table prepared by author.

### **Household food insecurity inequities**

Household food security is defined as “access by all people at all times to enough food for an active healthy life”, and includes, at a minimum: (1) the ready availability of nutritionally adequate and safe foods and (2) an assured availability to acquire acceptable foods in socially acceptable ways (e.g., without emergency food supplies, scavenging, stealing, or other coping strategies). Thus, food insecurity (FI) exists when there is limited or uncertain availability of nutritionally adequate and safe foods or limited or uncertain ability to acquire acceptable foods in socially acceptable ways. The US Census Bureau has reported annual household FI since 1995, estimated from the 18-item Household Food Security Supplement Module (HFSSM) applied through the Current Population Survey Food Security Supplement.

The reference time period of the HFSSM is the 12 months preceding the survey and households are classified as having either food security, low food security, or very low food security, based on the number of affirmative answers to the HFSSM items. In 2021, 10.1% of US households were food insecure (i.e., with either low or very low food security) and 3.8% were very food insecure corresponding to 5.1 million households. Households are more likely to be food insecure if they are poor, headed by a single female, if there are children living in the household or if the head of household is Hispanic or African-American. Thus, the distribution of household FI is also a reflection of the strong socio-economic inequities in the USA. Similar conclusions have been reached in very diverse countries located across world regions.

### **Obesity inequities**

Obesity is a major public health problem in both developed and developing countries. Indeed, maternal–child obesity rates in Mexico are now as high as in the USA. Consistent evidence indicates that, within developed countries and increasingly among developing countries as well, poverty is associated with higher obesity risk. This is not surprising, as lack of access to healthy, nutrient-dense foods and opportunities for physical activity are important obesity risk factors. In the USA, 76.9% of Hispanic and 73.7% of non-Hispanic Black women, vs. 67.5% of Non-Hispanic White women, are overweight or obese (body mass index (BMI)  $\geq 25$ ). The corresponding rates for morbid obesity (i.e., BMI  $\geq 35$ ) are 18.9%, 27.9%, and 16.6%, respectively. The prevalence of type 2 diabetes in the USA is about twice as high among Hispanic and Black than non-Hispanic White individuals, and hypertension is substantially more prevalent among Blacks. Because obesity is a major risk factor for chronic diseases, such as cardiovascular disease and type 2 diabetes, it is not surprising that the distribution of these chronic conditions is inversely associated with socio-economic status (Millen et al., 2016).

Ethnic/racial differences in obesity in the USA are evident since very early childhood (Pérez-Escamilla et al., 2017; Taveras et al., 2010). The obesity prevalence among 2–5-year-old non-Hispanic White children was 10.7%, compared with 14.9% among non-Hispanic Black and 16.7% among Mexican-American preschoolers. As expected, these differences reflect greater prevalence of early life obesity-related risk factors, including maternal depression, rapid weight gain during infancy, lower breast-feeding, introduction of complementary feeding before recommended age, more restrictive maternal feeding style, higher intake of sugar-sweetened beverages and fast food, and insufficient sleep during infancy. These findings are of concern, as there is increasing evidence that intrauterine and early childhood environments are determinants of health outcomes later in life, including the development of obesity and chronic diseases. This is known as the “developmental origin of health and disease” hypothesis (Gillman, 2005).

## **Health inequities**

### **Health care access inequities**

Tens of millions of individuals living in the USA do not have health insurance and, thus, lack access to basic health care and often-times end up receiving needed medical attention in emergency room services. Millions more low-income individuals with limited

insurance coverage also do not have access to adequate physical, mental, and dental health care. In the USA the risk of not having access to health care is higher among low-income families, even though the majority of these households have employed members. This risk increases considerably among non-citizens, many of whom are migrant farm workers, not fluent in English and living in isolated communities. Thus, social exclusion and lack of adequate health care are largely responsible for the highly visible health care access inequities in the USA. This is emphasized by the improved health care access and health outcomes that populations living in other developed countries have. These countries' systems are characterized by a "not-for-profit" health insurance structure, coupled with a single payer health care system focused on primary and secondary prevention.

### **Life expectancy inequities**

Inequities in life expectancy are substantial in both lower and higher income countries (Danaei et al., 2010; World Health Organization, 2003). According to the World Health Organization (WHO) the probability of a man dying between the ages of 15 and 60 y ranges from 8.3% in Sweden to 90.2% in Lesotho. Life expectancy is almost 50 years longer in Japan than in Sierra Leone. These remarkable differences have also been documented within countries. In Australia, aboriginal people have a life expectancy that is 20 y less than the national average. In the USA, the difference between counties with the highest vs. lowest life expectancy is 18.4 y for men and 14.3 y for women. In the USA, Black men live 6.3 y less and Black women 4.5 y less than their White counterparts. In England, people living in the poorest neighborhoods die on average 7 y earlier, and their disability-free life expectancy is 13 y lower, compared with those living in the wealthiest neighborhoods. Further, clear social gradients have been documented within both developed and developing countries, showing that social and economic position is a powerful determinant of health outcomes. Although genetic susceptibilities play a role in the development of disease within populations and subgroups, the large between-group differences in health outcomes are largely explained by the SDH and, thus, need to be addressed accordingly. When equitable development approaches are used, key maternal, child, and adult health indicators rapidly improve, thus ruling out a "genetic" explanation. For example, Brazil recently demonstrated how large-scale investments in social programs capable of reducing income and wealth inequities across socio-economic groups led to improvements in public health indicators, especially among the most vulnerable (Barros et al., 2010; Pérez-Escamilla et al., 2018).

## **Understanding the determinants of health and nutrition inequities**

### **Socio-ecological model of health**

Health inequities can best be explained by the Social-ecological model of health. This model posits that multilevel factors ranging from the individual to the macrosocial level interact in determining health outcomes. This model, consistent with the SDH construct, recognizes that the social distribution of wealth, resources, and power strongly determine access to healthy lifestyle, including health screenings and timely treatment. Communities with low access to quality education and employment opportunities are characterized by unhealthy environments. These have low social capital and poor infrastructure, including limited availability of healthy foods (e.g., fresh fruits and vegetables), limited opportunities for leisure-time physical activities (e.g., safe green areas and sports facilities), and limited access to quality primary, secondary, and tertiary health care. They are also characterized by high levels of crime, violence, and other psychosocial stressors. This stressful environment, coupled with inadequate coping responses among low-income individuals, represents another major barrier to a healthy lifestyle.

Research conducted in the US has shown that self-perceived discrimination related to skin color has a negative impact on health, independent of socio-economic status (Williams et al., 2019). Self-perceived discrimination has been associated with high blood pressure, arterial plaque, and high inflammation markers and visceral fat. These are important risk factors in the development of cardiovascular disease. Because cardiovascular disease explains a substantial amount of health inequities between Blacks and Whites in the USA, racial discrimination needs to be understood and addressed from the health inequities perspective.

Health inequities may be substantially explained by the direct biological impact (e.g., resulting from poor nutrition, low physical activity, substance abuse) as well as higher levels of chronic stress experienced by disadvantaged communities. In other words, individual level health outcomes are the result of lifestyle choices (diet, physical activity, substance abuse, sex practices) that are strongly shaped by the social policies and physical and social environments where people grow, live, and work (i.e., the SDH). Thus, correcting health inequities requires addressing the macro (e.g., safety net policies, minimum wage, social exclusion), meso (e.g., neighborhood safety, access to healthy foods, good quality schools, and adequate health care), and proximal lifestyle determinants (e.g., dietary intake, physical activity, substance abuse, sex behaviors) of health, and the interaction among them.

## **Solutions**

International organizations and governments worldwide now fully acknowledge the existence and pressing need for addressing the major health and nutrition inequities worldwide. The United Nations Sustainable Development Goals (SDGs) call for significant reductions in extreme poverty and hunger, as well as in major communicable diseases. The SDGs place strong emphasis on addressing socio-economic, gender inequities and other SDH including universal access to education and health care. The SDGs also emphasize the profound links between human and planetary health in the context of environmental sustainability (Pérez-Escamilla, 2017).

Through the SDGs there is now global consensus that SDH determine the risk factors and health outcomes for chronic diseases. This is due to the evidence indicating that lower socio-economic position is linked with undernutrition, obesity, less access to

healthy foods, and fewer opportunities for leisure-time physical activity, proper screenings, medical referrals, and good-quality health care.

Although the existence of health and nutrition inequities is increasingly acknowledged, there is still no consensus on the best ways to approach them. The SDGs specifically call for emphasizing sustainable economic growth and national development approaches based on strong multisectorial partnerships. Thus far, most efforts have focused on communicable disease prevention, food assistance, conditional cash transfers provision of microcredits, and universal health insurance strategies.

Few developed countries have based their national development approaches on the SDH including access to education, adequate work environments, social and economic security, and health care access. Scandinavian countries have taken this approach and, as a result, have some of the best health indicators in the world. The UK recently released a major report on health inequalities in England addressing social determinants findings. A demonstration of the power of the social determinants approach is illustrated by strong reduction of stunting inequities in Brazil between 2003 and 2014 when its government reformed social, health and economic policies to become much more equitable and inclusive in the context of sustainable economic growth.

### **Conditional cash transfer programs**

Conditional cash transfer programs (CCTPs) represent a pragmatic way of addressing the major food, education, and health care needs of the poor (Lagarde et al., 2007; Segura-Pérez et al., 2016). CCTPs provide a “small” cash allowance to low-income households with the condition that they keep children in school and bring them to primary health care centers. In some programs, caregivers are required to attend health and nutrition workshops. CCTPs originated in Latin America and have shown positive effects on maternal–child health behaviors and outcomes. In countries as diverse as Mexico, Brazil, Colombia, Honduras, and Nicaragua, CCTPs have been shown to lift families out of extreme poverty (Segura-Pérez et al., 2016). However, from the social determinants perspective, they represent only a partial solution, as they do not address the underlying social gradient. In other words, CCTPs do not benefit poor and lower middle-class families that are above the program financial inclusion criteria, and are not able to lift families from extreme poverty into the middle class. As other regions of the world, including Sub-Saharan Africa, consider incorporating CCTPs as a strategy for reducing extreme poverty and improving education, health, and nutrition outcomes, it is essential that health and education infrastructures are in place before the program is implemented so that participants can truly meet the program’s “conditions.”

### **Access to nutritious foods**

A key indicator of dietary quality is the consumption of fresh fruits and vegetables. For this reason, food assistance programs heavily emphasize the need for improving access to these healthy and nutritious foods in disadvantaged communities. The US Supplementary Nutrition Assistance Program (SNAP), formerly known as the food stamp program, provides a cash transfer to low-income families earmarked for purchasing food but does not place conditions as to the nutritional value of the foods purchased. One approach that SNAP has used for improving participant intake of fruits and vegetables is to provide nutrition education through the SNAP-Ed program. Because education alone is not enough to meet this goal, SNAP is piloting fiscal incentives to foster availability, access, and purchase of fruits and vegetables by program participants. An important incentive program being piloted is providing recipients with a “bonus” or “discount” incentive when using their SNAP benefits to purchase fruits and vegetables. At the same time, SNAP is supportive of the development of more points of access to fruits and vegetables in low-income areas, including corner stores and farmers markets, and by facilitating the use of the program electronic benefit cards at these points of purchase. This example illustrates how food systems, as a whole, need to be revamped for vulnerable communities to have access to healthy and nutritious foods, and for their residents to be able to purchase them. Culturally appropriate health and nutrition education is crucial for ensuring that the products are actually consumed in recommended amounts. Otherwise, the impact of these major investments will not impact obesity and health inequities in the US.

In developing countries micronutrient fortification has become a major strategy for improving the nutritional status of populations. These strategies include provision of micronutrient powders (i.e., “sprinkles”) or of energy- and micronutrient-dense spreads to improve the nutritional value of foods given to young children. These approaches have been shown to be effective to a limited extent relative to the major health and nutrition deficits experienced by low-income individuals as a result of pervasive social inequities. Although some of these short- and medium-term biomedical-type solutions are needed to address under-nutrition in developing countries, the problem will not be solved unless policies based on the SDH and nutrition inequities are implemented. These policies are expected to reduce economic and social inequities and, as a result, improve access to better education, employment, and housing opportunities. This, in turn, would facilitate the adoption and dissemination of lifestyles compatible with good health and quality of life.

Structural changes in global food and water systems governance are needed to development sustainable food systems that promote the health of individuals, communities, and the planet (Pérez-Escamilla, 2017; Young et al., 2021).

### **Unhealthy foods taxes and regulation**

Driven in large part by initiatives launched in Latin America, nations across the globe continue to launch policies and legislation designed to tax ultraprocessed foods and beverages, front of package nutrition warnings, and protecting children and against marketing of these foods. Although initial findings look promising, it is unclear if and how these measures are addressing health and nutrition inequities (Pérez-Escamilla et al., 2021).

### Physical activity

Urban areas in Latin America have launched innovative “public space use” and “public transportation” initiatives to increase physical activity. These include the development and maintenance of safe green areas for people engaged in individual and group leisure-time activities, provision of low bicycle rental fees to move around downtown areas, and the closing of major city streets to vehicular traffic during weekends (Pérez-Escamilla et al., 2021). Although few, if any, of these structural changes in the physical environment have been formally evaluated, their emphasis on facilitating “access for all” represents a step in the right direction to bringing more equity to opportunities for leisure-time physical activity. These opportunities in public open spaces improve levels of social capital and air quality, and directly benefit the health of individuals through increased levels of physical activity.

### Health care reform

Many nations have reformed their health care systems to provide “universal” access to timely health care. This is the case of the former “Seguro Popular” effort in Mexico, the “single health system” in Brazil, and, more recently, the effort by the US government to have all individuals covered by health insurance based on a sliding scale system with subsidies for those who cannot afford it. In the US, ongoing health care reform efforts also include forbidding health insurance companies from denying coverage to individuals with preexisting medical conditions. This reform however excludes from its coverage millions of individuals living in the country who are non-citizens, highlighting the need to simultaneously address immigration reform. This illustrates how ignoring relevant SDH, in this instance the exclusion of individuals based on their immigration status, precludes a country from truly correcting major health care access inequities. In fact, it may make this inequity even worse for the most vulnerable.

### Reduce discrimination

Because of the impact that stress associated with self-perceived racial discrimination has on the risk of poor mental health and chronic diseases (Williams et al., 2019) it is important that individuals who are vulnerable to this type of discrimination are protected through civil rights laws and awareness of the general public. Racial discrimination is not always intentional and when this is the case it can be addressed through improvements in cultural sensitivity and diversity and inclusiveness education and trainings. Structural racism which in many ways is the legacy of colonialism and neocolonialism will require major food, health care and education systems reforms.

## Conclusion

Breaking the cycle between poverty, disease, and malnutrition requires a new way of thinking to move forward within a health and nutrition equity framework. This approach will indeed require substantially changing the social and political structures responsible for the inequitable distribution of power, wealth, and resources within and across countries. This is unlikely to happen without including the active participation of the most vulnerable communities in the shaping of this “new” development paradigm. The WHO commission on SDH concluded that social inequities are of such a magnitude that they are responsible for excessive morbidity and the premature deaths of people on a massive scale. Correcting these inequities will take time. The commission however concluded that health outcomes can continue to improve and persistent health inequity gaps can be substantially narrowed within a generation, as long as social injustice is addressed through policies and programs based on the well-documented SDH. These efforts should consider establishing universal guaranteed basic income, livable minimum wages, and should heavily invest in opening access to quality education, employment opportunities, and improved built environments. At a macro level it is essential to overhaul and restructure inequitable global trade policies and the major political, social and economic power imbalances that characterize the world in which we live. To be successful at reducing health and nutrition inequities, these combined efforts must result in a more just distribution of wealth, power, and resources between and within nations.

### Glossary

**Ahimsa** The practice of nonviolence in all aspects of life, including taking the life of living creatures for food.

**Brahmin** The highest caste among Hindus, with the greatest number of food restrictions.

**Eucharist** The celebration of the Mass in Roman Catholicism, in which wine is said to miraculously transform into the Blood of Jesus and bread, normally a consecrated wafer, changes into His flesh.

**Halal** The food laws of Islam, which forbid pork and alcohol. It's opposite is haram.

**Kosher** The complex food laws of Judaism, which originate in the book of Leviticus, which are still practiced by devout Jews today, with some modifications.

### Introduction

Religion is among the most pervasive forces influencing the human diet, even among those who do not actively practice a particular faith. Religion shapes individual and group preferences in the form of taboos, celebratory foods, and ritual offerings, it prescribes the modes of commensality and attitudes toward indulgence and abstinence, and throughout history religious leaders have carefully defined the meaning of alimentary sustenance in ways that continue to resonate into the present, having a direct impact on people's dietary choices. This article will recount attitudes toward food in the major world religions, and their origin and historical development as necessary for a full appreciation of the complexity of how religion shapes food cultures today.

The origin of the deep connections between food and faith lie without doubt in the earliest polytheistic religions. Since prehistoric times, the Gods were invoked to ensure good harvests and thanked for their bounty; they also had to be appeased with sacrifice. Ancestral spirits were provided with offerings to maintain their good will and a cycle of festivals marked the agricultural and religious calendar. Many religious festivals retain features of these original agricultural rites. With the discovery of alcohol and other intoxicants, communities could enter into an ecstatic union with the Godhead, a numinous state of oneness, bridging the earthly and otherworldly planes. To this day all these primal elements of the relationship between food and religiosity survive as rudiments, altered in form, but still discernible among modern practices.

### Judaism

Perhaps more than any other civilization, the ancient Hebrews defined their relationship to God in terms of what they ate, what was considered clean and unclean and what was sacrificed to God. A succession of dietary codes in various historical epochs also explains how that relationship changed. In the biblical narrative, following creation, in the first epoch humans were intended to be not only vegetarian in the state of innocence, but fruitarian, meaning that Adam and Eve's Edenic diet was obtained without killing any living thing. They ate only fruits and seeds and leaves, which could be taken without killing the plant. Plants also produced fruit spontaneously without human effort. This initial ban on murder will help explain the internal logic of the complex rules of kashrut and sacrifice, which were anything but arbitrary or capricious. Following the fall, as punishment for their disobedience in eating from the Tree of Knowledge the couple were forced to subsist through labor. In this second epoch, Adam had to earn his bread by the sweat of his brow, i.e., by planting crops, and for Eve it meant pain in childbirth as well as subjection to man.

Although it is not clear exactly what was eaten in this second epoch, the professions of Cain and Abel, a shepherd and farmer, closely match the early economy of the Fertile Crescent after the Neolithic Revolution. It is not until after the flood (the third epoch)

that Noah is given explicit permission to kill for food. "Every creature that lives and moves shall be food for you; I give you them all, as once I gave you all green plants." It is an admission on God's part that humans are faulty. Only the blood, which contains the life, must be poured on the ground, as it belongs to God. This blood prohibition remains in effect as central to Judaism, and kosher meat must be salted to drain it of all traces of blood. It was also at this time that the first sacrifice was made. It is clear that the burning fat and entrails provide a soothing odor to the Lord, that He is in a sense sustained by the smoke. More importantly, the sacrifice, explained only in later books of the bible, reinstates justice in the universe. To compensate for the act of killing, some creature must be punished, normally an unblemished "scapegoat."

It is only with the giving of the law under Moses, the fourth and final historical epoch, that the Hebrews were given a complex dietary code, which is still for the most part in effect among observant Jews. At its root is still the prohibition against murder. Unclean animals are those, which kill in order to eat. Rather than catalog all clean animals, the Levitical Priests devised a shorthand way to recognize the innocent herbivores: those which chew their cud and have a cloven hoof. Thus the omnivorous pig was banned along with other creatures, which did not seem to fit into this scheme, such as camels and hares. It has been suggested that the real origin of this ban was an informal knowledge of trichinosis, or perhaps the fact that pigs are inefficient in the desert, being unable to sweat and thus requiring watering holes, and more importantly competing for resources with humans because pigs are unable to convert grass (indigestible to humans) into food, the way ruminants can. The Hebrews may have banned pigs in order to maintain distinction from their pig-eating neighbors and keep their identity intact, for to eat with someone is one step away from intermarriage. Yet none of these explanations is as convincing as the original ban on murder, which translated into considering all predatory animals unclean.

More difficult is explaining the ban on shellfish and other creatures, which seems to defy the categorical schema of the priests. According to their logic, a fish must have scales and swim, birds must have feathers and fly, animals must have legs and walk. Scaleless fish, flightless birds, etc., defy the rational categorization and are thus also unclean. Another stricture demands that milk and meat must never be mixed, which by tradition stems from not seething a calf in its own mother's milk. This means that a cheeseburger is not kosher. Even among nonobservant Jews, through cultural conditioning foods categorized as *trayf* may be unappetizing or even repugnant.

In addition there are numerous holidays, which revolve around food, or lack thereof. Most important is the fast, which takes place from sundown to sundown on Yom Kippur, a time to reflect on and atone for one's sins in the preceding year. Passover is also essentially a food holiday, though no leavened bread (*chometz*) may be eaten in commemoration of the Jews' escaping Egypt who had no time to let their bread rise. The seder plate also recalls other aspects of the captivity in Egypt: salt water for tears and bitter herbs for suffering, *charoseth* – a thick fruit and nut paste that reminds one of mortar. The passover seder ritual revolves around food stories drawn from Exodus. The dining practices of the meal itself however date from the period when the Holy Land was ruled by Seleucid Greeks, and is essentially a form of symposium, particularly in the reclining while eating, drinking four glasses of wine, and hiding the *afikomen* (i.e., *epicorium*, outside the meal) – a matzoh that the children search for at the end of the ritual. Today, sticking to the exact letter of the law, matzoh meal is used to make a kind of passover bread, cakes, and other products, which because not technically leavened, are still allowed.

In general, modern Judaism retains the kosher rules, though sacrifice ended with the destruction of the second temple in AD 70. However, a good proportion of practicing Jews, particularly in the Reformed tradition no longer adhere to any dietary restrictions, and there is also a broad range of levels of compliance, from those who keep kosher only in the home, to those who merely avoid pork, but follow no other restrictions. Nonetheless, food is so intimately bound to Jews' cultural identity, that active or not, certain foods are absolutely requisite at family gatherings and holidays, which at least for Ashkenazi Jews include familiar items such as bagels and lox, corned beef and pastrami, knishes, gefilte fish, and matzoh ball soup.

## Christianity

Christianity grew directly from Judaism and in an effort to distinguish itself therefrom, the early church made an explicit point of abandoning the kosher rules. It is not what goes into the mouth but what comes out that defiles a man, as Jesus himself explained, meaning food cannot pollute a person, only cruel words. There is also a scene recounted by Matthew in which Jesus is asked why he doesn't fast and he responds that "when the Bridegroom will be taken from them, then shall you fast" meaning that once he is gone there will be occasion to fast, but fasts should not be regularly scheduled and habitual as among standard Jewish practice. Regarding clean and unclean food, there is also a vivid dream told by Peter in which a huge net teeming with creatures lowers from heaven and he is ordered by God to kill and eat. Not that the early church was entirely bereft of attitudes toward food, though.

The letter to the Corinthians resolves the question of whether it is alright to consume meat that had been sacrificed to pagan gods. Although technically permissible, Paul counsels to avoid it lest one lead fellow Christians astray. In this time the central sacrament of the church also developed, based on the Last Supper when Jesus was sitting at a Passover seder with his disciples and asked them to remember him when they ate bread and drank wine, alluding to the fact that he would be gone the next day, and reminding them, "this is my body; this is my blood." The sacrament of the holy communion is based on these words, and in 1215 the Lateran Council decreed that the bread and wine literally transform into the flesh and blood of Christ, which is consumed by communicants. It is in this way that the faithful obtain grace, forgiveness of sins, through the act of eating.

Early Christians also fasted, not only in miraculous ways as had Moses and Jesus who ate nothing at all for 40 days, but as a whole community during impending disaster to ask for God's mercy, or as individuals as an act of penitence. The early church also saw the

development of monastic orders, which followed ascetic regimens limiting the amount of food eaten and frequently abstaining from meat, which was believed by medical theorists to stimulate the production of blood and sperm and ultimately incite the libido (in both men and women). Celibate orders naturally restricted meat consumption, though the *Rule of St Benedict*, which generally set the pattern for orders in the West is not entirely abstemious, allowing for example, the equivalent of a few glasses of wine, though ideally it would be best if monks could abstain. Certainly an antipathy toward the sin of gluttony pervades Christian thought, for it was not only the first sin in Eden, and leads to other sins like sloth and lust, but prevents one from exercising virtues such as charity.

The general ascetic attitude toward meat did eventually, in the course of the institutionalization of the church, lead to a number of official fast days. These were every Saturday (starting on Friday night, hence fish on Friday), the vigils of saints days and the entire 40-day period of Lent stretching from Ash Wednesday to Easter, minus Sundays. The fast was defined as abstinence from meat and all meat products such as butter, eggs, and milk, though typically a dispensation could be obtained for children, pregnant women, the infirm, and for special cases. Fasts alternated with feast days, the best known being Mardi Gras, the celebration preceding Lent when all remaining meat has to be consumed, as well as eggs and butter – in pancakes and other confections. In general this was a time for ritual subversion, serving as a safety valve for society, which would naturally return to the status quo once the celebrations were over. Most places abolished these celebrations in the course of the sixteenth century though, the rare exceptions being Venice and New Orleans where Carnival is still celebrated.

These fasting regulations remained uniform in the Roman Catholic Church until the 1960s and the Vatican II Council, when adherents were asked to give up something important as a sacrifice, but not necessarily meat. However by custom certain days do remain fish days, including Christmas Eve among Italians. Fasting regulations also remain in place in the Eastern Orthodox Church and are even more extensive, and for certain fasts a broader range of foods is prohibited, such as olive oil.

The Protestant denominations returning to scriptural authority over tradition took a number of different positions on official fasts. The Church of England kept a “Political Lent” requiring fish consumption as a way to support the fishing industry and the navy. Eventually the practice fell into abeyance, likewise in Lutheran Churches. In the Reformed tradition (i.e., The Swiss, Dutch, Scots, English Puritans, and French Huguenots) fasting once again took its biblical form, as a complete abstinence from food as an act of penitence or a communal fast to avert God's wrath. In general, however the practice ceased, though many evangelical Christians still fast for religious purposes. Nonetheless, the Reformed churches did adopt a new attitude toward food stressing frugality, simplicity, and at times abstinence from alcohol. The Prohibition of alcohol in the US in the early twentieth century sprung directly from the work of the Women's Christian Temperance movement, which may seem ironic given that Jesus drank wine and even miraculously provided guests with a bounteous supply on one occasion.

A number of unique attitudes toward food developed among more recent Christian sects, for example, the modern vegetarian movement sprang from Bible Christian Societies on both sides of the Atlantic, and the 7<sup>th</sup> Day Adventists, following the visions of Ellen White are the only sect that demands total abstinence from meat, alcohol, and tobacco, though Mormons (Church of Jesus Christ of Latter Day Saints) do abstain from the latter two as well. Historically Christian sects have expressed their ethical positions in ways that have a direct bearing on food practices. For example, Quakers who opposed slavery in the nineteenth century abstained from products made by the plantation economy, including sugar, molasses, and rum. More recently there have been explicitly Christian weight loss diets, Christian groups advocating fair trade or ethical treatment of animals. Suffice to say that although all Christian sects promote charity, any number of ethical positions and dietary regimes may fit under its umbrella today.

## Islam

The food tenets of Islam also bear a relation to the previous two faiths. The most obvious similarity with Judaism is the ban on pork. In general there is not the great number or complexity of food rules, though birds of prey and similar animals are not considered halal (legal to eat). Animals to be consumed must however be ritually slaughtered without pain, thanking the animal and giving praise to Allah. The most important food custom is the month-long fast of Ramadan, when the faithful must eat and drink nothing between sunrise and sundown. The meal in the evening, to break the fast, traditionally eaten on the floor and with fingers of the right hand only, may be quite elaborate and sumptuous; some even report gaining weight during the holy month. The fast is also broken with Eid al-Fitr, a resplendent feast with special foods for the occasion, such as dates, which are a traditional food of the Arabian Peninsula.

A unique prohibition in Islam is the ban on alcohol. This, as much of the religion, stems from the personal experience of the prophet Mohammed, who after having witnessed a scene of drunken violence, understood that it would be best if alcohol is never consumed. Some Muslim countries forbid the sale of alcohol entirely, whereas others are more lax and even produce excellent spirits such as Raki in Turkey or Arak elsewhere. It has been suggested that the importance of coffee and coffee houses in the Muslim world is a result of the ban on alcohol, and caffeine is also purported to keep holy men awake for long hours of prayer.

Perhaps the most pervasive custom in the Muslim world is the charge to perform acts of charity and show effusive hospitality to guests. Originating in the very practical need to feed strangers who would otherwise starve in the desert, generosity with food has become an essential part of the practicing Muslim daily life. Devout Muslims will say a prayer before eating and thank Allah when finished. There are also a number of religious festivals celebrated with food. Eid-al-Adha commemorates the willingness of Abraham to sacrifice his son Ishmael (not Isaac as in the biblical tradition). On this day a ram is sacrificed and a third is kept for the family, a third given to friends and neighbors, and the last third given to the needy.

A unique phenomenon among African-Americans is the movement founded by Elijah Mohammed known as the Nation of Islam. Its tenets include rejection of what its founder considered slave food; pork and offal meats, black-eyed-peas and greens stewed with fatty meat. Mohammed was not only interested in dietary reform but wrote an entire book on the topic, which also counseled abstinence from debilitating intoxicants which cause dependency and subjection. Though many members have gravitated toward traditional Sunni Islam, the group still survives.

## Hinduism

The origins of Hinduism can be traced to the Indo-European invaders (Aryans) who arrived in the Indian subcontinent after approximately 1500 BC. They were originally sacrificers and consumers of cattle and how exactly they came to ban cows for food is among the more hotly debated topics among scholars. First it is important to understand that the ancient Vedic texts regard all living creatures as manifestations of the first primordial principle, known as Atman, which translates as "self." Atman, having divided and subdivided gave rise, therefore, to all living beings, which are manifestations of the original Atman. In daily life people often have difficulty recognizing the unity of all creation, which is how abstinence and yogic practices, including meditation, help us to recognize the self – which is every creature. Moreover, on death all creatures are reincarnated in a different form in accordance with their conduct in the previous life. These ideas, at least to start with were not implemented in a way that determined diet.

Second and equally important was the division of society into separate castes, seemingly at odds with the idea of the unity of creation, but separating people by various professions with no possibility of social mobility. Unless you were demoted by marrying below your caste, you and your descendants were always and forever in the same caste. This social structure had a profound impact on food customs, because one could not eat with or accept food from those of a lower caste, which would become polluted. The highest of castes, the priestly Brahmins had, as we shall see, the most restricted diet, with the greatest possible sources of pollution.

At first the Brahmins were eaters of meat, but apparently a period of widespread famine challenged their position at the top of society as the lower castes threatened them with violence. The Brahmins maintained their status by implementing the full ramifications of their sacred texts into practice. That is, they asserted that because the cow is the highest order of reincarnation, it should be sacred, revered, and never consumed. Hindus went from cow consumers to ardent reverers of cows. Because the priests had the most abstemious diet, they could no longer be the object of envy or violence from the lower castes, as they ate less and their diet was much more restricted. In fact the lower the caste, the more foods were allowed. The idea that cattle are more efficient as providers of traction for plows, dairy products, and manure for fuel than they would be if used for meat, may be true but it does not explain the origin of cow reverence.

Although the caste system has for the most part broken down in the modern era, beef is still prohibited for Hindus, and certain cow products like ghee (clarified butter) are considered the most sacred. A countless number of holy festivals also revolve around food. It is important to remember that Hinduism is a polytheistic faith, and thus festivals worship any number of different gods, the three main gods Brahma, Vishnu and Shiva, but also their many avatars and family members. Offerings to the gods, *prasad*, often consist of foodstuffs: fruits, sweets, or milk products. The offerings are consumed after the ritual. There are an extraordinary number of festivals throughout the year as well, seasonal, honoring particular deities, all of which include eating particular festival foods. For example, Mahashivarati celebrates the marriage of Shiva to Parvati when the temples flow with offerings of milk, yoghurt, honey, and ghee, but devotees fast through the day and the fast is broken by a special vegetarian meal made with no grains. Janmashtami celebrates the birth of Lord Krishna, Ganesh Chaturthi the birthday of the elephant-headed Ganesh. Diwali, the Festival of Lights features sweets, which are given to children and even fed to cattle.

## Buddhism

Buddhism developed directly from Hinduism when Siddhartha Gautama in the c. 6th BC was searching for the meaning of life and was suddenly enlightened with the realization that suffering in the world comes from never being satisfied with what one has, from being far too attached to one's self. Neither extreme asceticism nor indulgence, both inherently selfish, lead to happiness, but rather the middle way, eating enough to survive. The key to ending suffering is simply to recognize the self as an illusion and to break the chain of causation, stop the endless cycle of reincarnation and achieve the state of nirvana, or nothingness.

Before this, however, were very practical Buddhist directions for living life in this world. Most important is the principle of nonviolence or *ahimsa*, not to cause suffering to any other creature. By logical extension, this meant also not killing them for food, and vegetarianism is thus at the core of Buddhist belief. There are varying degrees of practice among the many forms of Buddhism though. Normally monks are the only strict vegetarians and they created an elaborate nonmeat cuisine featuring items like high protein tofu. Though many modern Buddhists around the world are vegetarian, among most varieties fish is eaten regularly, and even meat in some.

Interestingly, when Buddhism became the state religion in India under the ruler Ashoka in the third century BC, meat eating became illegal as well. Although the religion did not survive in India it spread northward through Asia influencing places as far away as Japan, where Zen Buddhists traditionally abstained from meat. Ironically the largely vegetarian population of southern India, although mostly Hindu, were most likely influenced by Buddhist practices. In East Asia, Buddhism is not considered an

exclusive faith, meaning that in China, for example, it may be mixed with elements of Taoism and Confucianism, or in Japan with traditional Shinto.

Although Confucianism does not have any explicit food-related rules, the practice of filial piety does require that people act with deference to superiors and care for inferiors. This often translates into a practical requirement to feed elders first, without neglecting to provide for those below one in status.

Another religion arising in India, the Jains, adopted an extreme vegetarian position, such that to harm any living creature, even accidentally is forbidden. They are naturally pacifists as well. In terms of diet, this also means avoiding root vegetables, the harvesting of which kills the entire plant and they may harbor many microorganisms. Jains often filter water to prevent destruction of the same. Monks and nuns in this tradition may also practice forms of asceticism, and among all Jains there are set times for fasting, though one may also elect to fast individually for a variety of reasons. There are also varying degrees of fasting, some lasting many days.

## **Conclusion**

Religion continues to shape foodways around the globe, not only in traditional forms of fasting and celebrations or food taboos, but in particular in the ethical attitude toward our fellow creatures as well as our responsibility for stewardship of the environment, and most importantly for the responsibility we owe to perform works of charity to help sustain our fellow humans.

## Key points

- Reorienting food systems for children and adolescents is central to improve children's healthy and sustainable diets.
- Interventions on food systems for children and adolescents focusing on schools offer promising venues for improving children's diets and health with a special focus on most vulnerable children and adolescents.
- School settings offer relevant opportunities for interventions that range from food subsidies and taxes, the provision of daily healthy and sustainable meals and the improvement of school food environments.
- School Food Systems changes should include a policy equity perspective to protect childhood optimal nutrition as a fundamental human right ensuring at least one healthy and sustainable meal per day.

## Introduction

An adequate nutrition in early childhood, the school-age years, and adolescence is a fundamental piece for physical growth, learning process and adult healthy life. Healthy children and adolescents (C&A) in our societies are the basis of a prosperous world. The current child and adolescent health situation around the world is far from the ideal levels of health achievement. Undernutrition—stunting and wasting—is still prevalent in young children, at the same time that overweight and obesity among children and adolescents continues rising or stagnated at high prevalence in most parts of the world including regions where undernutrition is still prevalent (Aguayo and Morris, 2020).

An important, and often neglected, matter when studying population health is the social gradient of health and nutrition that characterizes our current populations. Malnutrition, in the forms of overweight and obesity disproportionately occurs in under-served and vulnerable communities within our populations. And these health and nutrition inequalities continue rising in most countries, including high income countries like the US and European countries. Food insecurity continues increasing in countries like the US and Spain, a situation that worsened during the COVID-19 pandemic. A relevant topic when addressing children health and nutrition is the high cost of healthy diets in comparison to cheap energy-dense, nutrient-poor foods. The recognition of health and nutrition as a human right specially for C&A needs to be moved forward in most countries' political agenda. The need for including health and nutrition as part of Child Guarantee schemes in our countries is an ongoing political debate in Europe.

In the last decades, it has become clearer that food production significantly contributes to the challenge of sustainability by contributing to biodiversity loss, climate change, freshwater usage, food loss and waste and long-distance transportation, for example. Individuals and families contribute to these problems through their daily food choices (Oostindjer et al., 2017).

A food systems approach has been developed in the last decades for addressing and understanding the complexity of all the factors that finally affect the dietary patterns we follow and the related nutritional and health outcomes in different societies. The most common definition of a food system is as follows: “a food system gathers all the elements (environment, people, inputs, processes, infrastructures, institutions, etc.) and activities that relate to the production, processing, distribution, preparation and consumption of food, and the output of these activities, including socio-economic and environmental outcomes” (HLPE, 2017).

Food systems thinking should also help ensuring that food is produced, distributed and consumed in a sustainable manner protecting the right to adequate food for present and future generations (HLPE, 2017). The way modern food systems are thought, helps policy-makers focusing on the availability and accessibility of diverse and healthy diets, particularly for the underserved and the most vulnerable.

## **Food systems for children and adolescents**

A food systems approach promoting C&A's adequate health and nutrition while minimizing environmental degradation is warranted. Food systems research had seldom considered children and adolescents as a focus until UNICEF and the Global Alliance for Improved Nutrition (GAIN) convened a Global Consultation on Food Systems for Children and Adolescents at the UNICEF Office of Research, Innocenti, from 5 to 7 November 2018. The results of this meeting have been published in a special issue on Food Systems for Children and Adolescents addressing the need for food system reorientation with a child-centered approach (Aguayo and Morris, 2020).

Food systems comprise actors, components, policies and services that influence and interact with each other in a complex ecology where the whole system needs to be synchronized to ensure nutritious, safe, affordable and sustainable children diets.

Actors lie both in public and private sector. Food systems require from all food system stakeholders the most difficult task of responsibly assuming their roles in shaping children diets.

Governments have the higher responsibility for upholding children rights to adequate nutrition and health and must set food standards aligned with the special needs of C&A. Producers and suppliers must ensure that their actions are aligned with those standards. Finally, governments shall generate the conditions to allow for participation of small-scale stakeholders, families, women and vulnerable groups among other players.

Raza et al. (2020) developed the Innocenti conceptual framework of food systems for C&A that shape their diets comprising four types of diet determinants: food supply chain, food environment, both personal and external, and children/household eating behaviors.

Within each determinant Raza et al. identified a series of “influencers” that are more immediate and individual/level factors determining the extent to which a determinant contributes or not to the goal of improving C&A diets becoming potential entry points for food system change.

## **Determinants of food systems for children and adolescents**

### **Food supply chains**

Food supply chains take food from production to consumption. Small and medium scale farms produce 50% of world food. They face challenges diversifying their production due to inputs cost. Public sector shall support them in aligning their practices with C&A dietary needs given the investments needed in practices and foods of current limited demand in the market.

Government can secure markets for these foods and sustainable food practices fostering partnerships with schools (farm-to-school twinning) and designing sustainable public food procurements strategies that truly value C&A nutritional health, community social justice and environmental integrity, the three pillars of sustainable development (Dos Santos et al., 2022).

### **Food environments**

#### **External food environments**

The school is a salient food environment for C&A as it allows reaching them at population level at least until mid-adolescence. C&A spend more time in school than in any other environment.

Food systems may differ by country even by state or region. For example, in the US around 30 million C&A participating in the National School Food Programs (lunch and breakfast) in public schools may consume up to half of their daily calories at school (Cohen et al., 2021), which underlines the importance for these calories being healthy ones.

Because of the time spent by C&A at school at a time in their lives where food habits are established and therefore might track into adulthood, the school setting provides multiple opportunities to learn healthy but also sustainable food behaviors, while mutually reinforcing each other.

School meals in any given country are a nutrition and health safety net for low-income and vulnerable children (HLPE, 2017). The availability and accessibility of water coolers and water fountains has received plenty of attention in the last years given the current situation of sugar sweetened consumption and plastic bottles and containers increased use.

### Personal food environments

Accessibility to healthy food options around schools and the place of residence remains an important factor within food systems thinking.

The affordability of healthy dietary patterns is a major economic problem for many families as shown in the high levels of food insecurity. Social protection schemes at schools providing healthy and free meals to low-income families and those in need is, again of most relevance.

Convenience foods offered in school and high-school breaks are mostly cheap and ready-to-eat foods, high in sugar, salt and calories compromising optimal diets.

### Behaviors of caregivers, children and adolescents

The Innocenti framework visualizes this final determinant where the external food environment i.e. school and personal food environments converge. Desirability and acceptability of food options are linked to social and cultural norms but can be heavily influenced by marketing and advertising (Fox and Timmer, 2020).

This framework conceptualized the dynamic linkages between the elements of food systems and highlighted the importance of continuously shaping food systems to deliver nutritious, safe, affordable, and sustainable diets to children and adolescents.

## School food systems

What children eat depends on the food system environments in the communities where they live and where they attend school. School settings have been identified for decades as places for change in public health nutrition.

The school food system is a subsystem within the broader food system of particular relevance for C&A. It also a food environment i.e. a physical and socio-cultural context whereby C&A interact with the broader food system to obtain the food they need most commonly as lunch but also as breakfast and/or snacking.

Because of the time dedicated to eating at schools, and the influence of school social environment (teachers and peers) on C&A food choices, schools are in a unique situation to influence the behavior of many children simultaneously cutting across socio economic status.

Healthy food habits are more easily acquired in childhood, and early learning increases the chances of habits persisting into adulthood. School meal programs are therefore a tool for improving dietary behaviors, nutritional outcomes in a sustainable way (Oostindjer et al., 2017).

Education and health policies also have the possibility to serve as examples and levers of change in other sectors of society where scaling up healthy and sustainable food production and consumption is also needed (e.g. hospitals, nursing homes, universities). School Food System approaches should acknowledge their transformative power and ability to drive change.

The SchoolFood4Change project (Website <https://schoolfood4change.eu>) funded by the EU scheme Horizon 2020 tackles the transformative power and ability to drive change of schools by bringing food and nutrition to the heart of the school mission reinforcing the health and sustainability parts of food consumption.

Researchers involved in the project used the following school food systems definition further explained in Fig. 1 for school food systems promoting healthy and sustainable school diets.

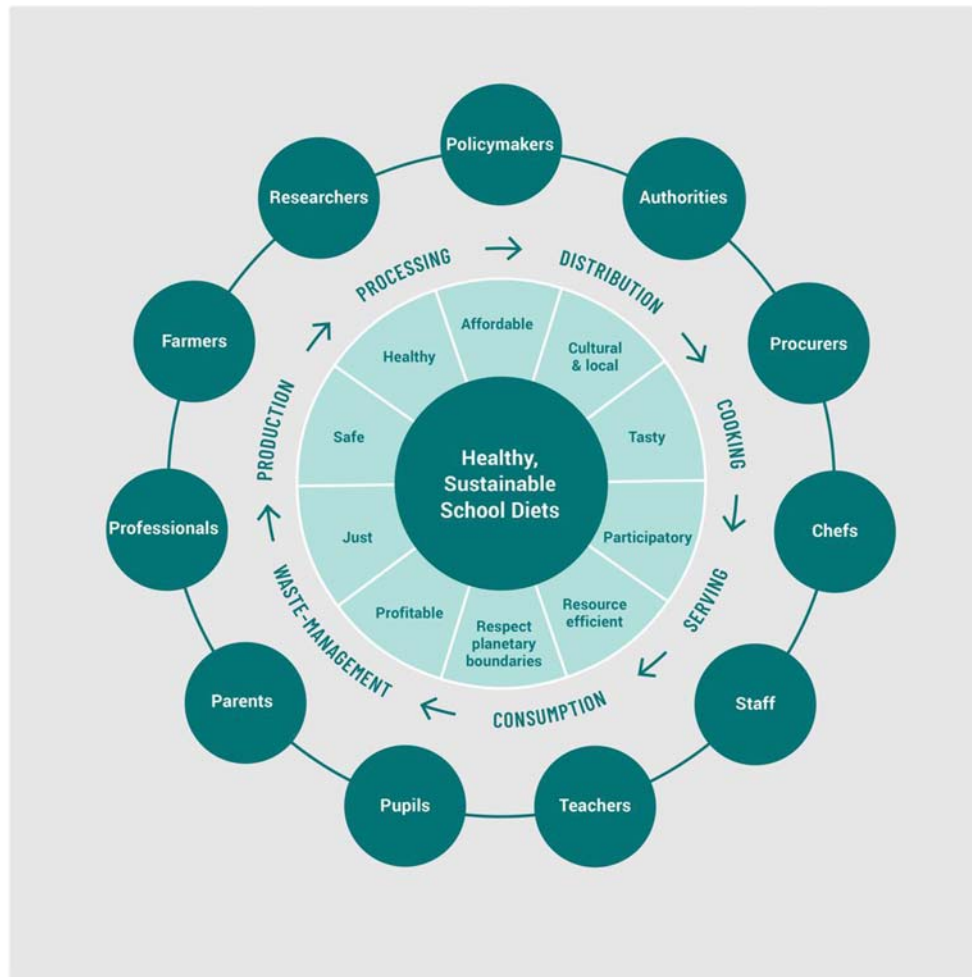

School food systems include the full range of **activities, components**, and actors related to the production, processing, distribution, cooking, serving, consumption, and waste management of food in schools, as well as the **spaces and contexts** where these processes occur, and all the related educational practices, that promote children and adolescents' health in a way that is profitable for each actor of the food value chain, respects the social and cultural context, and safeguard, restore, and regenerate natural resources and ecological processes while respecting planetary boundaries. School food systems shall be governed democratically in a participatory way by all its **actors**, including farmers, procurers, chefs, teachers, pupils, parents, administrative municipal and school staff, researchers, other professionals, and policymakers.

Following a systemic approach, the school food system is a collection of subsystems with components, spaces, actors interacting in different processes through feedback loops. This is a fundamental characteristic of systems thinking that in the case of School Food Systems should help us focusing on the goals of promoting healthy and sustainable school diets for all the children attending with a focus on those most vulnerable.

## School food systems and food programs

Within the school food system, the school food environment greatly interacts with C&A influencing their food choice since they spend a considerable part of their day at school where they have at least one meal (Cohen et al., 2021).

School food programs (SFPs) are frequently nationally mandated initiatives, sometimes regional and even municipal, to promote healthy and sustainable food behavior in C&A attending the different schools. Their interest lies on the fact that can reach school-aged C&A at population level across socioeconomic classes, particularly when school food programs are free, in a children development stage when food habits are formed and might therefore track into adulthood (Oostindjer et al., 2017).

**Fig. 1** Components of school food systems promoting healthy and sustainable school diets. This conceptual framework figure was proposed within the school food four change project. <https://schoolfood4change.eu>.

These programs provide lunch, but also breakfast or just one commodity such as school fruit or milk programs. In the USA, 95% of non-profit schools participate in the school meal programs administered by the United States Department of Agriculture (USDA). Both the National School Lunch Program (NSLP) and the School Breakfast Program (SBP) provide children and adolescents with healthy, low-cost meals throughout the school year. Additionally, before the COVID-19 pandemic, approximately three-quarters of the NSLP participants came from low-income households, with many relying on school meals for up to half of their daily energy intake (Cohen et al., 2021).

Schools are therefore in a unique situation to promote healthy and sustainable eating among C & A while at the same time, reducing disparities in the consumption of healthy foods such as vegetables and fruits (Longacre et al., 2014).

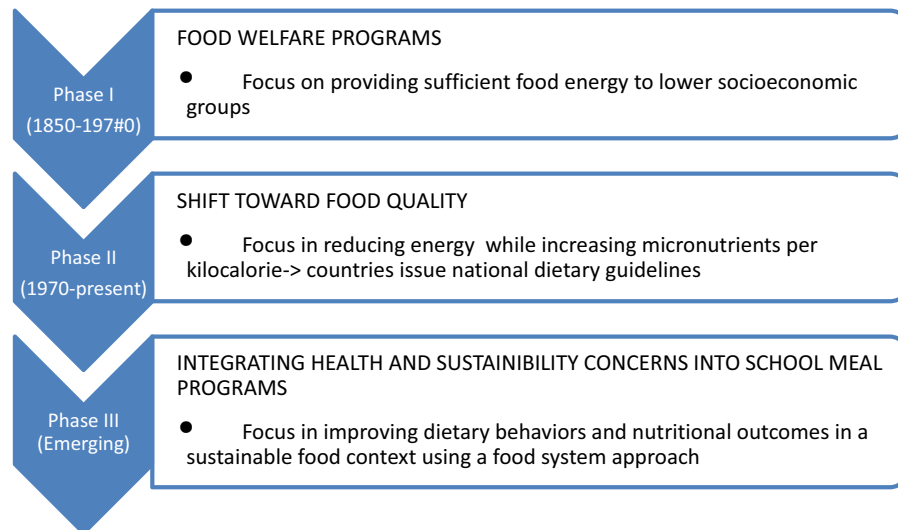

### Historical development of school food programs (1850-present)

Oostindjer et al. (2017) have suggested three phases in the progression of nationally mandated SFPs in high-income countries. Those phases are described in Fig. 2.

In phase I (1850–1970) SFPs were introduced as a response to hunger and as such they were considered welfare programs aiming at providing sufficient food energy to low socioeconomic status children.

During phase II there was a shift toward food quality around 1970s in some European countries and in 1990s and 2000s in the USA and the UK as a response to increased prevalence of diet-related diseases resulting from increased food availability. Many developed countries, including USA and most European countries, issued national dietary guidelines focusing in reducing energy levels while increasing the number of nutrients per kilocalorie. This phase still continues as of today in many countries.

Phase III emerges since phase II seems unable to respond to individual (providing high-quality food to reduce all forms of malnutrition) and societal (preserving the environment to do the same for future generations) challenges in a sustainable food context. This phase is in its infancy in many countries coexisting with phase II. It aims at transforming SFPs in integrative learning

**Fig. 2** Progression of school meal programs in the world after Oostindjer et al. (2017).

platforms for healthy and sustainable food behaviors at school using a food systems approach. This systemic approach requires synchronized changes across the food system components, given the interdependencies in the process of bringing food from farm to school fork and from there to school food waste (Hernandez et al., 2018). These concepts are being discussed and developed as of 2022 and therefore have not extensively studied yet.

### The example of the Brazilian national SFP

The Brazilian SFP (PNAE in Portuguese) is a long standing national SFP that currently and after 2009 modified legislation, is world-wide recognized as a healthy diet promoting initiative (Boklis-Berer et al., 2021) offering Brazilian C&A attending public schools, free meals where products rich in Na, sugar and saturated and trans fats are restricted and the provision of low nutrition drinks prohibited including in the menus at least three portions of fruits and vegetables weekly 30% of their funds have to invested in local farm products provision and hence contributing to local development and food security of the community (Horta et al., 2019).

Regular consumption of PNAE provided meals at Brazilian schools has been associated with improvements in children diets by increasing consumption of healthy foods (pulses, vegetables and fruits) and decreasing unhealthy ones (salty snacks, crackers, sweet biscuits and sweets) further reaching those on higher social vulnerability risk (Horta et al., 2019). Additionally, the adherence to PNAE meals in adolescents (11–19 years) was associated with decreased obesity indicators (BMI, BMI z-score) showing a dose-response relationship (Boklis-Berer et al., 2021).

### School food systems interventions

Downs and Demler (2020) identified in a scoping review the most effective interventions in the school food systems to improve diets and reduce the risk of malnutrition for C&A.

The school interventions showing most promising results were as follows:

- Food/snack/beverages subsidies and taxes in schools
- Provision of free or subsidized fruit and vegetables
- Provision of free school meals
- Increased water access in schools
- Setting up school meal and competitive food & beverages standards
- Salad bar in cafeterias
- Menu labeling in schools
- School food environment changes
- Portion size changes
- Social marketing of healthier foods and beverages
- Cafeteria nudges and choice architecture

Storcksdieck Genannt Bonsmann et al. on their 2014 report of European school food interventions and policies, offer a number of suggestions to increase their acceptance and hence increasing their chances of success:

- Co-involvement of head teachers: Buy-in from them
- Building partnership at different levels
- Ensuring family and local engagement
- Local ownership and co-creation (engage children, teachers, canteen staff): use bottom-up approaches, social marketing, involve C&A in design and assessment
- Capacity building (teachers, coordinators, chefs, canteen staff, caterers): provision of materials made available through a centralized good practices portal or knowledge hub.
- Synchronized multi-component interventions

School food systems interventions are aimed to have impact at different aspects of C&A health. Next, we discuss the already studied and published intervention impacts on dietary behaviors, anthropometric and metabolic outcomes. We also include a discussion on why impacts school food systems interventions have been rather unsuccessful to show positive impact on C&A health outcomes.

### **School food interventions and impact on dietary behaviors**

[Downs and Demler \(2020\)](#) indicate that the choice of food in C&A can be shaped by economic incentives i.e. subsidizing healthy foods such as fruits and vegetables and taxing unhealthy ones (energy dense snacks and/or beverages). The free provision in school of fruits and vegetables (F&V) has been more successful in increasing just fruit consumption in-school and habitual intake in the short term and to some extent in the long one ([Micha et al., 2018](#)). Provision of free school meals have brought up positive changes in dietary intakes such as in the case of the Brazilian SFP ([Horta et al., 2019](#)). School meal standards have increased intake of F&V reducing fat, saturated fat and Na with no effect on calories while competitive food/beverages standards has decreased reduced sugar-sweetened beverage intake and unhealthy snacks with no effect on total sugars. Improved access to water coolers in school has shown a non-significant trend to increased water consumptions ([Micha et al., 2018](#)). Salad bars, menu labeling and social marketing campaigns showed small increases in fruit and vegetables consumption and a reduction on energy and total and saturated fat intakes. Gender based differences were detected in the use of salad bars ([Down and Demler, 2020](#)). Approaches to cafeteria nudges and choice architecture that led to improvements in favorable foods included photographs of F&V in lunch trays, strategic placement of these foods in the lunch line, etc. Further description of the effect of these interventions on health outcomes can be consulted on Down and Demler article (2020).

### **School food interventions and impact on anthropometrics and metabolic outcomes**

The formerly mentioned school food interventions were more likely to bring up changes in dietary intake, that in other more distal health outcomes such as anthropometrics.

The effect of school food interventions on anthropometrics (body mass index (BMI), weight status) has been variable and inconsistent in European countries as reported by [Storcksdieck Genannt Bonsmann et al. \(2014\)](#). Likewise, in LMICs, there is also limited evidence to support the modification of anthropometric outcomes through school-based food environment interventions such as eliminating unhealthy foods (absence snack bars/vending machines) and promoting school staff modeling C&A ([Carducci et al., 2020](#)). [Boklis-Berer et al. \(2021\)](#) have recently reported a positive effect on adolescents' rates of obesity in the Brazilian SFP.

Concerning metabolic risks indicators such as abdominal obesity, a recent systematic review on C&A by [Leis et al. \(2019\)](#) supports the role of nutritional education decreasing central obesity although effects on the remaining markers of metabolic syndrome were inconclusive. Changes in the availability of competitive foods and beverages in schools i.e. sugar sweetened beverages and unhealthy snacks have shown effect decreasing C&A metabolic risk ([Downs and Demler, 2020](#)).

### **Barriers evaluating school food interventions impact on health outcomes**

In all, there is little evidence both from HICs and LMICs countries as to whether school food and school food policies can effectively improve C&A health status and/or eating habits. The barrier to gather this evidence relies on the difficulty in implementing comprehensive and well-designed studies, inferring causal effect from observational studies and the paucity of school food interventions sustained over a significant amount of time (enough duration) with sufficient intensity (multicomponent interventions required) and adequate and continued funding ([Colley et al., 2019](#); [Storcksdieck Genannt Bonsmann et al., 2014](#)).

Lack of clear definition of measurable health outcomes (endpoints) has also hampered school food interventions evaluation and comparability. Proximal indicators i.e. short-term outcomes have been suggested to evaluate school food environment interventions such as the increase in favorable food intakes (F&V, pulses) or the increase in number of children of low income families participating in school meals ([Oostindjer et al., 2017](#)) as well as process indicators (implementation fidelity, C&A/teachers/canteen staff satisfaction, etc). However it is unclear how these short-term health outcomes relate to long-term outcomes such as overweight/obesity and type 2 diabetes ([Oostindjer et al., 2017](#)). Using indicators revealing additional forms of malnutrition have also being suggested to show school food interventions impact on C&A health e.g. vitamin deficiency, muscle mass loss, anemia in adolescent girls or metabolic risk (central adiposity).

## School food interventions and sustainability

Food production, processing, distribution, consumption and waste management are associated with significant environmental impacts. Schools are not only an adequate context to bring up positive dietary and nutritional outcomes in C&A, they are also prominent environments for sustainability practices i.e. providing C&A with a sustainable food offer as well as building citizen conscience on sustainability issues integrating education for sustainability in the school curricula (Dos Santos et al., 2022).

Focusing school food interventions on the provision of healthy but also sustainable foods along with the promotion of sustainable food behaviors through school gardening and learning how to reduce food waste, might work in a mutually reinforcing way and in doing so, spilling into life away from school (family, community) (Colley et al., 2019). Schools sustainability practices might therefore impact the environmental pillar of sustainability but also the economic and social ones.

Dos Santos et al. in a recent systematic review (2022) identified the most frequently adopted food sustainability policies and interventions worldwide as follows:

- Educational activities for sustainability:
  - School gardens providing experiential learning i.e. hands-on experience on growing vegetables and workshops on using and cooking garden produce, travel field studies, etc.
- Food services:
  - Food supply/provision->sustainable food procurement including, beyond price: environmental criteria in the food supply contracts i.e. local or short chain, seasonal and organic foods, socioeconomic criteria i.e. farm to school or fish to school programs, provision from small producers, prioritizing supply from women and other vulnerable groups.
  - Menu planning: mainly plant-based, reduced meat supply, one day vegetarian/vegan menus, exposure of children to unfamiliar/unappreciated foods)
  - Menu production/consumption/distribution:
    - Reducing energy and water consumption in meal cooking, reduce organic waste (age-range adjustment of portion sizes, single dish menu)
    - Reduce inorganic waste->reusable devices, purchase in bulk or minimizing packaging, use of returnable bottles, and replacement of bottled mineral water by filtered water
    - Recycling/Composting
    - Food donation: serving people in vulnerable situations with relatively low investment

In 2021, the Food and Agriculture Organization (FAO) highlighted the importance of schools sustainable food procurement embedded in a wider public food procurement (PFP) strategy as a key lever for food systems transformation. In their report describe how PFP can influence both, food consumption and food production patterns and how it can be used as a development tool in the framework of school meals programs delivering multiple social, economic, and environmental benefits as well as health and cultural ones.

The EU funded SchoolFood4Change project (<https://schoolfood4change.eu>) is an example of innovative use of sustainable school food procurement to ensure healthy and sustainable food to C&A, particularly those more deprived.

## Next steps and opportunities

In order to keep on developing School Food Systems knowledge and interventions that can have the highest impacts on C&A health and sustainability there are several topics where more and better knowledge is needed.

- As suggested by Oostindjer et al. (2017), being at the forefront of the shift toward phase three of school food programs will require a curricular integration of school meals with a focus on disease prevention and sustainability, as well as including current societal concerns such as climate change, environmental degradation, social justice and equity.
- A policy equity perspective is of paramount relevance given the highly unequal societies we live in nowadays with a well-known social gradient of C&A malnutrition. Protecting children health and nutrition as a fundamental human right and providing at least one healthy and sustainable meal per day in every school is a current challenge and opportunity.
- Harmonizing school food programs indicators for C&A dietary behavior and nutritional health and food sustainability will allow for evaluation and comparability and it is still the next step in knowledge and innovation application in schools worldwide.

As suggested by Hawkes et al. (2020), reorienting food systems toward healthier diet for C&A in any context is one relevant next step. Hawkes et al. recently developed a 6-step tool to identify actions toward child-centered food systems making healthy diets AAAA i.e. available, affordable, appealing, and aspirational in the context of children lives. The tool starts with the context in which children live or in our case, the school they attend and works back upstream;

1. Collecting data on nutritional health burden at the school level->malnutrition target e.g. overweight/obesity
2. Perform dietary assessment to identify both the eat more and eat less foods.

3. Use qualitative methods to understand the C&A dietary behaviors context (i.e. mapping of school food provision practices and assets).
4. Children-centered food environment measures at school->targeting food environment aspects to be changed to make certain foods more or less AAAA in short- and long-term.
5. Analysis of local food supply systems: Incentives or disincentives to create healthier food environment via a school food procurement supporting food offer diversification and sustainable food production practices (e.g. organic).
6. Develop mutually complementary actions: For example, the EU SchoolFood4Change project mix of actions: (1) healthy and sustainable food procurement, (2) Planetary healthy diets and cooking, (3) Whole School Food Approach to achieve a child-friendly food culture at school.

## Conclusion

The current children and adolescent's health and nutrition status worldwide should be understood from three relevant features: High and rising prevalence of overweight and obesity in most countries of the world. The existence of a clear social gradient of health and nutrition in children and adolescents worldwide. The food system needs to take into account not only the provision and consumption of healthy foods, but the sustainability of all processes of food production and distribution to protect biodiversity and reduce its impact on climate change.

The study of school food systems offers different intervention opportunities to improve the health and nutrition status of children and adolescents, especially for the most vulnerable. School food systems interventions should also promote more sustainable diets.

Several conclusions emerge from this work on school food systems. First, interventions should include a wide range of intersectoral policies and actions comprehensively implemented in concert to achieve highest impact. Second, education and health policies need to be advocate for the relevant issue of healthy food affordability. Finally, engagement and accountability of both public and private sectors are needed.

School settings offer a clear opportunity for sustainable, healthy and equitable food system change including the development of innovative and sustainable food procurement criteria, the promotion of planetary healthy diets and cooking, and the use of a whole school food approach for schools to become integrative learning platforms.

### Key points

- Characterize seasonality in a way that captures the complex interactions among social, ecological, and agro-climatological systems which influence the seasonality of nutrition and health outcomes.
  - Demonstrate that seasonality is an observable property of every system, including both earth and social systems.
  - Show how the drivers of seasonality in nutrition and health outcomes relate to each other through complex systems and mutually reinforcing feedback loops.
  - Describe how seasonality in outcomes is a function of the interplay between human behavior and earth system seasonality, and how policy mediates this link.
- Propose systematic methods for defining and measuring seasonality in nutritional outcomes, considering climatic seasonality and spatial variability.
- Critically evaluate existing evidence on the seasonality of nutrition and health outcomes.
- Discuss how greater understanding of seasonality within a complex systems framework can be leveraged to improve well-being.

## Introduction

At the most basic level, seasonality is defined as the periodic oscillation of systems and events with respect to a calendar. These cyclical patterns observed in human systems, including those that influence nutrition and health outcomes, are fundamentally tied to the earth's rotation on its axis and around the sun. Cyclical planetary movement generates seasons, which directly and indirectly affect agricultural production, food availability and prices (Chambers, 2009; Chambers et al., 1981; Gertel and Sippel, 2014; Gilbert et al., 2017; Kiehne and Mendoza, 2015; Sibhatu and Qaim, 2017), and infectious disease susceptibility. Such cycles can also be related to incomes, labor demands (Feuerbacher et al., 2020; Fink et al., 2020), and caregiving practices (Madan et al., 2018; Rao et al., 2019; Rao and Raju, 2020). Earth systems further determine social and institutional calendars as major holidays and festivals often occur during solstice, equinox, or planting and harvest periods. Environmental, social, and behavioral factors thus generate seasonality in all forms of malnutrition and its drivers, across all contexts (Kuhn, 2018).

Historically, nutrition researchers and practitioners have approached the seasonality of nutritional status considering the effects of a region's agroclimatic characteristics on nutritional status primarily in a unidirectional manner. Most of what we understand about seasonality in nutrition comes from research employing this linear framework due to its pragmatic utility. However, linearity obscures the complex and interconnected drivers of nutritional status, each having respective seasonal fluctuations, which interact in a series of feedback loops. We now envision nutrition seasonality as a byproduct of the complex interplay of several interconnected systems, environmental and health policies, technological innovations, and social and evolutionary factors (Fig. 1). These patterns reflect complex processes, encapsulating various spatial and temporal climatic behaviors that follow natural cycles, sensitive to

**Fig. 1** Conceptual framework for seasonality of nutritional outcomes.

public policies, natural and manmade disasters, within-year cycles that affect local ecosystems, or between-year cycles in climatic patterns such as El Nino/La Nina (Marshak et al., 2021; Naumova, 2006; Naumova and MacNeil, 2006). Multiple scientific disciplines intersect in the field of nutrition, including human and molecular biology, epidemiology, economics, sociology, anthropology, demography, and public policy. Further complicating matters, each discipline defines and addresses seasonality using either disparate terminology or similar terms defined differently based on their respective theory, empirical evidence, and research methodologies. The resulting body of evidence lacks cohesion, contributing to a field-wide failure to fully understand the depths of nutrition-related seasonality.

Climate change, globalization, urbanization, and environmental degradation continue to exacerbate weather extremes and undermine the predictability of climate, threatening food systems and human health. A better understanding of the seasonal drivers of malnutrition is critical to design the most effective policies and programs that avoid the detrimental effects of seasonal climatic cycles on nutritional outcomes. Such understanding can inform a precise approach to nutrition, whereby programs and interventions are more specifically targeted in terms of timing, location, population, and delivery.

This article proposes a paradigm shift from the linear, imprecise, and disaggregated approach to the seasonality of nutrition outcomes, to a holistic, complex systems approach that considers the interconnections and feedback loops in the drivers and mediators of nutritional status as well as the patterns observable in nutrition outcomes. The article proceeds as follows: first, we define seasonality in relation to the Earth's systems and discuss how it can be characterized and measured. Next, we examine the features of seasonality through the lenses of feedback loops within several complex systems that interact with each other to influence the seasonality of nutritional status. We conclude the article with the observed seasonality of nutritional outcomes and thoughts on how knowledge of seasonality as it functions through complex systems can help optimize policy, programming, and research instruments to increase well-being.

## Origins of seasonality

Seasons are the result of planetary, continental, and regional factors that influence air and water dynamics in the atmosphere. Seasonal climatic patterns vary by geography and underlie cyclic fluctuations in many biological systems sensitive to weather and photoperiods, including malnutrition and related health outcomes. The earth's annual orbit around the sun determines the seasonal transition from winter (cooler temperatures, shorter days) to spring, summer (higher temperatures, longer days), autumn, and back to winter. Due to the earth's tilted axis, the northern and southern hemispheres experience generally opposing seasonal cycles with seasonal extremes being more pronounced near the poles. Areas close to the equator, known as the tropics, experience only minor variations in temperature due to consistent direct sun exposure. Tropical regions are more humid and generally experience two distinct wet seasons, or a bimodal precipitation profile. Temperate regions away from the equator commonly experience a broader range of temperatures throughout the year, and often a unimodal profile with only one rainy season or monsoon (Moran, 2009; Rohli and Vega, 2017; Stevens, 2010). These climates sustain drier air, less humidity, and precipitation in the form of snow in the dry seasons. The physical environment also influences the flora and fauna of a region, giving rise to complex ecosystems (Rohli and Vega, 2017).

Climate informs human cycles of agricultural production, food consumption, and social traditions, all of which have important consequences for the seasonality of nutritional outcomes. All crops require a favorable range of temperature and sufficient rainfall for growth; the availability of these conditions determines regional crop calendars and growth cycles. Tropical areas have favorable temperatures year-round, but water availability for agriculture is often limited to few key times of year. Temperate regions have a smaller window of favorable conditions for agriculture when temperatures are sufficiently warm to prevent frost damage and sufficiently cool to avoid heat stress for plants. Therefore, tropical regions often have two or sometimes even three cropping cycles per year, whereas temperate regions may only have one major harvest with a smaller winter crop. These climatological patterns are critical for rainfed agriculture which occupies 75% of cultivated area globally (FAO, 2020).

Each location has its own climatological conditions, and what is considered the norm in one location could be an extreme in another. For a given region, extreme or near-extreme precipitation or temperature can result in a broad range of extreme weather events such as droughts, floods, hailstorms, tornadoes, and heatwaves. Climate systems across large areas are also interlinked, resulting in seasonal storms and cyclones which affect large portions of the Pacific and Atlantic coasts (Moran, 2009). These extreme weather events can cause damage to agricultural production and infrastructure with serious consequences for humans and animals. A single harvest in unimodal regions further increases the livelihood risk in case of a particularly bad harvest leading to diminished stores to last until the following harvest (Schofield, 1974). Although the rainy season can bring necessary water for agriculture, it can also cause outbreaks of water-borne diseases such as diarrhea, cholera, and typhoid or vector-borne diseases such as malaria and dengue fever. Climate extremes can thus increase the likelihood of adverse nutrition outcomes through compromised health, increased livelihood pressures, and diminished resilience (Watts et al., 2018, 2021).

## Defining and measuring seasonality

*Seasonality* refers to systematic periodic (or cyclic) fluctuations in an outcome of interest. *Periodic* implies that the outcome repeats itself in regular intervals, and *systematic* refers to the fixed nature of this pattern within a range of natural variation. A *cycle* is defined

as the time needed to complete a pattern, or the time taken for the system to reset to initial conditions. The duration of this cycle can be defined analytically, derived from data, or arbitrarily selected based on biological, physical, physiological, or other assumptions. Often a calendar year serves as a proxy for a cycle or seasonal period.

### Timekeeping

The first step in depicting seasonality is defining time and its units. Humans are continuously designing and redesigning tools to keep the record of seasonal features in nature and to assign meaning to seasonality. Social traditions have evolved over centuries in reaction to specific weather patterns, and humans have developed tools such as clocks and calendars to keep track of essential events, periods, and their sequence and repetition. A calendar is a system of reckoning time over extended periods with respect to the natural units: the day, the lunar month, and the year. From antiquity, calendars have provided the basis for planning agricultural, hunting, and migration cycles, for divination and prognostication, and for maintaining cycles of religious and civil events. Common astronomical cycles used to define time include the Earth's rotation on its axis (day), revolutions of the moon around the Earth (month), and revolutions of the Earth around the sun (year). There are roughly 40 different calendars used by humans in the world today, each using different parameters to define time (i.e., lunar, solar, lunisolar).

Understanding how the systems of defining time vary in different cultures is essential for further defining time for seasonal studies of health and nutrition outcomes. Researchers most commonly use the solar Gregorian calendar to operationalize seasonality due to its modern use as the international standard for civil purposes (Simpson et al., 2019). However, considering other ways of defining time may be important in contexts where the Gregorian calendar is not used and/or is not aligned with social traditions, migration patterns, or religious events (FAO and Tufts University, 2019). Regional and local calendars may have differently defined seasons and may also be more closely aligned with key environmental transitions affecting nutrition and health (Kulinkina et al., 2016b).

Every calendar also includes special days or sequences of days known as holidays or notable events. These events may vary by community and have substantial, multifaceted effects on health and nutrition. Most cultures mark planetary holidays indicating seasonal transitions based on the earth's rotation around the sun. Such festivals include the equinox, when day and night are approximately equal in length, and solstice, when day length is shortest or longest. Holidays may also follow fixed dates, falling on the same day each year in relation to the calendar which defines them (for example, Christmas on 25 December of the Gregorian calendar, Yom Kippur on the 10th day of Tishrei in the lunar Jewish calendar, or Ramadan, the ninth month of the Islamic lunar calendar commemorated by Eid-al-Fitr on the first day of Shabaan). Alternatively, holidays can occur each year on the same day of the week within the same month (for example, Independence days across the globe). State, federal, religious, and community-specific holidays can affect nutritional outcomes and the transmission and severity of related diseases through changes in food consumption patterns, widespread travel, days not in school or work, and restrictions on alcohol sales (Simpson et al., 2019).

### Defining temporal units

In economic and epidemiological literature, calendar months are commonly grouped into a fewer number of periods to represent seasons (e.g., trimesters (four-month periods); quarters (three-month periods); semesters/half-year/6-month periods). The grouping of months into specific periods, even among studies in similar contexts, also differs across the literature. For example, in temperate climates of the northern hemisphere, some define January to March as the winter season, others define winter as December to February. Calendar years can also be divided into periods of unequal numbers of months, for example: summer (June to August) and remaining months (September to May). This is often done in contexts with unimodal rainy seasons, to separate the rainy from the dry season in analyses of nutritional outcomes.

The grouping of monthly data into periods raises methodological concerns and obscures true seasonality. Most parts of the world experience daily, weekly, and monthly variability in temperature as well as rainfall amounts, timing, and distribution. Aggregation of days or months to seasons (e.g., lean vs. plenty, dry vs. rainy) discards a meaningful sequence in temporal data for a rudimentary grouping. Treating continuous time as discrete categories through dummy variables (e.g., calendar months) in statistical analysis also masks the sequential and cyclical nature of the climatological phenomena that form the basis of our human-derived calendars. Climate-related characteristics such as temperature and precipitation are typically presented as a time series, or a sequence of values that are ordered with respect to a time reference. The ordered and cyclical nature of the time series must be preserved for accurate modeling. Furthermore, discrete models of time erroneously discount interannual variations in the environment and can diminish the importance of the time of rainy (or other) season onset. For example, if the rains began on 3rd April instead of 20th March, discrete approaches would document a shift of greater magnitude across categories rather than a delay of two weeks. Major calendars, including the Gregorian calendar, contain months with unequal number of day and thus the discrete representation discards the difference in true durations (Alarcon Falconi et al., 2020).

### Defining spatial units

Considering spatial units is equally important for seasonality analysis. Spatial extent is most often defined by administrative boundaries at increasingly local scales, for example: country, state, county, and district. Administrative boundaries are frequently aligned with geographic features such as rivers and mountains which can physically separate communities. Existing surveillance systems

may also use administrative hierarchies for monitoring and reporting purposes; therefore, these boundaries are particularly useful for epidemiological and nutrition data (Lawson, 2013). However, administrative boundaries serve institutional purposes and are not inherently indicative of distinct demographic or climatological extents. Aggregation of outcomes across regions must be performed with care as administrative boundaries can be very different from agroclimatic, geographic, or demographic boundaries (Lawson, 2013; Tate and Atkinson, 2001). Spatial aggregation to the country or administrative unit scale can mask spatial variability in outcomes; for example, analysis of an outcome measured at the household scale in a small number of communities may not be meaningful when aggregated to the state level (Bordt, 2015; Tate and Atkinson, 2001). Physical proximity of communities also does not imply sufficient justification for aggregation as communities with different identities, livelihoods, migration patterns, and social calendars—and hence potentially different seasonal patterns in nutrition—can live in close proximity (Buzzelli, 2020). Therefore, high spatial granularity might not be sufficient to detect seasonality, while high spatial aggregation might lead to mixing seasonal patterns, making them indistinguishable. A meaningful spatial extent with sufficient resolution and internal variation is thus required for capturing seasonal patterns.

### Quantifying seasonality

To measure seasonality and its effects on nutrition outcomes, there are two groups of statistical methods that can be performed using most commercial statistical packages. The first approach involves the use of indicator variables that reflect discrete time periods. Results are usually interpreted with respect to a reference category. For example, seasonality of malnutrition may be measured as the magnitude increase in prevalence of wasting in the dry season compared to a reference category of the wet season (Marshak et al., 2021). This approach is widely utilized due to its simplicity. Although insufficient for modern seasonality analyses that depict complex patterns and enable comparison of multiple seasonal patterns, this approach can provide basic insight into potential seasonal behavior when used with caution.

The second approach includes a broad range of modern methods such as harmonic regression to describe the timing, magnitude, and duration of a seasonal cycle. This approach utilizes a rich vocabulary to ease general comprehension and ensure reproducibility. Table 1 provides a list of terms to define seasonality in conducting research and policy analysis.

Following the terminology, to quantify the timing of seasonal peaks (highest values) and nadirs (lowest values), measures to estimate the position of these points on a seasonal curve of the outcome of interest (i.e., malnutrition incidence or exposure) are needed. The magnitude related measures include peak and nadir values of the seasonal curve, the amplitude (the difference between peak and nadir values) and the relative intensity (the ratio of peak values and nadir values) (Marshak et al., 2021; Naumova and MacNeil, 2006; Ramanathan et al., 2020). Fig. 2 depicts an example showing daily time series of weight-dependent nutrition outcomes and illustrates the seasonal attributes.

Additional characteristics may describe peak duration (when the outcome of interest is above a given threshold) and the degree of symmetry in the seasonal rise and fall of variables. The composition and relationship among these measures form seasonal signatures with their positioning, lead, and delay times relative to each other. In some cases, more than one seasonal peak is observed during a calendar year. When this happens, the peak with highest outcome values is defined as the primary peak, and the other as secondary (Naumova and MacNeil, 2006). By examining the relationships across different seasonal characteristics, for example peak timing and intensity, one could investigate potential drivers of seasonality or predict the changes in seasonal behaviors. These characteristics can also be used to study synchronicity across time series (Simpson et al., 2020). Similar peak timings of temperature and wasting, for example, can point to synchronization of the incidence of malnutrition with environmental and/or social processes.

### Interactions of climatic seasonality with multiple systems

Climatic seasonality resulting from the earth systems underpins seasonality within food, livelihood, and environmental systems (Fig. 1). It also impacts the interactions between humans, other living organisms, and pathogens, influencing patterns of disease and malnutrition. Interactions among these interconnected systems affect seasonal patterns in nearly all drivers of nutritional status including food security; consumer demand and preferences; food safety; diet quality; labor demands (energy expenditures and incomes); time use and care practices; availability of adequate clean water, hygiene facilities and practices, and adequate sanitation; and disease incidence.

The impact of agroclimatic seasonality on malnutrition is mediated by the interaction of these systems with technology, institutions, policies, and processes. Interactions can take the form of feedback loops in which drivers and outcomes interact as mutually reinforcing forces mediated by human behavior. These feedback loops can either strengthen seasonal fluctuations or balance the impact of agroclimatic seasonality such that outcomes do not exhibit strong seasonal patterns (Meadows and Wright, 2008). Identifying feedback loops also reveals entry points for policy instruments to reduce negative impacts of seasonality on people's health and well-being.

### Food systems

Food systems encompass all of the people, institutions, environments, and infrastructure relating to the production, processing, distribution, marketing, sale, and consumption of food (Fanzo et al., 2021, 2020; Global Panel on Agriculture and Food Systems

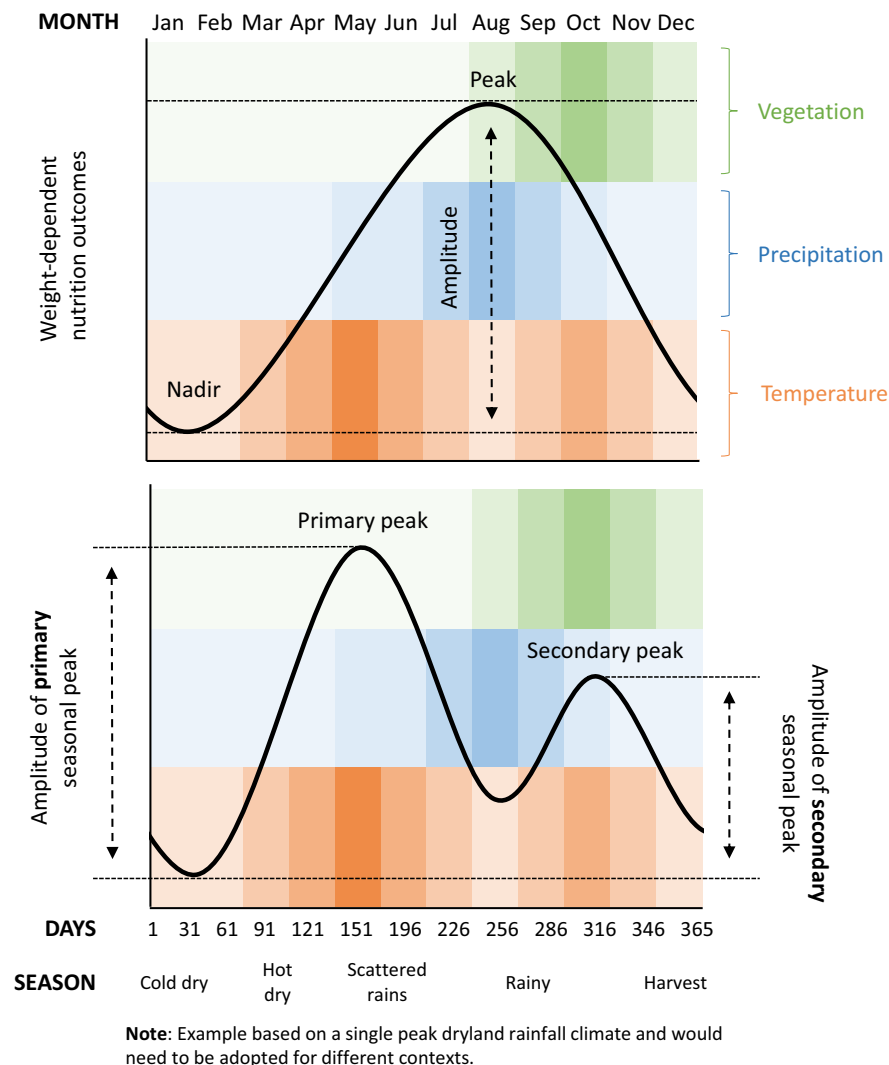

**Table 1** Suggested terminology to describe seasonality in conducting research and policy analysis.

<i>Term</i>	<i>Definition</i>
Time series data	A set or a sample of time-referenced observations or records with an identified time period, time cycle, and time unit recorded by a timestamp.
Timestamp	Information on day, week, month in a conventional format (e.g. YYYY:MM:DD or YYYY:MM:DD:HH:mm) of data collection or processing.
Time series plot	A graph illustrating time series data by dot, line, or needle plots with axes reflecting time and an outcome(s) of interest.
Distribution of time series data	A general summary of frequencies in time-referenced data—i.e., how often an outcome of interest reaches a certain level with respect to time units.
Distribution plot of time series data	Often illustrated with histograms and density plots.
Time series analyses	A collection of methods to describe, explain, and predict temporal processes with time-referenced data for an outcome of interest.
Trend	General temporal behavior in an outcome of interest that can exhibit steady incremental changes (linear) or varying incremental changes (non-linear) over time.
Season	An interval of time within one time cycle (typically one calendar year) defined by a specific biological, environmental, physical, physiological, or other property or feature in a biological or non-biological system [ref].
Seasonal pattern	A recurrence of periods in an outcome of interest with alternating values (e.g., high and low) over the course of a time cycle, commonly one calendar year.
Seasonality	A systematic periodic fluctuation in an outcome of interest over the course of one cycle (typically one calendar year) as an observable property of a biological or non-biological system.
Seasonal curve	An analytical representation of seasonal periodic fluctuations in an outcome of interest within one time cycle (typically one calendar year).
Seasonality features	A set of measurable characteristics to describe seasonality and a seasonal curve within one year, including seasonal peak, nadir, intensity, duration, speed at which a seasonal curve reaches its peak, and speed at which a seasonal curve declines to its nadir (Naumova, 2006).
Peak or nadir timing	A seasonality feature that represents times when a seasonal curve of an outcome reaches its maximum or minimum (Naumova, 2006).
Amplitude or intensity	A seasonality feature that represents the difference between seasonal peaks and nadirs (Naumova, 2006).
Duration	A seasonality feature that represents the time interval when incidence rises above a specified threshold (Naumova, 2006).

for Nutrition, 2016; HLPE, 2017) (Fig. 3). Food systems contribute to diet quality and nutrition outcomes by determining the food that is available to a consumer at any given place or time, including the costs and quality of the food. Consumers will choose different available foods based on their income, food prices, cultural traditions, and their preferences. Climatic patterns intersect with the economic forces of supply and demand by affecting food production and defining the cycles around which human eating patterns have evolved over hundreds of years. Social traditions have developed alongside climate patterns, which reinforce seasonal fluctuations in demand for foods around traditions like celebrations of agricultural cycle events (planting, rains, harvests) or solar and lunar cycle events (new or full moons, solstices, equinoxes).

### **Food supply, demand, and prices**

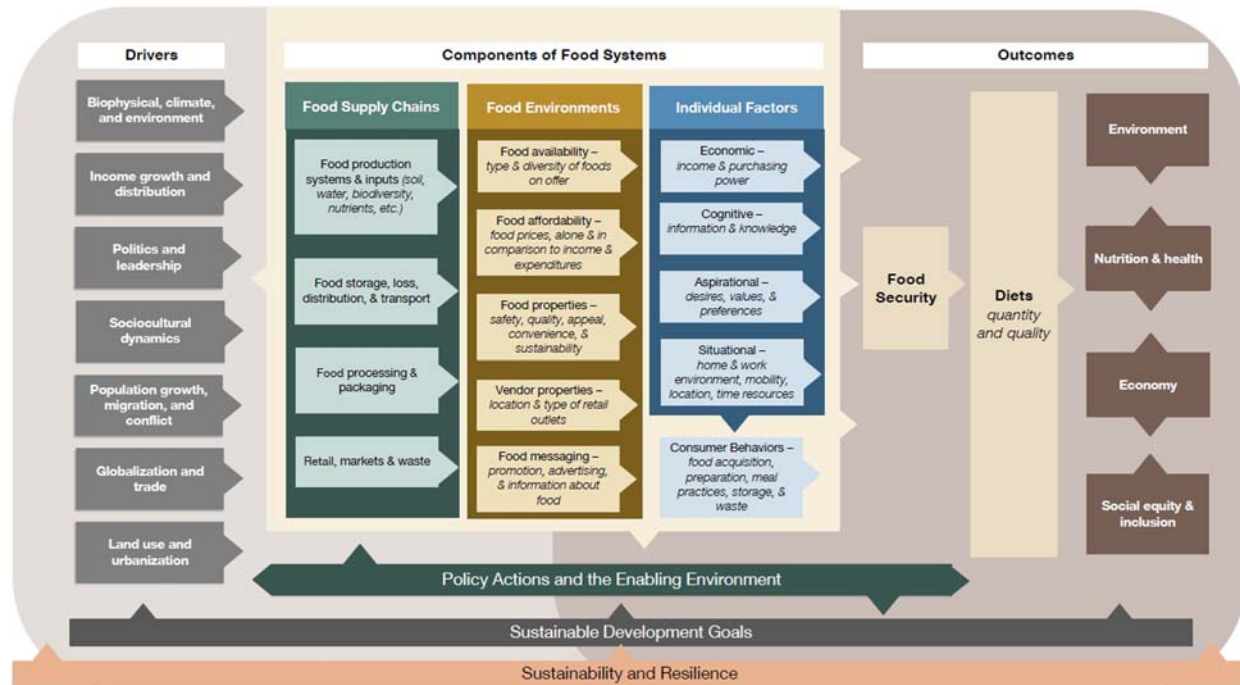

Places where agriculture is the predominant economic activity tend to exhibit seasonal patterns in food supply, demand (due to seasonal incomes), and prices, affecting many people and permeating all sectors of the economy. The reasons are multifaceted, owing to the large proportion of gross domestic product (a measure of the size of the total economy) from agriculture (Devereux

**Fig. 2** Example seasonal curves of weight-dependent nutrition outcomes.

et al., 2013; Dillon and Barrett, 2017; Zania, 1999) and poorly functioning markets. Market imperfections limit the opportunity to use trade to smooth supply and demand of goods and services (including labor) throughout the year, resulting in more fluctuations of supply, demand, and prices based on local conditions (Dillon and Barrett, 2017; Kaminski et al., 2016; Zania, 1999).

In agriculturally-dominant economies diet quality is largely driven by the foods available at different points in the agricultural calendar, and the coincident fluctuations in food prices and incomes (Branca and D'Acapito, 2012; Devereux et al., 2013; Gilbert et al., 2017; Gill, 1992; Kaminski et al., 2016; Vaarst et al., 2018; Vaitla et al., 2009). Where markets are isolated, changes in supply can have immediate and lagged effects on local prices. Decreased supply results in higher prices and increased supply the reverse, a pattern that is most pronounced for goods with inelastic demand (necessities) that does not change much as prices oscillate. Where trade is costly or infeasible, local supply affects aggregate supply since compensation for shortages or surpluses is not possible. Further complications to food availability arise from insufficient infrastructure and technology to preserve and store goods, and lack of financial services for savings and credit to smooth incomes over time or make investments that create more stability throughout the year. The result is a transformation of the inherently neutral seasonal property of the climate system into seasonal patterns that are detrimental to wellbeing, health, and nutrition (Biding et al., 1986; Christian and Dillon, 2018; Feuerbacher et al., 2020; Fink et al., 2020; Gilbert et al., 2017; Gill, 1992; Chris Hillbruner and Egan, 2008; Kaminski et al., 2016; Sahn, 1989; Stelmach-Mardas et al., 2016; Vaitla et al., 2009; Zania, 1999). For example, the commonly known "lean season" occurs when household food stocks and cash from the prior harvest are depleted while supply in markets is limited, leading to high prices and unaffordability among those with limited financial resources (Anderson et al., 2018; Gelli et al., 2017; Vaitla et al., 2009). Timing of the "lean season" can vary by livelihood specialization—for pastoralists, milk production is highest during the rainy season given improved access to pasture, but for those who rely on starchy staples, supplies are lowest during the rainy season. Beyond cereals and animal protein, fruits and vegetables are often only available certain times of the year, limiting access to essential

**Fig. 3** Food systems framework: components, drivers, and outcomes. Reproduced with permission from Fanzo et al. (2021).

micronutrients (Abizari et al., 2017; Ambikapathi et al., 2021; Aparicio-Ugarriza et al., 2018; Bonis-Profumo et al., 2021; Crane et al., 2019; Jahns et al., 2016; van der Toorn et al., 2020).

In economies that do not depend on agriculture and where there are fewer transaction costs to trade, seasonal fluctuations in local production generally do not affect local supply. Stable supply and demand produce stable prices. The exception, however, is when an extreme weather event is large enough to impact total global production, in which case global and domestic prices can be affected, depending on policy responses. Trade restrictions (export or import bans) can have immediate and negative impacts on both world and domestic prices as they interfere with market competition but are often used by governments in times of crises to pursue domestic political stability (Pinstrup-Andersen, 2015).

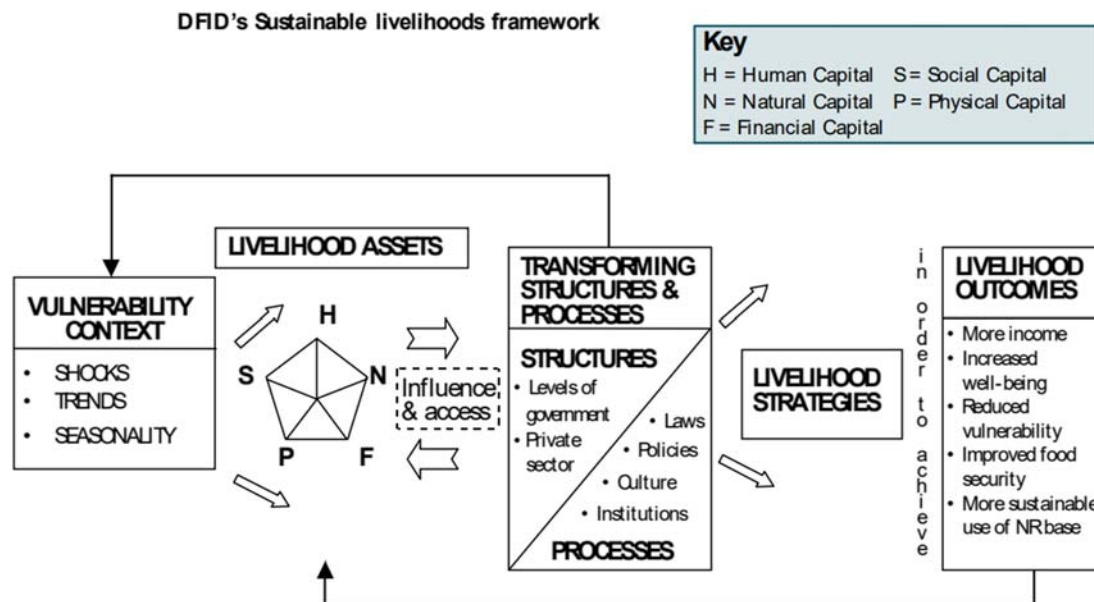

### Cultures and traditions

School calendars, holiday traditions, lifecycle traditions and celebrations, seasonal work patterns, and the cadence of social protection benefit cycles all intersect with climatic seasonality to affect food supply, incomes, and/or demand leading to impacts on nutrition (Beatty et al., 2019; Cotti et al., 2018; Graham et al., 2018; Kuhn, 2018; Laurito and Schwartz, 2019; Lerche, 2012). Religious practices often dictate certain foods be consumed (or abstained from) in relation to certain holidays, which affect patterns of demand. Examples include Ethiopian orthodox fasting (D’Haene et al., 2019), Ramadan, and Passover. Cultural traditions around holidays may also include traditions of relatively unbalanced diets during the Thanksgiving to New Year’s period in the United States. Changes in eating patterns around holidays and special events can either be detrimental to nutritional status (e.g., increased added sugar) or can contribute positively to overall nutrition (e.g., access to animal-source foods that are lacking the rest of the year), depending on the context.

Recently, public health and environmental behavior change communications have encouraged “seasonal” eating patterns, meaning consuming mainly the products and especially fresh produce that are in season in one’s local region. From the public health perspective, this is a way to encourage variety in diets and increase diet quality (WHO, 2018). From an environmental perspective, it encourages consuming foods that have not been flown around the world. However, while local food consumption may support seasonal eating patterns and local food systems, farmers, and economies, it sometimes comes with higher greenhouse gas emissions and water footprints than more efficient larger scale production and transportation methods, and may increase an area’s reliance on exploitative labor practices (Coley et al., 2009; Edwards-Jones, 2010; Edwards-Jones et al., 2008; Enthoven and Van den Broeck, 2021). Technological innovation is essential to mitigate this current tradeoff (Barrett et al., 2020).

### Livelihood systems

Livelihoods encompass all of the capabilities, assets, and activities necessary to obtain a means of living (Serrat, 2017) and are linked to food systems through labor, demand, and incomes. Fig. 4 presents a commonly used sustainable livelihoods framework. Capabilities are the power and freedom for a person to live the life they find most fulfilling (Sen, 2000). Assets include natural

**Fig. 4** Sustainable livelihoods framework. Reproduced with permissions from the Foreign, Commonwealth & Development Office.

resources (e.g., land, water), financial resources (e.g., income, savings, credit), physical assets (e.g., infrastructure, tools, technology, and livestock), social capital (e.g., relationships, networks), and human capital (e.g., health, knowledge, education). Activities encompass income-earning activities as well as those necessary to sustain life and households, including self-care and caregiving (Fernandez et al., 2016; Gottfried and Chun, 2018; Robinson and on behalf of CARE USA, 2010). The interactions between one's assets and experienced vulnerabilities are mediated by policies and institutions, together guiding livelihood strategy choices and contributing to nutrition, health, and poverty (DFID, 1999; Serrat, 2017).

### Labor

All workers who provide goods and services where demand fluctuates with seasons may experience seasonal changes in their incomes, time and labor demand, and physical and mental health (Chaney and Torres, 2017; Devereux et al., 2013; Guidetti et al., 2020; Harriss-White, 2010; Mishra, 2020; Pattenden, 2016; Routh and Borghi, 2016). As energy expenditure fluctuates with seasonal variations in temperature and physical labor demand, availability and affordability of sufficient food and water to meet people's needs change in tandem. For smallholder farmers, increased labor demands of harvest and post-harvest processing often coincide with the lean season, as food and incomes from the prior harvest have run out (Bacon et al., 2014; Branca and D'Acapito, 2012; Devereux et al., 2013). The combined effects that this period can have on nutrition and health is especially important for women farmers who are pregnant or breastfeeding, due to intergenerational transmission of nutritional status (Bonis-Profumo et al., 2021; Vir, 2015). Not only does energy expenditure during pregnancy and lactation affect child growth, birth outcomes, and nutritional status, but also affects mothers' time available for caregiving (Higgins and Alderman, 1997; Johnston et al., 2018).

Seasonal labor also tracks patterns of tourism, as well as demand for food and other goods typically consumed at certain times of the year (e.g., holiday foods and gifts, "back-to-school" shopping, "wedding season"). Those without stable employment often work seasonal jobs and may migrate to follow work opportunities (Bozkurt, 2015; Chaney and Torres, 2017; Frank-Miller et al., 2015; Geremew and Gourio, 2018; Guidetti et al., 2020). Farmworkers living and working in high income countries are an especially vulnerable group, often migrating seasonally with children whose learning, health, and food security then follow the migration and work cycles (Arcury and Quandt, 2020; Castañeda et al., 2015; Kiehne and Mendoza, 2015; Lim et al., 2017; Quandt et al., 2016, 2021; Smith and Cuesta, 2020). In addition, hourly workers' schedules depend on factors such as customer volumes, holidays, or school calendars, which similarly affect incomes, time, and stress (Bozkurt, 2015). The consequences are fluctuating incomes and therefore ability to meet basic needs for health and nutrition, including quality diet, shelter, access to sanitary facilities, caregiving, and sleep (Hill et al., 2013).

Food system workers required to be outdoors (e.g., farmers, market vendors) may also be exposed to extreme heat conditions, which significantly increase the body's need for water. If clean water is scarce, dehydration and heat stress can occur rapidly. This is especially dangerous for those with chronic diseases such as diabetes (Kenny et al., 2010). In addition, these conditions reduce labor productivity, further exacerbating the burden of livelihoods based on manual or mobile labor (Cheuvront et al., 2010).

### Environmental systems

Environmental systems encompass the physical surrounding and conditions in which people live and are directly influenced by climatic seasonality. Mutually reinforcing feedback loops within environmental systems interact to influence care practices, hygiene,

use and availability of clean water, pathogen survival, and food safety. These factors are in turn related to additional feedback loops between infectious disease susceptibility and diet quality, which ultimately influence nutrition outcomes.

### **Infectious disease and nutritional status**

Morbidity due to infectious disease is both a driver and consequence of undernutrition among vulnerable populations, including children and pregnant/lactating women (Scrimshaw et al., 1968). Inflammation due to infection inhibits the anabolic processes that build organs and tissues, and increases the permeability of the small intestinal walls, leading to malabsorption of nutrients (Keusch et al., 2014; Millward, 2017). The body adapts by using the available nutrients to support immune function, prioritizing survival, and downregulating growth (Gluckman and Hanson, 2004). In addition to nutrient malabsorption, infection and inflammation also lead to loss of appetite and decreased dietary intake, which then lead to compromised immunity, increasing risk for infection in a vicious cycle (Egorov et al., 2010; Katona and Katona-Apte, 2008; Schaible and Kaufmann, 2007; Scrimshaw et al., 1968). Evidence that the association between acute malnutrition and mortality is context dependent, with higher levels of mortality from acute malnutrition in regions with highly prevalent infectious disease, points toward morbidity as the main mediating factor between acute malnutrition and mortality (Pelletier et al., 1995; Young et al., 2006). The burden of infectious disease is impacted both directly through conditions more favorable to disease transmission and through higher susceptibility to disease at certain times of the year (Naumova, 2006).

### **Pathogen survival**

In low- and middle-income countries (many of which have agriculturally-dominant economies), the cyclic relationship between morbidity and undernutrition is characterized by seasonal fluctuations in intensity and magnitude resulting from the effects of agro-climatic seasonality on disease dynamics (Pascual and Dobson, 2005). At certain temperature, precipitation, and vegetation levels, infections spread more rapidly than at others. However, peaks in each of these climatic factors usually do not happen simultaneously, and vary across geographic regions (Marshak et al., 2021). It is thus useful to think about seasonality of infectious disease in relation to specific permutations of these climatic factors that combine to favor high transmission of infectious disease, either through their influence on the safety and hygiene of the environment, or through differential pathogen survival under various conditions.

For example, high ambient temperatures support pathogen survival, precipitation can increase water contamination with fecal matter, and food scarcity during some agricultural seasons can increase host susceptibility to disease and malnutrition. In places with high burdens of undernutrition, such as sub-Saharan Africa and Southeast Asia, it is widely accepted that many undernutrition-adjacent diseases spread most rapidly during periods of intense rain. Rainfall is associated with increased standing water, which propagates disease-transmitting pathogens, such as mosquito vectors that increase the burden of malaria and dengue fever (Bayoh et al., 2001; Dao et al., 2014; Roca-Feltrer et al., 2009), and with increased fecal contamination of drinking water with diarrheagenic bacterial pathogens (Dongzagla et al., 2021; Ercumen et al., 2017; Hossain et al., 2019; Kirby et al., 2016). Respiratory illnesses and pneumonia are also associated with undernutrition; however, while these diseases are more common during rainy seasons in tropical climates with high humidity (Li et al., 2019; Obando-Pacheco et al., 2018), there is substantial spatial variation in their seasonality, and they happen more frequently in cold or dry seasons in some contexts (Li et al., 2019).

High ambient temperature also plays an important role in nutrition outcomes, and in some contexts may be an even more important driver than precipitation (Chikhungu and Madise, 2014; Cliffer et al., 2021; Fentahun et al., 2018; Marshak, 2021). Pathogens replicate more efficiently and survive longer in high temperatures (Azage et al., 2017; Hashizume et al., 2007; Islam et al., 2009; Vargas et al., 2004). The highest risk period for diarrheagenic *E. coli*, for example, is during the pre-rainy season when temperatures are highest, and rains are sparse (Azage et al., 2017; Vargas et al., 2004). The lack of sufficient clean water during the hot, dry season, when precipitation is low but not zero, may also lead to consumption of unsafe water and require reduced hygiene practices that leave people vulnerable to infection (Fewtrell et al., 2005; Jagai et al., 2012; Kulinkina et al., 2016a).

Disease transmission dynamics may also be modified by geological factors. For example, in dryer regions of India, cholera transmission has been found to peak during the monsoon season; however, in the estuarine regions surrounded by wetlands, cholera was at its lowest point during the monsoons (Pascual et al., 2002). Understanding how specific combinations of peaks and nadirs in the magnitude of climatic factors affect pathogen survival and disease transmission risk, and how these factors vary both temporally and spatially, is important in interrupting feedback loops between infectious disease and nutrition outcomes.

### **Feeding and caregiving**

Host susceptibility to disease fluctuates in relation to food intake and security, time for caregiving and breastfeeding, and access to and use of health services. Studies across multiple low- and middle-income country contexts have shown that people have higher food insecurity (Bangladesh, Kenya, The Gambia) (Chris Hillbruner and Egan, 2008; Nabwera et al., 2017; Shell-Duncan, 1995), and fewer resources for caregiving (The Gambia, Nepal) (Nabwera et al., 2017; Panter-Brick, 1997), including breastfeeding time (India) (Das et al., 2016), during periods of high precipitation, since these periods coincide with the agricultural planting season. In addition, for pastoralist communities, undernutrition peaks during the dry season when access to animal milk is lowest (Sadler et al., 2009). In the past, the idea that undernutrition was primarily driven by lack of inadequate food consumption, known as the “food-first bias” dominated the literature, and led programming and policy efforts to prioritize food-related interventions (Pelletier et al., 1995). However, several studies have linked the relationship between decreased food intake/less caregiving time and increased

vulnerability to growth faltering during the rainy season to the feedback loops and synergistic effects between inadequate diet and higher disease incidence (Bohler et al., 1995; Ercumen et al., 2017; Madan et al., 2018; Nabwera et al., 2017).

### **Food safety**

Diseases that threaten food safety, particularly mycotoxins, also follow seasonal patterns in tropical settings with inadequate control measures. Mycotoxins such as aflatoxins, fumonisins, and deoxyvalinol, are toxins produced by fungi known to be carcinogenic and harmful to human health even in small amounts (Adeyeye, 2020; Marasas et al., 2008). The molds that produce these toxins proliferate in hot, humid climates characteristic of the rainy season in tropical areas (Adeyeye, 2020; Fraeyman et al., 2017; Gong et al., 2016; Marasas et al., 2008; Smith et al., 2016). Outbreaks of acute aflatoxin poisoning (aflatoxicosis) have occurred in recent years, with the most studied being the Kenya outbreak of 2004, and affect both human and animal health (Groopman and Kensler, 2005; Rumbeiha and Oehme, 2005). Long-term exposure, such as chronic seasonal exposure, causes liver cancer and is a suspected contributor to low birth weights and child stunting (Coppock and Dziwenka, 2014; Gong et al., 2016; Lauer et al., 2019). Other animal diseases also follow seasonal patterns, which can increase animal morbidity and mortality, reducing the income and food-source opportunity of livestock keeping (van Dijk et al., 2010; Nwanta et al., 2008; Thornton, 2010).

### **Access to water**

Water access follows seasonal patterns related to rainfall and temperature. Lack of water can increase exposure to disease, reduce livestock health, and increase labor burdens. During the dry season, people may access poorer quality water sources, or walk long distances to get water (Brewis et al., 2020; WHO and UNICEF, 2021). This reduces the total water availability for drinking, cooking, cleaning, and personal hygiene and propagates water-borne diseases. However, the start of the rains can also bring increased pathogenic contamination as fecal matter and other contaminants get washed into seasonal and permanent water sources (Kulinkina et al., 2016b). The water access pathway thus influences nutrition via disease prevalence, reduced drinking water access, and increased labor burden in settings where households do not have access to potable water piped directly to their homes. Even where piped water infrastructure exists, increasing seasonal droughts are threatening water for households and agriculture (Aho-pelto et al., 2019; Lindqvist et al., 2021; Mekonnen and Hoekstra, 2016).

### **Climate change**

Global climate changes will continue to exacerbate many of the agroclimatic drivers of poor nutritional status through food system, livelihood, and disease pathways (Clark et al., 2020; Crippa et al., 2021; Davis et al., 2016; Myers et al., 2017; Rosenzweig et al., 2020; Springmann et al., 2018; Willett et al., 2019). Food systems are estimated to be responsible for approximately 30% of global greenhouse gas emissions. Greenhouse gas emissions worsen climate change, which is anticipated to further destabilize climatic patterns and increase weather extremes (Tubiello et al., 2021). Extreme weather negatively impacts agricultural production, water availability, disease prevalence (food-borne, water-borne, human, and animal), interrupts transportation networks, changes labor and time demands, and reduces incomes, all of which stand to threaten food security, diet quality, and health (Park et al., 2019; Springmann et al., 2016).

## **Seasonality of nutritional outcomes**

The complex interactions of seasonal fluctuations in the feedback loops within food, livelihood, and environmental systems culminate in observed seasonality of nutrition outcomes.

### **Growth, anthropometry, and body composition**

Seasonal changes in nutrition and anthropometry have been documented since as far back as the late 18th century when Le Comte de Montbeillard of France measured his son's height every six months for 18 years and found that the boy grew twice as much in the summer as in the winter (Tanner, 1981). Subsequent studies in similar contexts with wide temperature variations found that child height growth was largest in the warmer spring months, and weight gain largest in autumn (Orr and Clark, 1930; Pollitt and Arthur, 1989). In more recent years, data from high income contexts have revealed more variability in the seasonality of weight gain, showing fluctuations within seasons and even weeks, with weekends and holidays characterized by higher weight gain (Turicchi et al., 2020). Seasonal anthropometry patterns in high income contexts can also be modified by major disasters or life events. A recent example is the Covid-19 pandemic; children's body mass index (BMI) increased in South Korea in spring 2020, as opposed to the expected decrease (Han et al., 2021).

Growth seasonality in low- and middle-income countries started receiving attention midway through the twentieth century when it became clear that identifying peak timing of poor nutrition outcomes was critical for more effective interventions and policies. The consensus from most studies conducted since then is that nutritional outcomes in low- and middle-income countries are worst during the rainy/monsoon/lean/pre-harvest period of the year (Abay and Hirvonen, 2017; Benefice et al., 1984; Bohler et al., 1995; Grellety et al., 2013; Chris Hillbruner and Egan, 2008; Miller et al., n.d.; Nabwera et al., 2017; Panter-Brick, 1997; Roba et al., 2016; Schwinger et al., 2014; Tomkins et al., 1986; Wright et al., 2001) as opposed to the harvest period or dry season, though

a handful of studies indicate worse weight-related anthropometric outcomes during the dry season (Bechir et al., 2010; Chikhungu and Madise, 2014; Chotard et al., 2010; Egata et al., 2013; Kinyoki et al., 2016; Loutan and Lamotte, 1984; Nielsen et al., 2011; Sellen, 2000; Trowbridge and Newton, 1979).

Recent research out of the African Sahel indicates that two seasonal peaks of undernutrition may be present within the same year. Primary research from Chad (Marshak, 2021) and Burkina Faso (Cliffer et al., 2021) among non-nomadic households (practicing both farming and livestock ownership) reveals two peaks of child undernutrition. A larger peak occurs during the hot dry season, right as sporadic rains begin, followed by an improvement during the rainy season, and a smaller peak as the rains taper off and temperatures rise again right before the harvest (as shown in Fig. 2 from the measuring seasonality section). Secondary data analysis across all dryland unimodal rainfall contexts in Africa's Sahel confirms this pattern (Venkat et al., 2023). These studies demonstrate that existing assumptions around seasonal patterns of nutrition outcomes require further investigation and underscore the notion that assuming a single pre-harvest/lean season peak is insufficient. In addition, they show the importance of considering combinations of climatic factors rather than thinking of seasonality as a function of discrete categories and support an important role for ambient temperature in child growth.

While most seasonality research focuses on weight-related anthropometric indicators that show short-term change, seasonality has also been observed in length attainment, length growth, and stunting. In Mali, Malawi, and Burkina Faso, the rainy season was associated with higher HAZ, lower prevalence of stunting, and higher length velocity, respectively (Adams, 1994; Chikhungu and Madise, 2014; Cliffer et al., 2021). Moreover, a four-decade cohort analysis from The Gambia indicates a time lag of three months between the seasonality of attained weight vs. height indicators (Schoenbuchner et al., 2019). Variation has been observed in the seasonality of different nutrition indicators, even within the same study. For example, a study in Ethiopia found diverging seasonal trends depending on the indicator used, with stunting and underweight peaking in the pre-harvest period and wasting peaking in the post-harvest period (Roba et al., 2016).

Further, looking beyond weight anthropometry at body composition measures shows that not all growth or weight gain is the same. Among a population of adults in the Netherlands, fat mass showed a maximal value in the winter and a minimal value in the summer, while fat-free mass showed no significant seasonal changes. The authors attribute these differences directly to variability in conditions conducive for physical activity (Westerterp, 2020). Similar findings have been found across multiple western contexts among adults (Haggarty et al., 1994; Plasqui et al., 2003) as well as children (Dalskov et al., 2016). Thus, different seasons may be associated with different physiological changes related to weight, height, and body composition.

### Micronutrient status and deficiencies

Micronutrient consumption and deficiencies have their own seasonal patterns due to variations in climate, agricultural activities, food availability, access to fortification and supplementation, and disease. A study of women of childbearing age in China showed lower concentrations of folate and hemoglobin in the summer, leading to a higher prevalence of moderate anemia, while concentrations of vitamin B-6 were lower in winter and spring (Ronnenberg et al., 2000). Among pregnant women in Nepal, micronutrient status was best during winter months when vegetables and fruit are abundant and more affordable. Serum-carotene and vitamin B-6 peaked immediately following the timing of the mango and banana harvest. Vitamin D concentrations, on the other hand peaked during the monsoon and hot summer months, presumably as a response to increased exposure to sunlight (Jiang et al., 2005). However, seasonal differences for certain contexts and populations can follow completely different patterns divorced from the agricultural cycle. Iron status among Japanese collegiate elite female rhythmic gymnasts was lowest during the preseason's weight loss period, due to lower protein intake (Kokubo et al., 2016). Thus, while there is a pattern of improved consumption of key micronutrients corresponding to the harvest, it is not unilateral across contexts or micronutrients and requires a keen understanding of livelihood activities, access to healthcare and nutrition programs, and dietary patterns.

### Variation in seasonal patterns of nutritional outcomes

Seasonal patterns in nutrition outcomes can change over time and can vary depending on the specific sub-population or geographic location.

#### Sub-population variation

One modifier of seasonal nutrition outcomes is age. In Senegal and Ethiopia, seasonal differences in body weight and weight-for-height z-scores (WHZ) were greater among adults compared to adolescents and school aged children respectively (Benefice et al., 1984; Ferro-Luzzi et al., 2002). Seasonal changes in body composition can also vary by age group. In The Gambia, younger adolescent girls gained weight in the form of lean mass across all seasons, while older adolescents lost lean mass during the lean season, likely due to the importance of adipose tissue for reproduction (Reiches et al., 2013). Among children under five, younger children show greater seasonal variability in their nutrition outcomes (Maleta et al., 2003; Simondon et al., 1993) corresponding to changes in breastfeeding, complementary feeding, and the child's immune system (Maleta et al., 2003).

Sex and gendered beliefs and practices also influence nutrition outcomes. In Senegal and Ethiopia, seasonal undernutrition was greater in adult men than women, attributed to sex-differentiated livelihoods (Ferro-Luzzi et al., 2002; Simondon et al., 1993). In Mali, The Gambia, and Chad, boys under the age of five showed greater seasonal variation in nutrition outcomes compared to girls (Adams, 1994; Marshak, 2021; Schoenbuchner et al., 2019). These trends correspond to differences found by sex and gender across

a host of health outcomes with males generally more vulnerable to mortality and morbidity (Elsmén et al., 2004). Biological factors also intertwine with social systems that may lead households to target certain foods to different household members based on (perceived) needs or biases, compensating for or exacerbating biological vulnerability (Berti, n.d.).

Distinctions have also historically been made between livelihood specializations, with farming communities more vulnerable to malnutrition in the rainy season and pastoralist communities more vulnerable in the dry season. However, this distinction may not always hold true, given that in many contexts there has been a transition into more mixed livelihood systems. A study in Chad found that acute malnutrition peaked in the dry season for children living in both nomadic and sedentary communities (Bechir et al., 2010). In the Horn of Africa, seasonal fluctuations in wasting were higher among children living in areas that predominately practices pastoralism as opposed to farming, but overall seasonal patterns were the same (Chotard et al., 2010). Moreover, several studies have revealed seasonal patterns that directly contradict previous historical assumptions. Among farming communities, worse nutrition outcomes have been found in the dry season as opposed to the rainy or pre-harvest season (Chikhungu and Madise, 2014; Chotard et al., 2010; Egata et al., 2013; Trowbridge and Newton, 1979), while a study in Senegal among nomadic households, found worse nutrition outcomes in the rainy season (Benefice et al., 1984).

### **Spatial-temporal variation**

Lastly, seasonal patterns vary over time and space. In a 2-year study in Senegal the authors found that peaks and nadirs in weight variation changed from one year to another, and differed for communities that had access to irrigation, which dampened seasonal variability in weight (Simondon et al., 1993). Thirty-six years of data from The Gambia shows how seasonality of multiple anthropometric outcomes decreased over time, as investments in health, development, and nutrition programming increased (Nabwera et al., 2017). Seasonality effects are also less pronounced in regions with bimodal vs. unimodal rainfall patterns, given the shorter gap between harvesting and the likelihood that at least one harvest will be successful (Schofield, 1974). Given the effects of climate change and general development, seasonal patterns cannot be seen as static from year to year or place to place.

### **Analytic decisions and observed nutrition seasonality**

Data collection and analysis methods affect whether and what seasonal patterns are identified. The spatiotemporal resolution and precision of collected records have significant implications on the ability to detect, define, and predict seasonal patterns in nutrition outcomes. A recent review of multiple seasonality studies in unimodal rainfall dryland contexts in Africa found that most studies treat time as a categorical variable, frequently splitting the analysis into wet vs. dry or pre-vs. post-harvest comparisons (Marshak et al., 2021). While this approach can simplify interpretation, it does not capture climatic variability and how it relates to human activities, nor does it account for the transitional periods between major seasons (i.e., sporadic rains during the dry season before the heavy rains arrive). Weight gain research in developed country contexts is one example of how this affects nutrition seasonality findings. Much of this research indicates that weight gain is highest in autumn/winter (Ma et al., 2006; Orr and Clark, 1930). However, more precise analysis using more granular time measurements specifically pinpoints that weight gain to the holiday seasons (Turicchi et al., 2020)—a distinction that allows for better informed programming and messaging. Similarly, divergent findings on seasonality of nutrition outcomes from the most recent studies in low-income contexts, including the discovery of two seasonal peaks of undernutrition as well as higher rates of malnutrition during the hot, dry season than the rainy season demonstrate the importance of modeling nutrition outcomes with precision (Cliffer et al., 2021; Marshak, 2021).

Our ability to link seasonal patterns in nutrition to changes in climate also depend on interdisciplinary collaboration, data sharing and exchange. Evidence is conclusive that human activity has already drastically altered the climate. Deforestation, urbanization, and industrialization have contributed to global surface temperatures being 1.09 °C higher in 2011–2020 than 1850–1900, with warmer temperatures and rising sea levels imminent. Climate change is already increasing the variability of established climatic phenomena, shifting climatological boundaries, and increasing the frequency and severity of extreme weather events (Mbow, 2019). Increasing temperatures and rising seas are expected to negatively impact agricultural production and reduce the amount, quality, and stability of crop yields. As climate becomes more variable, analytical methods for seasonality must become more adaptable and accommodate minimal pre-determination for greatest accuracy (FAO, 2020; Phalkey et al., 2015; Rohli and Vega, 2017).

Consideration of study design, analyses, research focus, terminology, interpretability and interoperability of data and models is important in determining, understanding, and predicting seasonal patterns and their interplay with climatic factors, demographic factors, livelihoods, and other potential mitigating or exacerbating correlates. Advances in statistical modeling software, including widespread availability of open-source software, has made using computationally sophisticated models much more accessible than they used to be. Improving our understanding of nutrition seasonality requires leaving behind error-prone computations of seasonal outcomes based on categorical variables and embracing methods and models that reflect the cyclical nature of the time series and allow for precise and accurate findings.

### **Conclusion**

Seasonality is a natural phenomenon. It is not inherently bad; however, without knowledge and precise understanding of seasonal fluctuations in the components of the complex systems that interact to produce seasonal nutrition outcomes, humans may struggle

to achieve well-being. Developing such precise understanding requires models that accurately describe and measure seasonality of nutrition outcomes, as well as unified terminology to describe seasonality. In addition, governance and policymaking within the complex systems involved in nutrition seasonality can go a long way in improving nutrition when considering and understanding the seasonal timing of drivers and outcomes.

Knowing when anthropometric and micronutrient deficiencies are likely to occur across different populations is the first step in helping governments and organizations implement the appropriate interventions at the correct time. Understanding the seasonality in the underlying drivers of those outcomes elucidates entry points for policy and programs. Direct policy leverage points to permanently increase seasonal stability of food supply, demand, and prices include appropriate trade policies, domestic stocks to address supply shocks, and adequate safety nets that smooth access to food when incomes decline and/or prices rise. Investments in infrastructure and agricultural productivity can increase supply resilience, strengthen markets, and provide jobs, increasing the quantity and quality of production, distribution, and consumption year-round. Further infrastructural improvements to water, sanitation, hygiene, and food storage can help reduce the seasonal patterns of infectious disease transmission and susceptibility.

As climate change continues to affect food supply and infectious disease transmission, not only will we need to adapt our nutrition seasonality models, but food, livelihood, and environmental systems transformation is essential to protect the nutrition of current and future generations.

### Key points

- Anthropogenic climate change has resulted in elevated global mean ambient temperatures, CO<sub>2</sub> concentration and disturbed the World's biogeochemical cycles. The consequences of these changes have been pervasive, resulting in direct and indirect pathways. **The direct pathways** include the erraticism of weather-related events, which have intensified and become more extreme. **Indirect pathways** include various insecurities to the dimensions of health, such as burdening socioeconomic positions, risk for diseases, displacement, unaffordability of food, etc.
- Climate related adversities are responsible for the decline in **agricultural yield and crop-loss, threatening food security** in low-and middle-income countries which already experience acute food shortages, such as Sub-Saharan African and South Asian countries but also some high-income countries including Canada, Australia, and the USA.
- Elevated temperatures and CO<sub>2</sub> levels alter the **quality of nutritional content in food crops**, diminishing the micronutrient and protein content in staple crops. On its own, CO<sub>2</sub> has increased yields for certain crops, but when acting synergistically with elevated temperatures, it usually has resulted in declines. C3 plants, the main type of food crops, seem to be more prone to these effects, as zinc, folate and protein content were studied to have reduced along with their yields. C4 crops are not as affected as C3 plants.
- Reduced yields and nutritional value of **Zinc, Iron, Vitamin A and Protein** will exacerbate existing micronutrient deficiencies, leading to risk of nutrition-associated diseases i.e., **childhood stunting, diarrhea and Non-Communicable Diseases** including diabetes mellitus and cardiovascular diseases.
- Climate change will make wet parts of the world wetter and drier parts drier. Increased incidences of floods cause devastation to life, destroy infrastructure and permeate the spread of infectious diseases due to unavailability of clean water. Inundations through **floods** will also lead to soil salinity making lands unfit for agriculture.
- **Pollinators**, which play a key role in the success of plant fertilizations, have been steadily declining due to climate change, and decoupling plant-pollinator relationships.
- **Women and children** will be particularly hard-hit due to existing social infrastructure and climatic shocks.
- Adaptation strategies to address food insecurity entail fortification of food, use of climate smart varieties, traditional ways of farming, and switching to plant-focused diets.

### Glossary

**Biofortification** Strategically enhancing the nutritional value of food crops using biotechnology or selective breeding  
**C3 plants** These plants utilize an enzyme called Ribulose-1,5-bisphosphate carboxylase oxygenase (RuBisCo) to accept atmospheric carbon dioxide during photosynthesis to produce a 3-carbon compound called 3-phosphoglyceric acid

**C4 plants** These plants utilize an enzyme called phosphoenolpyruvate (PEP) to accept atmospheric carbon dioxide during photosynthesis to produce a 4-carbon compound called oxaloacetate (OAA)

**Climate resilience** The capacity for infrastructures and socio-economic spheres to be able to withstand upcoming climate threats

**Food security** As defined by the UN, it is the ability of a person to access affordable, nutritious food that is in accordance of their preferences at all times

**Hydroponics** Plants are grown in nutrient and mineral solutions in highly controlled environments without the use of soil

**Malnutrition** It occurs when a person has inadequate nutrients in their bodies

**Micronutrient Deficiency** Insufficient quantity of minerals and vitamins in an individual's body, which don't meet the requirement for optimal growth and well-being

**Overnutrition** Excess of nutrients in the body which arise from disproportionately high food consumption

## Introduction

Climate Change (CC) has been gaining momentum in the last few years as global weather patterns have become more and more inconsistent due to anthropogenic activities, which have accelerated the Earth's natural course of climate modification. This accelerated progression has destructive consequences and disturbs whole ecosystems, which further ramify into consequences for human well-being. Greenhouse gas emissions have led to an increase in ambient temperatures—with an overall 1 °C rise recorded in 2015 when compared with pre-industrial times. There's now almost a 50-50% chance that temperatures will exceed 1.5 °C by 2027.

Nearly 1 in 3 people do not have access to food and clean drinking water. Depletion of food security leads to 'hidden hunger' where malnutrition and micronutrient deficiencies co-exist. There are over 2 billion people globally who are deficient in micronutrients such as Vitamin A & B, Zinc, Folate, and Calcium. These micronutrients (vitamins and minerals) are essential to normal development and growth.

Climate change will exacerbate these conditions if substantial action is not undertaken immediately. All the four dimensions of food security highlighted by the Food and Agriculture Organization, which entail availability, accessibility, utilization, and stability will consequently be disrupted.

Berry et al. (2018) examined the direct and indirect pathways of climate change on health (Fig. 1). Direct pathways include increased weather variability and changes in frequency and intensity of extreme weather impacts due to CC. These lead to increased exposures to disease vectors and several types of pollution. Direct pathways also have consequences for fluctuations in the nutrition values of crops. Indirect pathways include food and price changes, water availability, displacement, and migration of communities. Additionally, climate change adversities contribute to existing social infrastructure and inequities of age and gender, public health infrastructure, mobility, socioeconomic and health and nutrition status as well as inequities in hygiene and social cohesion.

**Fig. 1** Pathways of climate change, sustainable development, and health. Source: Berry et al. (2018).

Together the direct and indirect pathways lead to health impacts in human populations including rise in infectious diseases, child development, loss of well-being, loss of productivity, allergies, poisoning, and death. Many of these impacts can be mitigated through building action-oriented mitigation strategies, enhancing social equity, and strengthening public health adaptation.

The article proceeds as follows. The next section assesses the impacts of climate-led adversities on health, nutrition, and food systems. The third section discusses impact of climate change on agricultural pathways in LMICs. The final section looks at climate-resilience approaches and policy interventions to mitigate the impacts of climate change on health and nutrition.

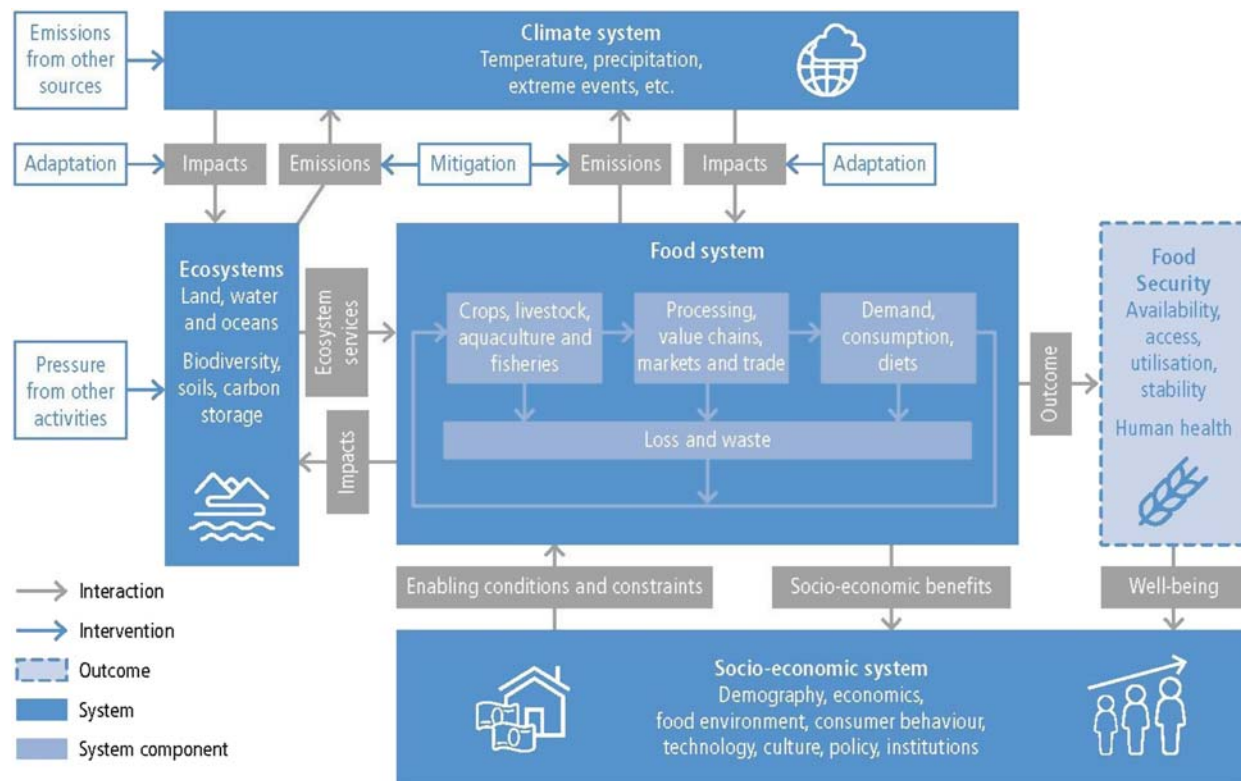

### Impacts of climate-led adversities on health, nutrition & food systems

Food systems are anticipated to modify extensively due to changing climatic conditions. To begin with, climate change adversely affects communities and areas heavily dependent on agricultural produce. In Africa alone, agricultural yields could dwindle by 30% by 2050 due to climate change, directly impacting the livelihoods of over 70% of Africa's total population. Vulnerable communities dependent on agriculture will not be able to cope with the rising food prices due to global inflation and be further pushed into poverty traps. Furthermore, many agricultural communities rely on rainfall patterns and ideal climate scenarios to produce staple and cash crops. Climate change will affect rainfall patterns and magnify the unpredictability of weather conditions. These will have impacts on food availability, access, utilization, and stability (Fig. 2). Overall disruptions will affect agricultural economies in LMICs like India, but also some high-income countries including Canada, Australia, and the USA.

#### Food availability

Potential impacts of CC include increased incidence of famine and weather-related disasters due to unexpected weather conditions. Over 54 million people in Ethiopia, Madagascar, South Sudan, and Yemen are currently encountering famine-like conditions as detrimental impacts of climate change interact with existing hunger, food shortages and conflict conditions. About 50% of total

**Fig. 2** Interlinkages between the climate system, food system, ecosystems (land, water and oceans) and socio-economic system. Source: (Mbow et al., 2019)

crop production globally comes from forest and mountain areas, rainfed and irrigated agriculture in dry lands accounts for 25% and rice in coastal areas forms only 12% of total crop produced globally. Environment factors like precipitation, soil dampness, temperature and radiation will compromise yields and dwindle food availability. India's heat wave in 2022 coupled with water scarcity in Brazil, the US and Europe due to climate change is predicted to have dire impacts on the supply chain of wheat across the World.

### Food affordability

Poor households in non-farming occupations rely on agricultural produce, market conditions, and the food supply chain for sustenance. Food storage will impact buying and trading prices in the market hereby, exposing poor households to further vulnerabilities. For example, in Southeast Asia, there has been a 6% increase in the costs of food due to extreme weather conditions. An 80% increase in food prices in Indonesia alone is predicted as the Government continues to push for net-zero by 2050.

### Food accessibility

Changes in farming and non-farming livelihoods limit the ability of the household to purchase food. Yield reductions will have an impact on the accessibility of the food in the market. This will reverse decades of progress made on food security in low-income countries and LMICs. Even within safety nets, food is dispensed through market actors and non-market circulation. In market circulation, those who receive food through safety nets are contingent upon income, remuneration, assets and the ratio of the cost of a minimum daily food basket to the average daily income. Social and political factors are key determinants in food allocation. In non-market circulation, food is received through social processes and reciprocal relations within agricultural families. If agricultural production declines (1) there will be lesser food to circulate through safety nets and, (2) agricultural families might take up other professions. Locally produced foods and dispersion within families might change or end. Finally, power dynamics will also decipher who gets more food within households, which will be the patriarch in most cases. CC impacts on food systems will spike effects on food access for women and children.

### Nutritional value of food

In addition to social and economic consequences, CC also affects the quality of food of the population. For example, elevated carbon dioxide concentrations in the air have been shown to reduce zinc concentrations (3%) and iron concentrations (5%) in

**Fig. 3** The main ways in which climate change influences diet and nutrition-associated diseases. Source: Fanzo and M. Downs (2021).

rice grains (Semba et al., 2022). In wheat grains, the combination of elevated carbon dioxide and temperature increased cadmium and lead (Semba et al., 2022). Fluctuations in nutritional properties of plants increase susceptibility to micronutrient deficiencies.

CC has profound impact on malnutrition. Fanzo and Downs (2021) have previously highlighted the relationship between CC and nutrition-associated diseases (Fig. 3). Climate change augments malnutrition in four ways. Firstly, rising food prices will impede the capacities of poor households in buying nutritious foods. This will have dire impacts on household food insecurity, overall calorie consumption and intake of unhealthy foods. Secondly, women and young mothers perform manual labor in agricultural landscapes across the world. Disruptions in agricultural systems and food security impact infant and child feeding practices, triggering early onset of childhood stunting & micronutrient deficiencies. Thirdly, nutrient absorption is contingent upon the process of consumption of nutritious foods. Poor water and sanitation qualities due to CC increase the chances of diarrhea and other arthropod infections and tick vectors. For instance, researchers in Canada and Sweden have traced the increasing incidence of Lyme disease to expansion of tick vectors due to climate change. These regions were earlier prevented to cold climate conditions. Regional warming has dispersed migratory birds, which are hosts of the tick vectors of Lyme disease. Prolonged illnesses will lead to the underutilization of essential nutrients in the body. Finally, CC also affects diet-related non-communicable diseases, such as diabetes mellitus and cardiovascular diseases (Fanzo and Downs, 2021). This is especially true in high-income countries where reductions in vegetable and fruit intake have been attributed as the primary reason of NCDs (Fanzo and Downs, 2021).

## Impacts of climate-led adversities on environmental pathways

### Agriculture

Plants are highly sensitive and dependent on abiotic factors (such as temperature, humidity, salinity, CO<sub>2</sub> concentration, etc.) and biotic factors (such as pollinators) for their optimal growth. Any deviation from these ambient conditions which surpasses a critical threshold will adversely impact plant growth and reduce crop yield. This makes Agro-ecosystems one of the most vulnerable targets of climate change, with the capacity to unfold into deleterious consequences both on people's livelihoods and on global food security. The world population is projected to reach over 9.7 billion people by 2050, while agricultural land remains not only finite but could become non-arable due to soil erosion, desertification, soil salinity, etc. Ensuring food security for this population in the face of climate catastrophe is going to be a major challenge if the current adversities aren't subdued.

Agriculture is the main source of food and income for people around the globe. It alone sustains livelihoods for 65% of the world's poor. Therefore, any impact that climate change has on agro-ecosystems is directly translated into impacts on food security, considering it the main source of dietary sustenance. When food insecurity increases, more and more people will have less access to affordable, healthy food, which in turn will affect their health by depleting them of adequate nutrition. Climate change exacerbates food insecurity primarily by destroying food systems in climatic events such as heatwaves, droughts, cyclones, etc. Between 2008 and 2018, 49 billion USD was lost in Asia alone as a result of declined agricultural and livestock produce. Secondly, elevated CO<sub>2</sub> levels, the main greenhouse gas responsible for climate change, along with increasing global ambient temperatures, dually act together to alter the nutritional content of food and reduce crop yields (Myers et al., 2017). CO<sub>2</sub> on its own increases yields for plants, and together with higher temperatures may lead to high-latitude regions such as North America & Europe with enhanced production of food due to the lengthening of the growing season. However, results will mostly be negative elsewhere as the increasing ambient temperatures override the fertilizing effect of CO<sub>2</sub>—especially in Africa and India where yields may decline up to 5%.

Depending on which metabolic process they use for carbon fixation during photosynthesis, plants are classified as C3 plants or C4 plants. C3 plants thrive in a colder, wet climate while C4 plants prefer hot and dry climates. C3 plants are the source of over 90% of food crops whereas C4 plants constitute only about 1%. At higher temperatures, plants produce more carbohydrates, which can reduce up to 8% of their mineral content (Semba et al., 2022). Due to their abundance as food sources, the vulnerability of C3 plants to climate change is concerning. They provide key sources of Zinc and Iron to people who suffer from micronutrient deficiencies. Yields of C4 plants such as maize have reduced up to 5% since 1980, however, they have no additional increase in yield due to elevated CO<sub>2</sub> levels (Myers et al., 2017). Elevated CO<sub>2</sub> levels have been associated with increasing the productivity of C3 crops (Myers et al., 2017). C3 crops rice and wheat are staple crops in South Asia—which is the world's largest consumer and producer of these two crops globally. Increasing temperatures reduce the yield of both these crops. In rice, elevated CO<sub>2</sub> may lower

the quantity of Zinc and folate, while in wheat it reduces Zinc and folate content by 9% and 5–7% respectively. Legumes, which are another major source of protein and micronutrients and are highly sensitive to heat, have reduced yields due to the dual action of elevated CO<sub>2</sub> and temperatures (Myers et al., 2017). The protein content of C3 plants (excluding legumes and C4 plants) is also reduced under conditions of elevated CO<sub>2</sub>.

Food sources declining in their mineral and iron content will have a major blow on micronutrient deficiencies, which is a major public health concern across all South Asian regions. Zinc deficiency predominates in the region, especially among children and pregnant and lactating mothers. While the deficiency is largely due to lowered uptake, studies have correlated lowered uptake of zinc due to consumption of plant diets rich in phytic acid, which lowers the bioavailability of zinc. Folate deficiency is predominantly associated with anemia, with a 48% prevalence rate in pregnant women across South Asia. Crops associated with reduced micronutrient contents pose a distressing hazard to exacerbating micronutrient deficiencies across these vulnerable populations. While changes in the climatic change are going to make lands unsuitable to produce various crops and plants, these same environments will become more conducive for growing others. Shabani et al. (2016) propose that lands will become more arable for growing the date palm (*Phoenix dactylifera*), which is an excellent and economical source of iron, zinc, calcium, potassium and boron. Intake of about 100 g of date flesh daily meets about 50% of the recommended micronutrient intake. Dates offer an excellent solution to curbing malnutrition and micronutrient deficiencies in food-insecure populations such as regions of Sub-Saharan Africa.

Higher temperatures encourage the formation of ozone (Myers et al., 2017), a dangerous toxin which impedes photosynthesis by minimizing the stomatal aperture and reducing plant yield. Estimates for crop yield losses due to ozone pollution may be worth 35 billion USD by 2030. A warmer climate also means prolonged breeding seasons for pests and insects like aphids, which result in loss of agricultural produce. Aphids survive better in hotter temperatures and elevated CO<sub>2</sub> levels. This will mobilize farmers to use chemical insecticides and carcinogenic pesticides on their produce, which can have a deleterious impact on humans if the residues of pesticides are not washed properly, enter inside the body.

Apart from agriculture, CC negatively affects livestock, which is a source income, but also protein (33%), calories (17%), and micronutrients like vitamin B12, iron and calcium. Increased ambient temperatures cause animals to face great heat stress. Reproductive capability is reduced in cattle as fertility declines due to heat stress, which also compromises the quality and quantity of meat and milk production. Increasing temperature also makes farm animals more prone to vector-borne diseases like Rift Valley Fever, Bluetongue & West Nile Virus. Due to reduced precipitation and drought, water bodies dry up. With only a few limited water bodies, animals flock around common water bodies, which increase their risk and exposure to these diseases.

People facing climate shocks, especially in drought-stricken areas, turn to livestock for consumption. As agricultural produce becomes scarcer, there will be growing dependence on meat consumption and processed food. Meat consumption is expected to grow in the largest proportion across the developing world. While meat is an excellent source of protein and Vitamin B12, livestock is a major contributor to GHGE accounting for over 14.5% of emissions. As native or indigenous diets will evolve to include more meat and processed food which are rich in saturated fats, cholesterol, salt, sugar and preservatives, the risk of non-communicable diseases like cardiovascular diseases, hypertension, and Type 2 diabetes increase substantially.

The last fifty years have witnessed a five-fold increase in the occurrences of natural disasters like cyclones, floods, storms, etc. These events can be attributed as being a direct manifestation of climate change since the earth's accelerated warming has disturbed the hydrological cycle by intensifying evaporation and precipitation patterns globally. In response, rains have become heavier and shorter as opposed to lighter and more consistent. Increasing temperatures cause the air to uptake more water vapor, leading to shorter & heavier downpours with the potential to cause flooding.

### **Floods and droughts**

Floods are one the most devastating natural calamities, affecting millions of lives annually. In 2019, the UN had reported floods killed at least 600 people and affected the lives of 25 million people across South Asia. Apart from the devastation they cause to human life, livelihoods and infrastructure, floods are also accompanied by a surge in cases of infections and disease. Heavy precipitation and floods are reported to be the primary antecedents during outbreaks of infectious diseases. Floodwaters cause the spread of infectious diseases by contaminating food and drinking water. Floodwaters overwhelm water-treatment plants and cause drains to overflow, leading to the intermixing of sewage water with local water bodies from where it reaches households. The provision of safe drinking water is pertinent during floods. Consumption of contaminated water leads to the spread of gastrointestinal diseases like typhoid, cholera and hepatitis A.

Unhygienic and overcrowded spaces expose people to these diseases, and infections spread rapidly, with waterborne diseases being the most common risk to health following floods in Asia. Leptospirosis is another common infection that is spread when people, especially children, come in contact with animal urine mixed in floodwater. The surge in cases of trypanosome infection leishmaniasis was seen after flooding across Bangladesh, Pakistan and India (Bihar). The stagnant floodwater water also acts as the ideal breeding ground for vectors like mosquitoes which spread malaria and dengue fever, which are already a chief public health concern across these regions. Runoffs from agricultural processes containing carcinogens like nitrates wash away with the floodwaters, as well as other heavy metals that may wash away and expose groups to an increased risk for cancer.

Another danger to life comes from the rising global mean sea levels caused by the melting ice caps and thermal expansion of water; threatening to submerge low elevation coastal zones underwater. This is deeply concerning as most populations in Low Elevation Coastal Zone (LECZ) are rural poor.

South Asia has a very large rural LECZ population, with over 93 million poor and vulnerable people at risk for this adversity. These inundations increase the soil salinity, making it unfit for cultivation as the saltwater intrusion reduces crop outputs. With inundations becoming increasingly common, several farmers across Bangladesh have switched from agriculture to aquaculture. Consumption of saline water has led to a surge in cases of preeclampsia and gestational hypertension in pregnant women across Bangladesh, with the country experiencing a 28% increase in cases since 2012.

Drought is another aspect of a perturbed hydrological cycle. Climate change intensifies precipitation and evapotranspiration variability, exacerbating drought conditions. Between 1970 and 2019, droughts have claimed the lives of 650,000 people globally. Prolonged droughts can manifest into famine. Severe famines are classified under IPC 5 (Integrated Food Security Classification) when over 30% of a population experience acute malnourishment, and every 2/10,000 people are dying from starvation. The beginning of 2022 marked the start of the worst drought the Horn of Africa has witnessed in over 40 years, with over 10 million children experiencing malnutrition and thirst. This drought can worsen further into a famine. Droughts inflict complete climate shocks on people. Apart from the central breakdown of food security, droughts destroy livestock, force people to migrate for survival and exacerbate social problems like dropping out of school, child brides, and conflict. Globally, 80% of agriculture is rain-fed, and of the 1.2 billion hectares of croplands watered by rainwater, 128 million hectares have been experiencing increased drought frequency. Erratic precipitation and drought have had harrowing impacts on smallholder farmers, who incur heavy monetary losses, and have their livelihoods collapsed. Farmers are usually able to cope with seasonal variability, but climate change will offset their scope for adaptation. Droughts will increase the dependency of countries on food donations, international aid and humanitarian assistance.

Droughts can dry up groundwater, the main source of freshwater accounting for 30% of all freshwater reserves. South Asia is the world's largest user of groundwater, with India, Bangladesh and Pakistan deriving most of its water for irrigational purposes, drinking purposes and livestock usage from the Indo-Gangetic Plain aquifers. Drought also concentrates pollutants in water bodies as they dry up. As ecosystems are continuously lost with deforestation, wildfires and urbanization, disturbances to the food web are leading to biodiversity loss.

### Biodiversity & pollinator loss

Loss of habitat, human interference and climate change are all accelerating species extinction by 1000–10,000 times more than the natural rate. Recent years have witnessed a decline in insect and animal pollinators. The pollinator-plant relationship has become unsynchronized due to climate change, as plants are now flowering and maturing earlier than their due timings. Flowers that contain pollen have responded to elevated temperatures by modifying the amount of UV pigment present in their petals, making them difficult to distinguish by their pollinators. Empirical evidence that pollinator loss worsens micronutrient deficiencies was presented in studies by Ellis et al. (2015). This is concerning as pollinators are associated with plants that provide 40% of nutrition globally. Pollinator loss, therefore, can further exacerbate the scope for micronutrient deficiencies and non-communicable diseases for populations that derive their nutrient sources from these plants. There has been a decline in the nutritional value of pollen (Myers et al., 2017). Over 150 nutrient-dense plants rich in Vitamin A & C, iron and folate are reliant on animal pollinators (Myers et al., 2017), and any disturbance to their pollinators has effects on the health and nutrition of individuals that consume them. The studies conducted by Ellis et al. (2015) also showed that Vitamin A deficiency was the most sensitive to pollinator loss in associated countries, as most fruit and vegetable sources of Vitamin A were heavily dependent on pollinators.

### Climate resilience approaches: adaption and mitigation as the way forward

As the effects of climate change become more and more pronounced on human health and our food systems, there is grave urgency to act immediately and curb climate change at its root cause and address its ill-effects by integrating both climate mitigation and adaptation. Climate mitigation requires us to massively cut down and stabilize our CO<sub>2</sub> and other GHG levels and to sequester carbon. This entails making changes to our agriculture, livestock, and food transport systems by adopting different techniques to help decrease the levels of greenhouse gases emitted. Agriculture alone is responsible for emitting 30% of global GHGs. Climate adaptation strategies aim at strengthening our existing food systems and infrastructure of agro-ecosystems to make them more resilient to the effects of climate-led adversities. In our current capacity, Climate adaptation is crucial at buffering the impacts of climate change on human health and nutrition, and to help mitigate the consequences it has on the most vulnerable populations.

### Adaptation approaches for food systems

There are several ways to enhance our agricultural outputs, both in terms of better yields and nutritional value. This can be achieved by artificially engineering climate-resilient varieties or utilizing farming techniques which have been associated with better agricultural and environmental results. Research and development of such varieties and breeds must be promoted to improve food and nutrition security.

- i Biofortification of food crops– Fortification of foods helps in increasing contents of beta carotene (Vitamin A), Zn, Fe, Ca, etc. It is a relatively easy, inexpensive and climate-friendly pathway to combat micronutrient deficiencies and offset the impacts of

climate change on food insecurity as well as provide monetary sustenance to small farmers. Biofortified crops have contributed to modest enrichment of nutrient content in the long run, and are well accepted by the public. They require dissemination and awareness about their benefit and have been shown to reduce neonatal and child mortality. Pearl millet and maize, C4 crops with relatively low nutritional value. Pearl millet was biofortified to increase its iron and essential amino acids, and varieties have been grown across India and the Republic of Niger. Provitamin A enriched Maize, hybridized to be drought and heat resilient, has been introduced in 11 countries. The article on “Biofortification: A primer on nutrient enriched crops” by Mbuya and colleagues in this Encyclopedia provides elaborate insights into the Biofortification and nutrition.

- ii. Use of improved cultivars—Short-duration cultivars such as early maturing pigeon pea, or cultivars which are saline or drought-resistant varieties. In the Indian state of Maharashtra, early maturing and drought-tolerant cultivars of green gram (BM 2002-1), chickpea and pigeon pea (BDN-708) yielded outputs 20–25% higher than the indigenous varieties.
- iii. Vermicomposting—It is an excellent source of natural fertilizer for sustainable agriculture. Studies from [Maharjan and Pradhanang \(2017\)](#) found that vermicompost prepared with vegetable scraps the red worm *Eisenia fetida* has high concentrations of Potassium, Phosphorus and Nitrogen, which are the 3 major macronutrients needed by plants for growth.
- iv. Employing traditional farming practices—Crop diversification and crop rotation both help boost soil health and ensures greater availability of nutrients. Diversifying crop rotations is linked to higher drought resilience and improved soil-water retention. Crop rotations have further shown to reduce climate change-induced yield losses for temperate cereals—both for winter and spring varieties.
- v. Agroforestry—Incorporating trees on farmlands providing an array of benefits including reforestation, improved productivity and better soil quality, better socio-economic opportunities and better health. They can aid climate change mitigation by sequestering atmospheric Carbon both in the underground (roots) and above ground (leaves, stems, branches) systems.
- vi. Use of hydroponics—This technology grows plants without the use of soil in strictly controlled environments, and presents as an innovative (albeit expensive) method to meet food requirements for the growing population. Hydroponics use up to 90% less water compared to traditional farming methods, and has shorter and faster yield time. It can help feed more people without exhausting resources, since it utilizes very little quantity of raw materials.
- vii. Sustainable diets—Promoting the transition to more sustainable diets cater not just to covering all aspects of human health and nutrition, but are also environmentally responsible. They promote affordable, accessible, nutritionally-adequate and low-environmental impact foods. Consumption patterns of High-income countries, which consume great amounts of red meat, are responsible for emitting 41% more emissions than countries LMICs. Switching to plant-based diets will reduce diet-related NCDs. Planetary health diets proposed by the Eat—Lancet commission are associated with reducing premature mortality by 34% and contribute to a reduction of GHGE by threefold ([Fanzo and Downs, 2021](#)).

It is important for us to attain nutritional security in the current scenario in an environmentally sustainable manner, apprehending any further climate degradation. [Gustafson et al. \(2016\)](#) formulated an assessment methodology called ‘Sustainable Nutrition Security’ (SNS). This methodology incorporates 7 metrics based on several indicators relevant to safeguarding nutritional outcomes for sustainable food systems and evaluates impacts of interventions, scored between (0–100). These metrics include food nutrient adequacy, ecosystem stability, food affordability and availability, sociocultural wellbeing, food safety, resilience and waste and loss reduction. The metrics can be used to influence and assess decision-making for food systems both in developed and developing countries.

- viii. Drastic food alternatives—These could include uncommon food choices such as entomophagy. Insects are already consumed by over 2 billion people globally and have high protein and micronutrient content. Algae-based foods such as spirulina supplements are nutrient-rich, have been shown to provide essential nutrients. These however may not be acceptable to all consumers.

### Managing risks of natural disasters by improving natural and man-made infrastructures

Damages caused by floods and droughts to human lives, and its consequent role in catalyzing the spread of diseases can be limited by improving our current infrastructures. Better urban designing and landscaping can withhold these impacts to an appreciable degree.

- i. Revival and protection of marshlands, mangroves, and wetlands—Mangroves and wetlands are biodiverse ecological systems that store CO<sub>2</sub> in their aquatic flora and provide sources of food and natural resources. These ecosystems are critical to protecting shorelines from flooding due to their water retention capabilities, catching sediments and reducing erosion. In Bangladesh, where several community-based mangrove restoration projects have been implemented, fossil fuel emissions were offset by 1.5% in 2014, and villages protected by mangroves faced half the monetary loss during cyclone *Sidr*.
- ii. Efficient Sewage systems—Sewage systems need to be better planned and built to be able to withstand floods, so that water so they don’t overwhelm and spill out into the floodwaters.
- iii. Storing water to use in times of droughts—Installing watersheds to store water, and rainwater harvesting in areas prone to drought is a great way to tackle water scarcity. In the drought-prone district of Purulia in West Bengal, [Roy \(2014\)](#) proposed micro water sheds and rainwater harvesting to help curb the district’s water scarcity. Run-offs from the Bandu Basin during the monsoon months could be stored and harvested to meet water needs and recharge groundwater during the drought months.

- iv. Better surveillance and monitoring systems to disseminate early warnings about upcoming floods/droughts—Monitoring bodies need to be provided with real-time data on moisture levels, soil water, etc. to spot irregularities in climatic patterns that forewarn the arrival of a flood or drought. Such warnings facilitate the early evacuation of people, as well as strategize mitigation and resilience plans. The South Asia Drought Monitoring System (SADMS) was developed by the CGIAR in 2014 and provides a weekly map of drought indices. Sri Lanka in particular has gained great benefit from this program, such as during the 2014 droughts.

### Political and policy-based interventions

Political commitment is critical to mitigating climate change and adapting to its adversities. Countries must take efforts to realize their Nationally Determined Contributions (NDC's) stipulated during The Paris Agreement, 2015 to achieve the 30% in global GHGEs.

Decarbonization of energy systems was a critical discourse of the Paris Agreement. Subsidies on fossil fuel usage need to be discarded, and renewable sources of energy must be pushed for. Most developing countries heavily depend on fossil fuels due to their growing populations and have a lot of scope for switching over to renewable sources such as wind power, solar power, etc. Sub-Saharan African countries have the capacity to obtain 100% of their energy requirements through renewable sources by 2050. Renewable sources of energy have high initial costs in installation, and some are expensive to upkeep as well. However, these expenses are reimbursed by great economic and health turnovers in the long run.

Policy-based interventions aim at addressing food security in the face of climate change using frameworks to regulate food supply, access and utilization. These interventions also provide incentives, which deliver both nutritional and economic benefits.

- i. Reducing food wastage—Enough food is produced to feed everyone across the world. However, 1/3rd or about 1.3 billion tons of all food produced is wasted, and is responsible for emitting 8% of the world's GHGE. Saving just a quarter of this food could feed an additional 870 million people. Policies need to limit this wastage and redistribute surplus production to communities that need it the most.
- ii. Regulating fisheries by halting fishery subsidies—Fisheries are sensitive ecosystems and their overexploitation has overwhelmed them. These have resulted in reduced fish catch, with over 90% of the world's marine stock overexploited. By 2050, projections estimate an 88% decline in global fish stocks (Myers et al., 2017). Policies need to encourage and ensure sustainable fishing and aquaculture practices, and impose bans on fishing in endangered zones.
- iii. Improving agricultural subsidies—Springmann and Freund (2022) call for inlining agricultural subsidies to address health and climate change concerns. They found that redirecting agricultural subsidies to healthier foods had positive impacts on health and environmental outcomes, albeit with an economic trade-off.
- iv. Social Protection Programs—These include Safety Net programs, food assistance, work for food and cash programs and nutrient supplementations to facilitate food and nutritional safety for vulnerable families during climate shocks. These programs are pertinent in protecting these groups, particularly women and children, from malnutrition, disease and displacement.
- v. Fostering partnerships between local communities and governments—Governmental support and initiatives offered to local communities can help bolster their food and nutritional security. By working together, they are able to better plan solutions related to food systems and implement inter-sectoral collaboration.
- vi. Microfinance Institutions—Microfinancing for smallholder farmers, especially women farmers is pivotal in increasing their productivity by proving them with credit. Such institutes also act as intermediaries for implementing climate adaptation by integrating climate change mitigation within their activities.

## Key points

- Food-based Dietary Guidelines (FBDG) address both nutrient adequacy and dietary factors that reduce risk of diet-related chronic diseases.
- FBDG express nutrition principles in the context of foods and dietary patterns.
- Evidence-based FBDG are based on data analysis, food pattern modeling, and systematic reviews of peer-reviewed literature.
- FBDG should reflect cultural preferences and foods available within a region or country.

## Introduction

Since the late 1970s, food-based dietary guidelines (FBDG) have become a cornerstone of nutrition policy in many countries and provide the basis for education to improve nutritional status. FBDG translate nutrient requirements and dietary recommendations to reduce the risk of diet-related chronic diseases into quantitative recommendations for foods to include in healthful dietary patterns. Each country must adapt FBDG to the needs of their population both in terms of the public health issues to be addressed as well as the foods available and relevant dietary strategies for the population (FAO and WHO, 1998). Across various countries several themes in FBDG have emerged and include energy balance, a healthful variety of foods, including fruits and vegetables, whole-grain products, food sources of protein, calcium, and unsaturated fatty acids and safe food handling as well as appropriate levels of physical activity. Cautionary messages focus on excess energy intake, saturated and *trans*-fatty acids, added sugars, salt, and alcohol (Fischer and Garnett, 2016).

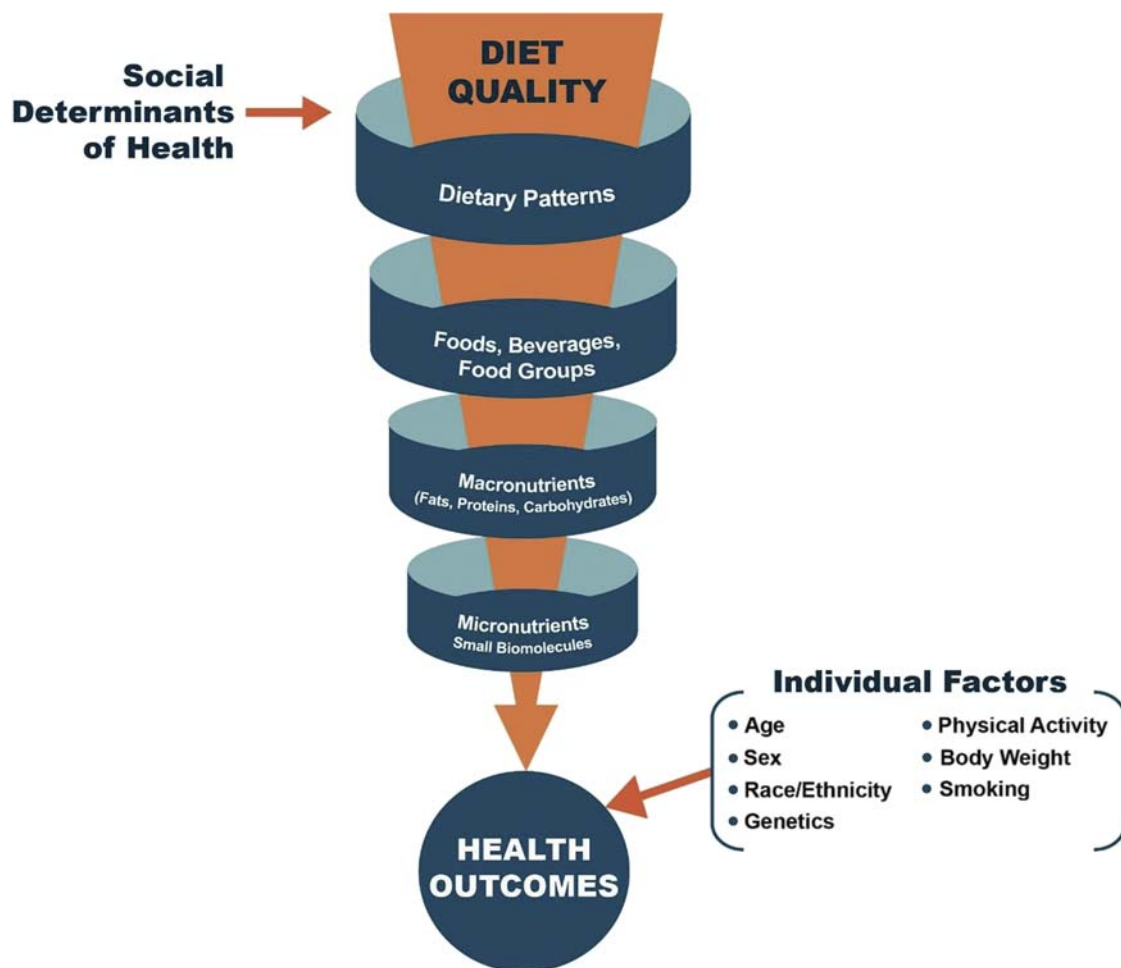

## Historical background

Throughout the ages, religious and philosophical writings have included dietary advice, which is reflected in an oft-quoted line from Hippocrates: "Let thy food be thy medicine." In the late 1800s, modern science began to influence the nature of recommendations regarding foods and beverages. The original focus of guidelines developed from Pasteur's discoveries of the disease-causing organisms that could be present in foods emphasized sanitation in food handling. In the early 1900s, the discovery of vitamins and minerals led to the realization that foods contain factors that are essential for health. This 'vitamin theory of disease' led to research throughout the first half of the twentieth century to discover these factors and determine their essential functions in the treatment of deficiency diseases. The knowledge that food was important in the prevention of diseases that were major public health problems, such as scurvy, beri-beri, night blindness, and pellagra, led to early efforts to develop and promote dietary recommendations or guidelines, even when the specific curative factors in foods had not yet been identified. Among the earliest examples, some cultures were known to use liver to correct night blindness, the British Navy used lemons or limes to prevent scurvy, and alkali treatment of corn was associated with a lower incidence of pellagra in Mexico. The understanding of the linkage between certain foods and the prevention of disease resulted in the development of food guides or groups illustrating a pattern of food choices that was most likely to prevent deficiency diseases. As the chemical nature of the factors in food that prevented or cured nutritional deficiencies became known, it was possible to determine the specific amount required in the diet to maintain health. These studies led to the development of recommended dietary allowances (RDAs), which are quantitative recommendations of the nutrient intakes that will meet the needs of the majority of the population and have been used to evaluate the adequacy of diets in populations. However, this

understanding of nutrient requirements encouraged a focus on single food components rather than the overall balance of macro- and micro-nutrients to promote health.

By the second half of the twentieth century, the primary causes of nutrition-related diseases in many developed countries had shifted from nutrient deficiencies to those associated with dietary excess. As noted by the [Surgeon General of the USA \(1988\)](#), micronutrient deficiencies were no longer major public health problems in the USA; and diseases associated with excess intakes of energy, saturated fat, total fat, cholesterol, alcohol, and sodium, in conjunction with inadequate fiber intake, were the major causes of morbidity and mortality in the USA. The economic transition experienced by many developing countries has led to a similar pattern and is sometimes referred to as the double burden of malnutrition diseases. Although nutritional deficiencies continue to be prevalent in large segments of the population, an increasing proportion of the population is at risk of developing diet-related chronic diseases, such as obesity, cardiovascular disease, cancer, and diabetes. This emerging pattern of disease has resulted in the development of FBDG, which recommend dietary patterns that are adequate in nutrient content and encourage food choices to lower the risk of noncommunicable diet-related diseases.

**Fig. 1**, developed by the [2020 Dietary Guidelines Advisory Committee \(DGAC\)](#) in the USA, illustrates the relationship between dietary patterns and their various components, which include foods and beverages, food groups, macronutrients, and micronutrients and recommended that all levels must be considered in relation to diet quality. For FBDG to be effective, each level must be considered in relation to the overall dietary pattern. For example, simply recommending that added sugars or saturated fats be limited in the diet needs to be presented in the country or regional context of the foods and beverages that are the major sources of these food components and the type of dietary pattern that will limit these food components and the foods and beverages that should be included in the pattern instead. Food pattern modeling was used by the DGAC to illustrate that, at various energy intake levels, 85–90% of energy is used for a healthful dietary pattern that meets nutrient requirements and goals for reducing risk for diet-related chronic diseases. Consequently, only a small portion of energy intake can be allocated to food components that provide energy but do not contribute to meeting nutrient and food component recommendations, such as added sugars, saturated fatty acids, trans fatty acids, and alcohol. The use of food pattern modeling to develop healthful dietary patterns illustrates the

**Fig. 1** Food-based dietary guidelines emphasize dietary patterns that encompass recommended foods, beverages, food groups, appropriate macronutrient balance, and recommended micronutrient levels that maintain health and promote well-being. At each level, overall diet quality needs to be considered in developing Dietary Guidelines. Figure is from the USA 2020 Dietary Guidelines Advisory Committee.

importance of nutrient dense foods as the core elements of such patterns because such foods are prepared or processed with none or a minimal amount of the food components to limit. Identification of the nutrient dense foods relevant to a population or culture is an essential step in developing relevant FBDG.

### Types of guidelines

Since the International Conference on Nutrition, which was held in 1992, FAO and WHO have encouraged the development of FBDGs for countries or regions (FAO/WHO, 1992). The second International Conference on Nutrition in 2014 again emphasized the importance of FBDGs (FAO/WHO, 2014). On the FAO website (<http://www.fao.org/nutrition/education/food-dietary-guidelines/background/fao-work-dietary-guidelines/en/>) links are provided to the numerous FBDGs that have been developed by countries and regions as well as resources for developing this capacity at the country or regional level. The section below characterizes the important relationships between three types of nutrition recommendations or guidelines, which include nutrient requirements, FBDG, and food guides.

Nutrient requirements are quantitative recommendations for the intake of individual nutrients. Such recommendations are referred to by terminology such as Recommended Daily Allowance (RDA), Nutrient Reference Values (NRV), Dietary Reference Intakes (DRI) or Population Reference Intakes (PRI). In many countries these values are developed by scientific, authoritative bodies (e.g., National Academy of Sciences, Engineering, and Medicine (<https://www.nal.usda.gov/fnic/dri-nutrient-reports>), European Food Safety Authority (<https://www.efsa.europa.eu/en/topics/topic/dietary-reference-values>), or WHO and FAO) through assessment of research evidence, including systematic reviews or meta-analyses. Initially such evaluations focused on essential nutrients but now also address recommendations for nutrients and other food components that are associated with risk of diet-related chronic diseases.

FBDG are quantitative recommendations for intake of food groups to meet nutrient requirements and maintain health. Consequently, they do not establish nutrient requirements but recommend dietary patterns that will achieve recommended intakes for different age groups while limiting the food components that are associated with increased risk of diet-related chronic diseases. To characterize FBDG, terminology may refer to dietary patterns, food group recommendations or foods to encourage, and foods or food components to limit. The development of FBDG relies on evidence obtained through data analysis of population food intake patterns, systematic reviews of evidence linking food groups and dietary patterns with risk of diet-related chronic diseases, and food pattern modeling to assess how changes in amounts or types of foods impact meeting nutrient needs and recommendations. FBDG that are developed using these methodologies to review evidence are typically technical and quantitative; thus, they form the basis of food and nutrition policy and can be used by healthcare providers for assessing adequacy of dietary patterns in the population.

Food guides illustrate recommended dietary patterns based on the recommendations in FBDG. These illustrations typically convey the proportion of various food groups associated with healthful dietary patterns and are used to develop educational materials for the general public. The illustrations can be adapted for various age groups and populations. In addition, where graphic images of foods are used in the Food Guides, the images should reflect foods and food groups that are familiar and accessible by the population. Variations in the food patterns illustrated in these guides may be necessary to reflect how the FBDG can be adapted for various population groups (e.g., vegetarian patterns, patterns for young children or toddlers).

FBDG developed or endorsed by governments can be used to make decisions on food and nutrition policy. Nongovernment organizations may also develop FBDG for targeted purposes such as weight loss, management of patients with diseases such as cardiovascular disease or diabetes, a specific segment of the population, or promotion of a specific food culture. Such guidelines should be evaluated for adequacy in meeting nutrient requirements and effectiveness in their targeted purpose using rigorous methods for evaluation of evidence. Such validation is important to assure the nutritional properties of such recommendations.

### The development of FBDG

FBDG express the principles of nutrition in terms of the food and food choices available to the population rather than in terms of specific nutrients or food components. Scientifically, these guidelines are based on the association between dietary patterns and the risk of diet-related diseases and incorporate recommendations that address major diet-related public health issues. In addition to communicating scientific knowledge about the association between food, dietary patterns, and health, development of FBDG provides an opportunity to strengthen consensus among various government and nongovernment organizations on important nutrition recommendations to be incorporated into educational programs. By expressing scientific principles in terms of food, FBDG recognize the consumer awareness of food rather than nutrients and emphasize to consumers the importance of meeting nutrient needs with foods. Thus, both the content of the FBDG and the development process are important.

Researchers often focus their studies on a specific nutrient or food component that may alter the risk of developing a disease. These studies are reviewed in the development of FBDG, but the information must be reorientated from a nutrient-based focus to a food-based recommendation by addressing the questions in Table 1. As indicated by these questions, the process is driven by the identification of diet-related public health issues and the development of food-based strategies that are relevant to the target population.

**Table 1** Reorientating from nutrients and food components to foods (FAO and WHO, 1998).**What are the important public health issues for the population? Do they have diet-related factors?**

Health statistics will indicate the major causes of morbidity and mortality in a population. Diet-related diseases include nutritional deficiency diseases and noncommunicable diseases, such as obesity, type 2 diabetes, certain types of cancer, and cardiovascular disease. It is important to determine whether nutrition is the primary cause of the disease or secondary to some other more prevalent problem (e.g., smoking, infectious agents).

**What are the target nutrients linked to the major public health issues? Are there related nutrients or other factors?**

In many nutrition-related problems, several nutrients or food factors may interact to cause the nutritional problem. For example, the fat content of the diet affects absorption of fat-soluble vitamins, obesity can be related to either excess energy intake or inadequate expenditure, multiple factors contribute to adequate bone formation, folic acid can mask anemia due to vitamin B<sub>12</sub> deficiency, and so on. Simply increasing the intake of a target nutrient and ignoring these other factors may not address the problem adequately.

**What foods are high in nutrient(s) or consumed in sufficient quantity to be a significant source of the nutrient(s)?**

Using both food-composition databases and food-consumption data, foods that are good sources of the nutrient and foods that are consumed in sufficient quantity to meet the target intake can be identified. Likewise, dietary patterns that lower the risk for the public health problem and are associated with adequate intake of the nutrient can be identified.

**What is likely to be acceptable to the target audience?**

For nutrition interventions to achieve success, recommendations must target food choices that can be integrated into the diet based on cost and acceptability of the foods.

**How do diet strategies integrate with other food policies?**

Economic, agricultural, and trade analysis is useful to determine which diet strategies can be implemented and are sustainable.

The process for developing FBDG is based on building consensus among various sectors and groups involved in public health. **Table 2** provides a general outline of the steps in the process, which can be adapted to the specific needs of a country or region. The goal is to have a set of guiding principles for food-based recommendations that lay out the overall policy agreed to by various agencies and groups.

The product of the working group is likely to be a document that outlines recommendations and includes background information on the rationale for the guidelines as well as guidance on implementing the recommendations. The FAO website has over 100 FBDG developed by different countries and regions. **Table 3** illustrates common themes among various FBDG. These themes are characterized as foods or behaviors that are encouraged or as cautionary messages that refer to foods or food components to limit. Based on foods available and cultural practices, the types of fruits, vegetables, and whole grains and the specific types of food that are emphasized as sources of protein, calcium, or unsaturated fatty acids may vary. The United States *Dietary Guidelines for Americans* provide an interesting picture of how FBDG have evolved because they have been reviewed and updated every 5 years since 1980. During this period the core messages have been similar; however, the methodology to evaluate evidence has improved and

**Table 2** Steps in the development of FBDGs (FAO and WHO, 1998).

- 1. Develop support from key government agencies.** The successful implementation of FBDG will depend on support from key ministries, such as health, agriculture, education, sports, and recreation. Building consensus among these agencies will result in consistent messages regarding diet, health, and lifestyle for the public. Examples of support include technical support for data analysis or a secretariat to maintain and coordinate activities.
- 2. Form a working group of experts.** The working group should include diverse expertise in areas, such as public health, nutrition, food science, agriculture, and behavioral sciences.
- 3. Solicit public comment and relevant input.** The expert panel needs to gather and evaluate scientific information to determine the guidelines that are most relevant to the target population. This information can be obtained from the scientific literature. In addition, professional groups may have important information to submit to the panel for consideration. Solicitation of information is consistent with an open process; however, the panel is responsible for evaluating the relevance of the information submitted.
- 4. Review and identify key public health issues and evaluate the diet–health relationships of concern for the population; determine the critical health, food, and nutrition issues to be targeted in the FBDG; and define the purpose, target groups, and content of the FBDG.** Even if data are limited, it is important for the working group to identify the key public health issues. This step may be especially important in countries in which both undernutrition and overnutrition are of concern. Identification of the public health issues allows the working group to address the questions in **Table 1**.
- 5. Develop and draft the main messages for the FBDG.** The working group will need to decide whether the draft document will be targeted primarily at health professionals, and hence may be more technical, or will be targeted toward the general public. In developing the main messages, they may identify consumer-orientated materials, such as a food guide, that will be useful in communicating the FBDG to the public.
- 6. Assess the cultural and economic appropriateness and credibility of the messages as perceived by the target groups.** Through focus groups or other types of consumer testing, the effectiveness of the FBDG can be assessed. This information can be used to revise the guidelines before developing the final draft.
- 7. Release and implement the FBDG.** It is valuable to have government leaders from key ministries involved in the release and implementation of the FBDG so that there is a commitment to integrate the guidelines into departmental policies. In addition, the implementation can require development of educational materials for different target groups as well as public–private partnerships to aid in dissemination of the messages to the public.
- 8. Monitoring and revision.** Monitoring can be used to assess the impact and implementation of the FBDG. In addition, monitoring data are useful for making appropriate revisions and updates to the guidelines on a periodic basis.

**Table 3** Common themes for food-based dietary guidelines.

<i>Foods or behaviors that are encouraged</i>	<i>Cautionary messages</i>
Energy balance	Limit saturated fatty acids and <i>trans</i> -fatty acids
A healthful variety of foods; healthful dietary patterns	Avoid excess energy intake
Inclusion of fruits and vegetables	Balance of energy from fat
Use of whole grains	Limit foods and beverages with added sugar
Protein-based foods from various sources	Limit use of salt and salty foods
Foods that are sources of calcium	Limit or avoid alcohol
Sources of unsaturated fatty acids	
Safe food handling	
Inclusion of physical activity	
Family practices related to meals	

strengthened. Within these core messages the importance of defining healthful dietary patterns and the role of nutrient dense foods has become more prominent. In addition, the *Guidelines* itself has evolved from a simple, consumer-oriented brochure to a more detailed science-based policy document used by decision-makers for policy decisions and the design of health promotion programs (National Academy of Sciences, Engineering, and Medicine, 2017).

Most countries that have developed FBDG have also developed a food guide to accompany the messages in the guidelines (Fischer and Garnett, 2016). The food guide is typically a simple graphic illustration of food choices and dietary patterns; the graphic can be constructed to illustrate the relative proportions of food groups within the pattern. Criteria for a food guide should include representation of foods common to the population that are consistent with the FBDG, use of clear graphics that are meaningful to the target population, and illustration of dietary patterns that meet the nutrient requirements of the population. Although a simple graphic is useful for visual communication, it should be clear that proper use of the food guide depends on understanding the more complete information in the FBDG.

## Conclusion

The use of FBDG has emerged as an important cornerstone of food and nutrition policies and education programs since the late 1970s and is valuable for addressing issues of both nutrient adequacy and risk of diet-related chronic diseases. Importantly, FBDG communicate nutritional principles in a manner that is relevant to the population. As a policy document, they should be revised periodically so that the information reflects current science on food and nutrition factors that promote health and prevent disease. Additionally, it is important for each country to develop their own set of FBDG so that the recommendations and presentation are relevant to the local population.

Emerging issues for consideration in FBDG include the need to develop systems approaches that reflect the numerous factors that influence food choices, including environment sustainability and socio-economic factors that affect access to healthful dietary patterns as well as taking steps to assure that the guidelines are relevant for all life stages and for populations with various health-related conditions. Addressing such issues will require expansion of expertise involved with FBDG development and access to relevant sources of evidence. In addition, addressing these broader issues of food production and availability requires consideration of appropriate mechanisms to address these topics with relevant expertise and evidence (Schneeman et al., 2021).

## Key points

- National household surveys useful for targeting subpopulations at risk
- Survey design considerations for disaggregation and group comparison
- Assessment methods for individual usual nutrient intake: 24 h recall and food frequency questionnaire
- Methodologic limitations and approaches to minimize them
- Emerging technologies to improve assessment

## Introduction

Dietary surveys are used for multiple purposes and range from measurement of food disappearance at the national level, to food use at the household level, to detailed multiple assessments of individual intake for linkage with health outcomes. Major methods for individual intake include the 24 h recall and the food frequency questionnaire. Each of these methods has strengths and limitations, depending on the survey purpose.

## Global research questions and data needs

At the national level, information on food use is needed for economic and agricultural policy decision making. For policy makers to advise on food production, food imports, pricing of staple foods and other factors that affect food availability, they require information on the production, inflow and outflow of food commodities and products. Most countries use food balance sheets to measure these flows, and total available nutrients are estimated in relation to the size and composition of the population (Food and Agriculture Organization of the United Nations, 2001). These surveys measure overall national food production, imports, and available food stocks, and subtract exports, food used for animals, and losses that occur during production, storage, and manufacturing. While not a survey in the formal sense, this is a collection of data from the food sector regarding wholesale distribution. After adjusting for expected wastage, these data are compared to nutrient values and then to the size and composition of the population to calculate per capita nutrient availability. Because this is a crude assessment, it does not account for all losses and, therefore, tends to overestimate availability. The FAO has compiled food balance sheets for many countries since 1949, allowing useful inter-country comparisons of food availability. However, the aggregate information obtained with food balance sheets does not consider food distribution within a country and does not quantify food intake or needs of subgroups of the population.

Most countries need more information on household level food use to target food and nutrition policies toward groups at need. Commonly administered surveys include the International Food Policy and Research Institute's Household consumption and expenditure surveys (HCES), which are used in more than 120 countries (Fiedler and Mwangi, 2016). Household food surveys capture the amounts and types of food that enter a household, and per capita intake equivalents are calculated by dividing the total nutrients available in the household from the edible portion of entering foods by the numbers of household members, weighted by age and sex. This information allows identification of groups at risk of inadequate intake of energy or of specific nutrients. For example, these surveys may highlight rural-urban differences, inland-coastal differences, differences by socio-economic strata, and so on. Such surveys provide critical information within countries for the development and targeting of economic, agricultural, and nutritional policies specific to regions or other sub-groups of the population. They do not, however, provide information on individual intakes within the household, and are not useful for understanding age- and sex-specific intakes.

To describe food and nutrient intake by age, sex and physiologic state, data are needed at the individual level. Surveys of individual dietary intake use methods that range from qualitative food checklists to multiple detailed records of food intake, with quantification of preparation methods and portion sizes. Individual level data are used for a variety of purposes and the survey design will depend on the primary data needs. At the national level, a primary objective is to identify sub-groups at risk of inadequate intake of energy or specific nutrients. The important advantage of individual level data is that target age and sex groups may be identified in addition to groups identified by region or other household level characteristics. A further objective is to determine the extent of under- or over-nutrition in relation to energy or specific nutrients in sub-populations. This requires consideration of the distribution of intakes in specific age, sex, and physiologic status groups. A more ambitious objective of some national or targeted dietary surveys is to associate aspects of individual dietary intake with the existence of health conditions. This objective requires that usual intake data be valid and reliable at the individual level.

### Issues in survey design

For a household level survey to be nationally representative, one must carefully consider the sampling design. This is generally done by multilevel selection of regions, then sub-regions, then households, in such a way that the resulting data may be generalized to the national level. For results at the regional level, coverage of all regions is necessary, although this will usually increase the cost of the survey. When the objective is more specific than national description, target areas may be selected, or subgroups oversampled, based on risk status or relevance to the question being addressed.

Similarly, for data to be representative of the greater population, complex sampling design is employed. Decisions on sampling design will generally be a balance between equal opportunity for individual inclusion against logistic and cost considerations of full randomization. The design may be similar to that of the household level survey, with the added step of randomly selecting individuals within households. Although surveys focused on the household level may interview all members of the household, this is not the most efficient way to get data representative of individuals in the population, due to the lack of independence of the observations. Members in the same family consume similar foods and therefore are more like each other than others in their community. Although this lack of independence can be adjusted in the analysis, it will require larger numbers of interviews to achieve representative stability of data estimates. The multistage approach of region, sub-region and community is less representative than a pure random sample, but this is corrected by consideration of the "design effect," which is calculated by comparing variation within, versus between, sampling units at each level (Kish, 1965). Although the design effect leads to the need for higher overall numbers of surveyed individuals, this is generally considerably less expensive than expanding coverage to all locations.

In addition to representation of the general population, many surveys also consider sub-groups that will not be well represented unless specifically over-sampled. Examples include pregnant women, ethnic subgroups or low-income groups. Individuals that meet the specified characteristic are identified within the existing sampling design but are selected in larger numbers than would be representative of the entire population. This allows sufficient sample size to present valid estimates separately for these groups. When included in measures of the total population, the over-representation of these sub-groups is adjusted using sampling weights. This design is used, for example, in the US National Health and Nutrition Examination Survey (NHANES), which provides intake data representative of the non-institutionalized US civilian population (NHANES). While multistage sampling is used, it is not sufficient to cover smaller subgroups within the population. Therefore, oversampling is conducted for selected subgroups. These have varied over time but, for example, the 2015–16 cycle included oversampling of Hispanic, non-Hispanic black, non-Hispanic Asian, individuals at or below 185% of the Department of Health and Human Services (HHS) poverty guidelines, and persons aged 80 years and older (NHANES).

The NHANES uses multi-stage cluster sampling throughout the country. Sampling weights to correct for design effects are provided online, along with detailed instructions for use, to be able to extrapolate results by age, sex, and race/ethnicity to the overall US population. Because of this design, the data are not useful at the state level. The Centers for Disease Control and Prevention

(CDC) conduct another survey, the Behavioral Risk Factor Surveillance System (BRFSS), to collect information at the state level. However, this survey, conducted by telephone, includes only a few questions on fruit and vegetable intake.

Another design consideration is the timing of the survey. Intake may vary considerably by season and it is, therefore, important that all seasons are represented. Although logistic and cost constraints often limit ideal design planning, it is optimal if data from all seasons are collected in all survey locations. If different locations are covered at different times of the year, comparisons across regions may be compromised. Additionally, intakes may be misrepresented if certain days of the week are not included in the data collection plan.

## Selection of dietary assessment measure

### Household level

Several alternative methods of dietary assessment are available. At the household level, one commonly used approach is the food account method ([Food and Agriculture Organization of the United Nations, 2008](#)). Such household consumption and expenditure surveys (HCES) are conducted globally in more than 120 countries. The person most responsible for the acquisition and/or use of food is asked to keep a daily record of all the food that enters the household for a specified period—often one week. This includes food purchases, food production and food received as gifts. There are several limitations to this approach, including the assumption of constant food stores, which may not be the case.

In some locations, it is not feasible for many individuals to accurately record this information. In this case, an interviewer-administered list-recall method is used. The interviewer asks the responsible household member to recall food purchases, production, or gifts in the household during a specified period, following a list of major foods that are relevant for that location. Additional information on age and sex of household members and number of meals each consume at home is collected to calculate adult equivalent per capita food availability for the household. Although edible portions of foods are generally considered in quantifying availability, most such surveys do not account for wastage or use by animals and, therefore, may overestimate household food use. On the other hand, if they do not account for food consumed away from the home, they may underestimate food intake. While useful for economic and food commodity flow information, this type of survey is, therefore, limited with respect to nutritional intake assessment.

To understand dietary intake within households, more elaborate methods are needed. One approach is to use a household diet record, where the household respondent is asked not only to report inflows of food, but also to record actual use and preparation of foods in the household over a specified period. Food consumed outside the home may also be assessed for each household member, and the number of individuals, including guests, who are present at each meal is recorded. While demanding for the respondent, this approach provides a better estimation of the total food consumed by the household than the inventory methods described above ([Fiedler and Mwangi, 2016](#)). Estimation of waste is included in some, but not all, such surveys and is a limitation of most. Because of the heavy respondent burden, incomplete response is also a major problem, which threatens the validity and generalizability of the survey.

### Individual level

The selection of dietary assessment methods depends on the questions to be addressed, balanced with cost considerations. Major uses of individual intake data from dietary surveys include the description of intake distributions by sub-group, description of proportions of the population with inadequate or excessive intake of specific foods or nutrients, and comparison of dietary intake with individual characteristics, including health status.

If the goal is to describe the mean and distribution of intakes of groups and sub-groups, the most efficient method is the use of a single 24 h dietary recall per selected individual. The 24 h recall is usually administered by a trained nutritionist who asks the individual to report each eating and drinking occasion throughout the previous day. Once the items are listed, details are requested, including specific portion sizes, recipes, brand name or source of the food item, use of condiments, etc. The automated multi-pass method (AMPM), developed by the U.S. Department of Agriculture (USDA), begins with (1) a quick list of foods and beverages, followed by (2) a probe for frequently forgotten foods (like snacks), (3) questions on the time and eating occasion (meal or snack) for each food, (4) detailed information on portion size, recipes, condiments, etc. and (5) a probe for anything that may have been missed.

This is the methodology used in the NHANES, providing a good description of nutrient intakes by age, sex and ethnic group. Until 2003–2004, a single recall was administered. As an aggregate measure, this design worked well. There are limitations to these estimates, however, and validation against quantified energy expenditure measurements has shown that most people tend to under-report intakes with the 24 h dietary recall method ([Subar et al., 2003](#)).

Although the mean intake of subgroups has been considered generally valid, the tails of the intake distribution from a single recall are extended, leading to overestimation of proportions either above or below a specified cutoff point, relative to what is seen when usual intake is assessed as the average of multiple days ([Fig. 1](#)) ([National Research Council \(US\) Subcommittee on](#)

**Fig. 1** Distribution with one vs. multiple days of intake (National Research Council (US) Subcommittee on Criteria for Dietary Evaluation, 1986).

Criteria for Dietary Evaluation, 1986). This occurs because individuals may under or over consume on any single day in a way that they would not, over the average of many days, resulting in misclassification of individual usual intake.

With repeated recalls on a representative subset of the population, the day-to-day variability may be quantified and used to adjust estimates to better represent usual intake (Beaton et al., 1983). Statistical correction methods have been developed by the National Cancer Institute (NCI) to further correct intake distributions (Tooze et al., 2010). These techniques pull in the tails and provide a more realistic distribution of usual intake, providing a more accurate estimate of the proportion of the population that falls below or above a specified cutoff point. For this reason, many studies, including the NHANES, now incorporate two recalls in their design. These methods continue to be updated (e.g. (Luo et al., 2021)) and SAS macros for public use are available on the NCI website (The NCI Method).

A third important objective of dietary surveys is to gain a better understanding of the correlates of nutrient intake with health outcomes. Day to day variability misclassification severely limits the ability to correlate intake data with individual characteristics. For many nutrients, this intra-individual variation in intake is considerable, and multiple days would be required to achieve stable estimates of individual usual intake. An extreme example is vitamin A, which tends to be concentrated in a few foods. If one frequently consumes liver and carrots but happened not to consume either of these on the day of the recall, that individual would be classified as having low vitamin A intake, when their usual intake is actually high. Conversely, one who almost never eats these foods, but had liver on the day of the recall would be incorrectly placed at the upper end of the vitamin A distribution. The greater the intra/inter individual variance ratios, the lower the ability to see true associations. The collection and averaging of multiple days of intake greatly improve this situation. For most nutrients three or four days are acceptable. However, for some nutrients, including vitamin A and vitamin B12, the variance ratios are so high that an unrealistic number of days would be needed for stable estimates.

Although variance ratios can be used to adjust the distribution of intake, this does not allow the true estimation of individual usual intake. For this reason, and others, the food frequency questionnaire (FFQ) remains the method of choice in most studies where diet—disease relationships are the primary objective. The FFQ asks respondents to report the frequency of consumption of a pre-specified list of specific foods, usually over the previous year. Additional questions on portion size and on preparation methods may be added, as appropriate. FFQ provide a lower cost alternative to multiple recall days, but also have limitations. Because they rely on a food list, their validity is dependent on the representativeness of that list, and of portion size and recipe assumptions. Most FFQ in wide use have been developed using data that represent the major sources of nutrient intakes in the US population. These include the Willett, Block and NCI questionnaires (Willett et al., 1985; Block et al., 1986; Subar et al., 2001). However, individuals with divergent eating patterns are not well represented using these tools due to limitations in the food list and differences in portion sizes and preparation methods (Tucker, 2010). For this reason, most large studies of different cultural groups develop unique FFQs with appropriate food lists for their population. This improves internal validity, but limits comparisons across studies.

To improve estimation further, the National Cancer Institute (NCI) proposed a combined method to better assess usual intakes in population-based studies. This method uses the data from 24 h recalls to adjust distributions for day-to-day variability and adds

additional information on frequency of specific food intake from a propensity questionnaire, to estimate the probability of consumption when the foods are absent in the 24 h recalls (Subar et al., 2006). The propensity questionnaire originally did include portion sizes but captured frequency of intake of foods which may not appear on any given day, but which may be added to statistical models to improve overall nutrient distributions. The most recent NCI FFQ, now called the Diet History Questionnaire (DHQ), is available for use with or without portion sizes. Methods for combining the information from these two sources to improve estimates continue to be developed (Freedman et al., 2018).

In addition to the day to day variation, which is random, another more complex issue is underreporting. Validation against quantified energy expenditure measurements using doubly labeled water has shown that most people tend to underreport intakes with the 24 h dietary recall method (Subar et al., 2003). Underreporting will affect the mean intake of groups and, if differential, may introduce bias in sub-group comparisons. Unfortunately, it has been determined that underreporting is usually not random and is more common among those with obesity, with restrained eating or who tend toward socially desirable responses (Kretsch et al., 1999; Hebert et al., 2001). However, the USDA AMPM system, applied carefully, has been shown to reduce underreporting and to yield relatively good intake estimates when compared with the biomarker doubly labeled water (Moshfegh et al., 2008), although underreporting remained more common among those with obesity.

### New technology

While traditional use of 24 h recalls and FFQ in surveys has involved interviewer administered questionnaires, originally on paper and then directly into a computer program (such as with the multiple pass system used by NHANES) (Moshfegh et al., 2008), there has been a recent shift to use of online questionnaires. The NCI developed an online 24 h recall, ASA24, which allows direct entry by participants from their home (ASA24) and have also placed their DHQ online. Additional tools have been developed in other countries (Dao et al., 2019).

Although not described in detail here, new biomarkers are being developed to assist in validation and calibration of dietary intake reports. Established biomarkers include recovery biomarkers, which capture total intakes with good precision. These include doubly labeled water for energy and urinary protein, sodium and potassium. Concentration biomarkers, which correlate well with intake include plasma vitamins, carotenoids and fatty acids (Potischman and Freudenheim, 2003). New biomarkers being explored include urinary sucrose and fructose, and plasma metabolites assessed with metabolomics (Gao et al., 2017). Other technologies, including photographs are being tested to capture portion size. However, although many advances using cameras have been made, they remain burdensome and cannot provide the ingredients of the item and, therefore, must be coupled with self-report.

With the emergence of human genome data and movement toward personalized nutrition for health, there is increasing demand for estimates of usual intake for use in studies of gene-diet interactions. Because these usually require very large samples, it is rarely feasible to include three dietary assessments. Further, there is a trend toward combining data from multiple studies to obtain sufficient sample size and this is not easily done when studies use different dietary assessment methods. More efficient methods of valid dietary assessment, which can be collected consistently across studies, are needed.

### Database limitations

Whatever dietary assessment measure is used; the utility of the data is dependent on the translation of reported food intake to nutrient intakes. This requires detailed and accurate nutrient databases. The USDA has an extensive nutrient database, allowing for good estimation of dietary intakes. Most other countries have not conducted this level of food composition analysis for their own locations. Therefore, the values in most existing databases stem from the US nutrient database, adding information as possible from locally analyzed products. Because the nutrient composition of many foods, including fruit, vegetables and even animal products, can vary widely by growing conditions and specific sub-variety, most available nutrient databases remain inadequate. Many databases use extrapolated values from similar foods when chemical analysis has not been completed. Furthermore, it is common for many country-specific databases to include information only on macronutrients and a few selected vitamins and minerals. The continual arrival of new manufactured products also complicates the upkeep and management of food composition databases. Considerable database work remains to expand the utility of worldwide dietary surveys. Major ongoing efforts in this regard include the international network of food data systems (INFOODS) and the Global Nutrient Database (Miller et al., 2021).

### Conclusions

Dietary surveys are critically important for understanding the dietary intake of populations, changes over time, and the prevalence of inadequate or excessive intakes by subgroups. This information is used by policy makers to make decisions on nutrition policy, including supplementation or fortification of foods, and for targeting groups at risk of malnutrition with nutrition intervention and education. Despite the importance of these surveys globally, many limitations continue to exist, including a tendency toward underreporting of intake, issues of day-to day and seasonal variability in intake, and limitations of existing nutrient databases. Advances in methodology continue to be implemented, including the automation of data collection and the development of

**Table 1** Advantages and disadvantages of different approaches for dietary surveys.

Level	Survey type	Advantages	Disadvantages
National	Food balance sheets	Inexpensive	Crude estimate; no consideration of wastage; does not allow disaggregation to sub-levels
Household	Food account method	Inexpensive	Does not account for food consumed away from home, inventory or wastage
	Interviewer-administered list-recall	More detail obtained on foods than in the food account method	List may limit responses; waste usually not accounted for
	Household diet record	Usually covers one week with detail. Most accurate of household methods	High respondent burden; expensive
Individual	24 h dietary recall	Detailed information on food intake, good estimate of mean intakes by sub-group	Misclassifies individuals; single recall per person is not useful for correlative investigation
	Multiple recalls	Average of multiple days can give good quantitative estimate of usual intake; with two recalls, intra/inter-individual variance can be calculated and used to correct correlations and linear coefficients for random error	Expensive; variability ratios are useful but not sufficient to correctly classify individuals; has limited utility in non-linear analyses.
	Food frequency questionnaire (FFQ)	Inexpensive, measures usual intake	Semi-quantitative, dependence on food list and recipe assumptions may lead to error in estimation of intake in sub-groups
	Combined approach with 2 24 h recalls and a qualitative FFQ or propensity questionnaire	Allows improved estimates of individual intakes by adjusting for the probability of consumption of food groups that may appear as zeros in 2 24 h recalls	Expensive; heavy respondent burden; requires considerable statistical expertise

statistical methods to maximize the use of repeat recalls with or without added information from FFQ. Further efforts to be inclusive of subgroups, to improve data collection with technology, to improve nutrient databases, and to validate methods against biomarkers, are needed (**Table 1**).

## Key points

- The global prevalence of displaced persons, whether within their home country or abroad as refugees, has increased in the past decade.
- Displaced persons are at risk for nutritional deficiencies given the high prevalence of food insecurity in refugee camps and conflict zones.
- Displaced persons form a vulnerable population that is prone to nutritional deficiencies, such as micronutrient deficiencies, wasting, and stunting.
- There are a number of treatment modalities that can be provided to displaced persons, including micronutrient fortified food baskets, micronutrient sprinkles, and meal replacements.
- Supplement feeding programs are vital to supporting the health of displaced persons and efforts are needed to maintain the sustainability of such programs.

## Glossary

**Community therapeutic care program (CTC)** A CTC program has the same initial metabolic stabilization phase as a traditional feeding program, and life-threatening infections are identified and treated in the same way. Once the patient is stabilized, they move directly to an outpatient therapeutic program that operates through existing health structures and initiates nutritional rehabilitation with ready to use therapeutic foods (RUTFs). When there is no longer a risk of severe malnutrition, they are referred to supplementary feeding programs for recuperation

**Internationally displaced persons (IDPs)** These are persons fleeing from war, civil disturbance, and violence of any kind but who do not cross international boundaries

**Ready to use therapeutic foods (RUTFs)** These foods are ready to eat and high in energy and protein. They also contain micronutrients and electrolytes. Their main use is for treatment of malnutrition. Their use to prevent stunting and wasting is also being evaluated

**Special feeding program** This program deals with provision of high-quality foods to be consumed in addition to the usual diet, with either targeted (to prevent persons with moderate acute malnutrition from becoming severely malnourished) or blanket (to prevent nutritional deterioration of a larger population) distribution

## Introduction

Since World War II, more than 100 million people have been forced to flee persecution or the violence of war to seek refuge in neighboring countries or in different areas of their own countries. The optimism following the end of the Cold War was short-lived as a number of civil conflicts erupted throughout the world. In 2020, there were 57 active conflicts, including eight wars, and 48 of these conflicts were internal ([PRIO Conflict Trends, 2020](#)). Most recently, the 2022 Russian invasion of Ukraine caused more than 2 million refugees to flee to Europe in less than two weeks. Armed conflicts have increasingly affected civilian populations, resulting in high mortality, widespread human rights abuses, forced migration, famine, and total collapse of governance in some countries. As well, climate change and the associated impact of agriculture and labor is becoming more common in lower income nations, adding to the numbers of displaced people in the world ([Balsari et al., 2020](#)). The focus of this article is to describe responses to humanitarian crises and the nutritional impact of being a displaced person.

## Displaced persons and refugees

Civil conflict, economic challenges, and climate change exist as the main drivers of displaced persons. Displaced persons are those who flee their homes and become refugees, or need to relocate within their own country and are considered “internally” displaced, or asylum seekers hoping to escape persecution. Displaced persons are often left with little to no medical care and access to safe and nutritious food is often entirely dependent on volunteer aid programs. Since these programs are not always sustainable long-term, the risk of undernutrition is extremely high for most displaced persons, but more so for growing children and the elderly.

The 1951 United Nations Convention defines a refugee as

any person who owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion is outside the country of his nationality and is unable, or owing to fear is unwilling to avail himself of the protection of the country.

In 1969, the Organization of African Unity expanded this definition to include persons fleeing from war, civil disturbance, and violence of any kind.

“Refugees” cross international borders, but “internally displaced persons” (IDPs) do not. However, both groups have been forced to leave their homes and undergo physical and mental trauma as they settle in harsh and unhealthy environments, where they are often unable to take responsibility for their own welfare. The terms “refugee” and “internally displaced person” have major implications for the people concerned, particularly regarding their rights to protection and assistance, which are embedded in international law. The United Nations High Commissioner for Refugees (UNHCR) is mandated by the international community to protect and provide assistance to refugees. Owing to state sovereignty, the internally displaced are not included within UNHCR’s mandate. Only on an *ad hoc* basis, at the request of the secretary general of the United Nations and the nation concerned, does UNHCR provide assistance to IDPs.

## Global trends

Globally, over 82 million people were forcibly displaced worldwide at the end of 2020, the highest number uprooted by conflict and persecution since the mid-1990s, according to UNHCR’s annual 2020 Global Trends report ([UNHCR, 2020](#)). The prevalence of all classifications of displaced persons (i.e., refugees, IDPs, and asylum seekers) has increased steadily since 2010 ([Fig. 1](#)). Specifically, the number of refugees increased from approximately 10 million in 2003 to a peak of more than 26 million in 2020. The majority of people who were displaced came from Syria, Venezuela, Afghanistan, and South Sudan with the remainder from various countries in Asia and Africa ([Fig. 2](#)). This estimate stayed level primarily due to the global COVID-19 pandemic that forced people to quarantine and limited global migration. In addition to the large numbers of refugees, in 2020 there were approximately 48 million IDPs worldwide, mostly driven by Venezuelans displaced abroad, and, as this article goes to print, the ongoing Russian war in Ukraine continues to generate millions of refugees.

In terms of refugees, according to the 2020 UNHCR report, the overall number of refugees increased from 15 million in 2012 to over 26 million in 2020. The largest numbers of refugees in 2020 were from Syria and Venezuela with the next largest numbers from Afghanistan, South Sudan, and Myanmar ([Fig. 3](#)). At the same time, the number of refugees voluntarily returning to their home countries was estimated to be 3.4 million by the end of 2019. However, by the end of March 2022, it was estimated that over 4.0 million Ukrainians became refugees, the largest number of European refugees since World War II, reversing gains observed in the past decade.

A major event that limited or even reduced the global prevalence of displaced persons was the global COVID-19 pandemic. By the end of 2020, an estimated 160 countries had closed their borders and nearly 100 countries did not make exemptions for those applying for asylum. While some refugees were able to leave their home country, many were not and the number of IDPs increased.

**Fig. 1** Trends in global displacement between 2010 and 2020 modified from the 2020 Global Report of the United Nations High Commissioner for Refugees (UNHCR, 2020).

As well, for those who were not allowed to leave conflict zones or seek asylum, a reported increase in food insecurity and domestic violence occurred, creating additional challenges beyond those they were hoping to escape.

### Nutrition implications of displacement

The public health and nutrition consequences of war and human displacement have been well documented during the past 40 years. The major determinants of high mortality among affected populations and priorities for intervention have been identified. Access to safe water, sanitation, shelter, and immunizations (measles) are essential, but an adequate and diverse diet remains central to the management of refugee operations. Today, it is acknowledged that acute undernutrition is a strong predictor of excess mortality among young children, and micronutrient deficiencies contribute significantly to diseases in emergencies. Therefore, resources and efforts must remain focused on these areas to best protect against mortality in refugee situations.

Undernutrition is defined as a state in which the physical function of an individual is impaired to the point at which he or she can no longer maintain adequate bodily performance processes, such as growth, pregnancy, lactation, physical work, and resisting and recovering from disease. This condition is generally due to the cumulative result of a lack of nutrients due to a combination of social conditions that limit access to nutritious foods, chronic food insecurity, and chronic intestinal infection. Undernutrition

**Fig. 2** Distribution of displaced persons by country of origin for the majority (68%) of refugees and Venezuelans placed abroad based on the 2020 Global Report of the United Nations High Commissioner for Refugees (UNHCR, 2020).

\*Excludes Palestine refugees under UNRWA's mandate

**Fig. 3** International displacement by country of origin at the end of 2020\* modified from the 2020 Global Report of the United Nations High Commissioner for Refugees (UNHCR, 2020). \*Excludes Palestine refugees under UNRWA's mandate.

results in a broad range of clinical conditions in children and adults that result from deficiencies in one or more nutrients and/or energy. The link between acute malnutrition and excess mortality has been documented for decades. The close correlation between these two factors was demonstrated during a Somali refugee operation in Ethiopia in 1988–89 and later in other emergencies (CDC, 1992). During the period of peak incidence of mortality and high prevalence of acute undernutrition, access to adequate food was less than 1400 kcal person<sup>-1</sup> day<sup>-1</sup> instead of the recommended 1900 kcal person<sup>-1</sup> day<sup>-1</sup> at the time and limited access to safe water, sanitation, shelter, and densely crowded conditions. Although the immediate aim of most food assistance programs in refugee emergencies is to prevent excess mortality, there is also increasing evidence that undernutrition during critical periods of life has long-lasting effects. Undernutrition, or the risk of being undernourished, may be carried from one generation to another in an intergenerational cycle (Martorell and Zongrone, 2012). Undernourished women give birth to undernourished infants who, in turn, are more likely to become undernourished adolescents and adults. Therefore, the nutritional status of refugees can have long-lasting effects on future health for individuals and generations.

## Macronutrients

An inadequate supply of macronutrients and micronutrients (protein, fat, carbohydrates, and vitamins and minerals) results in protein-energy malnutrition (PEM), the most common form of malnutrition, especially among infants and young children. The two main forms of growth failure associated with PEM includes wasting (acute undernutrition) and stunting (chronic undernutrition). Wasted individuals, defined as a weight for height < -2.0 Z-scores, are extremely thin, whereas stunted individuals, defined as height for age < -2.0 Z-scores, are short for their age as a result of impaired growth during childhood. Severe PEM has a high case fatality rate and is often classified into two forms, marasmus and kwashiorkor. Both conditions are identifiable by severe weight loss, however, the oedema associated with kwashiorkor can mask the otherwise dramatic skeletal appearance of marasmic individuals. Nutritional issues among refugees vary greatly from one region of the world to another. The prevalence of wasting, defined as weight for height less than -2 standard deviations of the reference population, has been as high as 50% in the Horn of Africa and as low as 5% in Southeast Asia, Malawi, and the Persian Gulf. Mortality rates in some of these populations during the acute phase of displacement have been extremely high, up to 60 times the expected rates.

## Micronutrients (vitamins and mineral deficiencies)

Micronutrients, although needed in small amounts, are as essential as macronutrients in addressing nutrition requirement of populations through food assistance programs. Micronutrient deficiency diseases are key in nutrition-related morbidity and mortality. There is a misconception that people do not die of micronutrient deficiencies because one does not often see the signs and symptoms as visibly as those for PEM. Nonetheless, these deficiencies can be fatal. In addition to deficiency diseases of vitamin A, iron, and iodine, conditions widely described as diseases of public health importance, epidemics of scurvy, beriberi, and pellagra, have been frequently reported among refugee populations, primarily because of limited access to a diverse diet and overreliance on one or two commodities (i.e., maize or polished rice) (Table 1). The importance of micronutrient deficiencies among the refugee population has only been documented since the late 1980s and more attention is being paid to the usefulness of inclusion of micronutrient-rich foods and/or supplements in the management of refugee nutrition. There are additional innovations for delivering micronutrients for home fortification. This represents one of the best potential opportunities to increase impact on child development and saving lives. Micronutrient powders, for example, known under the trade names MixMe and Sprinkles, are provided to fortify foods after preparation, just before consumption, to ensure an adequate intake of micronutrients essential for body functions. Micronutrient powders come in small individual sachets containing one full recommended nutrient intake of 15 vitamins and minerals in one gram of powder for one person per day and are currently used in many refugee and emergency operations.

## Conflicts and refugees and long-term health

The health implications of being a refugee or IDP are centered around issues of personal safety and food security given the often tenuous living conditions either in refugee camps or as a refugee. Yet, migration of refugees is major concern to host countries as many refugees may have experienced nutritional and emotional challenges before arriving. This dramatic transition to a new environment with improved access to processed foods or even continued food insecurity due to financial or language challenges may create the background against which elements of the “developmental origins” become manifest and result in nutrition-related chronic diseases among refugee immigrants (Hoffman et al., 2021).

Clearly, as has been witnessed recently in the Russian invasion and occupation of Ukraine, IDP or refugees are often exposed to poor nutritional environments prior to emigrating. For example, refugee immigrant children have a five-fold higher risk of being stunted compared to non-refugee immigrant children (Lane et al., 2018). As well, one study reported that 30% of refugee children were growth retarded (Sarr et al., 2014). Indeed, 30% of Sudanese refugee children are reported to have low bone mineral content and elevated cholesterol, triglycerides, and insulin resistance (Alasagheirin and Clark, 2018). Many refugees suffer psychosocial and nutritional stressors and 40% of refugees have reported past and current food insecurity, making dietary intake and quality important factors to consider. Finding appropriate residence relieves these stresses and the height and BMI z-score of refugee children increased during a 5-year follow-up. Interestingly, obesity may be a factor associated with refugee migration that may contribute to the prevalence of nutrition-related chronic diseases. In the US, refugee children had a higher BMI z-score compared to the low-income non-refugee children who attended the same health centers (Dawson-Hahn et al., 2016). Moreover, stunted refugee children experienced an increase in their BMI z-score yet, the control children had a decrease over one year. It is hoped that understanding the long-term health implications of being displaced may promote improved health and nutrition aid programs for refugees when civil strife and unrest prompt the unfortunate migration of people.

**Table 1** Micronutrient deficiencies in refugees.

<i>Micronutrient</i>	<i>Deficiency disease</i>	<i>Symptoms</i>
Iron	Anemia	Pallor, tiredness, headaches, breathlessness
Iodine	Goiter	Swelling of the thyroid gland in the neck
	Cretinism	Severe mental and physical disability that occurs in the offspring of women with severe iodine deficiency
Vitamin A	Night blindness	Inability to see well in the dark—an early sign of vitamin A deficiency
	Xerophthalmia	Including Bitot spots and corneal ulceration and night blindness
Niacin	Pellagra	Affects the skin, gastrointestinal tract, and nervous system and is sometimes called the 3Ds: dermatitis, diarrhea, and dementia
Thiamin	Beriberi	Loss of tendon reflexes; drooping of arms and feet; wet or cardiac beriberi resulting in heart failure
Vitamin C	Scurvy	Painful joints, swollen and bleeding gums, and slow healing or reopening of old wounds

## Addressing nutrition in refugees

Owing to the nature of displacement and the loss of livelihoods, refugee populations are extremely vulnerable. Often, refugees settle in camps with support from the international community and host government. In some cases, refugees may live in open situations in which they integrate into the local community. In almost all cases, refugees are dependent on outside assistance, although the level of need depends on the level of self-reliance the refugees can achieve. In some instances, refugees are able to bring some assets with them when they flee and/or have some sort of income-generating activity, such as access to land and labor and employment. However, this very much depends on the policies of host governments. In these cases, refugees are not totally dependent on external assistance, and nutrition management response takes these factors into account by adjusting humanitarian assistance and the food assistance in particular to meet the assessed needs. There has been an evolution in the standards of food energy required for refugee populations as previous standards were based on estimates of energy requirements for body weight, demographic composition, environmental temperature, and activity levels. In the 1980s, the standard was approximately 1500 kcal person<sup>-1</sup> day<sup>-1</sup>, the minimum deemed adequate for survival. In the late 1980s, this was recalculated to 1900 kcal person<sup>-1</sup> day<sup>-1</sup> as a preliminary standard to include expenditure of energy for light activity as opposed to merely the basal metabolic rate. In the 1990s, the benchmark value was modified to a more realistic 2100 kcal/person/day (FAO, 2004). The revised estimate was based on an increase in energy required for physical activity, some adjustments to the demographic composition, and an increase in the proportion of pregnant and lactating women in the population. It should be recognized that this recommended value is the average of the individual requirements based on developing nation population demographics and is not a specific provision for individual needs. In addition to the recommended kilocalorie content of the daily food ration, nutritional science has determined that the ration should have an optimal balance of fat and of protein (17 and 12%, respectively).

## Food baskets for populations (general food distribution)

The sudden and massive reduction in food availability associated with displacement immediately affects the nutritional status of refugees. The first response is intervention through the implementation of adequate food distribution to all to ensure all refugees have access to the required food ration. A general food distribution is the first line of intervention and the highest priority when a refugee population does not have access to sufficient food to meet its nutritional requirements. If the recommended adequate ration of 2100 kcal person<sup>-1</sup> day<sup>-1</sup> and the quality of food basket is not available, malnutrition levels may escalate.

Even if the overall food needs of refugees are adequately met, inequities in the distribution system, disease, and various social factors may contribute to a high level of malnutrition among certain groups. Children younger than 5 years of age, pregnant and lactating women, the chronically ill (e.g., tuberculosis and HIV/AIDS patients), and the elderly are considered vulnerable groups since they have specific nutritional requirements. A special nutrition intervention program targets these nutritionally vulnerable groups through supplementary feeding programs and those in need of nutritional rehabilitation through therapeutic feeding programs. Malnutrition prevalence, as well as an assessment of aggravating factors in the environment, are used as guidelines to determine if a nutrition intervention program needs to be initiated. Aggravating factors that influence the nutritional situation include an elevated crude mortality rate; epidemics of communicable diseases such as measles, diarrheal diseases, and respiratory infections; and an unstable social, political, or environmental situation.

Nutrition programs are primarily managed by nongovernmental organizations (NGOs) that have specialization in the management of refugee nutrition. Other humanitarian partners have roles to play in response to refugee situations, including host country authorities, United Nations agencies such as the World Food Program, UNHCR, and UNICEF; and other multisectoral NGOs. There exist memorandums of understanding and partnership agreements among agencies to provide assistance to the affected populations. The need for partnership is essential for management of refugee nutrition and health programs. The Sphere Project was launched in 1997 to develop a set of universal minimum standards in vital sectors of humanitarian assistance. The aim of the project is to improve the quality of assistance provided to affected populations and to enhance the accountability of the humanitarian system in emergency response.

## Addressing acute malnutrition among young children

### *Management of moderate acute malnutrition*

The most common nutrition intervention is supplementary feeding programs (SFPs) to address moderate acute malnutrition in emergency situations. SFPs provide a high-quality food as a nutritional supplementation to the daily diet of malnourished populations. There are two main types of SFP—targeted and blanket. The goal of targeted supplementary feeding is to prevent people who are moderately malnourished from becoming severely malnourished. Blanket supplementary feeding, which provides all members of a vulnerable group with a food supplement, is intended to prevent the deterioration of nutritional status among a larger population group rather than narrowly defined individuals at specific nutritional risk. Implementation of SFPs can take two forms: Prepared meals consumed on site (wet rations) or food rations issued weekly or monthly to take home for preparation (dry rations). Food supplements usually consist of a fortified blended food (FBF) mixed with oil, and sometimes sugar is included. Wet rations should provide 500–700 kcal, whereas the recommended dry ration is doubled to 1000–1200 kcal to account for sharing at home. There have been many advances in improving the food commodities to address nutritional needs for SFPs. The composition of

fortified blended food has been enhanced by including animal proteins (dried milk) and additional vitamins and minerals. In addition, ready to use lipid nutrient products—such as plumpy doz, supplementary plumpy, nutri butter, and other ready to use supplementary foods for children are proven to be more effective for improving nutritional status and speed of recovery.

### **Addressing severe acute malnutrition**

Therapeutic feeding programs (TFPs) provide the severely malnourished with their full nutritional requirements in addition to medical care. They are initiated to reduce excess mortality among individuals facing severe malnutrition and have played an important role in reducing malnutrition-related mortality in emergencies. The first phase of a TFP focuses on treatment of infections, management of other medical complications, and metabolic stabilization. This phase has the highest mortality rate of all nutrition interventions due to the poor state of the patients and the intensive treatment required. The second phase of a TFP is a rapid weight gain period designed to rehabilitate the patient's nutritional status.

Recognition of severe acute malnutrition as a complex nutritional condition during the 1990s led to the development of certain foods defined explicitly for therapeutic treatment of malnutrition with the appropriate balance of energy, protein, and micronutrients in order to avoid overloading the body's metabolism, which potentially may lead to cardiac shock. These products include F-75, F-100, and BP-100 biscuits and other ready-to-use therapeutic foods (RUTFs) such as "plumpy nut."

Community-based care is a recently developed public health approach to deal with severe malnutrition and aims to treat the majority of people suffering from severe acute malnutrition in their homes. A community therapeutic care (CTC) program initially is set up complimentary to traditional TFP components and represents a new approach to managing malnutrition at the community level. A CTC program has the same initial metabolic stabilization phase, and life-threatening infections are identified and treated just as in a TFP. However, once the patient is stabilized, he or she moves directly to an outpatient therapeutic program that operates through existing health structures and, with the use of RUTFs, nutritional rehabilitation is initiated. When patients are no longer at risk of severe malnutrition, they are referred to SFPs for recuperation. This phase is followed by greater emphasis on community mobilization to increase the population's involvement and training of mothers. CTC is an innovative approach and is proven to be successful. Proposed benefits of this method are the improved coverage to increase the number of people treated and reduce overall mortality rates. In addition, local production of RUTFs has been initiated in few countries to reduce the cost of treatment and shorten the length of stay in centers away from the family. Finally, the decentralized nature of CTC can enable earlier detection of malnutrition, thereby reducing the incidence of severe malnutrition (Table 2).

### **Challenges**

Nutrition interventions alone are not adequate to address the multiple causes of undernutrition in refugees. The access to public health inputs is essential in preventing and reducing excess mortality and malnutrition and in ensuring that nutrition interventions have the desired effects.

Although the quality of nutrition assistance and interventions has improved considerably since the 1970s, the international community is still searching and moving forward to improve the quality of food products provided to address undernutrition. This is an exciting time in the field of nutrition to develop appropriate strategies, interventions, and products to address undernutrition. 1000 days is a global effort for addressing undernutrition during pregnancy and early childhood. This refers to a special window of opportunity to take action to combat undernutrition. 1000 days refers to the critical period of growth from conception through 2 years of age. Research shows that children who are undernourished during this period are far more likely to suffer from long-term health problems, poorer education performance, and lower economic prosperity.

Given that a number of factors, such as food, health care, and the environment, interact to determine nutritional well being, a partnership among agencies with different mandates is essential to effectively address and correct nutritional issues. Refugee nutrition must be addressed in tandem with other services to ensure that underlying factors of malnutrition are being met and that nutrition interventions are effective.

### **Summary**

The world in 2022 faces challenges that were outside of our collective imagination even in 2018. The combined effects of a global pandemic, outbreak of war in Ukraine, along with the stress of economic sanctions and rising oil and food prices are far-reaching and have the potential to reverse decades of positive changes in the number of displaced persons. While existing aid programs continue to receive adequate funding, recent events should be a reminder for all members of our modern society to support programs that aid the least fortunate of our planet. Providing basic medical and nutritional support to refugees and IDPs is a moral imperative for the global community and the work by volunteer organizations and multi-lateral groups, such as WFP, are vital to promoting health and safety during times of crisis.

**Table 2** Milestones in addressing nutrition in refugees.

1960s:	Food response based on commodities available (donated) Limited recognition of relevance of nutritional content of rations Food provided based on resources rather than nutritional needs
1970s:	Focus on protein deficiency (in protein-energy malnutrition) Food ration comprised mainly cereal, pluses/beans, and oil Fortified blended foods (FBFs) used only in supplementary feeding
1980s:	Major relief agencies raise planning figure from 1500 to 1900 kcal person <sup>-1</sup> day <sup>-1</sup>
1990s:	Relief agencies raise planning figure for fully food aid-dependent populations from 1900 to 2100 kcal person <sup>-1</sup> day <sup>-1</sup> FBF included in most rations for completely dependent populations Basic six-commodity food basket becoming common: cereal, pulses, oil, salt, sugar, FBF UNHCR/WFP memorandum of understanding signed with clear roles and responsibilities Development of multi-UN agency and NGO policies and guidelines on common approaches to addressing malnutrition in emergencies Fortification of oil, salt, and flours, on international market Development of therapeutic foods for treatment of malnutrition (F100-F75) Local production of fortified blended foods
2000s:	Development of community management of acute malnutrition (CMAM) Creation of inter-agency clusters (IASC)—Nutrition, food security, health, wash, education, protection, logistics, and telecommunication Development of capacity in nutrition in humanitarian staff Pilot testing of on-site milling and fortification in a refugee camp Development of ready to use foods Provision of multimicronutrient powders Provision of cash and or cash vouchers to address malnutrition

## Key points

- The double burden of malnutrition is defined as the coexistence of under- and overnutrition.
- Populations undergoing a rapid nutrition transition, notably those living in low- and middle-income countries, are disproportionately affected by the double burden of malnutrition.
- The global increase in modernization, urbanization, and economic development has contributed to a sedentary lifestyle and an increased intake of processed foods.
- “Hidden hunger” is characterized by the co-occurrence of micronutrient deficiency and obesity at the individual level.
- Conflict, climate change, and economic downturns are challenges to global food systems, threatening food security.

## Introduction

Over the past 50 years, there has been a worldwide shift in diet and lifestyle that has contributed to changes in human nutrition and global health. A decrease in the prevalence of infectious disease and undernutrition marked the beginning of the nutrition transition and an increased prevalence of nutrition-related chronic diseases (NRCs) throughout the world (Popkin and Gordon-Larsen, 2004). As the 21st century began, the prevalence of NRCs continued to increase while the prevalence of undernutrition decreased, but at a slower rate. The world now faces a complicated coexistence of over- and undernutrition occurring within the same households, communities, and countries, most particularly in low- and middle-income countries, a phenomenon termed the double burden of malnutrition (DBM).

Yet, the COVID-19 pandemic that began in late 2019 and continued through 2022, resulted in a major disruption of supply chains and humanitarian aid along with a near cessation of migration from lower income to higher income countries. Almost all countries in the world implemented quarantines and limited international travel in the hope of quelling the spread of the virus. These measures created drastic situations for people living in marginal communities and for those who could not transition to “work from home” such that food insecurity increased and the risk of contracting COVID remained high. This disproportionate burden was further exacerbated when vaccines became available since distribution was primarily in higher income countries before beginning in the poorest countries of the world. Thus, many gains that were made in the fight against obesity and undernutrition were muted or reversed during the pandemic. These current events will have profound effects on the state of the nutrition in the world, but exactly what those effects may be, such as a decrease in the prevalence of obesity or an increase in the prevalence of food insecurity and wasting, will not be known for several years.

Given the social and technological changes over the past several decades, it is important to consider not only the causes of the DBM, but to understand how the DBM is affecting the health and economies of countries across the world. In particular, what once seen as a continued decrease in undernutrition since the end of World War II, often linked to sustained economic growth, is now being challenged by both the COVID-19 pandemic and ongoing civil conflict and economic sanctions placed against Russia following its invasion of Ukraine in February of 2022. In short, while aspects of the DBM become better understood, the task of

preventing and treating nutrition-related chronic diseases (NRCs) is becoming more important than ever. To stem the tide of food insecurity and undernutrition, efforts to prevent undernutrition and obesity, as well as micronutrient deficiencies, need to be made given that many of the same factors promoting these conditions also promote overnutrition.

## Epidemiology of the DBM

The DBM is characterized by the co-occurrence of undernutrition and overweight, obesity, and other NRCs and can manifest at the individual, household, and population level. Briefly, population-level DBM is defined by a high prevalence of both undernutrition and overweight and obesity in the same community, region, or nation. The double-burden household, most common in middle-income countries undergoing a rapid nutrition transition, pertains to the co-existence of under- and excess nutrition within the same household. Individual-level DBM occurs by the simultaneous or temporally separated development of two or more forms of malnutrition. Here we will further explore factors that influence the DBM at these three levels.

At the population level, the DBM affects most LMICs. A coexistence of under- and overnutrition is especially prevalent in sub-Saharan Africa, South Asia, East Asia, and the Pacific. Between the 1990s and 2010s, the DBM worsened particularly in Asia and improved in Latin America, the Caribbean, the Middle East, and North Africa (Popkin et al., 2020). Among the countries with a DBM, there was an observable increase in the prevalence of adult overweight and a decline in child wasting and stunting between the 1990s and 2010s as shown in Fig. 1A and B. The lowest income LMICs are facing a growing DBM that is primarily driven by the rapidly increasing prevalence of overweight and relatively slow decline in childhood wasting and stunting and undernutrition. It is notable that the percent of deaths due to non-communicable diseases is 87% in developed regions and as low as 28% in Africa and as high as 83% in Eastern Asia. At the same time, infant mortality continues to decline throughout the world while adult mortality has shown consistent declines with some increases in parts of Africa and Asia. The cumulative effect of these changes is a generally healthy population with fewer undernourished, but a growing population of over nourished, children and adults.

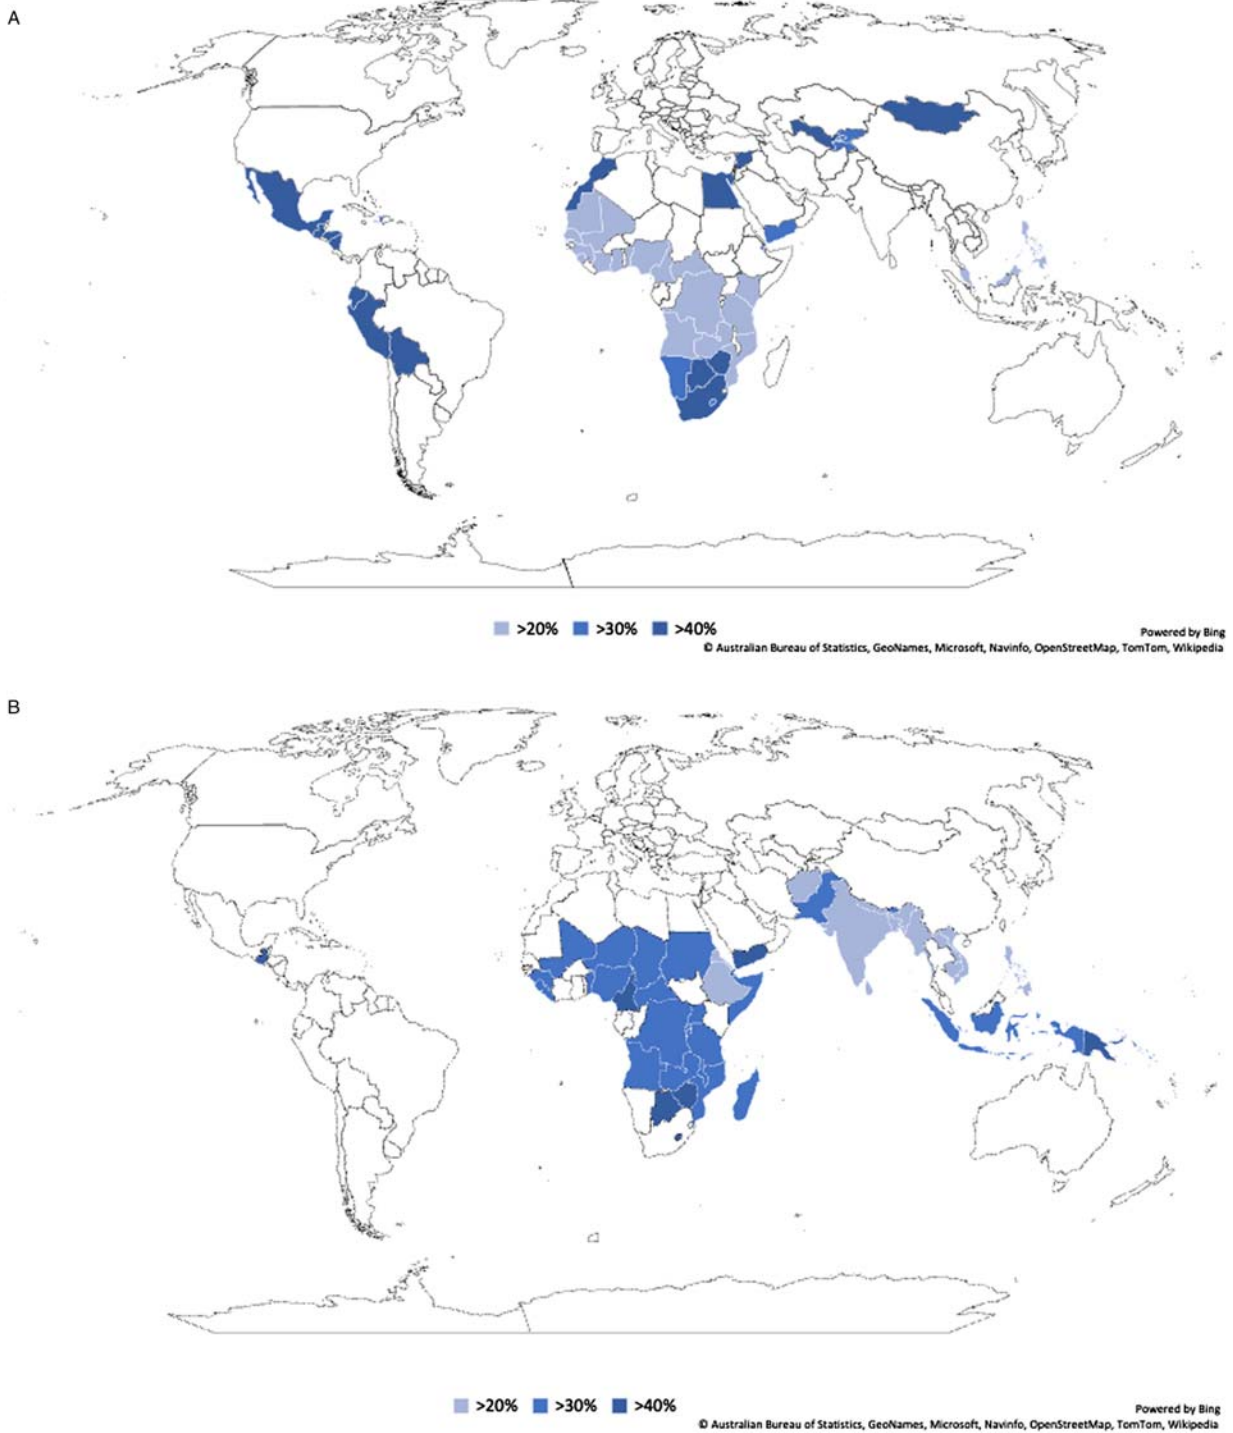

There are growing disparities between the lowest and highest wealth quartiles associated with the DBM. It has been reported that members of the lowest wealth quartile face a greater prevalence of overweight and obesity than those in the highest quartile (Fig. 2A and B). Most countries in Latin America, the Caribbean, Eastern Europe, Central Asia, and East Asia, particularly in China and Indonesia, have reported an increased prevalence of overweight and obesity among lower-wealth households (Popkin et al., 2020). On the other hand, in Sub-Saharan Africa and South Asia, the largest increase in obesity prevalence occurred among higher-wealth households. Generally, rates of overweight and obesity are growing rapidly in low-income countries that still have a relatively high prevalence of stunting, wasting, or thinness. Thus, the DBM is exacerbated in those countries that lack the wealth and potential resources necessary to mitigate undernutrition.

Economic change has been central to the reduction in wasting, stunting, and undernutrition as many development programs in LMICs have improved sanitation, vaccination programs, and reduced food insecurity. However, as a key component of the nutrition transition, economic change is also associated with important shifts in both physical labor and food systems, which have resulted in lower physical activity and an increased consumption of energy-dense diets (Popkin and Gordon-Larsen, 2004). Diet, which plays a critical role in the growing prevalence of obesity and non-communicable diseases, is a key factor in the DBM. Evidence suggests that diets largely consisting of ultra-processed foods, rich in refined carbohydrates, fat, sugar, and salt, are increasingly accessible in countries undergoing economic change. As LMICs economically expand, they face significant shifts, particularly in the composition of their diet, promoting obesogenic behavior (Fig. 3).

DBM at the household level is defined as one or more individuals with wasting, stunting, or underweight and one or more individuals with overweight or obesity within the same household. Most commonly, household-level DBM involves the combination of overweight or obese mothers and stunted children. The presence of household-level DBM varies greatly between different countries such that the reported prevalence of household-level DBM ranges from 0 to 26.8%. The prevalence of overweight mother and stunted child pairs, however, remained less than ten percent in most countries. In comparison to African countries, Asian countries have been found to have a lower percentage of overweight mother and stunted child pairs. Moreover, evidence suggests that middle-income countries tend to have higher percentage of the double-burdened dyad. However, new data indicates that the incidence of household-level DBM is increasing at a faster rate in lower-income compared to middle-income countries.

A number of factors are associated with the “double burden” household, including urban residence, income, and education (WHO, 2017). Families who live in urban areas are more likely to report a co-occurrence of malnutrition at the household level. As well, urban areas generally provide greater access to processed or fast foods and less physically demanding jobs. Households facing the double burden of under- and excess nutrition tend to also have higher income than undernourished households. As well, maternal or household-head education level is associated with the household-level DBM. Indeed, highly educated mothers are less likely to have stunted children, and are therefore, less likely to reside in double-burden households. Importantly, social factors generally associated with household-level DBM do not exist independent of each other. A meaningful interaction among urban residence, income, and education level generally exists, however, this relationship has not consistently translated into the research regarding household-level DBM.

**Fig. 1** (A) Global prevalence of the double burden of malnutrition, Global double burden of malnutrition based on height/weight data in the 1990s. (B) Global prevalence of the double burden of malnutrition, Global double burden of malnutrition based on height/weight data in the 2010s. Adapted from [Popkin et al. \(2020\)](#).

At the individual level, different forms of malnutrition can develop simultaneously or across the life course. While many LMICs experience chronic undernutrition, individuals most commonly exposed to nutritional deficiencies now find themselves in an obesogenic environment, consuming a diet void of essential micronutrients, due to rapid population-level nutrition transition. It has also been suggested that the intergenerational emergence of malnutrition can influence DBM at the individual level. It has been

\*DBM = at least 1 child, adolescent, or adult in the household with severe levels of wasting/stunting/thinness and 1 with overweight/obesity; only includes countries with DBM data available for both time periods (1990s & 2010s)

shown previously that chronic maternal undernutrition can compromise fetal growth and increase the risk of childhood wasting or stunting. In addition, maternal obesity, particularly compounded with gestational diabetes, is associated with elevated fetal adiposity and micronutrient deficiency.

Early nutritional insults alter the long-term consequences of subsequent exposure to obesity and its metabolic impacts (Hoffman et al., 2021). For instance, rapid weight gain following early undernutrition might predispose an individual to central adiposity and noncommunicable disease. Moreover, intrauterine growth restriction can expose the fetus to oxidative stress and altered metabolism, which can affect various health-related factors. For instance, early nutritional insult can affect insulin metabolism and hypothalamic function. Therefore, infants with low birthweight, born sensitive to insulin, are susceptible to insulin resistance later in life due to rapid weight gain in childhood. Evidence generally suggests that there is a developmental link among stunting, obesity, and non-communicable disease. Various mechanisms have been proposed regarding the fetal origins of individual-level DBM. First, it is thought that by sparing energy, early undernutrition promotes survival through endocrine changes that affect growth, energy expenditure, and body composition. These changes then interact with the diet composition. A potential physiological mechanism for these observations is that poor growth prompts a metabolic adaption through a reduced capacity for fat oxidation, which manifests in stunted children as reduced lean mass and increased central adiposity under favorable environmental conditions (Hoffman et al., 2021). Indeed, individual-level DBM can be multifactorial and it requires the consideration of intergenerational malnutrition and interconnected factors to best prevent the vicious cycle of poor growth and poverty.

## Nutrition transition

Over the past 50 years, increased modernization, urbanization, and economic development in many LMICs has influenced a rapid shift in dietary intake and physical activity (Popkin and Gordon-Larsen, 2004). This shift, known as the “nutrition transition,” is

**Table 1** Stages of the nutrition transition.

<i>Characteristic</i>	<i>Stages</i>		
	<i>Pre-transition</i>	<i>Transition</i>	<i>Post-transition</i>
Diet (prevalent)	Grains, tubers, vegetables, fruits	Increased consumption of sugar, fats, and processed foods	Processed foods with high content of fat and sugar; low fiber content
Nutritional problems	Undernutrition and nutritional deficiencies predominate	Undernutrition, nutritional deficiencies, and obesity coexist	Overweight, obesity and hyperlipidemia predominate

Adapted from FAO, UNICEF, WFP, WHO, 2018. The State of Food Security and Nutrition in the World 2018. Building Climate Resilience for Food Security and Nutrition. FAO, Rome.

characterized by an increase in the consumption of processed foods that are energy-dense, high in sugar, salt, and saturated fats, and low in fiber (FAO et al., 2018). Such shifts increase one's risk of overweight, obesity, and NRCs. The nutritional profiles and health outcomes related to the 3 stages of the nutrition transition summarized in **Table 1**.

### Ultra-processed foods

In 2009, the NOVA classification system for food was developed to provide an objective profile of food products, focusing on the degree of processing (Monteiro et al., 2019). The NOVA system classifies food according to one of the following four groups: Group 1, unprocessed or minimally processed foods (e.g. fresh or frozen vegetables, dried pasta, coffee, or herbs and spices); Group 2, oils, fats, salt, and sugar, or "Processed Culinary Ingredients"; Group 3, processed foods (e.g. canned or pickled vegetables, canned or cured meat and fish, fermented alcoholic beverages, or fruit and vegetable extracts); and Group 4, ultra-processed foods (e.g. fat, sweet, or salty snack, sugar-sweetened beverages, pre-prepared meals, or infant formulas). Part of the rationale for developing the NOVA system was to allow for dietary recommendations to be consistently based on the degree of processing and for research studies to use the system as a means of studying the role of ultra-processed foods (UPF) in health and disease. A key element of the NOVA system is that no single food or product is considered "off limits," rather the system exists under a broad "golden rule" that instructs consumers to "Always prefer natural or minimally processed foods and freshly made dishes and meals to ultra-processed foods." The processes and ingredients used to manufacture UPFs not only make them highly convenient and hyper-palatable, but also highly profitable to the manufacturers that produce them (Monteiro et al., 2019). The convenience, flavor and texture, and aggressive marketing of UPFs contribute to their increased consumption globally (Monteiro et al., 2019). A brief discussion below expands on this point and illustrates how UPF may be a major contributor to the DBM, especially in LMICs.

The consumption of UPF, has increased dramatically throughout the world as sales of UPF increased dramatically in the past two decades compared to high-income countries (Baker et al., 2020). For example, from 2000 to 2013, sales of UPF increased by 30% in Brazil, while sales dropped in the United States and Canada (−9% and −7.3%, respectively). In terms of total energy intake, the proportion of daily calories provided by UPF varies by country and is highest in high-income compared to LMICs. For example, UPF account for 20–30% of daily energy intake in Spain, Lebanon, Brazil, and France with up to 55% in the United States with less than 20% in other countries. At the same time, several studies have shown that high consumption of UPF is associated with lower quality diets assessed by NOVA. As well, several studies have reported that UPF consumption is associated with an increased risk of overweight and obesity, and related conditions, such as hypertension, CVD, and cancer (Monteiro et al., 2019).

### Obesity

Energy imbalance, related to the consumption of processed and ultra-processed foods, has led to an increased prevalence of overweight and obesity, affecting more than 672 million adults and 38 million children globally. Obesity is of particular concern given its association with NRCs such as type II diabetes, cardiovascular disease, and hypertension (Monteiro et al., 2019). Worldwide, it has been estimated that approximately 11 million deaths each year are attributed to NRCs (Afshin et al., 2019). A review of studies on UPF and obesity reported that in Sweden, there was a 142% increase in UPF intake between 1980 and 2020 and the prevalence of obesity for men and women increased from 25% to 56% and 26% to 29%, respectively (Elizabeth et al., 2020). It was also determined that for every percentage increase in UPF consumption, the prevalence of obesity increased by 0.25%. Similar results have been found in both cross-sectional and cohort studies. For example, high UPF intake was associated with a higher BMI in Brazil and France. As well, in both Spain and Brazil, a high intake of UPF was associated with a 26% higher risk of obesity compared to those with a low UPF intake. Thus, regardless of the study design, an increased intake of UPF not only appears to promote obesity, but there are also no positive nutritional outcomes associated with UPF.

## Activity

In recent years, there has been a decline in physical activity associated with a number of factors such as increased sedentary behavior at work and at home as well as more “passive” forms of transportation (e.g. car, train, bus, etc.). The WHO defines physical activity as any form of movement that requires energy expenditure, including during leisure time, for transport to and from places, or as part of a person’s work. To be sufficiently active, it is recommended that adults partake in at least 150 min of moderate-intensity activity, 75 min of vigorous-intensity activity, or any combination of the two per week. Insufficient physical activity is associated with a 20%–30% increased risk of death due to NRCs such as those related to dietary intake. Globally, 28% of the total population and 80% of the adolescent-population is insufficiently active (Guthold et al., 2018). Therefore, promoting activity across the globes, especially for those living in urban settings, is a key preventive approach to stem the DBM.

## Micronutrient deficiency

Approximately 1.5 billion people are affected by one or more micronutrient deficiencies worldwide (GBD 2015 Mortality and Causes of Death Collaborators, 2016). In the “pre-transition” nutritional environment, individuals were often characterized as being malnourished and micronutrient deficient, with visible symptoms such as stunting or wasting. During the nutrition transition, obese and overweight individuals, although seemingly well-fed, may also experience micronutrient deficiencies, referred to as “hidden hunger” since there are usually no visible signs of deficiencies. Indeed, some have proposed referring to the “triple burden of malnutrition” to highlight the co-occurrence of undernutrition, overnutrition, and micronutrient deficiencies. For example, iron deficiency anemia, which affects over 20% of women of reproductive age, is just one micronutrient deficiency that may be present in individuals who are overweight or obese as well as those who are underweight (Fig. 4). Thus, it is important to recognize that important micronutrient deficiencies are not limited to the undernourished and that “hidden hunger” is a central aspect of the DBM that merits research and prevention.

In summary, the DBM is clearly influenced by many structural and behavioral factors that make up the nutrition transition, such as the global exposure to and increased consumption of UPF. The confluence of biological and environmental factors that promote NRCs, low physical activity, and obesity as well as those limiting growth or promoting undernutrition, illustrate the complexity of stemming the rise of the DBM, especially in LMICs that are undergoing the nutrition transition.

## Food systems

### Marketing

The modern global food environment consists of a variety of food and drink products that not only offer palatability, but also convenience and novelty. Of note, many of these foods are energy-dense and nutrient-poor, with a high fat, sugar, and/or salt

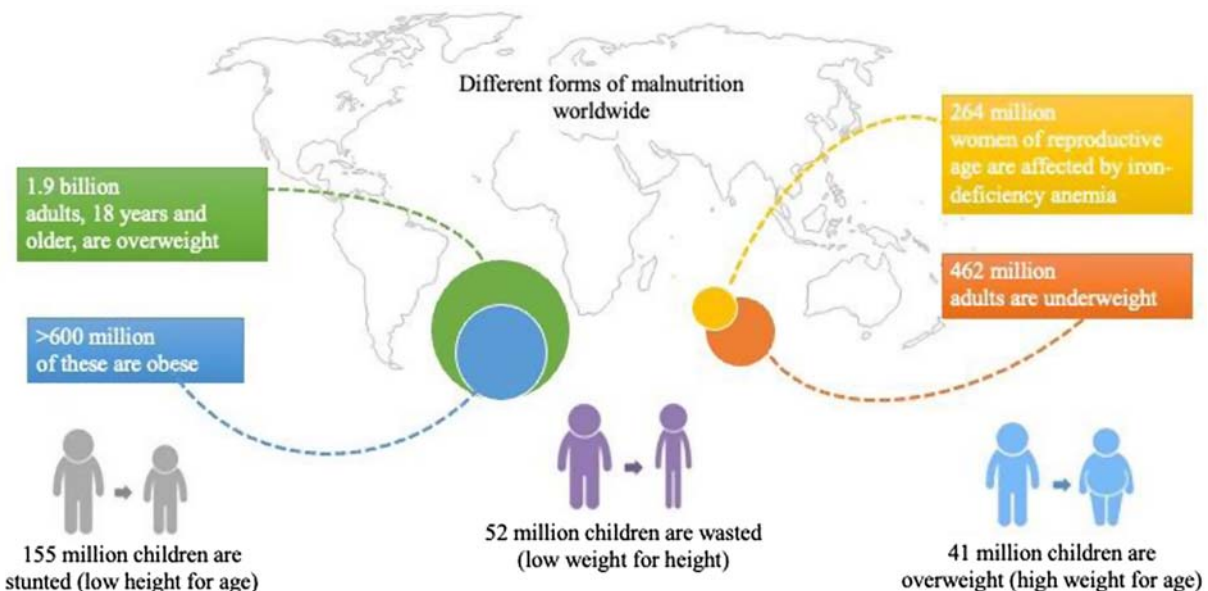

Fig. 4 Mapping the double burden of malnutrition as. Adapted from WHO (2017).

content, which is a major contributor to the rise in obesity, malnutrition, and NRCs. Marketing of these products hinder efforts to promote a healthy diet and weight maintenance and have been considered one of the main drivers of unhealthy dietary patterns worldwide. A wide range of techniques are used to influence food preferences and dietary patterns, reaching individuals in schools, nurseries, and supermarkets; through the television and internet; and in many other settings.

The marketing of food has a significant impact on food preference and consumption, typically in ways that the consumer is not generally aware. An example of the adverse impacts of food marketing includes the promotion of breastmilk substitutes, which deters mothers from breastfeeding and weakens support for lactating women (FAO et al., 2021). Further, fast food companies tend to target much of their marketing toward youth, who are not developmentally equipped to understand the purpose of marketing and assess marketing claims. This has been of major concern as the largest increase in obesity is taking place among adolescents.

In 2010, the WHO developed recommendations to reduce the marketing of unhealthy foods to children (WHO, 2010). Over a decade later and very few countries have implemented such restrictions. Globally, the poor state of implementation is concerning, with notable consequences in LMICs, where corporations seek to enter new or under-developed markets. Indeed, through their global food marketing and promotion practices, fast food companies contribute significantly to the nutrition transition, and subsequent DBM, observed in LMICs.

It can be argued that the rising trends in obesity and NRCs may be reversed by protecting youth from the marketing of energy-dense, nutrient-poor foods. To fully address the DBM, restrictions on food marketing to children could be part of a comprehensive package of policies to create food environments that encourage health and optimal nutrition, and also reduce malnutrition throughout the lifespan.

### Food supply

Conflict, climate extremes, and economic downturns all present significant challenges to global food systems (FAO and WFP, 2019). Such challenges may occur through effects on systems supporting food production, food supply chains, food environments, consumer preferences, or a combination of these factors. Food security (the reliable access to safe, affordable, and nutritious food) is inextricably linked to predictable food systems; therefore, anything that threatens these systems poses serious risks to global health.

Conflicts contribute to food insecurity through the disruption of food systems in several ways. Among countries engaged in international and civil wars, starvation of civilians is often used as a method of warfare. The use of food as a weapon can be accomplished through the destruction of farms, livestock, and infrastructure or through civilian entrapment and isolation, resulting in food shortages and deprivation. Further, conflict and violence are major predictors of forced displacement (FAO and WFP, 2019). In situations where people are forced to flee their homes, access to, and availability of, food becomes insecure (UNHCR, 2020), creating an increased risk of hunger and malnutrition with long-term implications.

Climate extremes (i.e. drought, flood, heat spell, storm, fire) threaten the production of food around the world (FAO and WFP, 2019). As global temperatures continue to rise, incidents of extreme weather will become more severe, limiting humanity's ability to produce enough nutritious food. In several parts of the world, such as East Africa and parts of Latin America, extreme heat, severe weather, and drought has led to a steep decline in yield growth for wheat, maize, and other staple crops. If these trends continue, it is expected that global yields of these crops could decline by up to 30% by 2050 (Shukla et al., 2019). Individuals living in countries that are already vulnerable to food insecurity, such as LMICs, will continue to be disproportionately affected by climate change if action is not taken soon.

The global rise in food insecurity has been associated with the economic downturns caused by the COVID-19 pandemic (FAO et al., 2021). In addition to higher food costs due to unprecedented stress on food supply chains (i.e. decreased production, labor shortages, limited travel, etc.), the socioeconomic impacts of pandemic-related restrictions have heightened disparities related to food access, particularly among those living in LMICs. This has led to an increase in the consumption of highly processed foods, which tend to be cheaper than more nutritious perishable foods. Together, these factors have been associated with diets that are insufficient in amount and diversity, increasing the risk of nutritional deficiencies and the development of NRCs long-term.

### Sugar-sweetened beverages

Sugar consumption is increasing globally, primarily through an increased intake of sugar-sweetened beverages (SSBs). Indeed, frequent consumption of SSBs is associated with several NRCs including type 2 diabetes, heart disease, and kidney disease (Basu et al., 2013). While intake of SSBs have either stabilized or declined in high-income countries, consumption of SSBs in LMICs have rapidly increased over the last 20 years. Trends in the consumption of SSBs may be attributed to their increased availability and affordability in LMICs. A global comparison of data found that, on average, the cost of SSBs tend to be cheaper than bottled water (Price et al., 2019). In LMICs, access to clean water is highly variable, particularly among low-income populations living in urban informal settlements. Due to widespread fear of contaminated tap water and limited access to clean water, SSBs tend to be considered the safer, more affordable option for people living in these settings.

Since SSBs are calorie-dense and nutrient-poor, their consumption contributes significantly to the double-burden of malnutrition. Generally, people do not compensate for their intake of SSBs by consuming fewer calories or healthier foods and regular consumption of SSBs likely contributes to a higher energy consumption than needed. Further, SSB consumption has been associated with a lower intake of nutrient-dense foods resulting in micronutrient deficiencies. To limit SSB consumption, several countries have implemented taxes on beverages with a high amount of sugar (FAO et al., 2021). “Soda taxes” not only limit the consumption of SSBs due to their increased price, but also act as a powerful driver for industries to reduce the sugar content of their products.

## Summary

As the world slowly recovers from a global pandemic that caused millions of deaths and many more recovering from the COVID-19 infection, the true impact of the pandemic on global health has yet to be seen. It is estimated that the number of undernourished and food insecure children and adults in many parts of the world has increased due to quarantines, supply chain issues, economic crises, and loss of employment, along with the lingering effects of “long COVID.” Adding to this somewhat pessimistic perspective is the war that rages in Ukraine as this article goes to press.

The global impact of the Russian invasion of Ukraine will be quite severe as not only have exports of grain and other crops ceased, the daily and prolific use of mines and artillery has not only destroyed productive fields but threaten the current and immediate future crop plantings and harvesting. The fact that almost 10% of the world grain supply comes from Ukraine is important, yet it is more important that almost 50% of the grain provided to the World Food Program comes from Ukraine. At present, food prices have increased in some of the most vulnerable parts of the world, but most particularly in East Africa in countries that are also highly dependent on the WFP for food supplements.

The relevance of the pandemic and ongoing civil unrest in Asia, Africa, and now Europe, is that these events are serious threats to the food security and health of millions of women and children. If these challenges persist, the prevalence of undernutrition will begin to increase and the long-term effects of undernutrition on children who grow to become adults is very likely to then contribute to chronic diseases well into the future. Thus, understanding how to address and reverse the DBM is more important now than ever before. The world now appears to be at a nexus in terms of nutritional advances and human health, one at which promoting health through personalized medicine and precision nutrition is being challenged by geo-political and infectious disease. Therefore, it is imperative that nutrition research continue to make the DBM a priority to reduce the global burden of NRCs in all parts of the world, especially the most vulnerable in marginal communities or lower income segments of our society.

## Key points

- Famine can be defined in terms of a sharp decline in access to food by large numbers of people, often attributed to crop failure from drought, flood or pestilence, hostilities or corrupt governance, leading to widespread starvation, disease and high mortality.
- Despite sophisticated surveillance, advances in agriculture, transnational food systems, and a transition globally toward greater food consumption and economic development, famine persists in the modern world.
- Famines are complex in their sets of causes, dominated by market failure, armed conflict, natural disasters and failure in central governance.
- Conflict, civil or foreign, has become the most consistent underlying or precipitative cause of famine in the past half-century, indicative that virtually all famines are preventable.
- Famine may best be prevented by strengthening resilience in vulnerable societies through infrastructural, commercial, educational, communications and agricultural development, a free press and diplomacy.

Those who do not learn history are doomed to repeat it.

George Santayana.

Starvation is a matter of some people not having enough food to eat, and not a matter of there being not enough food to eat.

Amartya Sen.

## Introduction

Famine has afflicted humankind from antiquity to the present day, shaping the survival, politics and history of societies. A *bas relief* depiction on the Causeway of the Pyramid of Unas in Saqqara is believed to depict famine from drought during Middle Kingdom in Egypt. Biblical accounts describe the devastation wrought by famine on society and the means by which Joseph predicted and managed with Pharaoh its consequences. The fall of the Roman Empire followed repeated food shortages and famines from 500 BC to AD 500, while the ranks of the Crusades in the 11th and 12th centuries swelled in response to assurances of food. European colonialism, with imposed cash cropping systems preconditioned vast areas of Africa and South Asia to famine, while

famine across Eurasia prompted migrations throughout the latter half of the second millennium (De Waal, 2018). The Great Irish Famine in the late 1840s, precipitated by a potato blight, caused one and a half million deaths and comparable migration, mostly to America as did decades of Russian famines in the late 19th century. Hundreds of famines frequented China throughout the first two millennia AD shaping its determination to rid itself of this scourge. This treatise largely focuses on famines of the past century, drawing lessons from history, to understand this persisting, modern phenomenon.

## Modern famine

While famine in the 20th and 21st centuries have occurred globally, historically prone regions have remained epicenters of risk. Despite its persistence, modern famine has become better understood with regard to populations at risk, environmental and societal causes, stages of progression, triggering events and the progression of responses that famine prompts at household, community, national and international levels (Devereux, 2000).

A consistent feature of famine is high mortality. As background, Fig. 1 provides global estimates of the extent to which deaths have been attributed to famines across regions, punctuated by notable historic events, against a curve depicting the global trend in population growth, from ~1.7 to 7 billion, from ~1900 into the new millennium. The figure reveals stark occurrences of famine in the first 60 years, followed by a dramatic decline in the numbers of famines and related deaths from the latter half of the 20th century onward. Most famines in the first half of the 20th century occurred during World War (WW) I, the intervening years leading to WW II, and during the second world war itself and were in countries with totalitarian rule. Unprepared for the stresses of losing farm labor and needing to feed over 15 million conscripts, the Russian empire endured famine throughout most of WW I. Some 450,000 people died in Persia (Iran) in 1917–18 from famine and disease during the war, attributed to drought, diversion of food stocks to sustain occupying forces and speculative hoarding, which was compounded by a flu pandemic.

Prolonged drought, exacerbated by revolution, civil war, and agricultural and economic collapse exacted famine in the Volga and Ural regions of Russia in 1921–22, where seed grain was eaten rather than sown, cannibalism was recorded and ultimately five million died. In the 1930s, famine-exacerbating policies of Stalin designed to deprive food to certain groups, instigate class warfare and crush a Cossack Revolution, led to ~3.3 million Ukrainian deaths. During WW II, the Nazi Hunger Plan, that diverted food stocks to support its expanding military occupation, starved ~4 million Russians, Ukrainians and Belarusians, while a Nazi blockade of Western Holland precipitated the “Dutch Hunger Winter” of 1944–45, killing 18–22,000 people (Collingham, 2011).

Over half of all famine deaths in the 20th century, however, occurred in China, starting with the understudied Great Qing Famine in the north in 1907, precipitated by floods the year before that destroyed crops and killed some 25 million people, and a famine in the north in 1927–30, that followed prolonged drought, in which ~6–10 million perished. Famine struck

**Fig. 1** Famine mortality by region and world population growth, 1900–2010. Since the 1960s, famine mortality has declined substantially despite world population growth. The geography of famines has shifted from being concentrated in Asia and Europe in the 1900–1950s to Africa where famines and related deaths more recently have been concentrated. Source: Tufts University Famine Database.

Hunan Province in 1942–43, amid WW II, where drought, locusts, flooding of the Yellow River region, extraction of meager harvests to feed Japanese occupational forces led to starvation, cannibalism, child trafficking, infectious diseases and ~1.5 million deaths. WW II extended its influence into South Asia as an external cause of famine, notably in Bengal in 1943, where a boat blockade on the Bay of Bengal to thwart an anticipated Japanese invasion, coupled with policies that redirected rural crops to subsidized urban centers, spiked market prices and led to ~3 million starvation-related deaths, mostly among rural, daily wage-earning classes.

Among famines in the second half of the 20th century, however, the “Great Leap” Famine from 1959 to 61 in China stands out as the worst in recorded history, precipitated by profound failure in centrally planned economic development and veiled by lack of transparent governance and a free press. Following several years of land reform that marginally increased grain production after birth of the Peoples’ Republic, Mao Zedong’s inconsistent farm collectivization policies, rural industrialization schemes and internecine politics destroyed peasant incentives and reduced crop output amid pronounced exaggerations in crop yields (Dikötter, 2010). State-sponsored vigilante groups extracting grain from farmers for urban centers, and state controls on food grain transport, access, purchase and taxation preconditioned China for an inevitable collapse of its food system when pushed by Mao to further accelerate production in 1958. The ensuing famine led to an estimated 18–32 million Chinese deaths in 1959–62, implicating a vital role for unbiased journalism that can alert and hold government accountable to mount prevention.

In Southern Asia, Bangladesh in its nascent period of independence, experienced famine, in 1974. Prompted by concerns of food shortage consequent to an unusually severe, mid-year monsoon flood, speculative hoarding led to a contagion of spikes in the price of rice and other food commodities across rural markets. Well described in terms of market failure, the sudden and sustained deprivation of vast segments of the population to sufficient food led to stress sales of assets, reliance on *famine foods*, child abandonment, mass migrations to urban centers, infectious disease and up to 1.5 million deaths.

Conflict has become a nearly uniform underlying or precipitating cause of famine in the past half-century, with modern famines occurring amid civil wars, for example, in the vulnerable deserts (e.g., the Sudan), highlands (e.g., Ethiopia in 1974, 1984 and 2021) coastal (e.g., Somalia in 1992 and 2011) regions of North Africa. While many factors interact to cause famine, the risk attributable to conflict was evident in Ethiopia in contrast to neighboring Somalia in 1984. In that year and those that preceded, both fragile states endured the same, underlying climate-induced drought and stresses on crop production, but famine occurred only in Ethiopia where civil society, infrastructure and the economy were disrupted amid a military campaign (Götz et al., 2020). The late 1970s witnessed famine in East Timor, induced by an Indonesian military blockade on food imports during the island nation’s war of independence. Famine under totalitarian rule occurred in North Korea from 1995 to 99, following floods and crop failures that was amplified by failed centralized government policies to mitigate a disaster that left as many as ~3 million dead, though estimates vary widely.

Famine has continued into the new millennium though the magnitude of famine-related deaths has decreased, revealing a stark reality that, despite more sophisticated surveillance systems, advances in agriculture, transnational food systems, and a steady “nutrition transition” toward greater food consumption attending gradual economic development, long sentence. Better: “...famine persists in the modern world. Prolonged military conflict plays a decisive, causal role.” Present day famines are the result of a combination of complex casual factors including deteriorating crop production associated with rainfall declines and changing climate patterns; failures in development and commerce; repressive and corrupt governance; and armed conflict which can limit the flow of goods and disrupt both markets and production, restrict aid flows and precipitate mass migrations. Countries with protracted conflict that have faced famine or been at near-famine conditions in since 2015 include South Sudan, Ethiopia, Yemen and Syria (Brück and d’Errico, 2019).

## Definition of famine

Famine can be defined in terms of a sharp decline in food availability or access for large numbers of people, often attributed to crop failure from drought, flood or pestilence, hostilities or corrupt governance, leading to starvation, disease and high mortality. While famine defies brief definition, most attempts to do so capture these basic features, illustrated in **Box 1**.

Comprehensive definitions of famine include elements of time dependency (e.g., steady, continuous erosion of or sudden collapse in food available for consumption), partial causation (e.g., due to natural calamity, armed conflict or convergence of

### Box 1 Example short definitions of famine

1. An extreme crisis of inaccessibility to adequate food, manifested in widespread malnutrition and loss of life due to starvation and infectious disease (Maxwell and Majid, 2016).
2. Sustained, extreme shortages of food among discrete populations sufficient to cause high rates of mortality (Scrimshaw, 1987).
3. The most severe form of food insecurity, during which mass starvation and death take place within a relatively short span of time (Yip, 1997).

other complex causal events), class (e.g., affecting certain ethnic, geographic, economic or occupational groups more than others), consequence to habitat (e.g., to flora and fauna), population responses (e.g., adoption of extreme coping strategies, breakdown of civility and social norms, mass migration) and health consequence on a population scale (e.g., severe malnutrition, epidemics of infectious disease and mortality exceeding certain rates). Definitions of famine have evolved from reflecting declines in food availability to an understanding that famines are complex and multi-causal and more often the result of populations not being able to access food that is available (e.g. Amartya Sen's Entitlement Theory).

Operational definitions based on data assembled from diverse sources also exist that can guide relief agencies in deciding when to mobilize resources to prevent further deterioration of pre-famine to famine conditions. Specifically, the United Nations uses a five-phase scale known as the Integrated Phase Classification to assess a country's food security situation, with famine as the most extreme phase which is defined as: (a) a severe food shortage that affects at least 20% of households; (b) wasting malnutrition that affects 30% or more of the population, and (c) a crude death rate exceeding 2 deaths per 10,000 people per day. Whether viewed to evolve as a continuous, erosive process or precipitated via a sudden shock, once unleashed famine is distinct and exacts a catastrophic toll on human society.

## Causes of famine

Starvation is a matter of some people not having enough food to eat, and not a matter of there being not enough food to eat.

Amartya Sen.

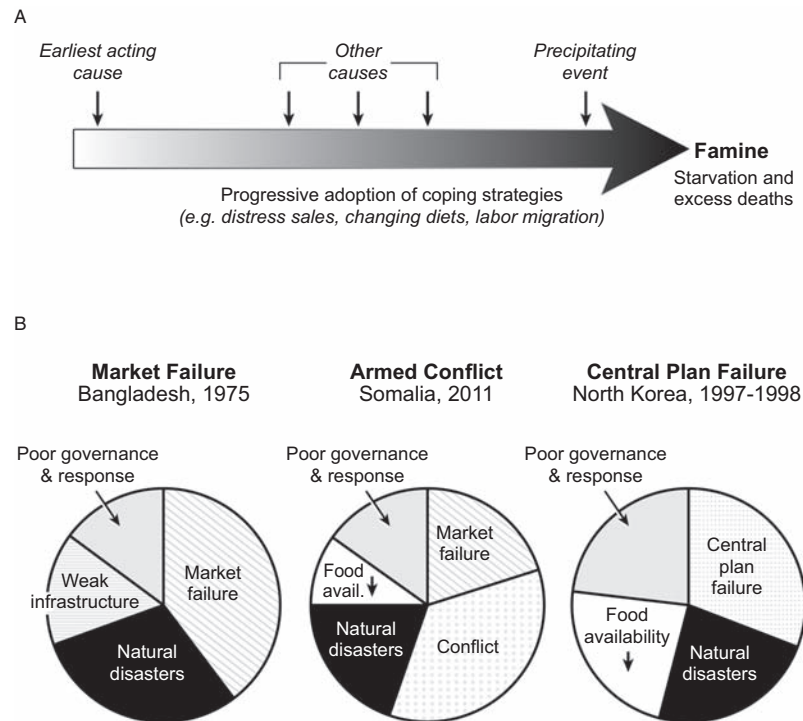

While a discreet event, famine is usually consequent to both antecedent and concurrent stresses, or *component causes* (borrowing a disease causation model from Kenneth Rothman in the 1980s) that combine to heighten risk of, and finally cause, a catastrophe. These include, for example, agricultural collapse due to flood, drought or pestilence, or conflict that can deplete food availability or deny access to food, even amid sufficient stocks, to segments of society. Either major pathway induces coping strategies among the most vulnerable to protect health, wages and productive and household assets (or *endowment*, see below), which are eventually depleted or transferred. Severe and persistent stress can lead to a breakdown in civil society, destitution, panic with mass migration, starvation with acute malnutrition, and a spiraling death rate. On their own, many component causes are associated with impoverishment, food insecurity, chronic hunger and malnutrition in many societies, but not necessarily famine. It is, rather, specific and rare sequences and combinations of stresses that act to become *sufficient* to precipitate famine. There appear to be at various sets of sufficient causes of famine, labeled to reflect their most distinctive, versus sole, feature (**Fig. 2**): market failure, armed conflict, natural or climate-driven disasters and failure in central planning.

### Market failure

Market failure represents an intermediate dynamic of famine that can result from many causes that can destabilize and raise food at prices to levels for which money, labor, skills, credit, bartering and other assets can no longer be exchanged for sufficient amounts of food by large, usually marginalized segments of society. Conflict also destabilizes markets, directly contributing to market failure. Beyond a decline in food production, reduced food imports, inefficient transport, unfavorable trade policies, and disrupted infrastructure can reduce food availability and increase prices. However, absent conflict, more often it is speculative hoarding causing spikes in staple grain prices and sharp declines in value of draft, dairy and meat-producing animals (who also need to be fed), coupled with severe economic depression with losses in jobs and wages, that combine to deny access to food for large numbers of people. These failures may be compounded by political instability and corrupt governance. Afflicted groups cope with prefamine or early famine conditions by working for lower wages or food, migrating long distances to find work, indenturing agreements, bartering, borrowing at exorbitant interest rates, reducing meal frequencies, eating less familiar and nutritious foods, selling assets and land at prices far below usual market value, and orphaning children. Crime increases as the law and order disintegrate. For those still mobile, migration to urban centers or into spontaneous camps enroute to cities becomes the sole alternative to starvation. Famine inevitably leads to pauperization of afflicted survivors, while wealthy merchants, and business, land and cattle owners who are able to adapt, purchase at low prices, loan with high interest rates, and control resources, become wealthier.

A major advance in understanding famine consequent to market collapse emerged from Amartya Sen's analysis in the 1970s of the Great Bengal Famine of 1943, for which he received the Nobel Prize in Economic Science in 1998. A Famine Inquiry Commission appointed by the British Raj Government concluded the famine resulted from a severe decline in availability of rice in the year leading up to the famine. Sen's analysis revealed, however, that rice production was nearly normal in 1943, ~5% lower than previous years, concluding that starvation resulted from *entitlement failure*, an inability of rural markets to supply affordable food, yielding unfavorable *terms of food exchange* for rural classes on low, daily wages (i.e., low *endowment*) such as laborers, fishermen and craftsmen, to survive. In contrast, other sectors of Bengal society, including landowning farmers, food vendors and urban dwellers with access to fair price shops, had adequate food (*Drèze and Sen, 1991*). Entitlement failure

**Fig. 2** The complex evolution and multicausal nature of famines. **Panel A.** Evolution of famine, depicting the sequence of causal events that, over time, combine to become sufficient to cause famine. **Panel B.** Conceptualization of three sufficient causes of famine, typified by their predominant cause (market failure, armed conflict and central planning failure), where slices in each circle depict component causes (subjectively sized, based on the literature) that interact when coexisting to cause famine, and include: **Market Failure** due spiraling food prices from speculation or decreased food availability, decreasing abilities to attain enough food via purchase, labor, credit or asset sales; **Conflict**, either declared war or internal violence preceding or amid famine; **Central Plan Failure**, whereby government directives disrupt infrastructure, productivity, food access and the economy; **Natural Disasters**, including slow-onset or repeated events such as drought, pestilence and catastrophic natural disasters such as floods and storms that can ruin crops; **Food Availability Decline**, resulting from crop failure or market disruptions; **Weak Infrastructure**, including inadequate finance systems, transportation, storage, communications and market infrastructures; **Poor Governance and Response**, reflecting inadequate policies and resource allocations in agriculture, employment and imports/export trades; fiscal mismanagement and corruption; absence of early warning systems, slow or in adequate humanitarian response to crises. Constructs were inspired by Rothman, K., Greenland, S., 1998. *Modern Epidemiology*. Philadelphia: Lippincott-Raven, pp. 7–28.

explains the dynamics of famine in Bangladesh in 1974–75, where speculation around the major *aman* rice crop failing (that never materialized) amid a flood, led to spikes in grain prices, a collapse in entitlement and access to food, starvation, mass migration and high mortality.

### Armed conflict

Famine has been precipitated both as a tactic and consequence of war. Examples of the former during WW II are the Nazi blockade of ports in Western Holland leading to the Dutch Hunger Winter of 1945 and the diversion of food stocks, leading to mass starvations in order to support occupying forces in Persia in WW I and Russia and China during WW II. Alternatively, civil war has played a prominent role precipitating famine, with stark modern examples in the Horn of Africa. For example, Somalia has regularly faced drought that has rarely led to famine. However, in the early nineties, local militia wars collapsed an already fragile government and exacerbated effects of drought through exaction of harvested crops by marauding gangs, preventing produced food from reaching markets and, as famine evolved, obstructing aid from reaching most severely affected areas. In 2011, internecine conflict again triggered famine in Somalia, killing a quarter of a million people and displacing hundreds of thousands of refugees into Kenya and Ethiopia (Checchi and Robinson, 2013). Persistent conflict with denial of food as a tactic of war within Yemen since 2015 has disrupted economies, infrastructure and livelihoods and precipitated a modern humanitarian crisis, threatening 13.5 million people with severe, acute food insecurity. As in Somalia, the transfer of weaponry to vigilante groups, use of land mines, lawlessness and violence have conspired to precipitate famine and hamper relief. With little sign of abatement entering the third decade of the 21st century, conflict-driven famines are stalking Ethiopia, the Democratic Republic of the Congo and Afghanistan. While all famines polarize wealth and increase destitution, in general contrast to those involving failure of free markets, famine of conflict destroys infrastructure, impairs institutions of governance and economic production, and thus can hamper economic recovery a decade or longer.

### Failure in central planning

A third, distinct class of famine results from failure by policy intent, indifference or incompetence of a centrally planned state to assure food to all sectors of society. Historic examples include notorious famines during the regime of Stalin in Soviet Russia in the 1920–30s, a period of instigated class warfare among peasantry, abolished economic incentives with farms collectivized into massive, inefficient production units, seizure and exportation of grain for foreign exchange, restricted population movements and brutal suppression of opposition. Agricultural production plummeted causing disastrous shortages that intensified state seizures of food grain, leading to ~15 million peasant deaths between 1930 and 37. Mentioned above, and modeled after Stalin, Mao Zedong's Great Leap Forward Famine was conditioned by erratic plans to collectivize farms to accelerate agricultural production and irrational rural industrialization schemes, and exacerbated by state control of grain production, procurement and taxation coupled with state terror and propaganda. Driven to be recognized globally as a success, at the peak of famine in 1960, Mao's government net exported more than a million metric tons of grain. Lacking an informed, free press, little was known about this famine for decades. A third modern example of catastrophic central planning failure lies with communist North Korea's inability to avert famine in 1997–8, that was preconditioned by chronic food insecurity and economic collapse from withdrawn Soviet aid in the previous decade, exacerbated by torrential floods, massive electricity outages, a precipitative drought and an isolationist government unable or unwilling to facilitate food aid as the crisis unfolded.

### Climate and natural disasters

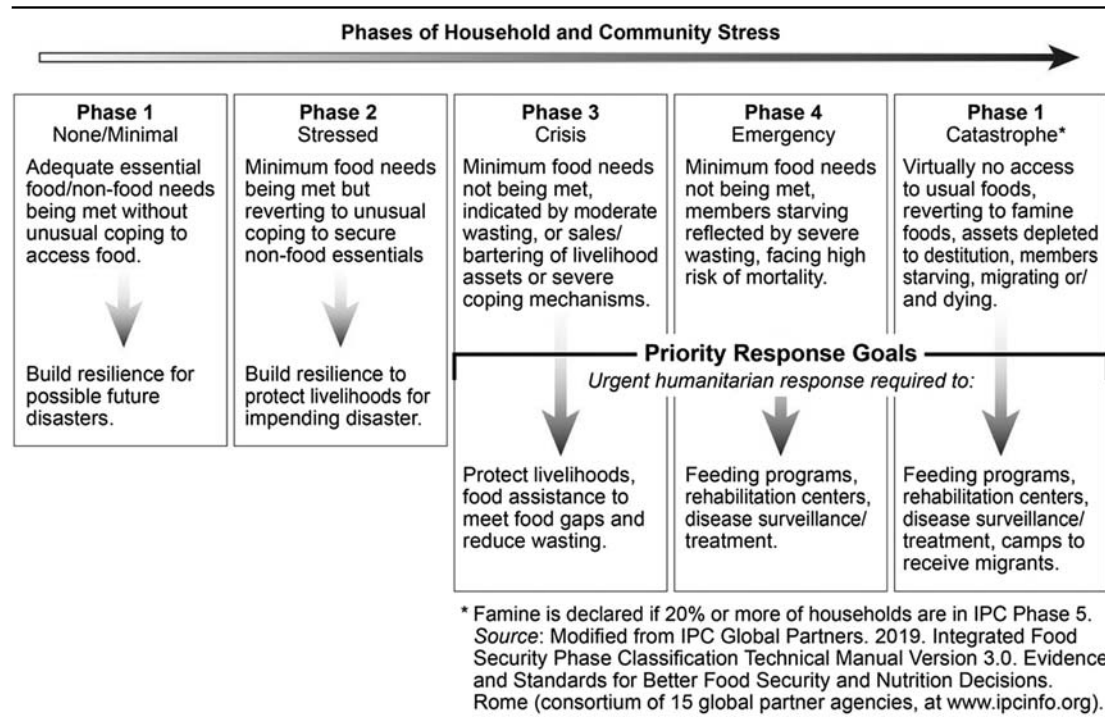

As a global phenomenon, climate change alone is not a complete cause of famine but is a major contributing factor when combined with other causes, and thus receiving increased attention. The global food systems produce enough to feed the world, yet the changing climate threatens global food security. Aggregate food shortage leading to a decline in availability has appeared to play a more prominent role in modern famines in the eastern Horn of Africa. In Ethiopia, Sudan, Eritrea, and Somalia, large tracts of land are drought prone, where average annual rainfall has been in decline since the 1930s. Concurrently, robust, indigenous farming and animal husbandry have been weakened as agricultural land has increasingly been converted for growing export crops. Global warming, and droughts and storms also contribute to famine risk where climate-related disasters have doubled since the early 1990s, intensifying underlying risk of famine (FAO et al., 2018). Climate change has the potential to impact the food system through droughts contributing to crop loss, heat waves killing crops, pestilence such as desert locusts destroying crops, unusually heavy rains leading to floods, and cyclones that further add wind damage. These events contribute to reduced food access due to poor crop productivity, high food prices, and loss of income. A modern example is the chronic, famine conditions facing southern Madagascar in 2021, attributed to recurrent drought resulting, exacerbated by an increasing frequency of cyclones from climate change, factors likely to continue to assume causal importance in the coming decades.

### Famine prevention

Efforts to prevent, mitigate or recover from all phases of a decline in food access potentially leading to famine occur at household, community, national and international levels of society. While populations in famine prone regions recognize and have developed coping strategies to food stress the timing of actions and their success in averting famine are determined by the mix of component causes, available resources, and government intervention response. Famine involving market failure are perhaps most readily forecasted and avertable, while famine amid conflict is least resourced, preventable and recoverable. Centrally planned famine tends to be insulated from outside assessment and intervention other than by diplomacy, typically leading to late-stage relief of acute food insecurity aimed at reducing mortality and rehabilitation.

### Coping strategies

Communities, households and individuals cope throughout periods of increasing food insecurity, pre-famine states and throughout famine. Irrespective of causes, food insecure households change their diets and livelihood strategies to fend off hunger and starvation. Anticipating drought, farmers may sow more resilient crops, disperse herds and, as conditions worsen, sell or barter for grain for their livestock, before animals become a liability. Early coping strategies involve eliminating costly foods, reducing meal frequency and foraging, often for less nutritious famine foods, such as unusual roots, husks and leaves. Households may seek to supplement income (endowment) through work for lower wages or food, if such projects are available, to protect their entitlement to food. Loss of nutritional health becomes a *de facto* coping mechanism. Non-essential assets (e.g., jewelry, utensils) may be sold, followed by more productive items (e.g., tools, plows, bicycles). In addition to informal interhousehold exchanges, families may seek credit or loans, often at exorbitant interest rates, or enter into indentured contracts, accruing future debt to survive. As famine conditions worsen, and basic food commodities become less accessible, crime may increase with a disintegration of law and order, land sales rise leading to further depletion and polarization of long-term wealth, and communal norms fracture leading to abandonment of dependent family members, such as children at orphanages, and distress migration to transient camps and urban centers. In famine's most florid stages, cannibalism has been reported as a last resort. Specifically, the Coping Strategy Index (CSI), developed by several aid agencies, is a highly adaptable tool for monitoring the extent and severity of coping strategies.

**Table 1** Integrated phase (acute food security) classifications.

## Surveillance

Food security surveillance systems that integrate local conditions with national indicators can inform and guide governments and international agencies to pre-empt threats of food insecurity that could progress to famine. All systems require reliable, adequate and routine collection, analysis and dissemination of data to guide intervention decisions, with aggregate approaches to surveillance possible to enact through consortia of governmental, non-governmental and international agencies. Modern prediction and classification of risk of famine is guided by the Integrated Phase (Acute Food Security) Classification (IPC, <https://www.ipcinfo.org/ipcinfo-website/ipc-overview-and-classification-system/ipc-acute-food-insecurity-classification/en/>) System (Table 1) which aggregates, synthesizes and provides a basis to interpret data on food availability and consumption patterns, coping behaviors, prevalence rates of acute (wasting) undernutrition, destitution and mortality. Market monitoring systems also exist that can be deployed to follow trends in diversity of available foods, food prices and grain-to-animal exchange rates.

Further complementing and feeding into the IPC System are several online early warning systems providing reasonably effective predictions of pre-famine conditions to guide national and international pre-emptive responses. The Famine Early Warning System Network (FEWS NET, <https://fews.net/>), launched by the US Agency for International Development (USAID) in the mid-1980s in response to famines in Africa, is a satellite-to-on-ground network designed to detect and forecast widespread food shortages in the world's most food insecure countries. The Food and Agriculture Organizations' Global Information and Early Warning System (GIEWS, <https://www.fao.org/giews/en/>) monitors food supply, demand and other key indicators that can provide an early warning of food crises in all countries that can also be aggregated by region. The WFP HungerMapLIVE (HungerMap, <https://hungermap.wfp.org/>) provides data on country-specific levels of food insecurity, prevalence of acute malnutrition, and market trends in food prices along with size estimates of populations at-risk.

Metrics from the systems and assessment methods can be compiled to classify countries facing risk of food insecurity as (1) none-to-minimal, (2) stressed, or in a state of (3) crisis, (4) emergency or (5) famine (*catastrophic*), with each phase having operational definitions and decision guidelines to enable agencies to develop response goals and plans. Approaching the end of the first quarter of the 21st century, use of the IPC system has revealed that, globally, more than 100 million people are regularly classified at Level 3, representing critical levels of food insecurity, with some of the affected countries facing crises of overwhelming proportion. For example, 28 million of those estimated to be facing a food crisis are surviving amid conflict in the Democratic Republic of the Congo, Yemen and Afghanistan, representing nearly one in five residents in these fragile states.

Surveillance systems that have been developed to inform multisectoral policies to stabilize food economies have likely prevented many crises from deteriorating to famine, although owing to the rarity of famine, both correct prediction and likely impact remains challenging as required counterfactual data are lacking. Further, the abilities of early warning systems to mitigate famine depend on the rapidity, completeness and timeliness of dissemination, and extents to which actions are taken at national and international levels.

## Famine intervention

Strategies to pre-empt famine that may be available to governments include drawing on grain banks/reserves and increasing imports, introducing staple subsidies through fair price outlets, organizing infrastructure projects, imposing export restrictions and launching social safety net programs for the most vulnerable groups or regions. For example, a common strategy to address food availability declines are to maintain grain stores or import staple foods and control their release into markets, thereby stabilizing access, expectations and prices. As governments of low-income countries are often unable to adequately mitigate impending famine, key roles exist for UN, bilateral and humanitarian agencies to offer effective assistance.

International responses to famine are usually coordinated via a United Nations appeal process, in which governments highlight need among severely affected groups, and request financial or material resources from member states to support a humanitarian response. Typically, UN government and non-governmental agencies organize around a cluster system (*cluster*, <https://www.humanitarianresponse.info/en/coordination/clusters/what-cluster-approach>) to coordinate interventions, guided by the classified IPC phase, to meet health, food security, nutrition and logistics needs in affected regions. Complementing a rising capability to monitor, gauge and preventively intervene in famine has been the evolution of guidelines known as the Sphere Standards (Sphere, 2018) for the principled conduct of humanitarian assistance across all sectors. The Sphere Standards prescribe the ethical basis and minimum to assure adequate food, shelter, sanitation, health care and security to alleviate suffering and preserve dignity of groups afflicted by emergencies. A common priority is to establish self-sufficiency by promoting food access, protecting assets and income of the poor, and stabilizing markets to restore entitlement. As the UN lead agency addressing food insecurity, WFP directs approximately two-thirds of its annual global budget, amounting to ~US\$ 5 billion, toward preventing severe food crises and famine through emergency humanitarian food assistance programs (World Food Program, 2021).

While relief operations are believed often successful in preventing famine, challenges in timely decision making and response persist with aid arriving too late, after the peak of famine has occurred. For example, in the Somalia famine on 2010–2011, early warning identified a high risk of famine, but timely action to prevent famine did not occur. The Tigray region of Ethiopia faced near famine conditions in 2021–2022 attributed, in large part, to the government blocking international aid to the region. It remains a difficult call to respond to food crises given uncertainties in prediction that accompany rare events such as famine, coupled with global humanitarian needs that far surpass the resources available for response. A basic tenet remains accepted that effective famine prevention requires a development agenda that strengthens resilience in famine-prone societies. Efforts can include enacting infrastructural, commercial, education, agricultural, and other policies that reduce poverty and create sustainable food systems that, over the long-term, reduce famine risk.

## Conclusions

Famine has plagued humankind through the millennia to the present day. While several component factors must usually combine to cause a rare famine, modern crises can be characterized by market failure, triggered by armed conflict or result from incompetent central economic planning. Major advances in early warning and humanitarian responses have likely stemmed risk of famine in prone regions. Modern famines have been severe and dominated by armed conflict that disrupts food systems, destabilizes economies, and can destroy infrastructures. Peace, competent governance, and sustained and equitable economic growth that benefits all society, a free press to hold governments accountable, and climate protection that could mitigate the impacts of natural disasters are global priorities for food systems to prosper and minimize risk of famine.

## Key points

- Food security and nutrition (FSN) survey data can be used to track changes in food security, dietary quality and nutritional status of populations, identify vulnerable groups for interventions and inform the development of national policies and programs in regular intervals.
- Many low- and middle-income countries face several challenges to the establishment and maintenance of FSN surveillance systems.
- The decision of what indicators to assess needs to be carefully considered based on the type of (available) routine and survey data, the purpose and context of the data assessment, and available resources.
- Routine FSN data provide estimates of food security and health service coverage that allow for early warning and comparison among and across sub-groups, regions and over time.
- Accurate and timely FSN surveillance data enable effective evidence-based effective policymaking and program implementation.

## Glossary

**Diet quality** Refers to the overall pattern of an individual or a population's food intake. It can be measured through various indicators that score food patterns to assess their alignment with recommendations and/or guidelines for different aspects of healthy diets. No single indicator of diet quality has been developed that captures all relevant aspects of dietary intake given the complexity of diets

**Food security** Refers to a state in which people have physical, social and economic access to sufficient, safe and nutritious food that meets their preferences and needs

**Food security and nutrition surveillance** Refers to a system of continuous and timely collection, analysis and reporting of data on dietary intakes, food security, nutritional status and nutrition-related health outcomes as well as aspects of access and availability of food, nutrition knowledge and behavior of a population or selected population groups

**Health service coverage** Refers to the proportion of a population for whom a health service is intended and who receive it

**Nutritional status** Refers to the condition of the body as influenced by diet and disease-related factors. It is commonly assessed by measuring weight and height and/or body fat (referred to as anthropometry) as well as by measuring concentrations of vitamins and minerals (also known as micronutrients) in biological samples such as blood and urine

**Routine data** Refer to data which are regularly collected and commonly obtained through existing systems, e.g., health facilities or agriculture and trade statistic bureaus

**Survey data** Refer to data that are collected through surveys that are conducted periodically and often include nationally and sub-nationally representative samples

## Introduction

Food security and nutrition (FSN) surveillance is a system of continuous and timely collection, analysis and reporting of data on dietary intakes, food security, nutritional status and nutrition-related health outcomes as well as aspects of access and availability of food, nutrition knowledge and behavior of a population or selected population groups (WHO, 2013). A well-designed surveillance system operates with integrated practices, tools, and processes to collect, organize, analyze, store and disseminate routine and survey FSN data from multiple sectors and sources. The ultimate goal of such surveillance systems is to provide data on FSN-related issues that can be used to inform and advise relevant policies and programs designed to improve nutrition and health in support of achievement of the Sustainable Development Goals (SDGs) (United Nations, 2015).

There are many opportunities and challenges to ensuring effective FSN surveillance, several of which differ in low- and middle-income countries (LMICs) compared to high-income countries (HICs) (HIC contexts are reviewed in a separate chapter of this book *ref*). In this chapter, we review the challenges facing FSN surveillance systems in LMICs, emphasizing their use for policymaking and program planning. We then provide an overview of the most common measures and indicators along the constructs of food security, health service coverage, dietary intake and nutritional status collected using routine or survey data, the methods used, and a description of the measures and indicators and their strengths and limitations. Finally, we highlight two country case studies and several international data platforms through which FSN surveillance data can be accessed and used to inform policymaking and program design in LMICs.

## Challenges informing policymaking and program planning for nutrition in LMICs

Rapidly changing food systems giving rise to the double burden of malnutrition and non-communicable diseases (NCDs) in many LMICs (Demmler et al., 2017; Popkin et al., 2020) present particular challenges to policy makers. In addition, limited resources in many LMICs imply that external funds, often from donor agencies, are required to set up and maintain effective FSN surveillance. The involvement of donors however, can unintentionally influence local decision making and weaken ownership of data and resultant policies (Khan et al., 2018).

Data-driven policymaking and program planning is often constrained by lack of availability or access to the necessary FSN-related indicators. Ideally, surveillance encompasses a wide range of FSN data and is embedded in information systems where data are coordinated, collected, curated, analyzed and disseminated by one central institution. Some LMICs have established such comprehensive information systems, such as the Emergency Nutrition Coordination Unit in Ethiopia (Tuffrey and Hall, 2016). However, many LMIC information systems are fragmented focusing on one or several, but not all, relevant components (e.g., food production and supply or nutrition and health). A lack of coordination and alignment among sectors with relevant data often results in critical data gaps or redundancies leading to inefficient use of resources and inability to explore the interconnected issues from food production through to diet-related health outcomes and use of data for decision making. Technical capacity is also a challenge in many contexts, particularly in the translation and use of data for decision making (Shroff et al., 2017).

Several initiatives aim to overcome these challenges at country, regional and global levels by strengthening the development and use of relevant and standardized indicators, developing and promoting the use of innovative tools, and strengthening the synthesis and translation of data for effective evidence-based policymaking (Verstraeten, 2021). For example, the “nutrition data value chain” highlights six key aspects (i.e., prioritization, creation and collection, curation, analysis, translation and dissemination, and decision making) for accountable FSN data and action (DataDENT, 2021). This approach further stresses the need for identifying gaps in nutrition measurement and advocating for investments to strengthen nutrition data value chains. Other efforts seek to overcome specific data-related challenges, such as the International Dietary Data Expansion (INDDEx) by Tufts University, which aims to support LMICs to overcome high costs, inaccessibility, low quality, and under-use of household- and individual-level dietary data (INDDEx Project, 2018).

## Deciding what data are needed

### Conceptual frameworks

Concise frameworks can support data informed decision making for FSN policies and programs by enhancing understanding of complex systems, identifying pathways through which nutrition-related outcomes are influenced, and using this to support data priorities. The High Level Panel of Experts on Food Security and Nutrition (HLPE-FSN) of the Committee on World Food Security (CFS) framework on data for food security and nutrition (HLPE, 2022) was designed explicitly for this purpose. The framework draws on two previous, well-known conceptual frameworks. First, the HLPE Food Systems framework (HLPE, 2017), which provides an overview of the relationship between the food system and diets, and the many drivers that may ultimately influence dietary intake and related outcomes. Second, the United Nations Children's Fund (UNICEF) framework of the causes of malnutrition (UNICEF, 1998), which provides an important complement to this by focusing on the multiple determinants of nutrition at the individual level that include, but go beyond, dietary intake. Most LMICs are now facing the double burden of malnutrition, thus this comprehensive focus, encompassing not only nutritional status and health outcomes but also their determinants at multiple levels, is critical.

### Core principles and terminology

Data collection should always be aligned with a country's priorities as outlined in national, sub-national or sectoral plans and corresponding, well defined, high-quality indicators should be selected. Meaningful disaggregation of data as well as flexibility allowing for the adaptation of indicators based on changing circumstances, requirements or data collection approaches, needs to be factored into a surveillance system from an early stage while ensuring cost-effectiveness (UNICEF and WHO, 2021).

One common challenge is the terminology used among the varying sectors and stakeholders involved in data collection and use for FSN. Confusion often exists between the underlying **construct** of interest (e.g., diet quality), the **indicator** used to assess that construct (e.g., minimum dietary diversity among women of reproductive age (i.e., MDD-W)), a **measure** that may be used to construct an indicator (e.g., number of food groups consumed in the past 24 h), and the **methodology** used to collect the raw data to generate the measure and indicator (e.g., a diet recall questionnaire). A **scale** may also be developed to reflect a construct with traits that are unobservable (e.g., perceptions of food insecurity). Ideally, indicators should be validated to ensure that they adequately reflect the construct of interest and methodologies should be properly adapted to the context to ensure that they will appropriately capture all needed data to generate the indicator. FSN data is unfortunately fraught with challenges in this regard. Continuing the diet quality example, while the MDD-W indicator provides a validated estimate of overall risk of micronutrient inadequacy among women (Martin-Prével et al., 2015), this reflects only one component of the broader construct of *diet quality*. Currently, there is no single universal indicator that captures all aspects of diet quality relevant for all forms of malnutrition among any population group. Nor is there consensus on the methodology and measures that should be used to assess other indicators of diet quality or the processes needed to adequately adapt such methodologies to diverse contexts (TEAM, 2021).

Despite these issues related to assessment of some FSN constructs, many relevant and validated indicators of FSN exist and the measures used to generate them are commonly collected from one or two primary **data sources** as part of a FSN surveillance system, i.e., routine and survey data. **Routine data** are regularly collected and commonly obtained through existing systems, e.g., health facilities or agriculture and trade statistic bureaus. **Survey data** include surveys that are conducted periodically and often include nationally and sub-nationally representative samples. They may be single country or multi-country efforts, such as the Demographic and Health Surveys (DHS) or Multiple Indicator Cluster Surveys (MICS), that include many common measures and indicators

### Box 1 Food security and nutrition (FSN) surveillance systems in times of crises

Crises, such as conflict, health emergencies and climate variability challenge food and health systems and can have severe effects on FSN. As such, FSN surveillance systems may need to expand beyond the collection of routine and survey data and embed additional rounds of existing indicator collection and/or add the collection of new indicators that respond to the specific situation at hand. For example, Action Against Hunger leads rapid and targeted surveys to understand the type of intervention most needed in emergency situations (e.g., nutrition, food security and livelihoods, or water, sanitation, and hygiene services) (Action Against Hunger, 2019). The COVID-19 pandemic has prompted the need for adjustment of the data collection approach (e.g., through no-touch assessments at community level, mobile data assessments or web-based surveys) to reduce the risk of COVID-19 transmission to protect survey staff and respondents and in response to restrictions imposed on movement in several country contexts. To support the implementation of FSN surveillance in the context of the pandemic, the United Nations Children's Fund (UNICEF), the Demographic and Health Survey (DHS) Program and others have developed recommendations, guidelines and support for the collection, analysis and management of FSN data (UNICEF, 2020).

For example, the 2020 Kenya Malaria Indicator Survey data collection stopped due to COVID-19 in June 2020. Aiming to resume data assessment as soon as possible, the Kenya National Bureau of Statistics (KNBS) together with the Kenya Ministry of Health Department of National Malaria Control Program (DNMP) and the DHS Program revised the data collection approach to include risk mitigation elements, e.g., the use of personal protective equipment for enumerators and revised interview protocols and training to protect survey staff and participants alike. Based on the adjusted approach and virtual training of fieldworkers, data collection could be resumed in October 2020 (USAID, 2021).

Exploring the expansion and innovation of routine and survey data collection approaches is of immense importance for keeping FSN surveillance systems running and avoiding surveillance systems coming to a halt in times of crises.

(appropriately adapted to context). Surveys may also be targeted to specific regions or in response to crises or similar situations (Box 1).

Both routine and survey data have varying strengths and limitations for various objectives and should therefore be used in a manner that maximizes their strengths where possible. For example, routine data is typically less resource intensive to collect than survey data. However, because data are collected through existing systems, data may not be representative of the full population. For example, nutrition-relevant health coverage data will only capture information from those who use the health system (e.g., weight of adult men seeking routine health care). Data quality and consistency in how it is collected may also vary much more in a routine system than in a survey where data protocols and interviewer training can be more tightly controlled. Furthermore, for routine systems, data are often collected at national level (e.g., food supply) and several assumptions must be made to extrapolate this to the adequacy of that supply for the population. Such data is vital for some purposes, for example analyzing time trends and accountability to meet national or international goals such as the SDGs. However, it does not actually assess what individual households consume and cannot be used to identify sub-groups within a population who may be vulnerable to food insufficiency for economic or other reasons or for whom food assistance or social protection programs may be needed.

The choice of data source for measuring constructs of interest within a surveillance system must therefore be defined by the purpose for which they are intended, with a deep understanding of data quality considerations and ensuring fit for purpose and to context (Frongillo et al., 2014). Table 1 provides an overview of illustrative examples of the purposes for which routine and survey data are often used in the context of FSN surveillance. Using a mix of routine and survey data and streamlining the inclusion of appropriate indicators in each source helps to provide integrated and comprehensive insights and may increase the cost-effectiveness and sustainability of FSN surveillance (UNICEF and WHO, 2021).

## FSN surveillance data in LMICs

The following presents FSN-related constructs, methodology, measures and indicators that are commonly assessed through routine and survey data as part of FSN surveillance systems (Table 2).

### Routine data for FSN surveillance

Routine food supply data can be used to monitor trends in national apparent food intake and food security for comparisons over time and across countries. Most countries worldwide collect information on food supply. Many LMICs display these data through their national statistical institutes (e.g., in Kenya the National Bureau of Statistics (KNBS)).<sup>1</sup>

In conjunction with national statistics offices and their records on production and trade of food commodities, the Food and Agriculture Organization of the United Nations (FAO) compiles Food Balance Sheets (FBSs) for over 245 countries and territories, including most LMICs. For a wide range of food commodities, the FBSs capture the sources of supply and its utilization. Total food utilization is classified by various categories (e.g., human consumption, foods export, used for livestock, and food losses). The human consumption estimates are of particular interest for FSN surveillance as they can be used to provide high-level estimates of dietary intake and food security by dividing the respective quantity by the total population. Data on per capita food supply are then displayed as annual or daily quantity of food availability for a wide range of food items and presented by country, region,

**Table 1** Illustrative examples of the purpose for food security and nutrition surveillance systems from routine data and surveys.

<i>Data sources</i>	<i>Purpose (examples)</i>
Routine	<ul style="list-style-type: none"> <li>• Snapshot of situation and comparison with goals.</li> <li>• Identification of specific issues that require attention.</li> <li>• Early warning of nutrition-related issues.</li> <li>• Comparison among subsets of the population.</li> <li>• Assess time trends.</li> </ul>
Survey	<ul style="list-style-type: none"> <li>• Inform the development of national policies and programs.</li> <li>• Monitor trends over time, in response to political and environmental changes.</li> <li>• Identify groups for intervention.</li> <li>• Assess the impact of policies and interventions of the population in different locations.</li> </ul>

and sub-region. Data are further converted to dietary energy supply (DES), dietary supply of protein and fat, and ultimately used to estimate dietary energy consumption (DEC) and the number of undernourishment (NoU) or prevalence of undernourishment (PoU) in countries. The PoU, which is also referred to as prevalence of hungry people in a country, provides an estimate of the percentage of the total population that are in a condition of undernourishment and hence can be used as an estimate for measuring the construct of food security. The PoU is also used as an indicator for tracking the progress on SDG 2.1 “End hunger, achieve food security and improved nutrition and promote sustainable agriculture” (FAO, 2021a).

Routine data from health systems (e.g., feeding centers and child clinics as well as nutrition-related program data) provide information relevant for FSN surveillance, such as service coverage rates for supplementation, food distribution and related efforts (Tuffrey and Hall, 2016; UNICEF and WHO, 2021). Some routine systems also collect and report on the nutritional status of the population.

### Strengths and limitations

Indicators of food supply provide important estimates of the adequacy of food availability to the population. Importantly, the data are collected in a relatively consistent manner, allowing for comparisons over time and across countries. These data have the advantage of being widely and freely available for most countries worldwide and are currently serving an important accountability objective, as PoU is used to track progress for SDG 2.1 (FAO, 2021a,b).

Although the indicators can be used for high-level estimates of apparent population food consumption and food security, they do not reflect actual food access and utilization by households or individuals and the quality of data used to generate the indicators can vary greatly among countries and commodities. Therefore, they should be interpreted with caution as routine food supply data is thought to underestimate total per capita energy availability in LMICs. Additionally, despite food supply data being available for a range of food commodities, the limited specificity of foods and processed foods prevents nuanced analyses of food supply (Thar et al., 2020).

While routine data can provide useful time-trends and early warning signals, data are available at the national level only and cannot be disaggregated to identify specific populations at risk, determine seasonal trends, predict food shortages or famine, nor to assess changes in food consumption or food security within specific population groups (Thar et al., 2020).

Routine health systems data are also an important source of information for assessing the utilization of nutrition-relevant health services including micronutrient supplementation coverage or breast and complementary feeding counseling. In some contexts, routine growth monitoring data from children and other population subgroups collected through health systems is included as part of FSN surveillance systems. This has an economic advantage as it could avoid the need for separate surveys. However, routine growth monitoring data are mostly incomplete, of poor quality and, particularly in some LMIC contexts, are not representative of any population sub-group due to limited access to and costs of health facilities (Tuffrey and Hall, 2016).

### Survey data for FSN surveillance

Surveys can be designed using a wide range of approaches, including large-scale multi-country surveys implemented on a periodic basis as well as nationally representative surveys that are not linked to any multi-country platform. Smaller (e.g., sub-nationally but not nationally representative) surveys designed to provide assessment of specific population subgroups at specific time points (i.e., assessing risks in the context of a crisis, see Box 1) may also form part of a FSN surveillance system.

Large-scale, multi-country assessments in LMICs are mostly implemented in collaboration with international partners and organizations that have developed survey programs with several modules, such as the Demographic and Health Surveys (DHS)<sup>2</sup> or the Multiple Indicator Cluster Surveys (MICS)<sup>3</sup> program by the United Nations Children’s Fund (UNICEF). Both programs include household- and individual-level nutrition and health data from nationally representative samples of women and young children.<sup>4</sup> DHS includes a variety of core modules relevant for FSN as well as optional modules that countries can opt to include if they wish. In addition to the publicly available full reports and data sets, which can be accessed via the DHS and MICS program page, data can be further explored via the DHS STATcompiler<sup>5</sup> and UNICEF’s Data & Analytics resource center.<sup>6</sup>

Similarly, household consumption and expenditure surveys (HCES) (also called household income and expenditure surveys (HIES), Living Standards Monitoring Surveys (LSMS) or national household budget surveys (NHBS)) are standardized, nationally representative surveys designed primarily to estimate levels of poverty, for setting consumer price index among related economic purposes. Several use a common methodology and are carried out in multiple countries worldwide and are supported by the World Bank.<sup>7</sup> In recent decades, the food consumption modules from HCES have been used as part of FSN surveillance specifically to

<sup>2</sup><https://dhsprogram.com/>.

<sup>3</sup><https://mics.unicef.org/>.

<sup>4</sup>To date, 320 and 345 surveys in over 90 and 118 countries have been conducted under the DHS program and the MICS program, respectively. Both survey programs typically include 5,000–30,000 households, and are conducted periodically, often at 3–5-year intervals.

<sup>5</sup><https://www.statcompiler.com/en/>.

<sup>6</sup><https://data.unicef.org/resources/resource-type/datasets/>.

<sup>7</sup>HCES surveys typically including 7,000–20,000 households and are periodically repeated every 3–5 years.

address gaps in household-level dietary information (Fiedler et al., 2012). While there is no single data platform for HCES, many countries have added to the IHSN Central Survey catalog<sup>8</sup> and the World Bank Microdata Library.<sup>9</sup>

### **Constructs and indicators commonly included in surveys as part of FSN surveillance**

#### **Food security**

Household food security commonly refers to the adequacy (real or perceived) of the food available to meet the needs of the household members, taking into consideration cultural and personal preferences (Pinstrup-Andersen, 2009). The Household Hunger Scale (HHS) and the Food Insecurity Experience Scale (FIES) are scales designed to measure food insecurity. The HHS measures food insecurity at the household level, while the FIES was initially developed for use at the individual-level but can also be adjusted to be used on household level. Both have been validated across multiple contexts and are particularly useful to understand and compare population groups and sub-groups within populations (Ballard et al., 2011). The scales collect information on the degree to which household members worry about running out of food and modify habits due to a lack of food without making any quantitative estimations of food availability. While the HHS focuses on severe food insecurity over a recall period of 30 days, the FIES includes a broader range of questions on household's (or individual's) food insecurity experience, commonly over a period of 1 year (Ballard et al., 2013).

The FIES is assessed annually through the Gallup World Poll (in collaboration with FAO) and used for measuring progress toward achieving SDG 2.1. The Gallup World Poll implements nationally representative surveys in a number of countries annually, including information on a variety of topics. As of 2021, Gallup has collected FIES data for 77 countries, with data available through FAO's Micronutrient Catalog.<sup>10</sup> Data on the HHS can be accessed via DHS and MICS.

#### **Diet quality**

Diet quality is a critical construct for FSN that is assessed through a variety of approaches to describe dietary intake (qualitatively or quantitatively). No single indicator of diet quality has been developed that captures all relevant aspects of dietary intake and given the complexity of diets, it is unlikely that a single indicator would do so. Diet quality indicators can be classified broadly into three types, either at aggregated household level based on food available and household composition, or for individuals. Nutrient adequacy provides a quantitative comparison of nutrient availability at household level, or intake of individuals with requirements. Food intake provides a quantitative comparison of food intake with guidance or recommendations, such as consumption of 400 g of fruit and vegetables daily. Diet quality may also be assessed by reviewing dietary patterns and their alignment with dietary patterns that have been associated with better health outcomes in some contexts (e.g., the Mediterranean diet) (Neufeld et al., 2021).

Household food consumption data provide an estimate of the amount of food or energy available to be consumed on a per capita or household basis (e.g., kcal/capita/day). Estimates are based on the reported amounts acquired and/or purchased for the household on a seven-day recall period, commonly assessed through HCES (FAO and The World Bank, 2018). In the absence of individual-level data on energy, food, and nutrient intakes, it is possible to apply the adult male equivalent (AME) method to such household-level data to generate individual-level estimates. The AME method provides estimates on intra-household food distribution in accordance with expected energy expenditures of the individual based on their age and sex (Weisell and Dop, 2012). Furthermore, individual-level nutrient intakes can be derived when multiplying the estimated individual food intakes (derived using the AME methodology) by nutrient content levels for each food using Food Composition Databases. This approach has been shown to provide comparable estimates of food, energy and nutrient intakes to 24 h recalls among most population groups with some exceptions among young children and for some foods (Coates et al., 2017; Dary and Jariseta, 2012; Engle-Stone and Brown, 2015; Jariseta et al., 2012; Sununtnasuk and Fiedler, 2017).

The Household Dietary Diversity Score (HDDS) and the Food Consumption Score (FCS) by the UN World Food Programme (WFP) are proxies for household caloric availability counts of food groups consumed. These indicators are based on some evidence that household consumption of a higher number of food groups is correlated with better diet adequacy for several nutrients (Swindale and Bilinsky, 2006). The HDDS counts the households consumption of up to 12 food groups in the past 24 h and can be further disaggregated for specific foods groups (Kennedy et al., 2011). The FCS includes the frequency of the households consumption of eight food groups in the past seven days and multiplies these with the food group weight according to their nutritive value (WFP VAM Resource Center, 2019). For both indicators reasonable correlations have been found with household socio-economic status. Similarly, to the approach taken by Gallup World Poll (see food security) WFP collects household dietary diversity data on a rolling basis, traditionally every 1–3 months, to update the platform on a daily basis. WFP's near real-time data are currently being assessed in 34 LMICs and are accessible through WFP's Hunger map.<sup>11</sup>

Individual-level dietary diversity indicators follow the same principle as the HDDS described above. The most common indicators used are the Minimum Dietary Diversity for Women of reproductive age (MDD-W) and the Minimum Dietary Diversity (MDD) for children. In many contexts, women's nutrition knowledge is central for household food security and nutrition as their child's diet quality tends to be closely linked to their own (Bonis-Profumo et al., 2020; Debela et al., 2017). Both indicators have been

<sup>8</sup><http://catalog.ihsn.org/catalog>.

<sup>9</sup><https://microdata.worldbank.org/index.php/home>.

<sup>10</sup><https://microdata.fao.org/index.php/catalog>.

<sup>11</sup><https://hungermap.wfp.org/>.

found to be positively associated with nutrient adequacy of diets and to reflect appropriate complementary feeding practices (Martin-Prével et al., 2015; Working Group on Infant and Young and Child Feeding Indicators, 2007). The MDD-W and MDD for children were set up to include ten and eight food groups, respectively (FAO, 2021c; WHO, 2017).

Questionnaire modules on HDDS, MDD-W and MDD for children are commonly added to the DHS and MICS and available via the respective platforms.

The Global Diet Quality Project, a collaboration of the Harvard Department of Global Health and Population, the Global Alliance for Improved Nutrition (GAIN), and the Gallup World Poll collects data on several aspects of diet quality. Based on consumption of 29 food groups, nutrient adequacy (MDD-W) and dietary risk factors for NCDs (GDR score<sup>12</sup>) are assessed and displayed on the project website.<sup>13</sup> Within the first phase (2021–2022) 56 countries were included in a multicountry assessment through the Gallup World Poll. The questionnaire has now been adapted to more than 100 countries (Global Diet Quality Project, 2021).

Individual dietary intake can be measured using a variety of measures including food records, 24 h dietary recalls and food frequency questionnaires (FFQs), all with a variety of strengths and limitations for varying purposes (Gibson, 2005). Food records and multi-day 24 h dietary recalls are needed to quantify usual food and nutrient intakes for individuals, but all methods have potential to characterize dietary patterns and generate several indicators of diet quality at population level. For example the Estimated Average Requirement (EAR) cut point or probability method can provide estimates of individual-level nutrient adequacy, which can be used as a proxy for risk of micronutrient deficiency (Yates et al., 1998).

The coverage of fortified foods is also an important indicator in FSN surveillance. Large-scale national surveys, including DHS or MICS, often include household-level coverage indicators for iodized salt. Additionally, Fortification Assessment Coverage Toolkit (FACT) surveys include household-level coverage indicator for all fortified foods in a country using a standardized methodology (Friesen et al., 2019). To date, FACT surveys have been conducted in more than 16 countries as part of ongoing program monitoring efforts (Aaron et al., 2016, 2017; Knowles et al., 2017; Rohner et al., 2016). In addition, data from HCES and other food intake surveys are also increasingly being used to inform the design of nutrition programs such as food fortification (e.g., selecting foods for fortification based on their patterns of consumption) (Fiedler et al., 2008).

### Nutritional status

Nutritional status is commonly assessed in surveys using anthropometric indicators, such as stunting, wasting, underweight, overweight and obesity. The assessments for these indicators include data on weight, height or length and age. Overweight/obesity as well as underweight are indicators that can be assessed for both adults and children. For adults, the body mass index (BMI) is used as method, whereas weight-for height and weight-for-age Z scores are used for child overweight/obesity and underweight, respectively. Overweight/obesity are proxies for abnormal fat accumulation, while underweight is a proxy for poor nutrition generally. Stunting and wasting are indicators only used for children and are interpreted as impaired growth and recent and severe weight loss, respectively. Data for these indicators and measures can be found via DHS and MICS programs as well as NCD-RisC<sup>14</sup> (for BMI only) and the WHO Global Database on Child Growth and Malnutrition.<sup>15</sup>

Ideally, biochemical measures of nutritional status, particularly for micronutrient status, should also be part of FSN surveillance. Some nationally representative surveys have included biological samples (usually blood and/or urine) for assessment of micronutrient status of individuals, but data are scarce (Brown et al., 2021). While DHS and MICS may include samples for multiple micronutrients (optional module), only hemoglobin concentration for assessment of anemia prevalence is part of the core modules. Where available, data on micronutrient status have been compiled and made publicly available through the Vitamin and Mineral Nutrition Information System (VMNIS)<sup>16</sup> maintained by the World Health Organization (WHO).

### Strengths and limitations

While the collection of survey data typically requires greater financial resources than routine data, an important advantage of multi-country surveys like DHS, MICS and HCES is that they provide nationally representative data using standardized questionnaires that allow for comparison over time and across countries. They also allow for the questionnaire modules to vary based on individual country needs. Conversely, the standardization of the questionnaire modules makes it difficult to add single questions into the surveys, although the DHS for example supports the use of qualitative research to complement the survey findings. Smaller, non-nationally representative surveys have the strength to focus specifically on high-risk groups, sub-regions, and local data needs thus providing data for those whom policy makers may need to design interventions (Tuffrey, 2016).

There are several limitations to the collection of household-level data on food availability in LMIC contexts, particularly among very poor households. For example, inventory methods may underestimate food availability in households that purchase food daily with little to no food stored in the home. For dietary intake indicators, household-level assessments are still not as accurate as individual-level methods as they do not allow for intra-household differentiation and may miss out on food being wasted, given away or consumed away from home.

<sup>12</sup>The Global Dietary Recommendations (GDR) score indicator reflects global dietary recommendations associated with non-communicable diseases (NCDs). A lower score is associated with a higher risk for NCDs (Herforth et al., 2020).

<sup>13</sup><https://www.globaldietquality.org/home>.

<sup>14</sup><https://ncdrisc.org/index.html>.

<sup>15</sup><https://apps.who.int/ntgrowthdb/database/search>.

<sup>16</sup><https://www.who.int/teams/nutrition-and-food-safety/databases/vitamin-and-mineral-nutrition-information-system>.

Individual dietary assessments such as 24 h recalls, and FFQs provide more accurate data on dietary intake. However, they are often resource intensive to implement and analyze and are subject to recall bias and underreporting. To ease the collection of such data, particularly in LMICs, innovative tools such as computer assisted personal interviewing (CAPI) on tablets or mobile phones are often used to replace the traditional paper-based questionnaires in many surveys. Furthermore, promising mobile phone-apps have been developed that use images of food plates before and after eating to estimate portion size and nutritional content (Ambrosini et al., 2018) as well as specific guidance related to the development of food photographs and portion size estimation in 24 h recalls for LMICs (Vossenaar et al., 2020).

Individual anthropometric and biochemical indicators provide the most objective measure of nutritional status. However, both are time and cost intensive, and technically challenging to collect and analyze. Improved methods have been developed to ease the level of effort required to assess anthropometric data, particularly in LMICs. For example, the Child Growth Monitor (CGM), an application using augmented reality with artificial intelligence (AI) was developed to determining weight and height and hence malnutrition indicators through a 3D scan of children (Welthungerhilfe, 2018).

Overall, dietary intake and nutritional status data that are available in LMICs focus mainly on children under 5 years of age and women of reproductive age. Data on nutritional status and dietary intake of other groups, particularly adolescents (Neufeld et al., 2021), but also older children, adult men, and older adults, remain very limited.

### Accessing data through international platforms

Survey data, particularly that generated from multi-country data platforms (e.g., DHS, MICS) are increasingly being made publicly available and there are several global efforts to support the compilation and increase public access to such nationally and sub-nationally representative data. For example, the joint Global Individual Food consumption data Tool (GIFT)<sup>17</sup> is a growing platform managed by FAO and WHO, which includes food-based indicators on individual dietary data conducted at national or sub-national levels. As of 2021, the platform included data from 23 mainly LMICs with a plan to expand. Similarly, WHO's Global Database on Child Growth and Malnutrition<sup>18</sup> compiles nationally and sub-nationally representative survey data from household and individual level assessments in over 230 countries (including DHS data). Indicators such as child anthropometric status disaggregated by sex and location (urban vs. rural) are included.

The Global Nutrition and Policy Consortium set up the Global Dietary Database (GDD),<sup>19</sup> which uses public and private data sources of individual level dietary data to model characteristics of diets in populations around the world. Currently, the database contains data on 54 dietary factors including foods, beverages, macro- and micronutrients. Estimates are disaggregated by age, sex, education level, and location.

The Global Burden of Diseases Platform<sup>20</sup> by the Institute for Health Metrics and Evaluation (IHME) focusses on the display of the prevalence of a given disease or risk factor and the relative harm it causes. Under this approach the platform makes use of over 30,000 data sources from administrative data assessments, demographic surveys, scientific data and other sources to compile FSN indicators. The estimates are available on annual basis, disaggregated by sub-national level, sex and age.

The newly established Food Systems Dashboard<sup>21</sup> is a large multi-country data platform including food system and nutrition data on food production, the food environment (e.g., access and availability of food, food prices, convenience or desirability), individual factors, consumption, dietary behavior and factors like policies and environment. While it is currently limited to national data only, there are plans to include sub-national level data in the near future.

## Case studies

### Continuous DHS assessment, Senegal

Senegal was one of 29 countries included in the first phase of the DHS program when it began in 1984. Between Senegal's first DHS in 1986 and 2010/11, six standard DHS and two Malaria Indicator Surveys (MIS) were collected. Like most countries, surveys were implemented once every 3–5 years or occasionally less frequently. In 2012, Senegal adopted a new, continuous approach to enhance data quality and provide more frequent and up-to-date data for planning, monitoring and tracking progress of health and population programs each year (DHS Senegal, 2013). Using more targeted surveys, Senegal has been able to adapt its data collection to meet specific decision-making needs. Since 2012/13, seven DHS and Service Provision Assessment (SPA) rounds have been conducted by the National Agency for Statistics and Demography (ANSD) in collaboration with the Ministry of Health and Social Action (MSAS) and technical assistance from the DHS Program. While the DHS assessments are led by the Government of Senegal, additional financial support is provided by the United States Agency for International Development (USAID), the Cellule de Lutte contre la Malnutrition (CLM), the World Bank, UNICEF, the United Nations Population Fund (UNFPA) and Nutrition International. In addition to socio-economic indicators, the continuous DHS captures data from households on fertility,

<sup>17</sup><http://www.fao.org/gift-individual-food-consumption/overview/en/>.

<sup>21</sup><https://foodsystemsdashboard.org/>.

contraception, child mortality, reproductive health, children's health (e.g., details on breastfeeding and nutritional status) and malaria. The SPA captures information on the availability of different health services (e.g., children, maternal health and family planning), the ability to diagnose diseases including HIV/AIDS, NCDs, tuberculosis and malaria and the availability of drugs and treatments for certain diseases (Agence Nationale de la Statistique et de la Démographie and ICF, 2020a,b).

### Integrated Reproductive Health and Nutrition Surveillance System (SIVESNU), Guatemala

In 2010, the Guatemalan government designed a population-based nutrition surveillance system with support from the Institute of Nutrition of Central America and Panama (INCAP), UNICEF, USAID, and the US Centers for Disease Control and Prevention (CDC). Based on the identified lack of standardized surveillance of important nutrition-related information (specifically related to all large-scale nutrition-specific interventions), a prototype was developed with the aim of providing accurate, timely, reliable and representative data—as a complement to information provided by the institutional surveillance system—to inform national decision making and program planning related to improving the health and nutritional status of women and children (CDC, 2020; INCAP, 2018). After testing the prototype in 2011, the surveillance system was expanded to include reproductive health and the Integrated Reproductive Health and Nutrition Surveillance System (SIVESNU) was launched in 2013. In detail, the SIVESNU monitors chronic malnutrition, overweight and obesity, micronutrient status (e.g., iron, zinc and vitamin A), anemia, supplementation and diets (i.e., breastfeeding and complementary feeding and dietary diversity for children and women, respectively) as well as household level socio-economic characteristics, food security, coverage of fortified salt, sugar, bread and the coverage of government programs and household level health, nutrition and food safety (INCAP, 2018). This nationally and sub-nationally representative sample collects data at household level and for individual population sub-groups within the household (children 0–59 months of age, non-pregnant women 15–49 years of age, and pregnant women) during each cycle. The survey is rolled out over about 6–8 months per cycle and repeated on an approximate annual basis (Friedman, 2014). The SIVESNU design is flexible, and content can be revised for each surveillance cycle. For example, in 2017/18, the SIVESNU added a Zika questionnaire module among a representative sample of school-aged children between 6 and 14 years and Zika biomarker testing among women. Given the lower cost and high quality of the SIVESNU compared to other national surveys, the surveillance system provides a sustainable source of accurate, timely, reliable and representative data, which aims to help the Guatemala government to determine its health priorities and improve programs and interventions (Palmieri et al., 2022).

### Conclusion

Rigorous FSN surveillance systems that provide accurate, timely and sub-nationally disaggregated data can help to ensure effective evidence-based policymaking and program implementation. LMICs face particularly high challenges to establish FSN surveillance systems due to rapidly transforming food systems, overburdened health systems, limited data infrastructure and a lack of technical capacity and resources. Especially in resource-limited settings, establishing FSN surveillance requires strategic decisions on what data to collect, driven by the purpose for which it will be used, ensuring appropriate and validated indicators that reflect the constructs of interest and with close consideration of data quality and resource implications. In most contexts a purposeful mix of routine and survey data will likely meet these needs.

### Conflict of Interest

The views expressed in this publication are those of the author(s) and do not necessarily reflect the views of FAO.

### Acknowledgments

We thank Maria Elena Jefferds for her review and input to the case study on Guatemala.

## Key points

- Globalization has resulted in dramatic shifts in diet and physical activity patterns that promote obesity and chronic diseases.
- Diets have shifted from high-fiber and low-processed sugar to high-fat and high in processed foods.
- Activity patterns have shifted as technology has globalized and communities and work forces are more sedentary than ever before.
- More people than ever are overweight or obese and the prevalence of chronic diseases is increasing rapidly in lower income countries.
- The consumption of ultra-processed foods, in both higher and lower income countries continues to increase and contribute to the global burden of chronic diseases.

## Glossary

**Dietary change** Foods consumed and overall food patterns

**Edible oils** Vegetable oils extracted from oil seeds

**Globalization** Commonly refers to increasing global norms in economic order, trade in goods and services or set of changes associated with the rapid exchange of goods, services, ways of thinking

**Mass media** All modern forms of communication: radio to TV to computer, cell phones, movies, magazines, etc.

**Nutrition transition** Stages of patterns of eating, drinking, and moving

**Obesity** BMI > 30

**Role of income** Measure of amount of money or money in kind we obtain over a period of time

**Sugar-sweetened beverages** Calorically sweetened waters -carbonated or noncarbonated, flavored in any manner from colas to energy drinks to vitamin waters

**Ultra-processed foods** Food products made from formulations of ingredients derived from a series of industrial processes

**Urbanization** Residence in urban area or process of modernization of a community to bring set of services and infrastructural changes linked with urban residency

## Introduction

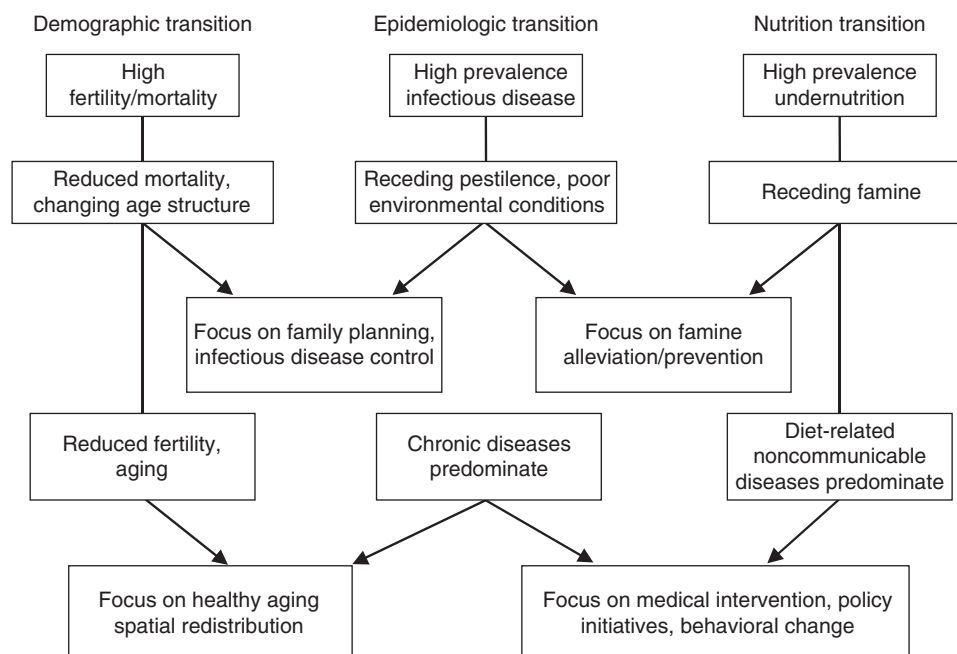

In the past 100 years, the world has undergone a transformation in international trade, development, and health. No longer faced with high mortality from infectious diseases, the globalization of food products coupled with labor shifts there has been an unprecedented increase in diets that are less than healthful and physical activity patterns that promote obesity and chronic diseases. At the same time, the world faces ongoing civil violence and health disparities that leave some communities food insecure, but with access to processed foods. These changes are commonly referred to as the “nutrition transition.” This article will explore various aspects of the nutrition transition to better understand how dietary and physical activity patterns influence global health.

## Demographic and epidemiological transitions

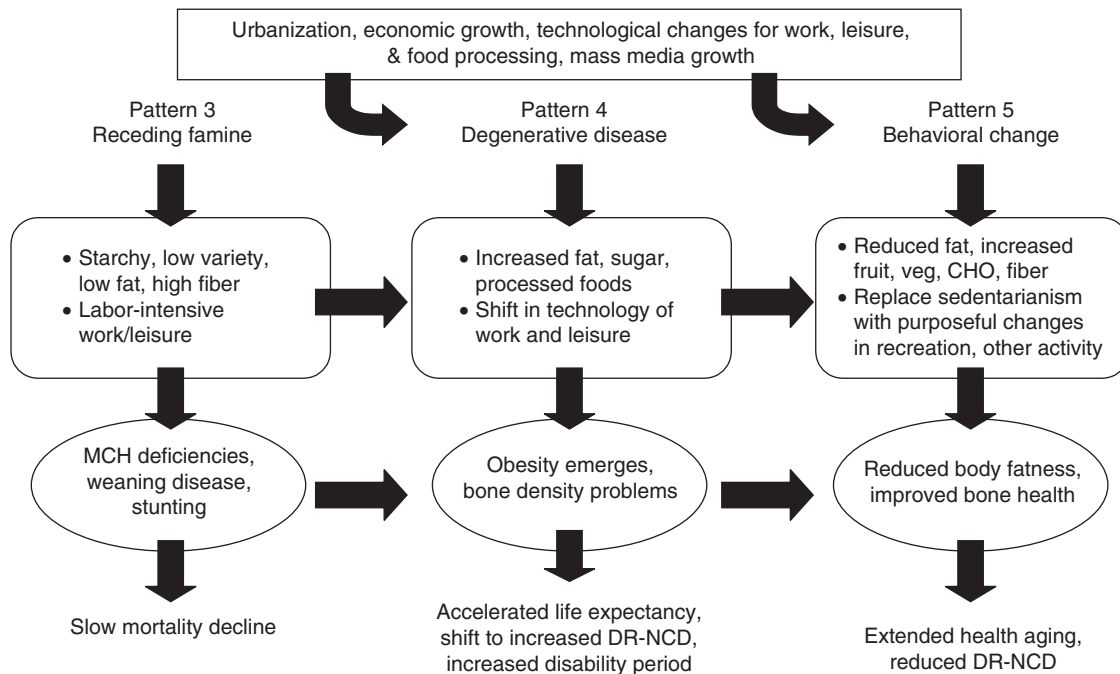

The world has experienced rapid shifts in dietary patterns and body composition that have several important implications for humans. In many ways, these shifts are a continuation of large-scale changes that have occurred repeatedly over time (Fig. 1). However, the changes facing low- and middle-income countries (LMICs) appear to be very rapid. Broad shifts continue to occur throughout the world in population size and demographics, disease patterns, as well as dietary and physical activity patterns. The former two sets of dynamic shifts are termed the demographic and epidemiological transitions. The latter, whose changes are reflected in nutritional outcomes, such as changes in stature and body composition, is termed the nutrition transition.

Human diet, physical activity patterns, and nutritional status have undergone a sequence of major shifts, defined as broad patterns of food use and their corresponding nutrition-related diseases (Popkin, 2002). During the past three centuries, the pace of dietary and activity changes appears to have accelerated to varying degrees in different regions of the world. Furthermore, dietary and activity changes are paralleled by major changes in health status as well as by major demographic and socioeconomic changes. Obesity emerges early under these shifting conditions, as does the level and age composition of morbidity and mortality. Although there are five broad nutrition patterns dating back to the origins of modern humans, the focus of this article is on the three most recent periods (Fig. 2). For convenience, the patterns are outlined as historical developments; however, earlier patterns are not restricted to the periods in which they first arose but, rather, they continue to characterize certain geographic and socioeconomic subpopulations. The first two patterns relate to earlier periods in the evolution of humans—the first pattern of collecting food and the second pattern of famine. The following are the three later periods.

Pattern 3: Receding famine: The consumption of starchy staples was predominant and continues to be so, but these items are less important in this low-fat diet as limited amounts of fruits, vegetables, and animal protein are increasingly added to this low-fat and high-fiber diet. Many earlier civilizations made great progress in reducing chronic hunger and famines, but only in the last third of the past millennium have these changes become widespread, leading to marked shifts in diets. However, famines continued well into the 18th century in some parts of Europe and unfortunately remain common in some regions of the world. Activity patterns are shifting, and inactivity and leisure have become a part of the lives of increasingly more individuals.

**Fig. 1** Stages of health, nutritional, and demographic change. Reproduced from Popkin (2002).

**Fig. 2** Stages of nutrition transition. Reproduced from [Popkin \(2002\)](#).

Pattern 4: Nutrition-related noncommunicable diseases (NR-NCD): A diet high in total fat, cholesterol, sugar, and other refined carbohydrates, low in polyunsaturated fatty acids and fiber, and often accompanied by an increasingly sedentary life is characteristic of most high-income societies (and increasing proportions of the population in low-income societies), resulting in an increased prevalence of obesity and NR-NCD that characterize the final epidemiologic transition stage ([Monteiro et al., 2004](#)).

Pattern 5: Behavioral change: A new dietary pattern emerged in the 1990s and early 2000s that was associated with the desire to prevent or delay degenerative diseases and prolong health. Whether these dietary changes, instituted in some countries by consumers and in others also prodded by government policy, will create a large-scale transition in dietary structure and body composition remains to be seen.

Research on global dietary changes has focused primarily on patterns 3–5, particularly the rapid shift in much of the world’s low- and middle-income countries from the stage of receding famine to NR-NCD as depicted in [Fig. 2](#). The concern about this period is so great for many that the term “nutrition transition” is synonymous with this shift from pattern 3 to 4.

### Rapid shifts in dietary and activity patterns and body composition

The pace of rapid shifts in diet and activity patterns from the period termed the receding famine pattern to one dominated by NR-NCD accelerated in LMICs between 2000 and 2015. The word “nutrition” rather than “diet” is used since the term NR-NCD incorporates the effects of diet, physical activity, and body composition rather than solely focusing on dietary patterns and their effects. Another element is that the rapid changes in urban populations are much greater than those experienced about a century ago in the West, yet another is the shift in occupation structure and the rapid introduction of modern mass media, social media, and ultra-processed foods. Underlying such changes is a general concern for rapid globalization as the root cause.

Clearly, there are quantitative and qualitative dimensions to these changes. On the one hand, changes toward a high-density diet, reduced complex carbohydrates, increased added sugar and other caloric sweeteners along with ultra-processed foods, and inactivity may be proceeding faster than in the past. The shift from labor-intensive occupations and leisure activities toward more capital-intensive, less strenuous work and leisure occurred very rapidly in many middle-income countries. On the other hand, qualitative dimensions related to multidimensional aspects of the diet, activity, body composition, and disease shifts may exist. The social and economic stresses that people face and feel as these changes occur may also be included.

Scholars often note that the pace and complexity of life, reflected in all aspects of work and play, are increasing exponentially. There are also unanticipated developments, new technologies, and the impact of a very modern, high-powered communications system. It is this sense of rapid change that makes it so important to understand what is happening and anticipate the way in which changes in the patterns of diet, activity, and body composition are occurring. Although the widespread influence of modern communications, technology, and economic systems related to “globalization” have been a dominant theme of the past few decades, there are many unique issues that have led to a rapid increase in globalization and its impact on nutritional status.

Stating that globalization is the cause of the nutrition transition results in a focus on broad and vaguely measured sets of forces that ignores the need to be focused and specific, which would allow us to develop potentially viable policy options. These processes certainly have been expanded, as indicated by enhanced free trade, a push toward reduction of trade barriers in the developing world, and the increasing penetration of international corporations into the commerce of each country (measured by share of gross national product (GNP) or manufacturing). Similarly, other economic issues related to enhanced value conferred to market forces and international capital markets are important. Equally, the increasing access to Western media and social media, the removal of communication barriers enhanced by the internet, cable television (TV), mobile telephone systems, etc., are important. The accelerated introduction of Western technology into manufacturing and the basic sectors of agriculture, mining, and services is also a key element.

To best illustrate the changes that have occurred in LMICs, consider the life of a person living in an urban shantytown compared to that in a rural village in China (Bell et al., 2001). During the 1970s, there were still major concerns about having an adequate food supply, there was no television, limited bus and mass transportation, minimal international food trade, minimal processed food available, and most rural and urban occupations were very labor intensive. Today, work and life activities have changed as small gas-powered tractors are available, modern industrial techniques are multiplying, offices are automated, soft drinks and many processed foods are abundant, televisions are in approximately 89% of households (at least one-fifth of which are linked to Hong Kong Star and Western advertising and programming), younger children do not ride bicycles, and mass transit is being heavily used. Considering that such changes are also occurring in much of Asia, North Africa, the Middle East, Latin America, and many areas (particularly cities) in sub-Saharan Africa, it is evident that the shift from a subsistence economy to a modern, industrialized one occurred in a span of 10–30 years, whereas in Europe and other industrialized high-income societies, this occurred more slowly, over many decades or centuries.

The elements of the nutrition transition known to be negatively associated with NR-NCD are obesity, poor dietary changes (i.e., shifts toward a greater intake of fat, added caloric sweeteners in food, and ultra-processed food, reduced fruit and vegetable intake, reduced fiber intake, greater energy density, and greater saturated fat intake), and reduced physical activity in work and leisure. The causes of these elements of the nutrition transition are not as well understood as their trends. In fact, few studies have attempted to research the causes of such changes, and only a few data sets allow such crucial policy analyses to be undertaken.

### Obesity trends

The nutrition transition has contributed to a parallel increase in the worldwide prevalence of obesity which has nearly tripled in the past 40 years (Jaacks et al., 2019). Obesity is a chronic condition in which sustained positive energy balance results in a person having excess adipose tissue, a factor that is known to contribute to NR-NCD. Recent trends in the prevalence of obesity for adults and children segregated by income are presented in Figs. 3–5. Currently, a lower proportion of LMICs populations are obese compared to populations in HICs; however, obesity appears to be increasing more rapidly in LMICs. Over the last 3 decades, the prevalence of obesity has increased significantly, particularly in countries that have historically been underweight. This shift is evident among women and children who, in most LMICs, have a prevalence of obesity that is higher than underweight. Gender differences in the prevalence of obesity exist across both LMICs and HICs such that women are more likely to be obese compared to men. Given that obesity in girls is generally comparable with boys, it appears that this disproportionate increase in obesity among women occurs later in life. These shifts are reflective of global changes in the prevalence of obesity and NR-NCD.

In 2018, it was estimated that 108 million children and 604 million adults were obese, defined as a body mass index [BMI, weight (kg)/height (m)<sup>2</sup>] > 30. It has been reported that adults with a high BMI accounted for nearly 4 million global deaths and 40% of these deaths were among adults with a BMI > 30. In terms of specific diseases, a high BMI accounted for 2.7 million deaths and 66 million disability-adjusted life-years lost (DALYs) from cardiovascular diseases. For type 2 diabetes, a high BMI was associated with 0.6 million deaths and 30 million DALYs. These estimates are the culmination of an ongoing global epidemic of excess fat such that from 1990 to 2015, deaths attributed to a high BMI increased nearly 28% and DALYs increased 36%. Interestingly, since the nutrition transition has not occurred independent of other epidemiological transitions, the age-standardized death rates and DALYs did not change as the death rates across all ages decreased.

**Fig. 3A** Obesity trends among adults living in lower- and middle-income countries. Adapted from data courtesy of Jaacks et al. (2019).

**Fig. 3B** Obesity trends among children living in lower- and middle-income countries. Adapted from data courtesy of [Jaacks et al. \(2019\)](#).

### Dietary changes: shift in the overall structure over time

While high-quality data on total energy intake in many countries are limited, there are reasonable data to examine shifts in the structure of the diet. Briefly, there has been a nearly global increase in the consumption of fat, animal products, and artificial sweeteners accompanied by a decrease in legumes and other high-fiber grains ([Popkin, 2015](#)). Together, these changes may be responsible for what is referred to as an obesogenic diet, one that is associated with NR-NCD.

Since the 1960s, there has been a major increase (10–13%) in the consumption of vegetable fats by almost all countries in the world. In fact, since 1985, the average intake of vegetable oils tripled in most countries of the world. At the same time, the consumption of fat from animal sources has decreased except for low-income countries. These decreases, combined with the increase in vegetable fat intake for all income countries, resulted in an overall decrease in fat intake for middle-income countries of approximately 3% but an increase in approximately 4% or 5% for low- and high-income countries. Changes in the relationship between GNP and the consumption of fat are presented in [Fig. 6](#).

The issue of animal-source foods is complicated as there are millions of people in the world with inadequate protein intake, a major contributor to poor growth and undernutrition in the most vulnerable communities of the globe. However, most increases in the production and consumption of animal-source products occurs in LMICs. Thus, it is a delicate balance to promote adequate protein intake while guarding against excess intake that can promote higher fat consumption and NR-NCD.

There is also an equally large and important shift in the proportion of energy from added caloric sweeteners in the diets of lower-income countries. In fact, an additional 100–200 kcal per day was available for daily consumption from added caloric sweeteners in the diet in 2000 compared with 1962 in the developing world. In the US, this added caloric sweetener increase derives mainly from soft drinks and fruit drinks, but in many other countries the source of this increase is other foods, even basic processed foods that have sweeteners added to them. High-fructose corn syrup (HFCS) is used as the sweetener of choice in some cases by food companies. Fructose, be it from HFCS, sugar, or other caloric sweeteners, appears to have unique adverse cardiometabolic attributes.

A relatively recent addition to the list of foods that promotes unhealthy diets is ultra-processed foods and beverages, UPF and UPB, respectively ([Elizabeth et al., 2020](#)). Based on the availability of global data on sales and consumption, the per capita sales of UPF increased 3 and 11 times faster in HICs compared to LMICs ([Lane et al., 2021](#)). Of particular concern is that a similar increase was reported for UPB given the positive relationship between UPB consumption and obesity. When the growth of sales of UPF and UPB were considered, it was found that LMICs experienced an 8% growth in sales of these products while HICs experienced only a 2% growth, highlighting the shift in marketing and sales of these foods in less wealthy countries. These increases in sales of UPF and UPB may be partly attributed to consumer demand or preferences, but one should not discount the impact of marketing and distribution of foods. Indeed, regarding market integration of fundamental food products, only four companies account for approximately 80% of the global grain trade. Moreover, given the high sugar content of these foods, it is important to recognize that global raw sugar production has increased from 50 million tons in 1961 to almost 160 million tons in 2014.

**Fig. 4A** Obesity trends among adults living in upper middle-income countries. Adapted from data courtesy of [Jaacks et al. \(2019\)](#).

**Fig. 4B** Obesity trends among children living in upper middle-income countries. Adapted from data courtesy of Jaacks et al., 2019.

Aside from changes in the consumption of foods that are associated with chronic diseases, there has been a decrease in the consumption of foods that may prevent chronic diseases. In particular, the consumption of high-fiber grains and vegetables has declined steadily in most developed and many LMICs since the 1960s. Recent advancements to national food guidelines, such as that developed by the Brazilian Ministry of Health, are emphasizing the intake of “whole” foods with minimal consumption of processed foods, an effort that could result in an increase in the consumption of higher fiber foods.

### Rapid social change is important: urbanization, rapid demographic change, and other behavioral changes are occurring simultaneously

Compared to rural areas, dietary patterns in urban areas of LMIC have shifted dramatically. While it is beyond the scope of this article to explore the complex issues related to the type of urban change that has occurred, critical sociodemographic issues include the following:

- Rapid reductions in fertility have enhanced the shift in the age distribution.
- Urbanization continues unabated in Asia and Africa. More poor will reside in urban than rural areas in future decades and upwards of 2/3 of the world population is expected to live in an urban setting by 2040.
- Economic changes, particularly increased income and income inequality, appear to define changes in many regions of the developing world.
- Globalization of mass and social media is occurring at an earlier stage of economic development than occurred in higher income countries in the past.

### Urbanization

Demographic predictions show that over two-thirds of the world population will live in urban settings by 2050. The structure of dietary patterns has shifted markedly as populations have urbanized. This relationship will, by itself, alter the structure of diets significantly at the national level as urbanization continues and as the proportion of the population in urban areas grows. There are a number of factors that contribute to this situation including an increase in food marketing, expansion of multi-national super- and hyper-markets, and access to ultra-processed foods.

**Fig. 5A** Obesity trends among adults living in high-income countries. Adapted from data courtesy of Jaacks et al. (2019).

**Fig. 5B** Obesity trends among children living in upper middle-income countries. Adapted from data courtesy of [Jaacks et al. \(2019\)](#).

### Structural shifts in income–diet relationships are occurring

Changes in dietary behavior can be caused either by shifts in the composition of society regarding the plurality of the educated, rich, or urban residents or by changes in the actual behavior of those with specific characteristics. The latter shifts may include changes in consumption behavior such that for the same level of education or income, a person would buy different amounts or types of commodities at different points in time. Research conducted in China shows that there have been profound behavioral shifts of this type during the past decade (i.e., for each extra dollar of income, additional high-fat foods are purchased vs. what would have been purchased in previous years for the equivalent extra dollar). Economists speak of this effect as one that shows how the decision-making demand pattern for food has changed; thus, for the same income level, the patterns of demand have changed significantly from earlier periods. This rapid increase in access and exposure to mass media and the internet may very well have created this situation.

### Mass media and internet use

Access to modern mass media and internet use has increased rapidly, particularly from 2000 to 2010. For example, 88.5% of Chinese households had televisions in 1997. While access to mass media and the internet have increased, it is important to note many media and internet providers rely heavily on US and British programming which provides modern TV advertising. Like television, the explosion of access to the internet via computers and cellular devices increased the access to a wide variety of messaging on diet, body satisfaction, new concepts of the “ideal” body, as well as misinformation on health and diet. The impact of these messages ranges from less than valid diet and health advice from unqualified websites to body shaming via social media platforms. Still, the complete picture of how mass media and the internet influence diet and activity is unclear, but one can speculate that for every “positive” message about diet and health, people encounter “negative” messages. Internet use and marketing of unhealthy foods is particularly worrisome among children worldwide.

**Fig. 6** Relationship between the percentage of energy from fat and GNP per capita, 1962 and 1990. Reproduced from [Guo et al. \(2000\)](#).

## Health effects: how does biology interact with these rapid social changes?

The question of how NR-NCD vary by country or social group raises the important question of determining the interaction between biology and society. For example, body composition and other social factors (i.e., income, class, and education) affect the susceptibility to NR-NCD. As well, previous disease patterns (i.e., famine, chronic food shortage, or the presence of malaria or other tropical diseases) may have led to disease patterns that predisposed the entire population to specific NR-NCD. The latter example is generally attributed to a phenomenon first reported by Dr. David Barker and is now referred to as the “developmental origins of health and disease” or DOHaD (Barker, 2001).

There is a growing body of research that shows that the international standards to classify someone as overweight or obese are not appropriate for many large subpopulations in the world. For example, the risk of hypertension is higher for Chinese men and women at lower BMIs (23–25 kg/m<sup>2</sup>) compared to adults from the Philippines and US (25–30 kg/m<sup>2</sup>) (Bell et al., 2002). Ethnic differences in the strength of the association between BMI and disease outcomes warrant further consideration. In response, a working group created by the World Health Organization and the International Obesity Task Force proposed lower BMI cutoffs for Asians of 23 kg/m<sup>2</sup> for overweight and 25 kg/m<sup>2</sup> for obesity.

For LMICs in particular, the highest genetic susceptibility for type 2 diabetes (T2D) is for Pacific Islanders, American-Indians, Mexican-Americans and other Hispanics, and Asian Indians. Those with modest genetic susceptibility include Africans, Japanese, and Chinese. The age of onset (usually after 50 years of age) of T2D is much lower for these susceptible populations, and it appears that the prevalence is higher for any level obesity and waist-to-hip ratio.

It is not clear how much of this difference between subpopulations regarding BMI–T2D or other BMI–morbidity relationships is a function of differences in body composition, metabolic or genetic factors, or social causes. While we may regard biological factors as fundamental to understanding these relationships, it is necessary to consider that several social factors, such as income, education, stress, and access to healthcare also play major roles in chronic disease risk. Thus, the confluence of biological and social risk factors for NR-NCD complicates the ability to discern exact causal pathways.

Several studies have provided an increasing body of evidence to support DOHaD, which attributes adverse nutritional and environmental exposures during early life to an increased risk of NR-NCD. This theory postulates that malnutrition during the pre- and post-natal periods causes an adaptive metabolic response which favors fat deposition to ensure both immediate viability and survival if a similar environment is encountered later in life. Indeed, several studies have reported that children and adults who are growth restricted in childhood (a condition generally attributed to insufficient energy and protein consumption during rapid periods of growth) experience changes in their metabolism such that fat metabolism is lower compared to normal height peers (Hoffman et al., 2000). However, exposure to a food environment opposite of what was experienced during this period in early life (i.e., increased exposure to adequate, energy-rich foods), creates a “mis-match” which promotes the development of NR-NCD long-term. Simply, when these individuals face a food environment rich in processed foods and high-fat foods, any excess intake may be deposited as fat and contribute to the development of obesity and other NR-NCD. Individuals living in LMICs, where food environments are shifting rapidly, are more likely to be exposed to both nutritional insufficiency and excess throughout the course of their lives. Notably, an increase in NR-NCD has been found among children in LMICs who experienced rapid catch-up growth after being born small-for-gestational-age (SGA). As dietary patterns continue to shift toward increased consumption of calorically dense, nutrient-poor foods, early life will pose a critical period for the development NR-NCD.

## Epidemic of CVD and type 2 diabetes

Evidence from many LMICs shows that NR-NCD results in premature morbidity and mortality affecting a large proportion of economically productive people; essentially, a preventable loss of precious human capital. Nearly 80% of deaths in LMICs can be attributed to NR-NCD. The current high burden of NR-NCD is contributed to 58.8% of global mortality and 43% of the global burden of disease, measured as DALYs. The contribution of LMICs to this burden is large where approximately 77% of the total mortality and 85% of the total burden of disease attributable to NR-NCD arise from these countries.

The burden of cardiovascular disease varies by global region and the nearly 21% lower mortality rate of CVD is attributed to a 42% decrease in high income countries compared to smaller decreases and some increases in lower income countries. In fact, The Global Burden of Disease Study projected those 6.4 million deaths would occur due to CVD in the developing countries in 2020, in the age group of 30–69 years (Roth et al., 2020). For other parameters, such as fasting glucose, hypertension, and BMI, similar patterns emerge in which the global changes do not necessarily reflect a consistent pattern when analyzed by GDP. For example, there has been a 14% global increase in fasting glucose and an 18% global decrease in total cholesterol, but these decreases are primarily seen in higher income countries (–25%) while lower-income countries experience anywhere from a 6% decrease in North Africa and the Middle East with some countries reporting up to 162% increase (e.g., Bangladesh). A similar pattern emerges for high BMI in which the global prevalence has increased 28% but reflects some decreases in HICs and up to 650% increase in Asia.

Reports from several global health agencies focus on the important role of obesity in CVD and cancer deaths in the developing world. There are major differences in the profiles of the CVD epidemic across the developing world. For instance, hypertension and stroke are more likely to emerge in east Asia, whereas diabetes occurs earlier in south Asia. As would be expected from the dietary and obesity data noted previously, CVD levels are far greater in urban areas of the developing world, but often the opposite is true in the developed higher income countries.

## Social burden of changes in diet, body composition, and health

In HICs, adults with higher income follow a more healthful lifestyle, whereas low-income individuals do not, which is often related to food insecurity. For example, higher income Americans consume a more healthful dietary pattern, exercise more, and smoke less; similar patterns can be found in other high-income countries. In contrast, the prevailing opinion has been that the opposite is found in the developing world, namely that the poor are less likely to have a heavy burden of NR-NCD compared with the rich. This is changing rapidly as obesity has declined among the higher educated and increased among the lower educated in southeastern Brazil. In fact, not only are less healthful dietary patterns consumed by higher income Chinese, but also other dimensions of lifestyle (inactivity, smoking, and drinking) are poorer among the higher SES Chinese (Jones-Smith et al., 2011). In other research, scholars of China have shown a rapid shift in food consumption patterns among different income groups in China that seems to indicate a shift in the burden of poor diets toward the poor in China. It has been shown that for countries with a GNP per capita of more than \$2500, the likelihood is very high that there will be more obesity among the lower SES groups compared with higher SES groups.

## Summary

Maintaining a healthy lifestyle includes eating a healthful diet and being physically active in a manner that promotes health and prevents chronic diseases. However, as described in this article, there are several factors that limit such lifestyles, such as poverty and food insecurity and dietary change toward a less healthful diet is universal. It remains to be seen how the global pandemic of COVID-19 affected these patterns as near-universal quarantines and disruptions to the food supply chains created a host of issues that resulted in increased food insecurity, especially in the countries with the least number of resources to respond to the pandemic. In particular, a rapid change is being seen in the poorest areas of the world. The challenge is to learn how to continue to improve the palatability and quality of our diet while doing so in a more healthful manner.

### Glossary

**AMPM** Automated Multiple Pass Method, a computerized method for collecting interview-administered 24-h dietary recalls in person and by telephone. Developed by the USDA Food Surveys Research Group, the research-based approach employs five steps that are designed to enhance data collection and reduce respondent burden.

**DPAS** The Global Strategy on Diet, Physical Activity was adopted by WHO member states in 2004. It is a prevention-based strategy aimed at significantly reducing the prevalence of NCDs and their common risk factors, mainly unhealthy diet and physical activity.

**EuroFIR** The European Food Information Resource Consortium is a partnership between several universities and 25 countries to develop and integrate a comprehensive cohort and validated network of food composition databanks in Europe.

**INFOODS** Established in 1984 to stimulate and coordinate efforts to improve the quality and availability of analytical food data worldwide.

**NCDs** Noncommunicable diseases such as diabetes or cardiovascular disease.

**Nutritional surveillance** A system established to continuously monitor the dietary intake and nutritional status of a population or selected population groups using a variety of data collection methods whose ultimate goal is to lead to policy formulation and action planning.

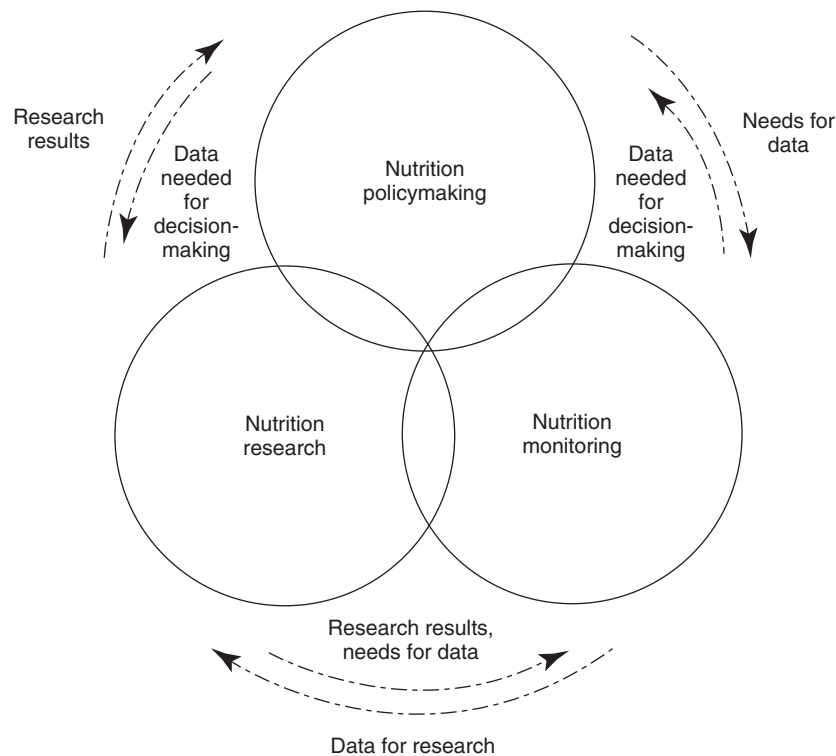

Nutritional surveillance is defined as a system established to continuously monitor the dietary intake and nutritional status of a population or selected population groups using a variety of data-collection methods whose ultimate goal is to lead to policy formulation and action planning. Continuous monitoring varies among countries such that annual, bi-annual, or other data-collection timeframes are determined by the funding and commitment of national governments. Increasingly, countries have come to recognize the need to collect dietary information in a systematic manner to make science-based policy decisions related to diet and health.

This article describes nutritional surveillance systems in developed countries. Emerging nutritional and health issues informed by these systems are reviewed. Examples of surveillance systems in Australia, Canada, Europe, Japan, New Zealand, South Korea, and the United States are described.

### Uses of Nutritional Surveillance Data

Most notably data generated from these systems are categorized broadly as (1) nutritional monitoring and surveillance, (2) research relating diet to health, and (3) informing the development of or enhancing existing nutritional policies and programs. **Figure 1** illustrates the interrelationships between data in a nutritional surveillance system. These data are used by government agencies, the private sector, the academic community, and the public. Government agencies use the data for nutritional policy, research, and programs. The private sector uses the data for marketing, product development, food labeling, and food safety compliance. Academics use the data to conduct research, develop programs, and train students.

**Figure 1** Relationships among nutrition policymaking, nutrition research, and nutritional monitoring. Reproduced from US Department of Health and Human Services/US Department of Agriculture (1993) Ten-year comprehensive plan for the National Nutrition Monitoring and Related Research Program. *Federal Register* 58: 32752–32806.

Data uses for public policy enable informed decision-making regarding cost-effective programs, policy, and regulations. For example, data can be used to:

- assess the status of national populations and identify high risk or vulnerable groups;
- identify problems that inform the development of new policies and programs;
- formulate food enrichment, fortification, and food labeling policies and regulations;
- determine risk and inform regulatory decisions;
- develop and update socio-culturally appropriate foods and food guidance;
- evaluate the effectiveness of existing policies and programs and;
- conduct epidemiological, socioeconomic, behavioral, and marketing research.

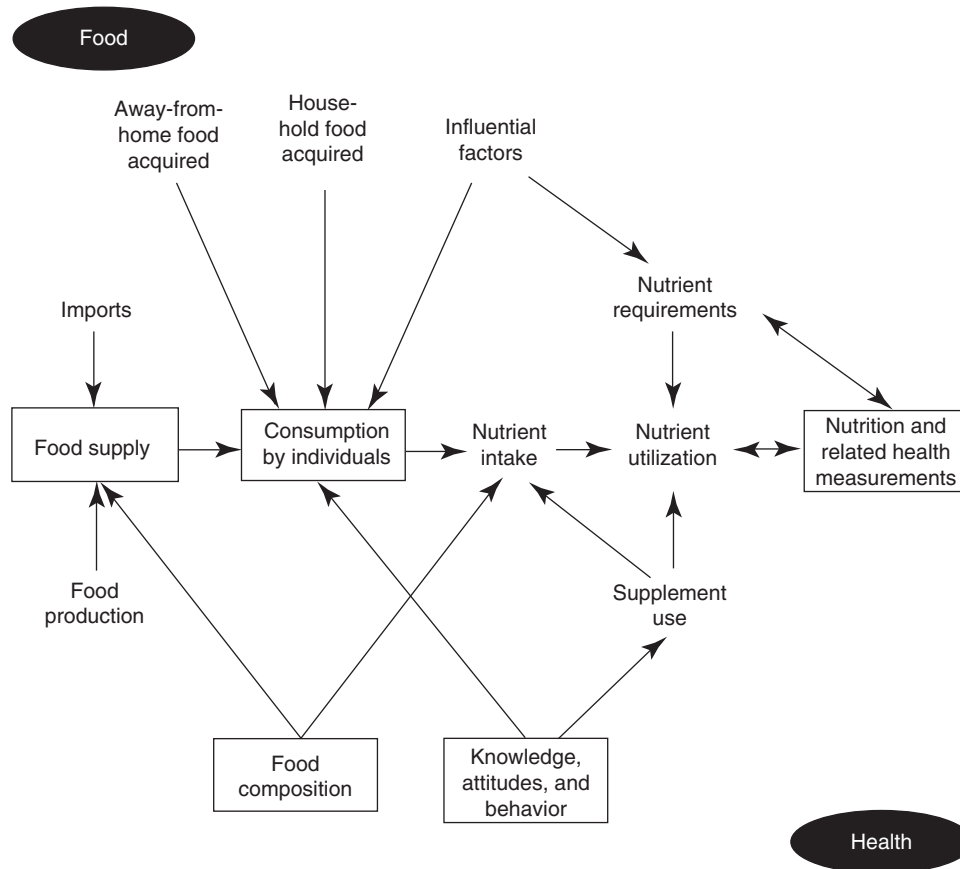

## Nutritional Surveillance Systems

The purpose of a nutritional surveillance system is to depict the relationship between food and health. Key information collected through the system includes data on nutritional and health status, food consumption patterns (household and individual levels), nutrient intakes, food supply, and food composition. There are many other influential factors on these data such as socio-demographic; culture; food knowledge, attitudes, and behavior; and food security. Although [Figure 2](#) highlights the traditionally accepted relationship between food and health, [Figure 3](#) begins to depict a new paradigm where globalization is included and may eventually include the effects of climate change.

## Dietary Data Collection Methods

### Food Supply Data

Food supply data reflect the type and amount of food available for consumption in a country. Food balance sheets are the primary tool used for assessing available food at the country level. This indirect measurement method estimates the amount of food consumed by a country's population at a certain point in time. Food balance sheets do not measure actual food consumption, but rather food disappearance. Calculations are based on using beginning and ending inventories, with the difference as the amount of food consumed. The beginning inventory includes measurements of food production, imports and exports, adjustments for

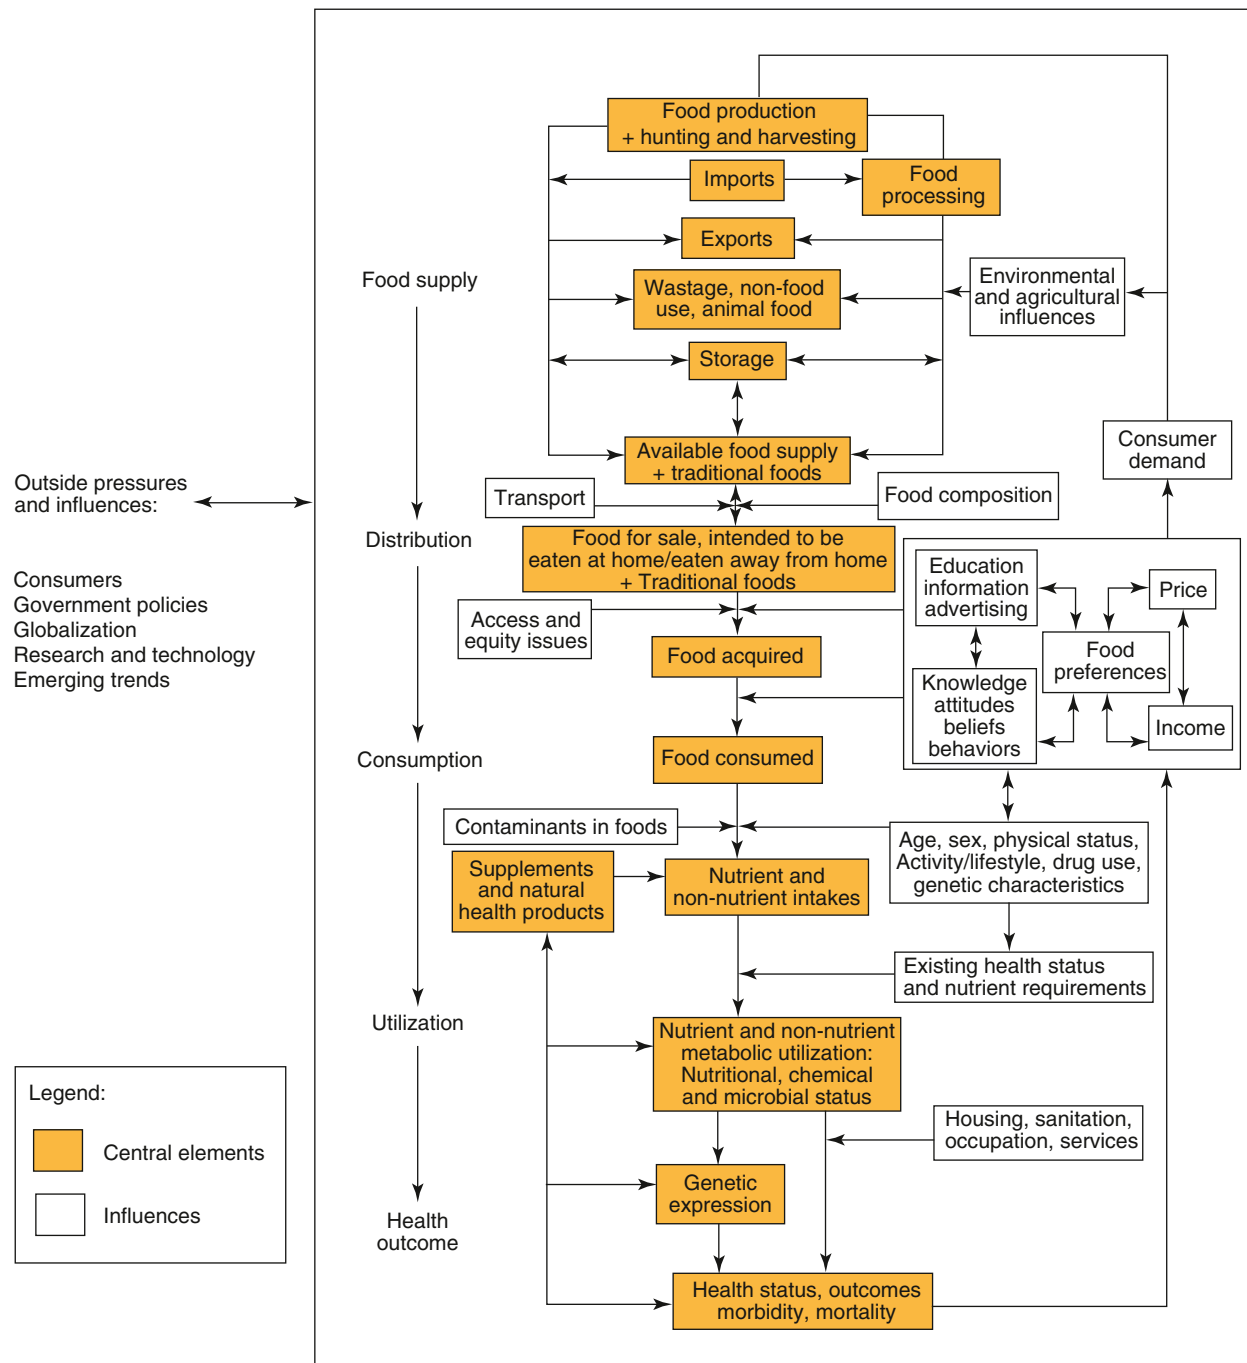

**Figure 2** A conceptual model of the relationships of food to health. Reproduced from US Department of Health and Human Services/US Department of Agriculture (1993) Ten-year comprehensive plan for the National Nutrition Monitoring and Related Research Program. *Federal Register* 58: 32752–32806.

nonhuman food consumption and estimates of waste. Mean per capita annual food consumption is determined by dividing total disappearance of food by a country's population. Each food commodity is then multiplied by the appropriate nutrient values and the results expressed as either kilograms per year or grams per day of individual food commodities and nutrient availability per person. Major limitations to this method include (1) the accuracy of data may be questionable, (2) data only represent food available for consumption, (3) does not account for waste, and (4) does not indicate how food was distributed among individuals. However, food balance sheets are useful for comparing available food supply within and between countries, monitoring trends, and forecasting food consumption patterns over time. They are also useful in formulating agricultural policies related to food production and consumption. For example, [Table 1](#) highlights the use of food balance sheets data and shows per person food consumption in kilocalories per day worldwide and by region of the world from 1990–1995 to 2003–2005.

### Food Consumption by Household

Several methods of assessing food consumption by households have been devised, which consider the per capita food consumption of the household. These methods account for all food and beverages on hand in the home at the beginning of the survey period, all items purchased or grown during the survey period, and all that remains at the end of the survey. They vary by the level of respondent burden and extent of recall or recordation expected. Four methods are primarily used: the food account, list-recall, inventory, and food record methods. For the food account, the head of household records daily the type and amount of food entering the household. The list-recall method includes an interview where the head of household recalls the foods used by the household on an 'as purchased' basis. The inventory and food record methods are probably the most burdensome to the respondent because they require a daily record of food acquired and changes to the food inventory, with detailed weighing and measuring of food. None of these methods provide data on actual food intake by individuals within the household or food consumed away from home. However, data from household food consumption surveys indicate the kinds, quantities, money value, and nutrient content of food used, which in turn, provides valuable data for determining the effects of income, household size, and other socioeconomic factors on total food and food group consumption. These data demonstrate how diets at the household level conform to nutritional and household budgeting constraints.

### Food Consumption by Individuals

A variety of methods are available to assess the food intake by individuals: diet history, 24-hour dietary recall, food record, and food frequency questionnaire. All of these methods provide advantages and limitations, and their applicability depends on the purpose and design of the survey. Diet histories can provide detailed information, but they require respondents to make judgments about

**Table 1** Per person food consumption by region

their usual food habits and can be very burdensome. Dietary recalls are most appropriate for assessing the intakes of groups of people, and the current gold standard requires at least the collection of two days of intake to assess an individual's usual intake. Food records are thought to be the best method for assessing individual dietary intake, but they are time consuming and may impart bias if respondents modify their eating behavior due to the data collection method. Although food frequency questionnaires provide less detailed information, they are designed to provide usual intake data and are particularly useful for epidemiological studies of large population groups. For all these methods, advanced computerized systems provide standardized probes and multiple inquiry passes of intake have improved data collection, coding, and the estimation of nutrient intake and dietary patterns.

### Examples of Nutritional Surveillance Activities

Most developed countries support a nutritional surveillance system and many conduct combined nutritional and health surveys. **Table 2** presents some of these surveys by region of the world and the method of dietary data collection selected by each country. For Asia, surveys conducted by Japan in 2007 and South Korea in 2005 represent their most recently reported data collection. The 2007 National Nutrition Survey in Japan collected dietary histories and behavior information, in addition to other assessments, from almost 9000 respondents aged one year and older. Whereas, the 2005 National Health and Nutrition Survey in South Korea included a 24-hour dietary recall, dietary behavior, food frequency questionnaire, anthropometric, biochemical, and clinical examinations.

With 24 European Union (EU) member countries plus Norway, a considerable amount of data is available through the European Nutrition and Health Report 2009. This report provides (1) an overview of available data on food and nutrient intake, (2) identifies major national and regional health and nutritional issues, (3) describes trends in food supply, (4) compares average daily individual food availability at the household level, (5) evaluates individual food consumption in adults and energy and nutrient intake in all ages, (6) describes data on diet-related health indicators and status, and (7) analyzes food and nutritional policies in EU countries. Individual national reports provide more detailed information on nutritional and health status in different participating countries, with much of that information obtained from national surveys. As evidenced by **Table 2** various dietary intake methodologies are used and anthropometrics appears to be collected by a majority of the surveys, with a few adding the collection of physical activity assessments. To date the 2009 report is the most current, comprehensive study of nutritional surveillance in a region of the world. It highlights both the considerable improvements in the quality of data collection and assessment methods employed and the continuing need for harmonization of databases and survey methods, which would allow more robust comparisons of data across countries.

The United States has one of the most comprehensive nutritional surveillance systems in the world. Since 1999, the periodic National Health and Nutrition Examination Survey (NHANES) became a continuous national nutritional surveillance system. A key component of the survey is the Automated Multiple Pass Method (AMPM), a computerized method for collecting interview-administered 24-hour dietary recalls in person and by telephone. The research-based, multiple pass approach employs five steps that are designed to enhance data collection and reduce respondent burden. Dietary data is collected from a nationally representative sample of 5000 individuals yearly and is released in 2-year cycles. The NHANES 2010–2011 is currently in the field. In Canada, the Canadian Community Health Survey, Cycle 2.2, Nutrition also used the AMPM to collect 24-hour recalls. Dietary data for greater than 35 000 individuals six months and older was released in Wave 1 (2005), Wave 2 (2006), and Wave 3 (2008).

In 2007, Australia conducted the National Children's Nutrition and Physical Activity Survey, which combined the collection of two days of dietary intake on children, aged 2–16 years old with anthropometric and physical activity assessments to strengthen the monitoring of childhood obesity in the country. A new National Nutrition and Physical Activity Survey Program, which will collect dietary data on 35 000 individuals plus an additional 15 000 individuals from indigenous population groups in the country is planned for 2011–2012. New Zealand's most recent survey, the Adult Nutrition Survey, was conducted in 2008–2009. Twenty-

		2002 Children's Nutrition Survey	5–14	3 275	24-h recall, FFQ,	A, BC
		2008–2009 Adult Nutrition Survey	15+	Results due in 2011	BH 24-h recall	A, BC, CE, BP

<sup>a</sup>Dietary method. 24-h recall; 24-h dietary, 1d FR; 1-day food record; FFQ, food frequency questionnaire; DH, dietary history; KN, dietary knowledge; ATT, dietary attitude; BH, dietary behavior.

<sup>b</sup>Other information. A, anthropometry; BC, biochemical tests; BP, blood pressure; CE, clinical exam; MH, medical history; F, Female; M, Male; PA Rcl, physical activity recall; PR, pedometer record.

<sup>c</sup>Starting in 1999, the CSFII and NHANES merged and became one integrated national survey.

four-hour recalls, anthropometrics, biochemical, clinical, and blood pressure assessments were completed on respondents 15 years and older. Results from this survey are due out in 2011.

### Food Composition Databases

Reliable food composition data is essential in calculating the food intake by individuals and ultimately assessing the nutritional status of population groups. Factors such as sampling, variability, and analytical methods used to determine the nutrient content of food are important in the development of these databases. To better expand the benefits of nutritional surveillance considerable work has been done to try and harmonize food composition tables regionally. Harmonization requires comparable criteria at the food level (number of foods covered, food classification and descriptions systems, and representativeness of nationally consumed foods), component level (coverage, identification, definition, analytical methods), and value level (missing nutrient data, documentation). Issues related to data management, including the compilation, software capacity, evaluation, data interchange, and ownership also must be considered. There are currently greater than 150 food composition tables or nutrient databases in use worldwide. Many are based on the USDA National Nutrient Database for Standard Reference available on the Nutrient Data Laboratory website, [www.ars.usda.gov/nutrientdata](http://www.ars.usda.gov/nutrientdata). For several years there has been a concerted effort to improve harmonization of analytical methods, definition, and mode of expression of foods and nutrients. INFOODS was established in 1984 to stimulate and coordinate efforts to improve the quality and availability of analytical food data worldwide. The European Food Information Resource Consortium, EuroFIR, is a partnership between several universities and 25 countries to develop and integrate a comprehensive cohort and validated network of food composition databanks in Europe. FAO also maintains a comprehensive list of food composition tables, which are grouped by region of the world at [www.fao.org/infoods/directory\\_en.stm](http://www.fao.org/infoods/directory_en.stm).

### Emerging Nutritional and Health Issues

Obesity continues to be a major health issue for the developed world. Obesity has been linked to multiple health disorders, such as Type 2 diabetes, cardiovascular disease, hypertension and stroke, some cancers, and disability. Globally, greater than one billion adults are overweight and at least 300 million are obese. Moreover, childhood obesity is one of the most critical public health challenges of the 21<sup>st</sup> century. The problem is global and the prevalence has increased exponentially. Worldwide, in 2010 the number of overweight children under the age of five is estimated to be greater than 22 million. Overweight and obese children are more likely to become obese adults and more likely to develop noncommunicable diseases (NCDs) such as diabetes or cardiovascular disease at a younger age. In 2004, a Global Strategy on Diet, Physical Activity, and Health (DPAS) was adopted by WHO member states. The primary purpose of DPAS, a prevention-based strategy, is to significantly reduce the prevalence of NCDs and their common risk factors, mainly unhealthy diet and physical activity. The role of WHO in implementing the DPAS is to provide leadership, evidence-based recommendations and advocacy for international action to improve dietary practices and increase physical activity. Thus in 2009, the WHO Forum and Technical Meeting in Population-based Prevention Strategies for Childhood Obesity was held in order to identify priorities for population-based strategies to prevent childhood obesity and to define roles and responsibilities for various stakeholders.

An aging population also remains an emerging global public health issue. On October 1, 2010 at the 20th Anniversary of the International Day of Older Persons, it was announced that the world's population is now as old as it has ever been. Women comprise the majority of the older population in most countries, because globally they tend to outlive men. In 2010, one in every 10 persons was aged 60 or more and by 2050, that figure will be one in 5. Because both lean body mass and basal metabolic rate decline with age, maintaining adequate nutritional status among the elderly is especially important. In some instances nutrient requirements may be reduced, where requirements for other essential nutrients may rise in later life. Although WHO has developed a policy framework that promotes active aging and focuses on the prevention and reduction of the burden of disabilities and associated NCD risk factors, there continues to be an increasing demand worldwide for WHO guidelines that address the nutritional needs of the growing elderly population.

Despite access to nutritious foods and nutrition marketing strategies, poor nutrition is growing in affluent developed countries. Studies reveal that adult intakes for certain vitamins and minerals, including vitamin A, E, D, and folate, are below the recommended intakes in some countries. Notably the 2010 US Dietary Guidelines concluded that the under-consumption of vitamin D, calcium, potassium, and dietary fiber for both adults and children was a substantial public health concern. Economic globalization, with increasingly powerful transnational companies shaping global consumer behaviors, in many ways has created an environment of unhealthy food choices, such as fast food and high-sugar beverages. Environmental and climate changes may also place the nutritional status and dietary behavior of populations even in developed countries at risk.

The ability to monitor these emerging nutritional and health issues becomes increasingly important for enabling countries to better make decisions regarding cost-effective programs, policy, and regulations. As evidenced by the number of surveys conducted since 2005, countries appear committed to strengthening and maintaining national nutritional surveillance systems.

### Glossary

**Anemia** Low blood hemoglobin levels, mostly usually caused by iron deficiency.

**Child Health Days** Outreach strategy allowing high coverage of interventions such as vaccines and supplements during quarterly or six monthly extension of specific services into villages on set days.

**Micronutrient supplementation** The provision of micronutrients as pills, capsules, or syrups, for periodic consumption.

**Randomized controlled trials** Experiments carried out with a control or placebo group that is randomly and blindly assigned.

**Therapeutic supplements** Supplements with a dose larger than the daily requirement, used to treat micronutrient deficiency.

### Introduction

Micronutrient supplementation is the distribution of specially formulated preparations of one or more micronutrients, usually in the form of a pill, a capsule, or sirup. It is often described as a 'short-term' option and a 'medical' approach and considered more appropriate for the treatment of severe micronutrient deficiencies in those most affected than to prevent deficiencies in whole populations. However, for the half of humanity affected by micronutrient deficiencies, especially of iodine, vitamin A, iron and zinc, the overwhelming majority of whom are the poor concentrated in the developing world, solving these problems through food-based approaches will take some time.

Vitamin A deficiency affects 30% of children younger than 5 years old in the developing world, compromising their immune systems and potentially contributing to some 1 million deaths each year. In the 6- to 24-month-old age group, mental development is impaired due to iron deficiency in 60% of the developing world's children. Severe iron deficiency also causes more than 60 000 deaths of women during pregnancy and childbirth every year, and 40% of pregnant women suffer from anemia, which is largely caused by iron deficiency. Approximately 18 million infants per year are born mentally impaired as a result of iodine deficiency during pregnancy despite the enormous advances in salt iodization programs. Providing vulnerable groups, such as children and women of childbearing age, with low-cost vitamin and mineral supplements is the least that governments can do to protect the survival, growth, and development of the next generation as a first step toward realizing the right of every individual to be adequately nourished.

Experience in achieving high coverage of those most at risk with micronutrient supplements is quite varied, with both successes and failures. A good communication strategy is an essential part of achieving high levels of adherence in micronutrient supplementation programs, but these aspects are not particular to nutrition programs and are not considered here. Deficiencies of iodine, iron, vitamin A, and folate are the most commonly recognized deficiencies for which there are programs, but in practice most of those affected have multiple vitamin and mineral deficiencies that overlap and interact at great cost. This article reviews the policy dimensions of the efforts to establish programs aimed at eliminating iodine deficiency, iron deficiency anemia, and vitamin A deficiency through supplementation, and it provides a perspective on zinc supplementation and multiple micronutrient supplementation as future components of nutrition programs in developing countries.

### Iodine Supplementation

Today, approximately 70% of the world's salt is iodized, compared to just 10% in 1990, and therefore the need for iodine supplementation programs is greatly reduced. Despite this progress almost 2 billion people still have low urinary iodine levels, and in

these populations iodine supplements should be used during pregnancy and early childhood. In the past, it was common to provide annual intramuscular injections of iodized oil to women of reproductive age in order to ensure iodine status during the first months of pregnancy when the risk of cretinism is greatest. In more recent years, oral iodized oil capsules have proven to be as efficacious and more effective in controlling iodine deficiency in both women of reproductive age and schoolchildren. Oral iodine supplements initially based on expensive poppy seed oil have since been replaced by cheaper rapeseed and peanut oil preparations, which are equally effective.

## Vitamin A Supplementation

The use of supplements to help control vitamin A deficiency has grown enormously during the past two decades. Although the elimination of vitamin A deficiency by the year 2000 was one of the goals set at the World Summit for Children in 1990, little progress was evident at mid-decade. Clinical vitamin A deficiency was estimated to affect approximately 3.3 million children younger than the age of 5 years in 1995, with an additional 100 million subject to subclinical deficiency. The periodic distribution of high-dose vitamin A supplements, originally employed in Indonesia during the 1970s for the prevention of blindness in children, was shown in the 1980s to also impact young child mortality. However, the lack of perception of vitamin A deficiency as a problem was a substantial barrier to establishing large-scale preventive supplementation programs. The prevalence of clinical signs of frank vitamin A deficiency, such as Bitot's spot and corneal lesions, which make it a 'public health problem', is very small at just 0.5%. Because clinical signs are often more common in rural populations, a significant vitamin A deficiency problem can easily go undetected. National representative surveys were thus a prerequisite for taking action.

Convincing proof of the efficacy of vitamin A capsules for child mortality reduction in the early 1990s helped to create increased momentum for population wide preventive supplementation programs. The turning point for increasing the coverage of vitamin A supplements was the meta-analysis of eight efficacy trials, which indicated that improving the vitamin A status of children aged 6 months to 5 years by massive-dose capsule distribution reduced child mortality rates by approximately 23%. The important conclusion of these meta-analyses was that increased risk of mortality from vitamin A deficiency was not just limited to those portions of the population with severe vitamin A deficiency problems but was present across the whole population distribution. Further subsequent meta-analysis carried out over the past two decades have all confirmed these findings.

What consisted of 'the justification' for carrying out vitamin A supplementation programs evolved rapidly during the latter half of the 1990s. Many of these discussions were held at the meetings of the International Vitamin A Consultative Group and the working group on vitamin A of the Standing Committee on Nutrition of the United Nations. A broad technical consensus was finally accepted that even in the absence of survey data, it was highly likely that the benefits of vitamin A supplements would be evident in populations in which the mortality rates for those younger than 5 years old were higher than 70 per 1000. Before this, vitamin A supplements were targeted to those children with illnesses such as measles and diarrhea. Subsequent to this consensus, a global policy to integrate vitamin A capsule distribution into regular immunization schedules, and also to incorporate vitamin A capsules into the national immunization programs was rapidly adopted.

Programmatic vitamin A interventions received considerable impetus from the Vitamin A Global Initiative, an informal inter-agency advocacy group that worked to promote the adoption of vitamin A supplementation programs. The initiative included World Health Organization (WHO) and United Nations International Children's Emergency Fund (UNICEF), together with Canadian International Development Agency (CIDA) from Canada, DIFID from UK, United States Agency for International Development (USAID) from USA, and the Micronutrient Initiative (MI). Through their networks, these various organizations worked together to convince governments with high mortality rates for children younger than age 5 years to introduce periodic vitamin A capsule distribution programs.

By the end of the 1990s, vitamin A supplementation programs had seen a remarkable expansion, which has been maintained during the first decade of the new millennium. The number of countries with vitamin A programs increased from 10 in 1995 to 72 in 2000, and 103 in 2004. These are mostly countries with high mortality rates for children younger than 5 years old and/or where vitamin A deficiency is a public health problem. The ways in which the vitamin A capsule programs were developed and implemented have varied by country and over time. The most common strategy was to use national immunization days for polio eradication to piggyback vitamin A supplements, but because the polio eradication strategy required two nationwide campaigns not more than 2 months apart, some countries also promoted separate micronutrient days, or child health days, so that children would get at least two capsules during the course of a year, 6 months apart. For example, as polio eradication has progressed and vaccination ceased, capsules have increasingly been delivered through child health days together with other interventions such as deworming and malaria bed net distribution.

The coverage of vitamin A capsules, which was already high by the turn of the century, has continued to climb during the first decade of the new millennium. Although 50% of children in 103 countries had received one dose in 1999, just 16 percent had received two doses. By 2004 those receiving two doses had climbed to 58% and by 2008 had reached 71% coverage. Extrapolation of the protective effect of a 23% reduction in child mortality shown by the meta-analysis to the increased coverage of capsules in the decade after 1998 suggests that many millions of lives would have been saved. Others have estimated child deaths saved as far fewer than this however, and many have lamented the lack of proof of any such impact. Furthermore despite this high coverage of capsules, the rates of vitamin A deficiency based on serum retinol levels remains high and stable during this period, still affecting some 163 million children or approximately 30%.

The challenge that remains for vitamin A supplementation is one of sustainability. Although supplements have always been viewed as a short-term solution, in reality they need to be maintained as long as mortality rates remain high and no dietary solutions are put in place. Sustaining the provision of the vitamin A capsules is likely to become a problem, as until now, supplements have been provided predominantly by the Canadian government and supplied through UNICEF. Whether governments will eventually pick up these costs remains to be seen. The costs for individual governments to take on are small, however, especially compared to the potential benefits in terms of mortality reduction. However, in most places more effort is also needed to increase access to other sources of vitamin A, be it through diet and/or fortification, so that capsules can be phased out.

### **Iron/Folate Supplementation**

Although iron deficiency is the most widespread of nutritional problems, and despite the existence of policy and programs in most countries, supplementation with iron has not proven to be a very successful intervention. Global policy recommendations to routinely provide iron/folate supplements for women during pregnancy and lactation have changed little in almost three decades. These are that all anemic pregnant women should receive such supplements in almost all contexts, i.e., there is no alternative to supplements for treating anemia and the recommendation is that at least ninety tablets should be taken during pregnancy to treat anemia. Despite most developing countries having national iron supplementation policies, the World Summit for Children's goal to reduce anemia in women by one-third was given little or no priority by the principal actors involved such that no progress was made during the past decade. In 2007 anemia was estimated to affect 40% of nonpregnant women and 41% of pregnant women in developing countries, virtually the same rates that existed in the nineties.

Although there is ample evidence that iron deficiency and the anemia associated with it are a great burden on society, especially the poor, the advocacy base for pushing for program implementation has remained weak. This is largely because the link of iron deficiency to maternal and child survival has not been concretely proven. The ethical difficulty of doing randomized controlled trials with a placebo group, when all countries have a policy to give iron supplements during pregnancy has contributed to this. However, new evidence from trials in nonanemic women in developed countries find that iron supplements increase birth weight by upward of 100 g compared to placebo, suggesting that iron supplements may well have unsuspected benefits for child survival, growth, and development. The effect of iron deficiency on cognitive deficits in children and on adults later in the life course have long been established. The absolute losses in Southeast Asia are estimated to be approximately \$5 billion annually, and for India the median value of productivity losses due to iron deficiency alone is approximately \$4 per capita or 0.9% of gross domestic product.

Despite high cost effectiveness, little or no priority has been given to iron deficiency anemia reduction programs. At \$0.002 per tablet, the iron supplement is relatively cheap, and the cost per disability adjusted life year of \$13 makes the supplementation of pregnant women with iron a very cost-effective intervention. At the national level, despite the existence of national policies, rarely is there a budget for the provision of supplements and/or supervision of iron deficiency anemia programs. Although UNICEF is a major supplier of iron/folate supplements to the developing world, the level of supply is far lower than that believed to be needed. In the period 1993–1996, 2.7 billion tablets were shipped to 122 countries at a cost of \$7.5 million as part of UNICEF assistance to programs aimed at eliminating maternal anemia. This was less than 5% of that needed to cover all pregnancies in developing countries. There have been few, if any, attempts to gauge the coverage of iron/folate supplements at any level, be it district, national, or international. Neither has there been any effort put into creating political accountability to ensure high coverage.

Many meetings and publications during the past few decades that have examined the causes and solutions of iron deficiency anemia conclude that lack of effectiveness of iron supplementation programs for anemia control is largely related to problems with supply of the supplement. Although the side effects of iron pills are often cited as the reason why iron supplementation programs do not work, this rarely seems to be the case. One of the major causes of nonadherence seems to be lack of understanding of the benefits the supplements can bring among health staff that deliver the tablets. Most of the program reviews have concluded that where supportive community-level delivery mechanisms are put in place that encourage adherence, and the supply of supplements is ensured, high levels of coverage can be achieved and sustained and anemia controlled. It is often the case, however, that in health systems in developing countries, nutrition is everybody's business and nobody's responsibility, and iron supplements have ended up low on the list of things to do.

Despite an international consensus that supplementation has a key role to play in the control of iron deficiency anemia, and that this will contribute to reducing maternal mortality, there is still little traction in this area. Demographic Health surveys include questions concerning how many mothers took at least 90 iron tablets during their last pregnancy, and very few countries achieve high coverage. In 1998, a technical consensus meeting on what was needed to solve the problem of iron deficiency made the recommendation that although the interventions already existed for reducing both iron deficiency and iron deficiency anemia, more work was needed to develop large-scale programs with packages of interventions delivered through multiple sectors, including hygiene and sanitation, because iron supplements alone will not ensure anemia control in many settings. Infections such as malaria and gastrointestinal parasites are also important causes. Furthermore, a global review of anemia causality revealed that perhaps only half of anemia is solely due to iron deficiency, with other micronutrient deficiencies such as vitamin A contributing as well. To be effective, maternal anemia control programs must include infection control, together with the community delivery of iron supplements.

It is much easier to treat anemia before pregnancy, when supplements can be taken once a week instead of daily. Such approaches have been shown to be very effective among adolescent school girls, for example, as well as in family planning

programs. To be effective the supplementation has to be supervised and accompanied by infection control, such as periodic deworming.

## Zinc Supplementation

The WHO/UNICEF recommendation is to give supplemental zinc for 10 day as part of the treatment of diarrhea. This is based on strong evidence for the efficacy of therapeutic zinc in improving the prognosis of children being treated for diarrheal disease. A pooled analysis of randomized controlled therapeutic zinc trials in children with diarrhea showed that zinc-supplemented children with acute diarrhea had a 15% lower probability of continuing diarrhea on a given day, and in those with persistent diarrhea there was a 24% lower probability. In addition, children with persistent diarrhea had a 42% lower rate of treatment failure or death if zinc supplemented. Given that even the current interventions included in child health programs for diarrheal disease treatment, such as oral rehydration therapy, face enormous barriers to achieving and maintaining high levels of coverage, the challenge for achieving high levels of coverage of zinc supplements in the treatment of diarrhea is likely to be considerable. If these efforts are successful however, then the impact is likely to be great. The most effective way to give preventive zinc supplements is an ongoing research question.

## Multiple Micronutrient Supplementation

In recent years, the case has increasingly been made for providing multiple micronutrient supplements instead of iron supplements for young children and women of reproductive age in developing countries. A woman's or an infant's diet that is deficient in iron is likely to be deficient in many other micronutrients. Outside of emergency situations, such as natural catastrophes, famine, and civil strife, poor dietary quality rather than quantity is the determinant of inadequate micronutrient status among infants and women. The nutrient-to-energy ratios of iron, zinc, folate, vitamins B<sub>6</sub> and B<sub>12</sub>, vitamin A, riboflavin, and calcium are commonly below the recommended levels needed, assuming energy needs are met.

The UN agencies agreed the composition of a multiple micronutrient supplement for use among pregnant and lactating women in developing countries a decade ago. The formulation includes 15 micronutrients (vitamins A, D, E, B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, B<sub>12</sub>, and C, niacin, and folic acid and minerals Fe, Zn, Cu, I, and Se), all at the RDA level, except for folic acid, which was included at the 400-μg level – considered sufficient to prevent neural tube defects if taken periconceptually. The main cost of the delivery of a nutrient supplement for women of reproductive age is not the cost of the supplement but the cost of the delivery system. Although it may not be working very well, a delivery system already exists for the iron/folate supplements that could be used to provide these other micronutrients. Adding the extra nutrients to the iron/folate tablets will not add more than 20% to the cost of the tablet, and although the incremental cost of distributing a multiple micronutrient supplement is likely to be small, the increased benefits may be large. Although the need for micronutrient supplementation in pregnancy is likely to be great because of widespread maternal undernutrition, and the supplements have been recommended for use in populations affected by emergencies, it was recognized that regular public health resources are always limited and priority is given to interventions that are both efficacious and effective. Proving the efficacy of multiple micronutrient supplements is thus essential for being able to advocate for their wide-scale use in nonemergency settings. Tablets of similar composition are regularly prescribed by physicians and/or purchased by mothers in developed countries, and they can be found in the pharmacies of the capitals of most developing countries and are widely consumed by the richer segments of the population.

This multiple micronutrient supplement was then tested in a series of 12 efficacy and six effectiveness trials covering 12 countries and spanning three continents – Asia, Latin America, and sub-Saharan Africa. A meta-analysis of these trials found that both supplements were equally effective in tackling maternal anemia, even though the iron content was often lower in the multiple micronutrient supplement than in the iron–folic acid supplement. There were no significant differences in the rates of stillbirth, early neonatal death, or neonatal death between the supplemented groups. The small, significant increase in mean birth weight (24 g) among infants of mothers receiving multiple micronutrients compared with infants of mothers receiving iron–folic acid is of similar magnitude to that often produced by food supplementation during pregnancy, and larger micronutrient doses seemed to produce greater impact. Meaningful improvements have also been observed in height and cognitive development by 2 years of age in the children of the mothers from the multiple micronutrient group.

WHO and UNICEF recommend the use of sirup and/or tablets containing iron for the treatment of anemia in young children, and such products are available through UNICEF supply division in Copenhagen. These products have very little penetration considering the size of the infant anemia problem in most developing countries, where half of all children are commonly affected. Despite the recognition that iron deficiency often coexists with zinc deficiency, together with inadequate intakes of other B vitamins (B<sub>6</sub>, riboflavin, and niacin) in infant dietaries, there is no multiple micronutrient supplement available for infants. UNICEF has also been testing the efficacy of a foodlet (a large crumbly pastille that is a cross between a tablet and a food) containing multiple micronutrients during infancy through the Infant Research on Infant Supplementation trials. Trials of multiple micronutrients as preventive supplements have also been carried out by many different groups using supplements provided in the form of sprinkles, tablets, and even as a beverage. Preliminary results of these trials point to a greater impact on anemia and enhancement of multiple micronutrient status by the multiple micronutrient supplements than that of iron supplements, as well as small improvements in growth.

There is a need to bring all of this broad spectrum of experimental and programmatic work together to reach conclusions and achieve consensus before policy and program recommendations can be made on how best to include multiple micronutrient supplements in programs to improve maternal and child health in developing countries.

## Notes

Cross-reference terms in *italics> are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to each article for additional cross-references – not all of these cross-references have been included in the index cross-references.*

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.

## A

A-type PAC, antibacterial activity of 2:542  
absorption 1:252–253, 1:283–285  
    effect of meal size on 2:445–446  
    and metabolism of flavonoids 2:534–535  
    of vitamins 2:217–221  
acceptable daily intake (ADI) 2:627  
Acceptable Macronutrient Distribution  
    Ranges (AMDR) 3:238–239,  
    3:239t  
acesulfame potassium (Ace-K) 2:626, 2:628,  
    2:631  
acetaldehyde  
    effects of 2:262–263  
    metabolism 2:255  
acetate  
    effects of 2:263  
    metabolism of 2:255  
acetyl-CoA carboxylase (ACC) 2:199  
acetylation 2:177  
acetylcholine 1:163  
acquired immuno deficiency syndrome  
    (AIDS) 3:535–536  
acute diseases, vitamin D and 1:540–543  
acute liver failure 3:460  
acute neuroglycopenia 3:404  
acyl-coenzyme A:cholesterol O-  
    acyltransferase (ACAT)  
    3:368–369  
acyltransferase (ACAT) 1:296  
adaptive thermogenesis 2:129–131  
    *See also* postprandial thermogenesis  
    efficiency of muscle work 2:131

 nutrients adversely affecting bone health  
 3:83  
 impact of physical activity on bone  
 health 3:84–85  
 protein intake and 3:82
- bone mineral content (BMC) 3:21–22
- bone mineral density (BMD) 3:175,  
 3:428–429
- boron 1:199, 1:450–451
- bowel obstruction 3:142–143
- brain and nervous system  
 design of nervous system 3:119  
 energy substrates 3:119  
 fat-soluble vitamins 3:123
- Brazil nut (*Bertholletia excelsa*) 2:514
- Brazilian national SFP, example of 4:345
- breakfast 4:9
- breast cancer 2:488, 2:682–683
- breast cancer-resistance protein (BCRP) 2:81
- breastfeeding 3:515–516, 3:675  
 breast milk composition 4:20–21  
 community 4:25–26  
 global and community factors affecting  
 breastfeeding 4:24–26  
 health system 4:24  
 maternal 4:26  
 and maternal and infant health 4:21–24  
 protection, promotion, and support  
 4:26–27  
 rates and trends 4:27–29
- brite adipocytes recruited in response to cold  
 exposure 2:29
- British Dietetic Association 4:146
- bromine 1:451–452
- bronchial asthma, eicosanoids and 2:100
- bronchiectasis 3:475
- brown adipose tissue 2:122–123  
 activation of BAT by  $\beta$ -adrenergic receptor  
 agonists 2:33  
 activity in humans 2:29–30  
 adaptive thermogenesis 2:28  
 in response to cold exposure 2:28–29  
 adipose tissue browning by peroxisome  
 proliferator-activated receptor- $\gamma$   
 agonists 2:34  
 alternative PET tracers to quantify 2:30
- assessment of brown adipocyte tissue mass  
 and function 2:34
- batokines as therapeutic target 2:34
- brite adipocytes recruited in response to  
 cold exposure 2:29
- by cold exposed 18F-FDG PET/CT scan 2:30
- contribution of human BAT to cold-induced  
 thermogenesis 2:31
- discovered in rodents 2:27
- discovery of 2:27–28
- early investigations of human 2:27–28
- as endocrine organ 2:31–32
- glucose uptake may be independent of  
 thermogenic capacity 2:30
- is metabolically significant 2:31
- metabolic significance of 2:30–33
- in obese individuals, dysfunction of 2:30
- pharmacological approaches to activation  
 of 2:33–34
- physiology of 2:28–29
- potential novel batokines recently identified  
 2:32–33
- re-discovery of active BAT in live humans  
 2:28
- retrospective analysis of 2:29–30
- sub population of acetate-secreting brown  
 adipocytes regulate thermogenesis  
 2:33
- as target to combat obesity 2:26–27
- as therapeutic target 2:33–34
- transplantation of 2:35
- Brucellosis* 2:372
- brush border membrane 1:379–380
- bulimia nervosa (BN) 3:305  
 associated psychopathology 3:306  
 comorbidity 3:306  
 developmental risk 3:307  
 diagnostic criteria 3:305  
 dietetic management 3:308–309  
 etiology and maintenance 3:307  
 family-based treatment 3:310  
 food insecurity 3:306  
 gender differences 3:305–306  
 genetic risk 3:307  
 health consequences of 3:307–308  
 long-term prognosis 3:311  
 medical consequences 3:308  
 nutrition care process 3:309  
 nutritional consequences 3:307  
 personality risk 3:307  
 pharmacotherapy 3:310  
 prevalence of 3:305–306  
 professional responsibilities 3:308  
 psychological treatment 3:309–310  
 racial/ethnic differences 3:306  
 screening 3:308  
 theories of BN maintenance 3:307  
 treatment 3:308  
 of underrepresented populations 3:311  
 weight/shape overvaluation 3:306
- burn injury  
 increased energy expenditure 3:525–526  
 pathophysiology 3:525  
 of burn injury and metabolism  
 3:523–524

requirements 3:526  
butter 2:485

## C

C/EBP homologous protein (CHOP) 2:204

cadmium 1:452, 2:357–358

dietary exposure 2:357  
permissible intakes 2:357  
toxicity 2:357–358  
toxicokinetics 2:357

caffeine 1:96, 4:218–219

caffeine-induced anxiety disorder 1:102  
caffeine-induced sleep disorder 1:102  
and cognitive performance 1:98–99  
dependence 1:102–103  
and food 1:103  
general concepts 1:96  
genetics 1:99  
intoxication 1:102  
mechanisms of action 1:97–98  
pharmacokinetics 1:97  
and physical exercise 1:99  
physiological and health effects of 1:98  
reinforcement 1:100  
subjective effects 1:99  
tolerance 1:101–102  
withdrawal 1:100

calcium 1:192, 2:184, 3:12, 3:80–81, 3:341,  
3:446, 3:613–615, 3:686, 4:38,  
4:94–96, 4:111, 4:172, 4:266

absorption 1:107–112  
balance 1:107  
bioavailability 1:108–109  
biologic functions of vitamin D on calcium  
metabolism 1:526  
dietary calcium intake 1:106–107  
functions 1:106  
health consequences  
of calcium deficiency 1:112  
of calcium excess 1:112–113  
hormonal control 1:110–111  
influence of life stages 1:111  
losses 1:109–110  
and magnesium 3:397  
mechanisms 1:107–109  
metabolism 1:107  
nonskeletal 1:112  
nutrient interactions 1:109  
race and genetics 1:112  
skeletal 1:112  
sources 1:106–107

caloric accretion in fetus 4:72

caloric restriction (CR) 2:181, 3:640

and intermittent fasting 2:45–46

calpain 10 (CAPN10) 3:256–257

*Campylobacter* infections 2:369–370

cancer 1:69–72, 1:255, 1:354–355, 1:418,  
1:500, 1:513, 1:538, 2:270,  
2:410–411, 2:488–489,  
2:633–635, 2:649, 2:657,  
2:680–681, 2:683–684, 4:62–63

alternative and complementary diets 3:144

analytical studies 3:149–151

animal bioassays 3:131–132

beverages 3:158–159

carbohydrate and 1:140

carcinogenic substances

present in edible plants 3:126–127  
produced by fungi and microorganisms  
3:127–130

carcinogenicity tests 3:131–133

carcinogens produced by food processing  
3:129–130

case-control studies 3:149–150

chemoprevention trials 3:159

children, teenagers, and young adults with  
cancer 3:138

cohort studies 3:149

contaminants present in food 3:128–129

descriptive studies 3:147–148

diet 3:156–157

and prevention 3:159–160

dietary associations with lung cancer

3:157–159

dietary hypotheses and mechanisms

3:156–157

epidemiological issues in study of diet and  
cancer 3:151

evidence from descriptive studies 3:148

fat 3:158

guidelines 3:137

intervention studies 3:150

living with and beyond cancer 3:143–144

lung cancer histopathology 3:155

meat and fish 3:159

mechanisms of carcinogenicity 3:130–131

meta-analysis 3:150–151

monitoring and control of hazards

3:133–134

naturally occurring carcinogens 3:126–127

nutritional interventions 3:138–139

nutritional needs of specific patient groups  
3:138

observation versus experiment 3:159–160

practical management of eating difficulties  
3:139

relations between diet and cancer 3:152

resolved and unresolved issues 3:151

risk factors 3:155

short-term predictive tests 3:132–133

sources of evidence linking diet and cancer  
3:147–151

special-exposure groups 3:148

taste changes 3:139

time trends within countries 3:148

candidate-gene association studies (CGAS)  
3:256

carbamazepine 2:87

carbohydrate response element (ChoRE)  
2:199

carbohydrate response element binding  
protein (ChREBP) 2:198–199,  
2:199t

carbohydrates 2:14–16, 2:117–118, 2:300,  
2:452, 2:482–483, 2:517, 3:242,  
3:451, 3:528–529, 4:34–36,
